The genotypes used in this investigation have been obtained from the Agricultural Research Center (ARC), Giza, Egypt. Pedigree of genotypes of these rice cultivars has been shown in Table 1.

The minimum data set required to run the CERES-RICE model and validate its outputs has been obtained from the previously mentioned experiment in addition to other sites like Central Laboratory for Agricultural Climate (CLAC), ARC, Egypt. All these data have been converted to fit the CERES-RICE model format. These data are site weather data for the duration of the growing season, site soil data, and management and experimental data for the experiment.

The root mean square error (RMSE) is a good overall measure of model performance. The weighting of (prediction-observation) by its square tends to inflate RMSE, particularly when extreme values are present. With respect to a good model, the root mean square error should approach zero.

The mean bias (MB) is the degree of correspondence between the mean prediction and the mean observation. Lower numbers are the best, and values less than zero indicate underprediction.

The equations for RMSE, MB, and its percentages are given by Eqs. 1, 2, 3, and 4:

$$\mathrm{RMSE} = \left(\sum_{i=1}^{n} \left(X_p - X_o \right)^2 / n \right)^{0.5} \tag{1}$$

$$\mathrm{RMSE}\% = \left(\mathrm{RMSE} / \overline{X_o} \right)^{*} 100 \tag{2}$$

$$\mathrm{MB} = \sum_{i=1}^{n} X_p - X_o / n \tag{3}$$

$$\mathrm{MB}\% = \left(\mathrm{MB} / \overline{X_o} \right)^{*} 100 \tag{4}$$

where n is the number of observations, X_p and X_o are predicted and observed values, respectively, and $\overline{X_o}$ is the average of observed values.

Weather Data

The weather data includes latitude and longitude of the weather station, daily values of incoming solar radiation (MJ/m^2-day), maximum and minimum air temperature (°C), and rainfall (mm). The length of weather records for validation must, at minimum, cover the duration of the experiment and preferably should begin a few weeks before planting and continue a few weeks after harvest so that "what-if" type analyses may be performed.

Soil Data

Rice is cultivated and concentrated mainly in the Nile Delta region north of Egypt, because of its soil fertility and suitability. Soil data includes soil classification, surface slope, color, permeability, and drainage class.

Delta and the flood plain of the River Nile are stratified loams or clays (calcaric fluvisols) which represent the most essential soils in this area. They are moderately calcareous with pH values ranging from 8.1 to 8.3; in saline-sodic patches, the pH value is greater than 8.5. These soils have high potential especially for irrigated crops such as rice. In the narrow coastal belt of the Delta region about 40 km wide, very strongly, saline soils (solonchaks) are found. In the eastern Mediterranean coastal strip, other soils of semi-arid Mediterranean climates (xerosols and yermosols) occur and extending from Alexandria in the east to the Libyan borders in the west. They are deep clay soils near the northwestern tip of the Nile Delta and sandy, loamy, and gravelly in other parts. However, for the limitations of climate, these soils have a medium to high potential for rice. The rest of the country consists mainly of stony, mountainous, and sandy desert areas with little potential for improvement except as poor rangelands (FAO database).

Management and Experiment Data

Management data includes information on planting date, dates when soil conditions were measured prior to planting, planting density, row spacing, planting depth, crop variety, irrigation, and fertilizer practices.

The strategy of the Ministry of Agriculture in Egypt is to study the impacts of climate change on the potential crops such as rice and wheat until year 2017. Therefore, we will stress ourselves to study the impacts of climate change on rice from 2010 to 2017.

The data of climate change of two emission scenarios SRES A2 and SRES B2 of HadCM3 model outputs are used as inputs for CERES-RICE model. These two emission scenarios have been interpolated to apply for the desired station at Sakha. Interpolation belongs to a very useful branch of mathematics, called approximation theory. Statistical interpolation considers fields having random fluctuations.

Various interpolation methods have been invented to solve interpolation problems in practical applications.

The output of two emission scenarios SRES A2 and SRES B2 was monthly values, and the CERES-RICE model needs a daily climate data; therefore, we used the weather generator embedded in DSSAT 3.5 to generate daily climate data. Stochastic weather generators are widely used to generate synthetic weather data, which can be arbitrarily long for input into impact models, such as crop models and hydrological models that are used for making long-term risk assessments. These weather generators may be used for predicting crop yields based on seasonal climate forecasts (Hansen and Indeje 2004) and interpolating between stations, e. g., to create gridded daily meteorological time series data sets (e.g., Kittel et al. 2004).

Validation of CERES-RICE Model

The model has been validated at Sakha through flowering date (number of days from sowing to flowering), physiological maturity date (number of days from sowing to physiological maturity), biomass at harvest or biological yield (kg/ha), and grain yield (kg/ha).

Flowering Date

Table 2 shows comparison between measured and predicted flowering date for rice cultivars at Sakha and its percentage difference. The percentage difference is the difference between predicted and measured values divided by measured value and multiplied by 100.

One may notice that the measured and predicted values of the cultivar Giza 171 have the maximum flowering date compared to other rice cultivars. However,

Table 2 Comparison between measured and predicted flowering date for rice cultivars at Sakha

Cultivar	Measured	Predicted	Difference %
Giza 171	105	107	1.90
Giza 172	103	103	0.00
Giza 176	95	94	−1.05
Giza 177	81	80	−1.23
Giza 178	86	88	2.33
Giza 181	96	98	2.08
Sakha 101	89	88	−1.12
Sakha 102	79	79	0.00
Sakha 103	82	80	−2.44
Sakha 104	87	87	0.00
Egyptian Yasmin	96	95	−1.04
Average	90.82	90.82	0.00

the cultivar Sakha 102 has the minimum measured and predicted values for flowering date. The measured and predicted values of the cultivars Giza 172, Sakha 102, and Sakha 104 have equal values and their percentage difference equals zero. Therefore, the CERES-RICE model gave an equal prediction compared to the measured values for these cultivars. The percentage differences for the cultivars Giza 171, Giza 178, and Giza 181 are positive with maximum value for Giza 178. This means the predicted flowering date for these rice cultivars using the CERES-RICE model are overestimated but within the acceptable range. The percentage differences for the cultivars Giza 176, Giza 177, Sakha 101, Sakha 103, and Egyptian Yasmin are negative values; Sakha 103 has the maximum negative value, but all negative percentages are acceptable. Thus, the predicted flowering date using the CERES-RICE model is underprediction for these rice cultivars. The average measured and predicted flowering dates for all rice cultivars have the same value of 90.82, so their percentage difference equals zero. The root mean square error (RMSE) for all rice cultivars equals 1.35 with percentage of 1.48, and its mean bias (MB) and percentage equal zero. Therefore, the CERES-RICE model successes to predict the flowering date for all rice cultivars with very high performance.

Physiological Maturity

Table 3 gives comparison between measured and predicted physiological maturity for rice cultivars at Sakha and its percentage difference. From it, one can deduce that the measured and predicted physiological maturity date of the cultivar Giza 171 has the maximum value compared to other rice cultivars. However, the cultivar Sakha 102 has the minimum value for both measured and predicted physiological maturity date, while the cultivar Giza 181 has an equal value for measured and predicted, so the percentage difference equals zero; therefore, CERES-RICE model gave an equal prediction compared to measurements for this cultivar. The

Table 3 Comparison between measured and predicted physiological maturity for rice cultivars at Sakha

Cultivar	Measured	Predicted	Difference %
Giza 171	150	152	1.33
Giza 172	140	143	2.14
Giza 176	140	138	−1.43
Giza 177	115	117	1.74
Giza 178	125	128	2.40
Giza 181	140	140	0
Sakha 101	130	129	−0.77
Sakha 102	115	116	0.87
Sakha 103	110	113	2.73
Sakha 104	130	129	−0.77
Egyptian Yasmin	140	139	−0.71
Average	130.45	131.27	0.63

percentage differences for the cultivars Giza 171, Giza 172, Giza 177, Giza 178, Sakha 102, and Sakha 103 are positive values with maximum value for Sakha 103. Hence, the CERES-RICE model can overpredict the physiological maturity date for these rice cultivars but within the acceptable range. The percentage differences for the cultivars Giza 176, Sakha 101, Sakha 104, and Egyptian Yasmin are negative values. Giza 176 has the maximum negative value, but all negative percentages are acceptable. Therefore, the predicted physiological maturity date using the CERES-RICE model is underprediction for these rice cultivars.

The average measured and predicted physiological maturity dates for all rice cultivars are 130.45 and 131.27 and have close values to each other, so its percentage difference equals 0.63. The RMSE for all rice cultivars equals 1.98 with percentage of 1.52, MB equals 0.82, and its percentage equals 0.63. Therefore, the CERES-RICE model successes to predict the physiological maturity date for all rice cultivars with very high performance.

Biomass at Harvest

Table 4 reports a comparison between measured and predicted biomass at harvest for rice cultivars at Sakha. It is obvious that the Egyptian Yasmin has the maximum value of measured biomass at harvest compared to other rice cultivars. On the other hand, the maximum predicted one has been recorded for the Giza 172. The minimum measured biomass at harvest has been reported for Sakha 103, while the minimum predicted one has been reported for Sakha 102. At the same time, there are no cultivars having equal values for both measured and predicted biomass at harvest. The percentage differences for the cultivars Giza 172, Giza 176, Giza 177, Giza 181, and Sakha 103 are positive values with maximum value for Giza 181. Therefore, CERES-RICE model gave an overestimation prediction for biomass at harvest for these cultivars but within the acceptable range except for Giza 181. The percentage differences for Giza 171, Giza 178, Sakha 101, Sakha

Table 4 Comparison between measured and predicted biomass at harvest for rice cultivars at Sakha

Cultivar	Measured	Predicted	Difference %
Giza 171	15,000	14,607	−2.62
Giza 172	14,280	14,801	3.65
Giza 176	13,620	14,116	3.64
Giza 177	12,180	12,435	2.09
Giza 178	13,560	13,414	−1.08
Giza 181	12,000	14,275	18.96
Sakha 101	14,220	13,749	−3.31
Sakha 102	14,220	11,956	−15.92
Sakha 103	12,000	12,308	2.57
Sakha 104	16,800	13,494	−19.68
Egyptian Yasmin	15,300	14,316	−6.43
Average	13,925.45	13,588.27	−2.42

102, Sakha 104, and Egyptian Yasmin are negative values. At the same time, Sakha 104 has the maximum negative value; all negative percentages are acceptable except for Sakha 104 and Sakha 102. It can be deduced that the CERES-RICE model gave an underestimated prediction for biomass at harvest for these cultivars.

The average measured and predicted biomass at harvest for all rice cultivars are 13925.45 and 13588.27, respectively, so its percentage difference equals −2.42. The RMSE for all rice cultivars equals 1454.59 with percentage of 10.45 and MB equals −337.18 with percentage equals −2.42. Therefore, the CERES-RICE model successes to predict biomass at harvest for all rice cultivars except for some of them with very high performance.

Grain Yield

Table 5 gives a comparison between measured and predicted grain yield for rice cultivars at Sakha.

It is obvious that Sakha 101 has the maximum measured grain yield compared to other rice cultivars, while the maximum predicted one has been reported for Giza 178. On the other hand, Giza 171 has the minimum measured grain yield but the minimum predicted value has been reported for Giza 172. In addition, comparison has revealed that there are no equal values for the measured and predicted grain yield for all cultivars. The percentage differences for the cultivars Giza 171, Giza 181, Sakha 102, Sakha 103, and Sakha 104 are positive values with maximum value for Sakha 102. This means the predicted grain yield using the CERES-RICE model is overestimated for these cultivars but within the acceptable range except for Sakha 102. At the same time, the percentage differences for the cultivars Giza 172, Giza 176, Giza 177, Giza 178, Sakha 101, and Egyptian Yasmin are negative. Sakha 101 has the maximum negative value, but all negative percentages are acceptable with some exception for some cultivars. Therefore, the predicted grain yield values

Table 5 Comparison between measured and predicted grain yield for rice cultivars at Sakha

Cultivar	Measured	Predicted	Difference %
Giza 171	7500	7686	2.48
Giza 172	8000	7604	−4.95
Giza 176	9000	8653	−3.86
Giza 177	7700	7665	−0.45
Giza 178	9900	9480	−4.24
Giza 181	8500	8647	1.73
Sakha 101	10,000	9288	−7.12
Sakha 102	7600	8260	8.68
Sakha 103	8100	8177	0.95
Sakha 104	8800	8949	1.69
Egyptian Yasmin	8500	8029	−5.54
Average	8509.09	8403.45	−1.24

using the CERES-RICE model were underestimated for the previous cultivars. The average measured and predicted grain yields for all rice cultivars are 8509.09 and 8403.45, respectively, so its percentage difference equals −1.24. The RMSE for all rice cultivars equals 393.54 with percentage of 4.62, and MB equals −105.64 with percentage equals −1.24. Therefore, the CERES-RICE model successes to predict grain yield for all rice cultivars with very high performance except for some cultivars.

From all previous discussions, one may conclude that CERES-RICE model has high performance percentage to predict flowering date and physiological maturity, while this performance decreases a little bit for grain yield and biomass at harvest predictions.

Simulation of the Impact of Climate Change on Rice

The impact of climate change on rice at Sakha will be measured through flowering date, physiological maturity, biomass at harvest or biological yield (kg/ha), and grain yield (kg/ha).

Flowering Date

Figure 1 report the comparison between measured and predicted flowering date using SRES A2 and SRES B2 emission scenarios of HadCM3. In addition, Table 6 represents the percentages of root mean square error and mean bias for rice cultivars at Sakha for the period 2010 to 2017.

It is noticed that there is a small difference between the two emission scenarios in predicting flowering date. In most rice cultivars, the predicted flowering date by SRES A2 scenario is greater than the one predicted by SRES B2 except for a few years. However, the predicted values by the two emission scenarios are small compared to the measured one. This is approximately true for all rice cultivars in all years except for Giza 171 and Giza 178 predicted by SRES A2 in 2014. Hence, it is easy to conclude that the flowering date of all rice cultivars will be smaller than the measured one during the period 2010 to 2017. From Table 6 one may notice that the maximum percentage ratio of root mean square error and the maximum negative percentage ratio of mean bias have been recorded for Sakha 102, while the minimum percentage ratio of root mean square error and the minimum negative percentage ratio of mean bias have been registered for the cultivar Giza 178. Therefore, the maximum decrease in flowering date will occur for Sakha 102 and the minimum decrease will happen in Giza 178.

Generally, one may conclude that the flowering date of all rice cultivars will be decreased compared to the measured one during the period 2010 to 2017 as a whole.

Physiological Maturity

Figure 2 show the comparison between measured and predicted physiological maturity by using SRES A2 and SRES B2 emission scenarios of HadCM3. In addition, Table 7 reports percentages of root mean square error and mean bias for rice cultivars at Sakha for the period 2010–2017.

It is noticed that there is a small difference between the two emission scenarios for predicting physiological maturity in most rice cultivars. At the same time, the

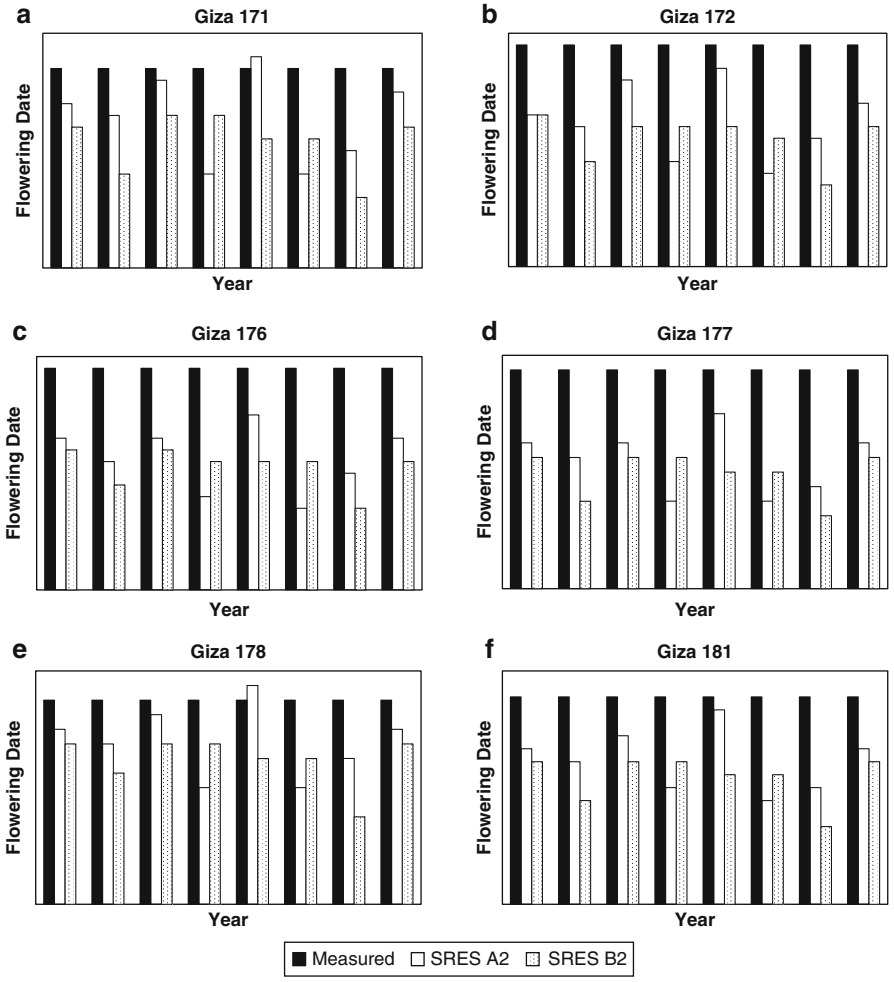

Fig. 1 (continued)

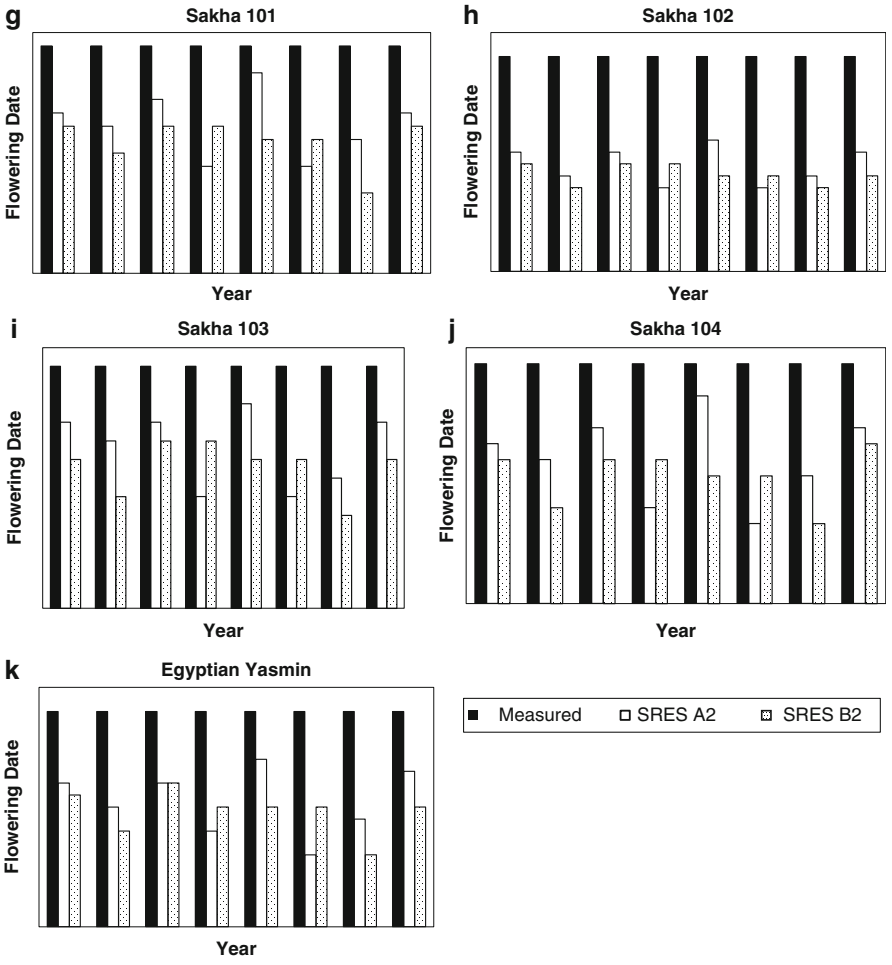

Fig. 1 (**a**–**k**) Comparison between measured and predicted flowering date by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

values predicted by SRES A2 scenario are greater than the one predicted by SRES B2 except for a few years. In addition, the predicted values by the two emission scenarios for physiological maturity are small compared to the measured one for all rice cultivars in all years without any exception. Hence, one can say that the physiological maturity of all rice cultivars will be decreased compared to the measured one during the period 2010 to 2017. It can be noticed in Table 7 that the cultivar Giza 176 has the maximum percentage ratio of root mean square error and the maximum negative percentage ratio mean bias in the two scenarios, while the minimum percentage ratio of root mean square error and the minimum negative percentage ratio mean bias have been recorded for the Sakha 103. Hence, the

Table 6 Comparison between measured and predicted flowering date and percentages of root mean square error and mean bias by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

Cultivar	Measured	SRES A2	SRES B2
Giza 171	105	101	99
Giza 172	103	97	96
Giza 176	95	87	87
Giza 177	81	75	74
Giza 178	86	83	81
Giza 181	96	91	90
Sakha 101	89	83	82
Sakha 102	82	73	72
Sakha 103	79	75	74
Sakha 104	87	81	80
Egyptian Yasmin	96	89	88

	RMSE %		MB %	
Cultivar	SRES A2	SRES B2	SRES A2	SRES B2
Giza 171	5.24	6.35	−4.05	−5.95
Giza 172	6.93	7.98	−6.31	−7.77
Giza 176	8.60	9.10	−8.16	−8.95
Giza 177	8.12	8.98	−7.72	−7.13
Giza 178	4.25	5.15	−3.34	−4.80
Giza 181	5.57	6.75	−5.08	−6.51
Sakha 101	7.07	8.21	−6.60	−8.01
Sakha 102	11.27	12.08	−11.13	−12.04
Sakha 103	6.02	7.01	−5.54	−6.80
Sakha 104	7.35	8.25	−6.75	−8.05
Egyptian Yasmin	8.25	8.91	−7.81	−8.72

maximum decrease in physiological maturity will occur for the cultivar Giza 176 and the minimum decrease will be for the cultivar Sakha 103. It is obvious that the physiological maturity of all rice cultivars will be decreased compared to the measured one during the period 2010 to 2017.

Biomass at Harvest

Figure 3 show a comparison between measured and predicted biomass at harvest by using SRES A2 and SRES B2 emission scenarios of HadCM3. In addition, Table 8 reports the percentages of root mean square error and mean bias for rice cultivars at Sakha for the period 2010–2017.

One may notice that there is a noticeable difference between the predicted biomass at harvest using the two emission scenarios. This difference is not small

compared to the prediction of both flowering date and physiological maturity. At the same time, not in most rice cultivars, the values predicted by SRES A2 scenario are greater than the ones predicted by SRES B2 except for a few years.

In addition, the predicted biomass at harvest using the two emission scenarios is smaller than the measured one for all rice cultivars except for Giza 172, Giza 176, and Giza 181. Hence, the biomass at harvest of rice cultivars, except for the previous three cultivars, will decrease compared to the measured one during the period of study. Table 8 showed that Sakha 104 has the maximum percentage ratio of root mean square error and maximum negative percentage ratio of mean bias in the two scenarios.

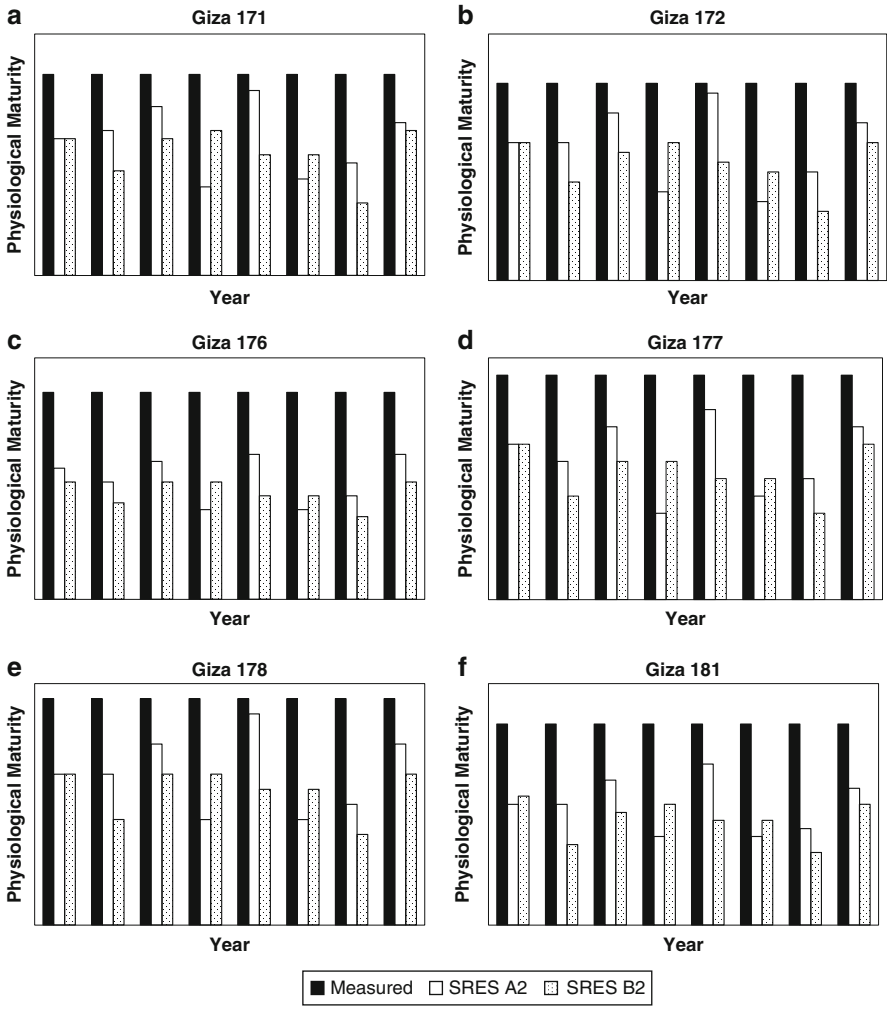

Fig. 2 (continued)

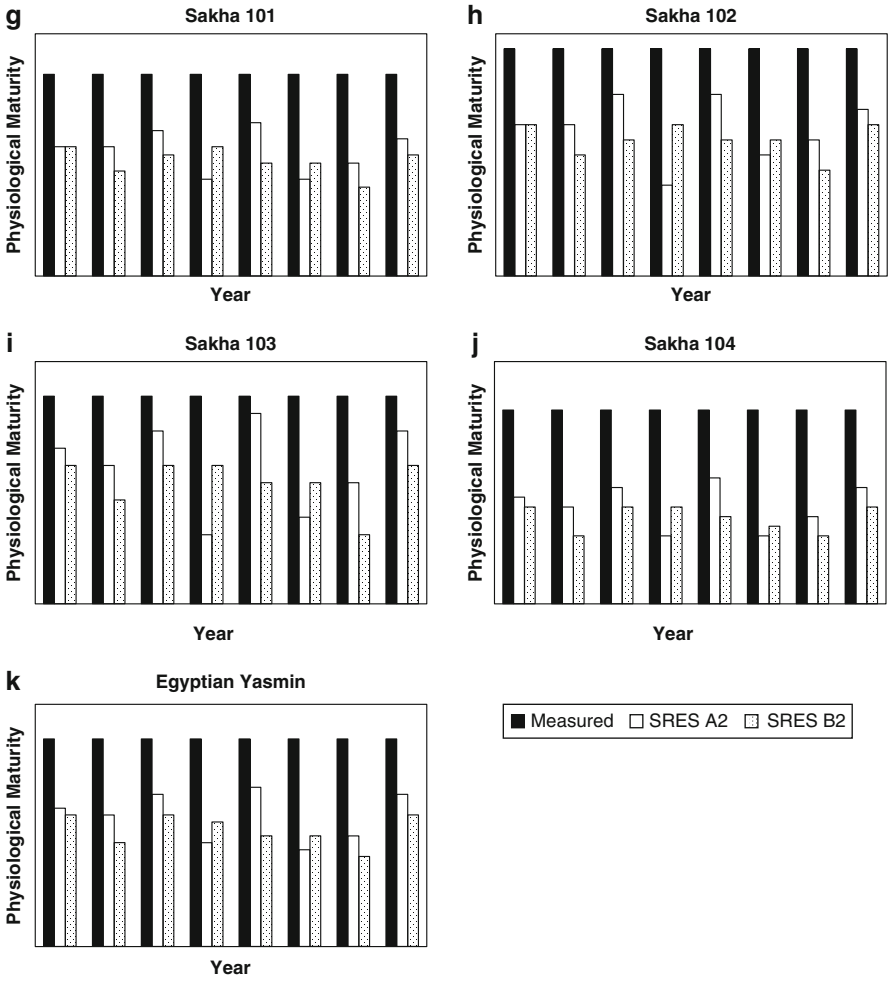

Fig. 2 (**a**–**k**) Comparison between measured and predicted physiological maturity by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

However, the minimum percentage ratio of root mean square error is reported for Giza 172 and the minimum negative percentage ratio mean bias is for Giza 171. Therefore, the maximum decrease in biomass at harvest will be for the cultivar Sakha 104, while the minimum increase will be for the cultivars Giza 172, Giza 176, and Giza 181 and the minimum decrease will be for the cultivar Giza 171.

It is obvious that the biomass at harvest for all rice cultivars will be decreased comparable to the measured one during the period 2010–2017 except for Giza 172, Giza 176, and Giza 181.

Table 7 Comparison between measured and predicted physiological maturity and percentages of root mean square error and mean bias by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

Cultivar	Measured	SRES A2	SRES B2
Giza 171	150	142	140
Giza 172	140	134	132
Giza 176	140	127	126
Giza 177	115	110	109
Giza 178	125	120	119
Giza 181	140	130	128
Sakha 101	130	121	119
Sakha 102	115	110	109
Sakha 103	110	106	105
Sakha 104	130	120	119
Egyptian Yasmin	140	129	127

	RMSE %		MB %	
Cultivar	SRES A2	SRES B2	SRES A2	SRES B2
Giza 171	6.03	6.77	−5.42	−6.50
Giza 172	5.32	6.03	−4.64	−5.80
Giza 176	9.30	10.43	−9.02	−10.36
Giza 177	4.48	5.02	−4.13	−4.89
Giza 178	4.44	5.04	−4.00	−4.90
Giza 181	7.57	8.64	−7.23	−8.48
Sakha 101	7.55	8.36	−7.31	−8.27
Sakha 102	4.86	5.29	−4.57	−5.22
Sakha 103	4.22	4.70	−3.64	−4.55
Sakha 104	7.77	8.61	−7.60	−8.56
Egyptian Yasmin	8.28	9.49	−7.95	−9.38

Grain Yield

Figure 4 show the comparison between measured and predicted grain yield using SRES A2 and SRES B2 emission scenarios of HadCM3. In addition, Table 9 reports the percentages of root mean square error and mean bias for rice cultivars at Sakha for the period 2010–2017.

One may notice that there is a small difference between the two emission scenarios in predicting grain yield. At the same time, the predicted values using SRES A2 scenario were greater than the one using SRES B2 except for a few years.

The predicted grain yield using the two emission scenarios was smaller than the measured ones for all rice cultivars in all years, except for both Giza 171 and Sakha 102. One may notice from Table 9 that the cultivar Sakha 101 has the maximum percentage ratio of root mean square error and maximum negative percentage ratio of mean bias in both scenarios. In addition, the minimum percentage ratio of root

mean square error is reported for cultivar Giza 171, while the minimum negative percentage ratio of mean bias is registered for Giza 181. Therefore, the maximum decrease in grain yield will be for the cultivar Sakha 101 and the minimum increase will be for the cultivars Giza 171 and Sakha 102. However, the minimum decrease will be for the cultivar Giza 181 according to SRES B2, but it increased in SERES A2. In addition, most of the decrease in predicted grain yield using SRES B2 is greater than SRES A2.

It is obvious that the grain yield for all rice cultivars will be decreased compared to the measured one during the period 2010–2017 except for the cultivars Giza 171, Sakha 102, and Giza 181.

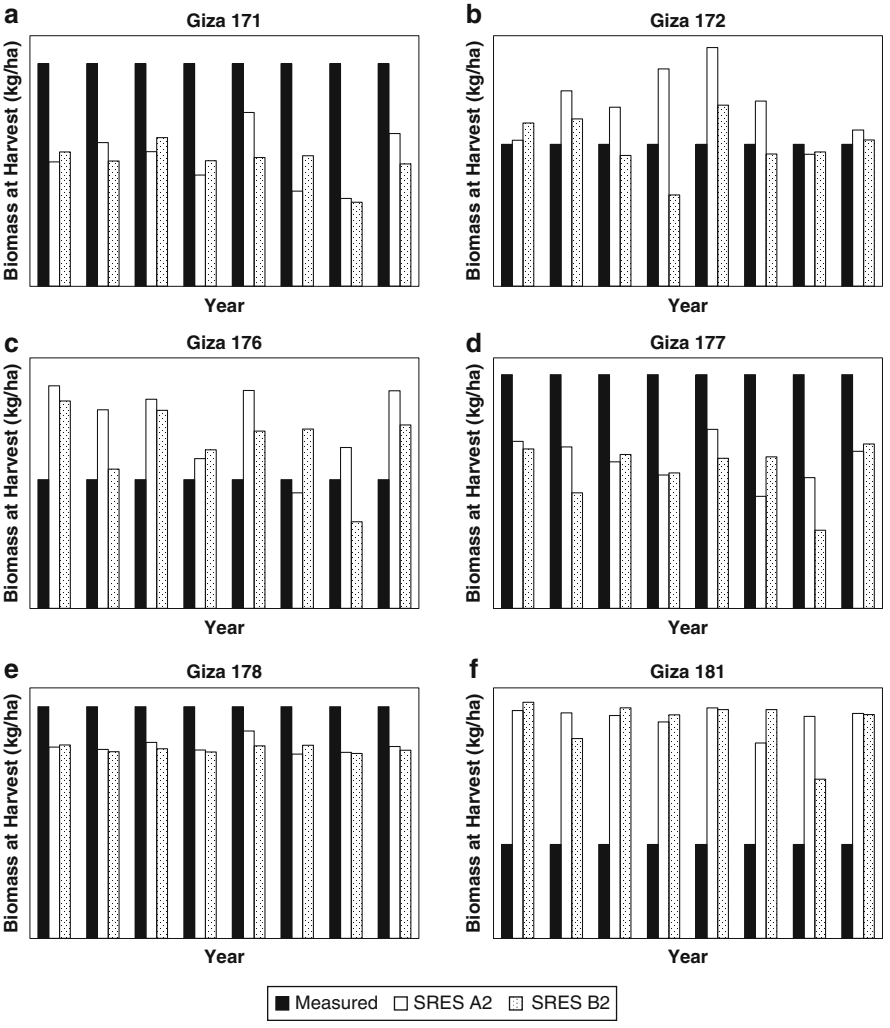

Fig. 3 (continued)

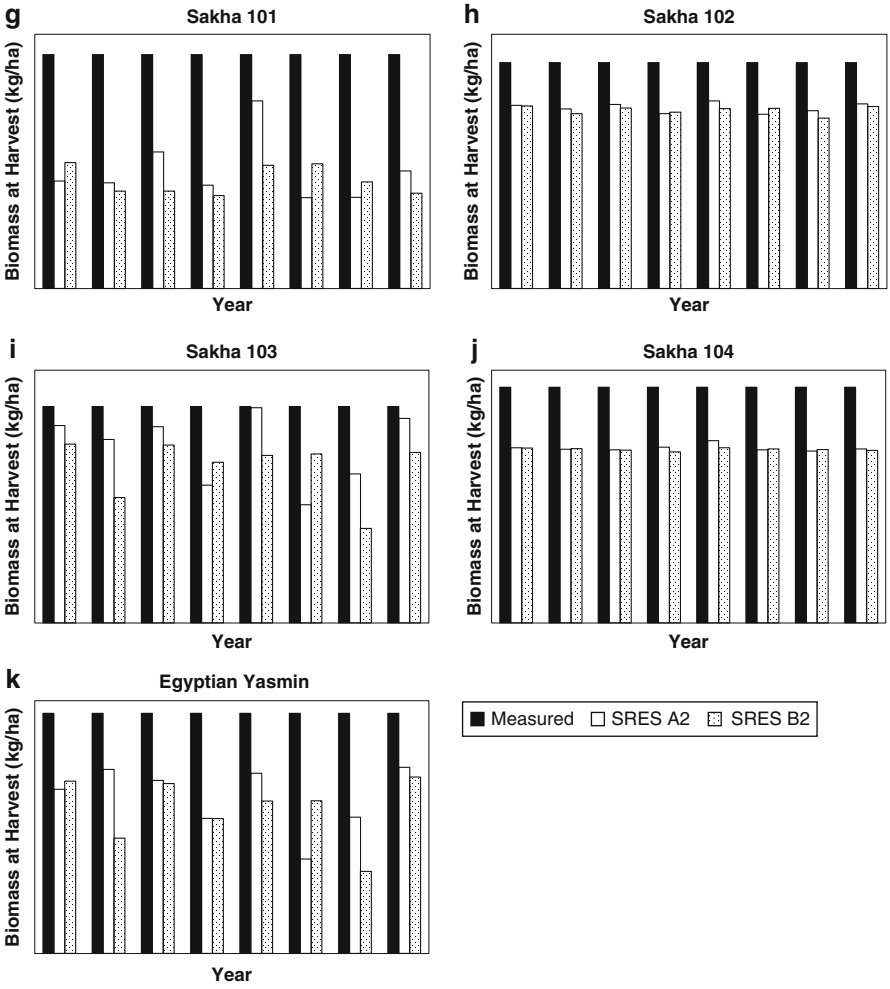

Fig. 3 (**a**–**k**) Comparison between measured and predicted biomass at harvest by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

Future Directions

- The validation of the model has proved its high accuracy in prediction of rice parameters compared to measurements.
- The CERES-RICE model has high-performance percentage to predict both flowering and physiological maturity dates. However, this performance slightly decreases in the prediction of grain yield and biomass at harvest.

Table 8 Comparison between measured and predicted biomass at harvest and percentages of root mean square error, mean bias by using SRES A2 and SRES B2 emission scenarios for rice cultivars at Sakha

Cultivar	Measured	SRES A2	SRES B2
Giza 171	15,000	14,319	14,298
Giza 172	14,280	14,469	14,287
Giza 176	12,800	13,607	13,323
Giza 177	12,800	11,779	11,659

Sakha 102	14,220	11,380	11,226
Sakha 103	12,000	11,427	11,154
Sakha 104	16,800	12,460	12,358
Egyptian Yasmin	15,300	13,981	13,786

	RMSE %		MB %	
Cultivar	SRES A2	SRES B2	SRES A2	SRES B2
Giza 171	4.72	4.76	−4.54	−4.68
Giza 172	1.74	0.88	1.32	0.05
Giza 176	7.49	5.67	6.31	4.09
Giza 177	8.21	9.26	−7.98	−8.91
Giza 178	17.44	18.30	−17.20	−18.25
Giza 181	16.94	16.60	16.89	16.29
Sakha 101	11.62	12.26	−11.26	−12.19
Sakha 102	20.07	21.13	−19.97	−21.06
Sakha 103	6.12	7.75	−4.77	−7.05
Sakha 104	25.86	26.44	−25.83	−26.44
Egyptian Yasmin	9.17	10.38	−8.62	−9.89

- The predicted flowering date, physiological maturity, and grain yield using SRES A2 scenario are greater than the predicted using SRES B2 except for a few years. However, in some rice cultivars, predicted biomass at harvest by SRES A2 is greater than the predicted by SRES B2 except for a few years.
- The predicted flowering date, physiological maturity, biomass at harvest, and grain yield for all rice cultivars decrease comparable to the measured ones during the period 2010–2017. However, the biomass at harvest and grain yield decrease greatly compared to both flowering date and physiological maturity.
- The results of this study indicate that the CERES-RICE model performance was very good under the Egyptian conditions. Therefore, the model could accurately be used in climate change impacts on rice.
- One may conclude that CERES-RICE model will be a very vital tool for farmers to avoid rice loss due to climate change.

Abstract

In recent decades, global climate change has continued to cause devastating impacts to various places on Earth. Geographic and socioeconomic characteristics in East Africa (EA) and South America (SA) make the regions among the most vulnerable to the current temperature variations attracting several studies with wider implications. Presently, in these two regions, remarkable evidence of climate change includes repeated droughts and increase in drylands affecting water and food availability for humans, livestock, and wildlife (EA); intensification of climate-sensitive diseases; sea level rise; fast retreat of glaciers on Mount Kilimanjaro in Tanzania, Mount Kenya in Kenya, and Andean Mountains of South America; change in the rainfall patterns in the Amazon forests and in the whole of EA; and increasing of the frequency and intensity of the El Niño and La Niña phenomenon in the South Pacific that affect both EA and SA, among others. Although these two regions are not major contributors of greenhouse gases (GHGs), the poor conservation of strategic ecosystems through deforestation of the Amazon forests in SA and various forests in EA coupled with intensification of agriculture, land degradation, rapid rates of urbanization, and industrialization all driven by rapid population increase are putting a strain on valuable natural resources whose conservation would be critical in mitigating climate change. Adaptation measures have been constrained by climate change impacts. In both regions, poverty is widespread and climate change impacts have jeopardized most poverty alleviation initiatives including realization of some of the Millennium Development Goals (MDGs). Moreover, both regions have a strong dependency on rain-fed agriculture for economic development with hydroelectricity and biomass as main sources of energy. Consequently, adaptation measures are required for all the sectors but especially in agriculture, health, and energy where the loss of soil productivity, increasing spread of climate-sensitive diseases, and reduction of water and energy source supply are already threatening the social and economic security of both regions. Both regions have a wealth of indigenous knowledge and coping mechanisms of various local communities that should be incorporated into conventional adaptation measures of climate change. This chapter describes the main climate change impacts in EA and SA, vulnerabilities thereon, and adaptation measures that offer an opportunity to the two regions to develop in a sustainable way.

Introduction

Increasingly, many people across the world agree that climate change is the latest challenge facing humanity today and that nations must unite in addressing it. The reality of global climate change has been more evident in the recent past as significant scientific evidence clearly shows a warming trend in changing Earth climatic systems. Human development, especially industrialization, is largely blamed for significant release of greenhouse gases (GHGs) into the atmosphere in recent decades that have led to catastrophic changes in sea level rise, increase in natural disasters, and increase in global temperatures, among others.

Climate statistics and models indicate that over the course of the past century, the global surface temperature has warmed by about 0.8 °C, where 0.6 °C is likely to be from the last three decades alone (Hansen et al. 2006).

Traditionally, the bulk of the global GHGs contribution was credited to industrialized countries. Presently, major growing economies (Brazil, China, and India) and the transport and manufacturing sectors from other big cities in the developing world have observed a more significant contribution. For other developing countries, including those in South America and the East African region, their contribution toward climate change is largely blamed on land use change, land degradation, deforestation, and increased household energy needs, especially fuel wood consumption.

Although a few conflicting stands still exist across the globe regarding climate change issues, the heated debates that were not uncommon in the past few years have become less important. Consequently, global efforts toward addressing climate change have thus been seen through the establishment of the United Nations Framework Convention on Climate Change (UNFCCC) which came into force on March 21, 1994, with an overall framework to address climate change through intergovernmental efforts. In addition, the Kyoto Protocol was established alongside the UNFCCC which commits Annex I countries to undertake measures aimed at stabilizing GHG concentration in the atmosphere. All countries of the East African Community (EAC) and South America have ratified both the UNFCCC and the Kyoto Protocol and have actively participated and put mechanisms in place to implement the various agreements accruing from the annual UNFCCC Conference of Parties serving as the meeting of parties under the Kyoto Protocol (COPs/CMPs).

This chapter has focused on two unrelated regions, EA and SA, that are very vulnerable to climate change impacts but at the same time offering interesting adaptation and mitigation mechanisms humanity can learn from. Major climate change impacts, vulnerability, and adaptation options have been discussed. Some climate change impacts still considered of potential effects elsewhere are already happening within these two regions and hence give a wake-up call to the rest of the world for immediate combating actions. For example, the presence of climate-sensitive equatorial glaciers in the region offers a good opportunity to follow climate change trends and vulnerability. Thus, because of the diverse regional environmental

settings and socioeconomic characteristics, the regions offer the best opportunity to understand climate change details and how the developing countries live with climate change impacts, adaptation, and mitigation options thereby. For instance, it is now known that in EA, the ability to adapt to new conditions, exposure, and sensitivity changes to climate are determinant factors to the extent to which individual places are vulnerable to climate change impacts (Kelly and Adger 2000). In addition, the regions host some of the least developed countries and one of the emerging economies and thus are a good platform for socioeconomic comparisons.

The East African (EA) Picture

Brief Introduction of the EA Region

In its widest sense, the EA region includes Kenya, Tanzania, Uganda, Burundi, Rwanda, Sudan, and Ethiopia. Traditionally, the region was known to include only the three countries, Kenya, Uganda, and Tanzania, while politically, the current East African Community (EAC) block hosts the first five countries. The latter block has a rapid growing population currently standing at about 120 million people, most of whom are directly or indirectly employed in the agricultural sector. The inhabitants of the region have more or less comparable lifestyles and some forms of cooperation, long existed even before and during colonialism. During colonialism, for example, the former three countries had a well-developed cooperation in energy, monetary, transport, and communications sectors. To date, such important links continue to exist where they offer important contribution to regional economic growth and livelihood support during needy times like natural disasters which are not uncommon in the region (Maingu et al. 2003).

Biologically, the diverse environmental setting of the region has resulted in a number of endemism and very rich biological diversities. A number of rare species of aquatic and terrestrial ecosystems flourish in the region, both of which have a very big contribution in the economic development of the region. Its major wildlife ecosystems are internationally appreciated for their uniqueness and flourish in the region, including, among others, the Masai Mara Game Reserve in Kenya, Ngorongoro, Kilimanjaro, and Serengeti Wildlife Parks in Tanzania. One of the five internationally recognized centers in terms of high species richness and endemism, otherwise known as biological hot spots, is found in the Eastern Arc Mountain forests of EA (United Republic of Tanzania, URT 2007). The region also hosts a large portion of the Savannah, the richest known grassland in the world. The Eastern Arc Mountain forests and other regional forests make an important contribution in the energy sector in the region in which up to 90 % of the total energy usage is biomass dependent (Maingu et al. 2003). Moreover, the forests and the vast ocean area are very crucial in the control of carbon via the carbon cycle, while the diverse water bodies like large rivers and lakes are crucial for the socioeconomic sustainability of the region. These water bodies offer important services like irrigation,

hydropower, and domestic water to its fast-growing population, especially because the region has frequently been affected by severe water shortages (Hulme et al. 2001).

In addition, EA hosts Africa's tallest mountains (Mt. Kenya and Kilimanjaro) that still harbor rare tropical glaciers. The mountains have attracted several climate change studies that have added regional and extra-regional understanding of climate change trends. Geologically, the region is marked by the presence of the Rift Valley, semiarid to arid regions, and some of the most spectacular waterfalls that have been harnessed for hydropower projects. Furthermore, the region is rich in natural gas, coal, and different precious minerals including diamond, gold, and tanzanite, among others (Maingu et al. 2003). The neutral gas of coal is a notable contribution to the regional energy balance, while tanzanite is globally found in Tanzania only (United Republic of Tanzania, URT 2007).

Demographically, the region is home to thousands of pastoralists who remarkably herd their livestock mostly in the semiarid to arid areas of the region. The pastoralists provide a major portion of the livestock to the markets both within and beyond the region (Ensminger 1992; Kerven 1992) and as such are an important part to the regional gross domestic product (GDP) besides providing employment and important nutritional balance in the region. However, the livestock industry in the region is threatened by periodic droughts, the use of low breeds, and livestock diseases, inter alia. On the other hand, agriculture is the most important sector in the region considering the number of people it directly employs and its contribution to GDP and foreign exchange. Unfortunately, agriculture is mostly rain fed and severely impacted by uncertainty in rainfall patterns and intensity. Characteristically, agriculture in EA is largely subsistent, has low input, and is rain fed with only isolated cases of large-scale agriculture. This in turn leaves the region vulnerable to repeated crop failures, food insecurity, and increases in food prices (Hulme et al. 2001). Irrespective of the presence of the most productive soils and numerous water bodies, sadly the region is among the places where malnutrition is very high and periodic food aid has had to be provided. The situation has been made worse by the present climate change where rainfall has continued to be unpredictable, increasingly unreliable, and insufficient.

Meteorologically, EA is located in a complex climatic region in which the diverse topographical and hydrological interactions play an important role. The climate is mostly controlled by interactions between sea surface temperature (SST) forcing, large-scale atmospheric patterns, synoptic-scale weather disturbances (namely, trade winds and monsoons), tropical cyclones, subtropical anticyclones, easterly/westerly wave perturbations, and extratropical weather systems that are superimposed with regional factors like large lakes, topography, and maritime influence (Nicholson 1996; Ellis 1994). The above complexity renders climatic patterns within the region to change rapidly within a short distance and time. Consequently, the diurnal temperature range varies between 10 °C and 20 °C, while the annual temperature range is only 2 °C. On the other hand, mean annual bright sunshine is between <7 to 8 and 8 to >9 h/day in highlands and lowlands, respectively, while the regional mean annual net radiation varies between 450 and 550 cals/cm^2/day. The most important regional wind and pressure patterns include the Congo airstream with westerly and

southwesterly airflow, together with the northeast and southeast monsoons. Unlike the Asian southwestern monsoon, both East African monsoons are relatively dry, while the Congo airstream is humid and associated with rainfall (Nicholson 1996). Generally, East African rainfall is bimodal that is characterized by uncertainty both spatially and temporally. Predominantly, the rainfall occurs during boreal spring and comprises of long rains (March–May), while short rains come in autumn (September/October–December) season. The two rainy seasons occur when the Intertropical Convergence Zone (ITCZ) migrates from south to north through the equator. However, the above pattern varies significantly across the region, the uncertainty of which increases toward the dryer zones. In other words, rainfall is more patchily scattered in arid than in mesic systems (Ellis 1994). Within the region, the fluctuations in rainfall intensity are largely associated with east–west adjustments in the zonal Walker circulations that are linked to El Niño Southern Oscillation (ENSO). Studies have shown that humid areas in EA will become wetter while dry parts will turn out to be drier. The former will increase runoff, while the latter will significantly reduce it. In Tanzania, for example, two river basins are already said to have their runoff reduced (Nicholson 1996).

In this chapter, the discussions will be limited to the EA political block, the socio-environmental settings of which are considered useful in understanding local, regional, and extra-regional vulnerability and adaptations to global climate change.

Brief Introduction of Climate Change in EA

Although vulnerability to climate change impacts is increasingly becoming of ubiquitous nature, the best way of understanding climate change in EA is to ask "why is the region particularly vulnerable?"

EA is vulnerable because of various reasons, namely, the overdependency on natural resources and primary production; overreliance on rain-fed agriculture for livelihood support; low level of development; and inadequate institutional and economic capacities, all of which leave many persons vulnerable (Hulme et al. 2001; O'Brien et al. 2000). Climate change effects like changes in precipitation patterns and rising global temperatures are clearly affecting the region where they already disrupt people's livelihood, biodiversity, and ecosystems (Christensen and Hewitson 2007). Recent studies have shown that the region's economy largely depends on agriculture, livestock, tourism, wildlife, forestry, mining, industries, and marine and coastal resources, all of which are climate dependent and directly affected by the ongoing climate variability. Any impact on agriculture, which is the dominant contributor in terms of employment opportunity, income generation, and support to the population, leaves many livelihoods disrupted. In addition to the overdependence on natural resources, the vulnerability also roots from low level of development and generally of per capita income. The majority of the population in the region lives below respective national poverty lines and most of them with less than a dollar per day, especially in rural areas.

Furthermore, socioeconomic inequality within the population increases vulnerability and limits adaptation options to some individuals. The most obvious of such

inequality could be seen between the urban and rural populations, in which the latter suffers more from low development, low income, and poor access to public services compared to their urban counterparts (United Republic of Tanzania, URT 2007). In some places like Tanzania, vulnerability to climate change has even taken a gender dimension in which women are categorized more vulnerable on account of the deep-rooted socioeconomic barriers in the country.

Working with regional climate change projections, the region is set to observe both decreases and increases in rainfall of between 5 % and 10 % (June–August) and 5 % and 20 % (December–February), respectively. Sadly, the projections show that the increase in rainfall may come as a few large storms in early traditional wet season and hence complicate water management, soil erosion, and health services. Several development activities/projects in the region are either directly or indirectly impacted by climate change. This occurs when the variability impairs climate-dependent projects such as forest management, infrastructural developments, and agriculture, while indirect impacts happen when socioeconomic projects like health and education are impacted. Regrettably, for a good number of years, most governments in the region did not strategically link climate change and socio-development projects. Climate change factor was not clearly reflected in individual national development plans and policies. Only recently, and after significant climate change impacts, some governments in the region have practically linked the two.

Arguably, the negative impacts of climate change in the region are also complicated by other factors such as rapid population growth, widespread poverty of the inhabitants, and human and livestock diseases, among others. Even worse, under the current population growth rate, some studies already estimate a doubling in demand for water, food, and rangeland within 30 years (Ministry of Lands, Water and Environment (MLWE) 2002). Such statistics put EA in a very desperate situation, and effective measures must be taken sooner rather than later to counter the effects of climate change in the region. EA already has some social stressors which make the region even more vulnerable to climate change and thus limit adaptation ability. Such stressors include the following: governance problems, high population growth, land scarcity in some places, conflicts, and diseases such as malaria and HIV/AIDS.

Given the socioeconomic and technological capacity of the region, dealing with climate change will continue to be problematic because of numerous reasons. Most official strategies to livelihoods impacted by climate change are expensive and technical which renders poor implementation. This is where indigenous coping options which are plenty in the region, as will be seen later, could be integrated into the national strategies.

Regional Climate Change Vulnerability

The global climate change impacts like intensification of extreme weather events, sea level rise, alteration in temperatures, and distribution of precipitation are all evident in EA. Within the region, however, distribution of the effects of climate change is known to be nonuniform and arguably more noticeable from variations in

precipitation than temperature. For example, most studies indicate that the region will warm by between 2 °C and 4 °C by 2100 which is notably less compared to inner South Africa and Mediterranean Northwest Africa. Further projections show that regional warming in the twentieth century has been of the order of about 0.05 °C per decade. However, within the region itself, the projected warming is unlikely to be uniform where inner parts of the region are likely to warm more than coastal regions. On the other hand, a number of climate change-related droughts have been recorded in recent years with severe consequences to livelihood support systems and even deaths of both human and livestock (O'Brien et al. 2000; Christensen and Hewitson 2007). For example, studies have indicated that warm sea surface temperature may be to blame for the recent droughts between the 1980s and 2000s in equatorial and subtropical EA. Interestingly, however, historical records in the region show that over the course of the last century, there has been a net increase in the amount of rainfall (Hulme et al. 2001). Further studies show that the increasing rainfall and decreasing temperature in presently humid areas may increase river flow by up to 10–20 %, for example, in Uganda (Hulme et al. 2001). However, more recent studies suggest that whereas parts of equatorial EA are likely to have a 5–20 % increase in rainfall from December to February, the region will also observe a 5–10 % decrease in rainfall from June to August by as early as 2050. Certain parts of the region are known to be more vulnerable to climate variation than others. For instance, both increase in regional temperature and decrease in rainfall would leave most parts of Northern Uganda and many places in Tanzania with serious water scarcity (Ministry of Lands, Water and Environment (MLWE) 2002). Generally, presently, wet and dry places within the region will become wetter and drier, respectively. In Tanzania, for example, two rivers have their flow reduced directly because of the dwindling regional rainfall. Even more worrying, the observations show that the decrease in regional precipitation will most likely occur in the rational dry spell in the region and hence worsen frequency and severity of drought, hence desertification. Such relatively drastic changes in precipitation already have many socioeconomic and ecological negative impacts, among them reduced agricultural harvests, increased insects and fungal infestations, decreased biological diversity, and complicated hydropower availability, inter alia (Hulme et al. 2001).

Although climate change affects many biophysical and social aspects in the regions, the following categories considered as major issues will be used as a guideline for the discussion. Worth noting, some of these impacts have far-reaching influences and tend to trigger other vulnerability.

Natural Disasters: Droughts, Flooding, and Wildfires

Probably the claim that climate change is projected to aggravate frequency and intensity of extreme weather events (El Niño events, storms, droughts, and flooding) and wildfires can superlatively be understood from the EA region. The increased frequency and severity of the named natural disasters have in recent years caused injuries, deaths, famine, disease outbreaks, and even population displacement.

For example, the region has in recent years observed severe floods both in urban and rural areas (Conway 2002; Hellmuth et al. 2008; Action Aid International 2007). Although considered natural hazards, floods increasingly happen in cities where human activities are to be blamed. Urbanization, for example, has been observed to cover large areas in cities with roofs, roads, and pavements and thus restrict natural flow of water and percolation. Moderate storms in typical East African cities thus end up collecting enough water to cause floods, and thus their intensity has been growing as cities expand. Major towns including Nairobi, Kampala, and Dar es Salaam have witnessed periodic flooding which have repeatedly left widespread infrastructural and humanitarian costs (Action Aid International 2007). Flooding has also impacted the agricultural sector in which crop fields were swept away, nutrients leached, and top soils eroded. Even more worrying, both frequency and intensity of floods are worsened by the warm ENSO events. For example, the El Niño event in 1997 resulted in heavy rainfall and widespread flooding that was responsible for up to 1.7 m rise in the water level in Lake Victoria and severe damage to the agricultural sector (see Box 1). The flooding left many famers and pastoralists stranded with massive losses. Arguably as a sign of worsening situation, regional statistics show that between 1992 and 2008 up to 3,137,675 USD worth of humanitarian aids was spent on flooding-related disasters. Apart from flooding, drought is another climate disaster that has been very common in the region and is documented to be in close agreement with the regional climate change statistics. Between 1992 and 2008, droughts have claimed about USD 28,383,288 in humanitarian contributions to rescue lives within the region. Based on regional meteorological data, however, drought events may decrease in a few places while at the same time increase in other areas with major potential agroecological implications. Some of the most common implications in the region include desertification and deforestation that have been recorded to increase in many places. Based on the above statistics, it is clear that droughts bring more hardships to the people and have wider economical implication in the region than flooding (Action Aid International 2007).

Box 1: Showing Effects of El Niño in EA

Much of EA observed severe droughts in 1997 that was followed by devastating El Niño rains from October 1997 to March 1998 (Government of Kenya Meteorological Service 1998). The El Niño season was responsible for up to a fivefold increase in rainfall (Hulme et al. 2001) with severe consequences in infrastructure, agriculture, and health problems to both livestock and humans. The available statistics shows that up to 4,000 people died of flooding and many more died due to increased cases of malaria and cholera in the region. In addition, thousands of livestock died as a result of the flooding. The El Niño was economically costly as two major cash crops in many areas within the region, tea and coffee, were severely reduced. In addition there were widespread rotting of cereals notably wheat and maize in the region and

(continued)

Box 1: (continued)
consequently increased prices of the cereals (Nicholson 1996; Horn of Africa Review 1997). Furthermore, the much dependent source of foreign income, from tourisms, was as well hampered due to infrastructural problems. Furthermore, movements of farm inputs to farming areas, agricultural produces, and livestock to marketplaces were all impacted with significant increases in production costs.

Apart from that, other recent studies already show a clear linkage between climate change and incidents of wildfire within the region. Cases of bushfire due to periodic droughts and high temperatures are presently not uncommon within the region. One of such studies was done on Mt. Kilimanjaro where apart from the receding glaciers that everybody is worried about, there is a silent danger, periodic fires that are feared to have more ecological consequences than the diminishing glaciers. Because of the periodic fires on the mountain, it is argued that one-third of the forest cover has already been lost within the past seven decades alone. The fires on the mountain have been very serious to the extent that it is feared that the water sources in the fog interception zone will completely disappear within the next few years. It is thus argued that fires on the mountain may have far-reaching impacts on the eco-hydrological balance of the receding glaciers (Hemp 2005; Thompson et al. 2001). Apart from Mount Kilimanjaro, fire events directly connected to climate change have also been observed on other forest resources including on one of the world's biodiversity hot spots, namely, West Usambara and Uluguru Mountains (Mwandosya et al. 1998). Incidents of wildfires have also been reported in other regional ecosystems and projected to have more detrimental impacts in countries like Kenya where already large parts of the country lie in the arid and semiarid areas (MOENR 2002).

Sea Level Rise and the Salt Water Intrusion into Freshwater Sources

The EA region hosts a long strip of coastal area along the Indian Ocean that is shared by both Tanzania and Kenya. The ocean resource supports millions of livelihood and important cities for regional growth are found along the coast. Hitherto, studies from many parts of the world have shown only a small increase in sea levels, and/or reports still treat it among the potential effects of climate change. The sea level rise due to climate change can clearly be studied in EA where small islands such as Maziwe Island in Tanzania that was once attractive for tourists, fishermen, and researchers are now most of the time submerged and only habitable for a few hours during the day. Located about 15 nautical miles from a coastal town of Pangani in Tanzania, *Maziwe* Island is a clear wake-up call that the region is already suffering from sea level rise and demands further studies to establish consequential hydrogeological and ecological impacts. Note: Because of its importance and richness, the island was named among the national marine reserves in 1975 and is home

to 35 species of corals and more than 200 species of fish and is a wealthy source of algae, sponges, and sea grasses (United Republic of Tanzania and URT 2007).

Although Maziwe Island is the clearest threat of sea level rise in the region, many coastal towns and cities in Kenya and Tanzania remain at risk from the rising sea level (Magadza 2000). As seen earlier, most of these coastal towns in the region are of historical importance and attract many tourists every year. Indeed the submerging of the island would have significant socioeconomic and ecological implications like disruption of livelihoods and most importantly the regional GDP. Even more worrying, the sea level rise is already threatening freshwater availability through seawater intrusion affecting millions of coastal inhabitants who mostly depend on groundwater for domestic water supply. One such place where sea level rise is threatening such an important source of freshwater is Tanzania in which her aquifers and deltas are known to be at high risk. Other potential risks of sea level rise in the region include coastal erosion and losses of coral reef and mangroves in both Kenya and Tanzania (Magadza 2000).

Impacts on Water Availability, Agriculture, and Food Security

As seen earlier, it is worth mentioning that, even without climate change, agriculture in the region has many serious challenges, among them the overdependence on rainfall and soil degradation. Climate change is of a special concern in the agricultural sector since increasing temperature, changes in precipitation patterns, flooding, and generally water scarcity have all been linked to recent food insecurity in the region. About 80 % of EA livelihood depends on agriculture which regionally contributes around 40 % of the GDP (International Food Policy Research Institute (IFPRI) 2004). Agriculture in EA is highly vulnerable to climate vulnerability which often results to repeated crop failures, lower export earnings, and low domestic revenues, inter alia. Most EA countries are among the world leaders in terms of food insecurity, and climate variability will worsen diminishing harvests (Devereux and Edward 2004). Presently, over 40 % of mortality rates among Uganda's children are due to chronic droughts in the country. Many more children across EA are either stunted or underweight because of climate change-related malnutrition (The Global Humanitarian Forum 2009).

Research has shown that the overdependence in rain-fed agriculture has been leaving many rural livelihoods vulnerable to food insecurity partly due to the recent shift in growing season within the region. Although climate variability has been blamed for the worsening food insecurity, the vulnerability in the agricultural sector is also complicated by heavy reliance on the subsistence farming by the majority of farmers (Hulme et al. 2001). Note: African agriculture is the slowest in terms of productivity increase. Thus, global warming will only add tension to the already overstretched region and hence likely to affect even a greater number of individuals.

The recorded slight increase in temperature and decrease in rainfall within the region have already claimed many victims in terms of food insecurity. For example, the recorded decrease in rainfall of between 50 and 150 mm between March and May

from 1996 to 2003 was observed to have a corresponding decline in long-cycle crops in the region. As a result, many households abandoned maize (one of the long-cycle crop), the harvest of which directly depends on the availability of enough rainfall during the mentioned season above (see Box 2). In recent years, generally, drought has been observed to decrease water supplies with consequences in reduced crop productivity and the associated widespread famine in Northern Kenya and the Southern and central parts of Tanzania (see section "Natural Disasters: Droughts, Flooding, and Wildfires"). Another drought-related disaster could be traced in Rwanda where in 2005, the country observed massive crop failures in the Eastern province. In addition to the decrease in the amount of rainfall, agricultural systems in certain parts of EA have also been affected by too much rainfall. Equatorial EA has particularly been receiving increased amount of rainfall during El Niño season which resulted in periodic flooding often associated with sweeping away of crops (Hulme et al. 2001).

Box 2: Showing Potential Impacts of Climate Change on Agriculture

Tanzania is likely to lose up to 10 % of its grain harvest per year by 2080 (Mwandosya et al. 1998), among them, corn, which is a staple food and traditionally the most important source of carbohydrate in Tanzania. Already farmers are witnessing a significant decline in corn harvests and have attempted to grow other crops in its place. Should [CO_2] double and temperature increase by between 2 °C and 4 °C, an average of 33 % of maize harvests is likely to be lost by as early as 2075 (United Republic of Tanzania, URT 2007). In some places in central Tanzania, up to 80 % decreases in the maize harvest have been linked to climate change (United Republic of Tanzania, URT 2007; Mwandosya et al. 1998). In Tanzania, the flood- and/or drought-related famines have increasingly been common since the mid-1990s.

Climate change impacts on the agricultural sector will also have significant economic implications via interference with cash crops (Box 3). In Kenya, for example, agricultural losses from three cash crops in coastal areas, namely, coconuts, mangoes, and cashew nuts, could amount to about USD 500 million under a 1 m increase in sea level. The three crops also make a significant livelihood to many coastal dwellers in Tanzania and are under more or less similar threats (Easterling et al. 2007).

Box 3: Showing Potential Impacts of Climate Change on Cash Crops and the Associated Economic Implications in Kenya

Apart from food crops, climate change is also projected to affect major cash crops in the region with wider socioeconomic implications. Studies have shown that should the temperatures increase by 1.2 °C and if the changes in

(continued)

Box 3: (continued)
precipitation patterns continue, large areas of the world's second producer of tea (Kenya) will be made unfavorable for the crop. The latter would mean interference with over 25 % of Kenya's foreign exchange and up to 10 % loss of employment opportunity (Easterling et al. 2007).

Impacts on Human, Livestock, and Wildlife Health

Climate variability is ubiquitously known to be central in the reproduction and geographical distribution of a number of disease vectors. For example, recent projections show that a global rise of between 13 °C and 3 °C would enable mosquitoes to expand their natural range while survival chances of other disease vectors are likely to be increased with increasing rainfall. Within the region, the unprecedented extreme weather events, namely, high temperatures and severe rainfall, are blamed for the initiation of malaria epidemic in highland Rwanda, Uganda, Western Kenya, and Tanzania. It is well known that mosquito vectors thrive better under warmer temperatures; hence, global warming will most likely worsen cases of malaria. Within the region, generally, intensity and severity of climate-sensitive diseases, namely, dengue fever, Rift Valley fever (RVF), typhoid, cholera, malaria, dysentery, and a number of respiratory diseases, are all projected to worsen with ongoing climate alteration (The Global Humanitarian Forum 2009).

Malaria

Worsening of malaria cases has been recorded in many places within EA, and the epidemic is directly a result of changes in rainfall patterns, higher temperatures, deforestation, and generally environmental degradation (Hulme et al. 2001; Conway 2002; Mwandosya et al. 1998; Zhou et al. 2004). In close agreement to increasing numbers of malaria victims, regional studies already indicate an upward creeping of malaria cases directly because of recent modifications of vector habitats due to climate change (Müller 2010). For example, between 1960 and 1980, there were no recorded cases of highland malaria in highland EA, the case of which is no longer true in many highland areas like Lushoto and Kilimanjaro in Tanzania. The creeping of malaria into the highlands of EA is of particular concern since the local inhabitants of such places do not have a well-developed immunity against the disease and thus have a relatively increased mortality rate (Mwandosya et al. 1998; Müller 2010). Worrying predictions exist that more highlanders are likely to be further affected if the current trends will continue. The above trend is already witnessed in many places within the region where on top of climate change which is known to modify vector/microbial adaptations, the situation is also aggravated by regional socioeconomic changes, worsening of food production, and crippling health-care systems, inter alia (Conway 2002; Hellmuth et al. 2008; Mwandosya et al. 1998; World Health Organisation (WHO) Regional Office for Europe 2003).

Rift Valley Fever (RVF)

Hitherto, it is ubiquitously known that outbreaks of RVF are usually associated with heavy rainfall and warm temperatures. Within the last decade, several outbreaks of RVF in EA were directly attributed to worsening climate change impacts. Thus, the effects of climate change on human health within the region can further be appreciated by the close correlation between regional El Niño events and Rift Valley fever (RVF) epidemics in recent years. The observed regional trend has been that during warm ENSO events, the EA highland tends to receive unusual high rainfall which has a positive relationship with the number of recorded RVF outbreaks. Going deeper into historical records would reveal that about 75 % of all recorded cases of RVF occurred during the warm ENSO events between 1950 and 1998 (Patz et al. 2005). Such statistics give a worrying sign of what is likely to happen if full-scale impacts of projected negative effects of climate change on health sector would occur.

Cholera

The relationship between regional climate change and health sector can further be understood from cholera epidemics. Studies have shown that prolonged droughts often associated with scarce water resources, poor sanitation, and changes in rainfall and temperatures are periodical reasons behind regular outbreaks of cholera and other waterborne and diarrheal diseases in EA. Cholera cases are known to be worsened by wet seasons; thus any increase in the amount of rainfall as already is the case in some parts of EA (section "Natural Disasters: Droughts, Flooding, and Wildfires") would further elevate cases of cholera. As seen earlier, regional rainfall is projected to increase in coastal areas and Lake Victoria Basin, and the named localities above have already witnessed a relative increase in cases of cholera outbreaks (Mwandosya et al. 1998). The acute intestinal infection diseases that are caused by *Vibrio cholerae* can often become fatal and are now declared endemic in Lake Victoria Basin and have been of repeated occurrence in the region since 1978 (Mwandosya et al. 1998; World Health Organisation (WHO) Regional Office for Europe 2003). Available statistics show that the disease first caught the attention of EA coastal dwellers in 1836 where it left over 20,000 deaths in Zanzibar (Tanzania) alone and killed many more people in Kilwa (Tanzania), Malindi, and Lamu (the latter two in Kenya). A direct sign of the climate variability factors in cases of cholera outbreak in EA is seen from the fact that, cumulatively, more cases of the disease have been recorded over the past three decades, the same duration in which there has been worsening of climate change impacts.

Recently, the outbreak of poorly known diseases such as Chikungunya fever has also been linked to climate change in EA. It is known that warm and dry climatic conditions precede a typical outbreak of the disease. Following the prolonged drought for many seasons in EA, about 500,000 people mostly in the coastal areas were reported to be afflicted by the mosquito-spread viral disease (Shongwe 2009).

Apart from human health, livestock health has also been impacted by climate change in which there could be further infestation of tsetse flies, ticks, snails, and other disease vectors to previously safe zones. The former are already observed to

spread to Northeast Tanzania with the potential of reducing safe grazing range in the areas (Mwandosya et al. 1998). Furthermore, the impacts of climate change on healthy systems in EA have even affected wildlife ecosystems. In 1989, for example, large numbers of wild animals died of rinderpest which was directly attributed to regional climate change impacts (Mwandosya et al. 1998). Such big losses of wildlife coupled with declining biodiversity due to repeated drought in the region are likely to cripple the tourism sector, the major sources of foreign currency in the region.

Impacts on Environment: Deforestation, Fisheries, Biodiversity, Wildlife, Ecosystems, and Seawater Intrusion into Freshwater

Although major impacts on biodiversity in the region is presently believed to come from humans via overexploitation of natural resources and land use change, recent climate change scenarios have equally been threatening the biodiversity. Already studies show that there are changes in the migratory roots of wild animals in several precious ecosystems of EA. Even more worrying, studies have shown an upward shift in vegetation composition in major mountains in the region particularly on Mount Kilimanjaro. Generally, the climate variability already has its detrimental effects in dynamics of regional biomes and biodiversity integrity and richness.

Although most of the tropical fishes have adapted to warm waters, most of them might not survive temperatures beyond their critical thermal maxima due to recent climate change trends. The population of important fish species (*Tilapia mariae*) that occur in EA and are used as an important source of protein is likely to be affected if their preferred temperature (between 25 °C and 33 °C) will be exceeded. This particular species of fish has a thermal maximum of 37 °C beyond which they will not survive (Vuorinen et al. 1999; Siemien and Stauffer 1989). Ecologically, however, global warming might have even more effects as any such ecological imbalances will disturb the ecosystem and might result to losses of many more species. Other studies show that due to recent climate variability impacts in Lake Tanganyika there has been a 20 % decrease in primary production estimated to correspond to about 30 % of fish yields (Vuorinen et al. 1999).

In addition, researchers are already worried of the effects of climate change on the hydro-geochemistry of water bodies in EA that have a potential of significantly decreasing fish populations. Regional studies show that any slight increase in temperature is likely to affect the amount of dissolved (O_2) and the limnology of major lakes in the region (Fick et al. 2005). Already worrying studies show that significant effects might occur in Lakes Tanganyika and Victoria. The latter lake has in the 1980s observed massive deaths of fisheries due to low levels of dissolved oxygen as a result of decreased turnover in the lake (United Republic of Tanzania, URT 2007). It is widely believed that the trend is likely to be the same in other lakes in the region and calls for ecological studies to be carried so as to establish the situation. Any escalation in the effects of climate change on great lakes fisheries will have major socioeconomic implications as the lakes offer an important source of

employment, food to millions of people within the region, and even foreign exchange (United Republic of Tanzania, URT 2007).

Even more worrying, among the negative impacts of climate change that are already witnessed in EA include the problem of species invasiveness. It is already known that invasive species have better adaptive ability to climate change which puts them in a better competitive situation compared to other species. The latter is very worrisome as EA region has already witnessed a number of exotic species becoming uncontainable with detrimental ecological implications. Very delicate forest ecosystems in the Eastern Arc Mountain forests, like the East Usambara forest reserves, are already struggling with ecological impacts of several invasive species including *Lantana camara* and *Maesopsis eminii.* The problems of species invasion are not limited to terrestrial ecosystems; marine ecosystems have also witnessed a number of invasions including the water hyacinth and Nile perch in Lake Victoria. Studies show that the region may further be victimized by more colonization of invasive and other exotic specifies directly because of the ongoing global climate change (United Republic of Tanzania, URT 2007).

Although climate change is not the only problem affecting regional ecosystems, combined with other factors like overexploitation of resources and particularly land use changes (destruction of habitats), it may result to severe effects to regional biodiversity. The latter has directly affected forest resources, and availability of important products like fuel wood has been significantly affected. In addition, regional desertification has also been observed to expand.

Climate Change and Energy Crisis in EA

In order to be able to get a better picture of how the global climate change is complicating availability of energy in EA, the following basic is information is considered vital.

EA is blessed with a rich mixture of energy varieties that can be generalized into natural gas and coal in Tanzania, geothermal energy in Kenya and Tanzania, numerous hydropower sources, significant biomass in nearly all member countries, and recent discovery of oil reserves in Uganda and potentially in other countries. There is also rich potential for wind energy, biogas, and solar power in many places within the region (Maingu et al. 2003). Within EA, however, low level of regional development is clearly reflected in the energy characteristics and can statistically be studied from the percentage (%) energy consumption characteristics (Table 1).

In EA, the effects of climate change on regional energy stability can be observed from diverse angles. These include reduced availability of biomass, diminishing/dwindling water flow for hydropower generation, and most importantly destruction of infrastructures (roads, railways, electric poles) needed to transport and distribute various forms of energy.

From the table above, it is clear that the energy balance in all countries is largely dominated by biomass (mostly fuel wood, charcoal, and agricultural wastes). Since the effects of climate change include desertification, this is where it possesses its

Table 1 Showing levels of energy consumption in East Africa (EA)

Country	Petroleum (%)	Electricity (%) (major source of electricity)	Biomass (%)	Others (natural gas, solar power, wind power, etc.) (%)
Kenya	21.0	3.0 (mainly from hydropower, petroleum, and geothermal energy)	75.0	1
Uganda	6.1	1.1 (mainly from hydropower and petroleum)	92.8	–
Tanzania	8.0	1.2 (mainly from hydropower, natural gas, coal, and petroleum)	90.6	0.3

effects on the major source of energy. Wood is increasingly becoming rare in many places due to both human pressure and climate change (desertification); see section "Impacts on Environment: Deforestation, Fisheries, Biodiversity, Wildlife, Ecosystems, and Seawater Intrusion into Freshwater" above.

One potential mitigation option in the region's energy supply would be to embark on renewables which are not limited. However, the inclusion of the renewable into the energy mix has not been of any significant contribution in comparison to the massive potentials available among other reasons due to high initial costs involved and poor availability of necessary technologies (Maingu et al. 2003). A few promising attempts however exist in Kenya and much less in other countries where more than 150,000 solar PV units are installed contributing to over 5 MW to the country's power needs. Kenya is again leading in terms of wind energy harvesting where some 450 kW wind power system is already installed. Other countries including Tanzania have already identified several potential locations where wind is abundant round the year and some implementation attempts are ongoing (Maingu et al. 2003). On the other hand, biogas would be another potential source of energy in the region on account of the presence of many livestock. However, biogas technology has been around in the region for over 20 years, but its implementation has faced similar problems like solar energy. Isolated hope exists in Uganda and in other countries where a few plants have been installed and running. Interestingly, Uganda has also been a leading player in terms of power generation from industrial biomass residues. Promising units of power are currently being produced in three different sugar mills in the country. Kakira Sugar Works, for example, is currently producing 2.5 MW and plans to produce 15 MW when the unit is fully running. Tanzania has comparable installations in Kilombero Sugar Company with a few other potentials in other sugar industries like Mtibwa (Maingu et al. 2003). Efforts can still be made by individual governments within the region to invest in renewable energy as the current installation is mostly from private sector. Strengthening of such renewable energy sources into regional energy balance would help in dealing with periodic shortage of power due to repeated droughts in hydropower basins within the region which have hampered many development projects (Maingu et al. 2003).

Although EA is desperate in meeting its energy demands, if not carefully planned, some adaptations to climate change impacts on the energy sector are likely to leave the region to follow the destructive way as currently the situation is in Asia, particularly China. The recent incorporation of coal energy as a source of energy in Tanzania is seen to be as one adaptation option. Poor technology of harnessing energy from coal may add regional contribution to GHGs. The country has about $1{,}200 \times 10^6$ metric ton of proved coal reserves which could meet most of the energy needs in the country and potentially of the neighboring countries. Already the country is contributing about 6 MW to the national grid from coal, and the plan is to increase production to about 600 MW as an adaptation to the drought-prone hydropower. Given the low level of technology in the country, however, the capitalization of coal into the energy mixture is likely to contribute further to the problems of global climate change (Maingu et al. 2003).

Concomitant with the effects of climate change on availability as seen on biomass, hydropower is also periodically affected by drought, the frequency of which has been very high in the recent years. Like the rest of EA countries, Rwanda is also facing power shortage because of the impacts of climate change in its hydropower plants. For example, in 2006, the country spent 65,000 USD per day to generate emergence electricity because the Rugezi wetland had its water reduced to very low levels. Although the 1997 El Niño triggered heavy rain and subsequent flooding in many places in EA, it left certain parts of Kenya with severe drought that badly disrupted hydroelectricity power generation (Siemien and Stauffer 1989). In nearly all countries in EA, hydropower generation has suffered from climate change-related problems, namely, low water levels and siltation (Maingu et al. 2003). Worth noting, the proportion of electrification in the region is very low among other reasons due to financial constraints to expand the network, high prices of electricity, and generally low level of development (Maingu et al. 2003).

Livestock Sector

EA region is home to thousands of pastoralists. Interestingly, most livestock are mainly found in drier part of the EA like arid to semiarid regions. Worth noting, the drylands comprise of about two-thirds of Africa's land in which about 50 million people depend on livestock and/or dryland agriculture. Although climate variability is a common phenomenon of most drylands, in Africa and particularly EA, it has particularly influenced ecosystem structures and functions and consequently land use and lifestyles. It is worrying that in arid and semiarid regions, climate change may lead to loss of palatable forage to livestock and more drought-tolerant vegetations that are not suitable to livestock (MOENR 2002). The major climate change vulnerability to livestock sector in the region comes via repeated droughts that leave the areas with severe shortage of pasture and water (Box 4). As a result, there has been an increase in the number of conflicts between pastoralists, farmers, and

wildlife. The recent droughts have been severe to the extent of triggering communal fighting and even interwar between neighboring countries. Other vulnerabilities to the livestock sector include flooding. In recent years, flooding has been reported to sweep a large number of animals and made pastureland unavailable for livestock. In addition to drought and periodic flooding, livestock industry in EA is also affected by other factors like diseases epidemic, intertribal raiding, and declining pastureland due to rapidly increasing human populations among others.

Box 4: Showing Effects of Drought on Livestock Husbandry in EA
In 1997 the whole of EA observed one of the worst droughts which led to huge economic impacts to the pastoralists (World Food Program (WFP) 2000). In Uganda, frequency of environmental insecurity, livestock rustling, and intertribal fighting has increased, largely blamed on increased frequency of droughts; thus, pastoralists are forced to move beyond their land areas (Davidson et al. 2003; World Food Program (WFP) 2000). It is projected that as a direct consequence of climate change, Uganda may have a significant reduction in suitable areas for dairy farming and the entire livelihood of some pastoralists would be disrupted (Davidson et al. 2003).

Other Sectors

Tourism is a very important regional sector in terms of foreign exchange earnings. Surprisingly, a very few regional literatures exist patterning impacts of climate change on tourism sector. The effects of climate change on regional tourism mainly come through demolition of infrastructures that support tourism or disruption of the natural beauty of the tourism attractions. Major tourism attraction in the region, namely, Mount Kilimanjaro and Mount Kenya, and spectacular ecosystems such as wildlife and natural forests are all threatened by climate change (see section "Impacts on Environment: Deforestation, Fisheries, Biodiversity, Wildlife, Ecosystems, and Seawater Intrusion into Freshwater"). Furthermore, major tourism cities like Malindi, Mombasa, Lamu (in Kenya) Zanzibar, Dar es Salaam, Bagamoyo, Mtwara, and Tanga (in Tanzania) all lie in the coast where the projected sea level rise will have major socioeconomic implications (Mwandosya et al. 1998). The livelihood of many people in the coastal areas directly depends on the sector for living. Major infrastructures like hotels and other recreation structures are also threatened by the projected sea level rise (Maingu et al. 2003; Mwandosya et al. 1998). Like in other developmental activities, infrastructures such as roads and railways are very important for the sector but have periodically been swept away by flooding. The recent flooding in Tanzania which was associated with El Niño event swept a large part of the railway, and it is estimated that the country would require at least 6 months to fix it.

Socioeconomic Implications of Climate Change on EA Mountains

Diverse verticality of mountain ecosystem offers numerous microenvironments which in turn creates rich biodiversity. However, mountains are known to be very sensitive ecosystems that are often faced with conflicts between environmental conservation and human activities. Yet scientific evidence shows that most mountains are among vulnerable ecosystems to global warming. Rare mountain glaciers are close to the equator in a phenomenon that is only present in the three regions of the Earth: the Ecuadorian Andes, New Guinea, and EA. The latter hosts the two tallest mountains in Africa, Mt. Kilimanjaro (5,895 m) in Tanzania and Mt. Kenya (5,199 m) in Kenya, both of which are socio-ecologically very important to millions of people within the region. Many similarities exist regarding these tropical mountains, both of which are important tourism attractions, serve as an important source of water, are very rich in biodiversity, and are probably the most important for now; both are badly threatened by climate change and human pressure (Shongwe 2009). EA mountain slopes are under constant pressure from both commercial and subsistence farming. The most important climate-related threats on regional mountains include the unprecedented glacier recessions and periodic fires. The disappearance of the glaciers is not limited to the two mountains named above; another mountain in the region, Mount Rwenzori, has observed more or less the same trend (Shongwe 2009). Apart from interference with regional hydrological balance, the thinning of the glaciers has reduced the scenic values of the mountains with potential negative ramification to the tourism sector. Historical records show that these three mountains in EA began thinning in 1,880 proportional to the drop of water levels in regional great lakes. In this chapter, the impacts of climate change on Mt. Kenya and Kilimanjaro are discussed in the Box 5 (Fig. 1).

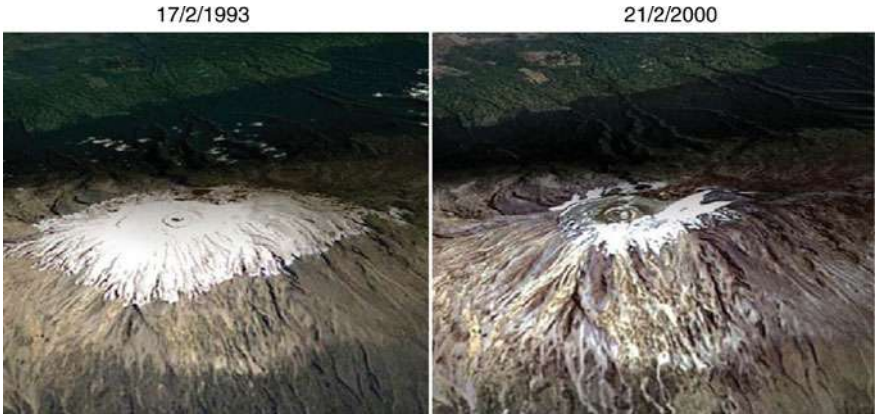

Fig. 1 Showing loss of Kilimanjaro glaciers and vegetation cover in a period of less than a decade (United Republic of Tanzania and URT 2007)

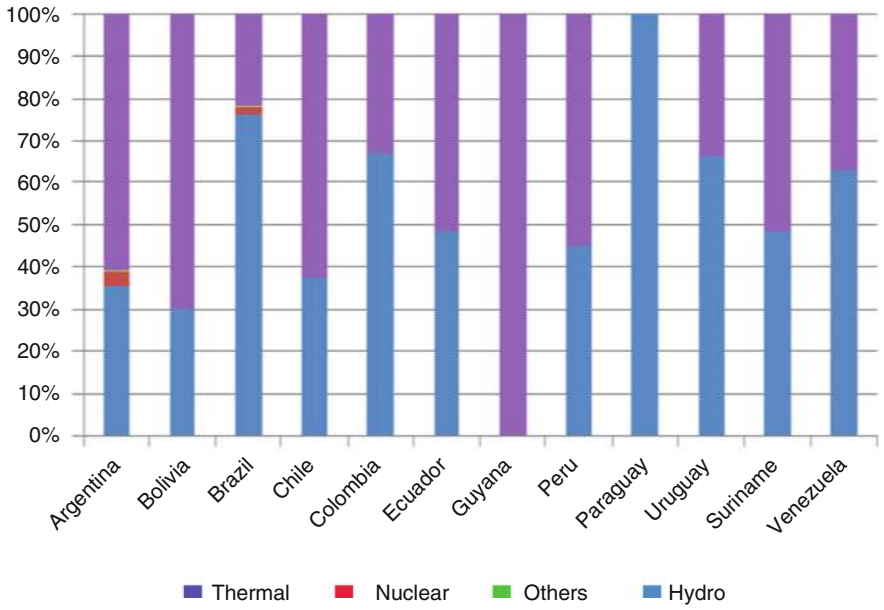

Fig. 2 Electricity production structure by country in 2008. Based on the information from the Latin American Energy Organization, OLADE, 2009. Energy Statistics Report 2009. Base year 2008

Box 5: Showing Retreat of Glaciers on Mount Kenya and Mount Kilimanjaro and the Associated Socioeconomic Impacts to the Society

Mount Kenya

On account of its uniqueness, Mt. Kenya is included among the list of world heritage sites and nicknamed a water tower in a semiarid region. The mountain contains several remnants of glaciers, all of which have been receding rapidly in the recent past (Fig. 2). For example, the Gregory and Lewis Glaciers have been showing unprecedented recession since the late nineteenth century. In 1990, there were 18 glaciers compared to only seven left by 2007. Studies show that the deteriorating water resources in the mountain and generally all other resources are attributed first and foremost to socioeconomic changes on the mountain but also on climate change consequences and seasonal aridity within the mountain's microclimates. The fast-thinning glaciers have badly affected the water supply to the already water-stressed areas of the region. In addition, nearly all the major rivers in Kenya begin from the mountain, with majority of the water coming from the middle and the summit of the mountain. The water levels in Tana and Athi Rivers among several rivers that originate from the mountain are currently among the worst affected. The flowing Tana

(continued)

Box 5: (continued)
and Athi Rivers are the main sources of water for the Seven Folks Dams, Kenya's key hydroelectric power generation plant. In addition to domestic use, the water is also used for agricultural activities that are important for the livelihood of the people. Hence, climate change consequences on the mountain could as well have impacts on the energy balance of the country. In addition, the mountain provides an important source of water to more than seven million people in the surrounding communities. Other studies in the region have indicated that reduction in water volume of these two rivers due to glacier disappearance on Mount Kenya will threaten the lives of over half of the Kenyan population (MOENR 2002).

Mount Kilimanjaro: The Roof of Africa

Like Mount Kenya, Mount Kilimanjaro which is found in Tanzania near the border with Kenya (3°04′S, 37°21′E) offers an excellent opportunity to study and understand regional climate change trends and vulnerability. Because of its importance, the mountain has received a worldwide attention that has attracted a series of studies, most of which giving worrying conclusions about its sustainability as a result of both climate change and human pressure. Arguably, the best way of studying the climate change vulnerability on Mt. Kilimanjaro is offered by its fast-thinning glaciers and its implications to the hydrology of the surrounding areas (Fig. 2). While the historical records show that the glaciers have been retreating since 1850, the current thinning is arguably the most alarming and fastest. Whereas the early retreat was likely due to natural climatic shifts, both the ongoing global warming and human pressure are blamed for the worse retreat ever recorded. Statistics show that there was about 4.2 km^2 of glaciers in 1976 compared to only 2.6 km^2 in 2000. The most recent studies on the mountain suggest that there will be no glaciers left on the mountain as early as 2020. The disappearance of the glaciers on the roof of Africa will have many negative consequences. The water from Mount Kilimanjaro is feeding the Pangani Basin where about 3.7 million Tanzanians live and many socioeconomic activities are carried out. The waters from the mountain are used for domestic, agricultural, and even hydropower production on the Nyumba ya Mungu dam. In addition, there are already changes in population dynamics and migration behaviors of species in the fragile ecosystems. Any further deterioration in the ecosystem would mean significant consequences as the Kilimanjaro National Park is the number one tourist attraction in the country. Unfortunately, because of climate variability and human pressure, there has been an increase in the number of fire events burning on the mountain that are likely to further degrade the eco-hydrological balance of the mountain (Christian 2006). Recent studies show that the fire is responsible for the ecological shift in species zones within

(continued)

Box 5: (continued)
the mountain (United Republic of Tanzania, URT 2007; Thompson et al. 2001; Mwandosya et al. 1998; Shongwe 2009; Sarmett and Faraji 1991).

Note: Because of its richness and shortage of land in Kilimanjaro region, Mt. Kilimanjaro area is among the most densely populated land in the country, the population of which is comparable to that of a typical city in Tanzania.

Coping with Extreme Climate Events

Indigenous Mechanisms

East Africans have a long history of living with consequences of extreme events like famine, drought, and invasion of locusts, among others. Historical records in Burundi, for example, show that during famine, affected population was forced to relocate to less affected places.

In addition to relocation, at times of extreme events, Burundians are documented to have worked as casual laborers in exchange for food. EA region is rich in such strategies albeit most of them need extra-local-level enforcement and might only help in a short term and/or for non-severe impacts (United Republic of Tanzania, URT 2007; Hulme et al. 2001; Davidson et al. 2003; Mwandosya et al. 1998). Although most of the local initiatives are unlikely to help people in the long term, they however do provide important help during disasters. Generally, important lessons can be learned from such initiatives and may be included in regional efforts to combat climate change.

An array of such coping mechanisms is analyzed and their strengths and weaknesses are discussed. The adaptive ability at the local level however differs from regions, households, and/or communities based on their respective environmental settings, socioeconomic backgrounds, and resource availability (Hulme et al. 2001).

Generally, most traditions in EA had strict customs and norms that ensured sustainable utilization of their natural conservation. One of such interesting forest ecosystem management could be traced to Burundi where certain biodiversity elements (plants and animals) were protected under traditional and religious beliefs. Apart from forest resources, such traditional conservation methods were presented for different plant types that were believed to have sacred values. Locally, referred to as *Intatemwa* and *Ikidasha* and translating, respectively, to what should not be cut and burned, such ecosystems were strictly prohibited from cutting and burning on account of their spiritual benefits. In the same society, felling down of live trees in Kibira forest was also firmly prohibited. Kinira forest, located at high altitude, was believed to be a conjunctiva between the Earth and the sky, and people generally respected both its virtual and physical services.

In addition, only a few people including the King and members of his kingdom were allowed to hunt in the forest. Generally, the combination of the traditional and religious beliefs above ensured sustainability of many of the sensitive ecosystems.

Such initiatives include the *shamba system* in Kenya and the *Ngitili* of the *Sukuma* agropastoralists of Tanzania. The former system works by allowing surrounding communities in the protected government forests to grow short seasonal food crops in the forest patches in which they are also expected to plant and manage trees. Farmers are not expected to establish permanent residence within the patches, and after a short time (3–5 years), they usually move and establish the same procedure to other forest patches. No payment is made to the farmers as both parties are beneficiaries in one way or another. The farmers are allowed to use the land the government assisted in reforestation. If this system is well managed and reinforced, it can save the twofold smoothly and help in improving the livelihood of the people and the carbon capture and storage (MOENR 2002). The latter system on the other hand is a common practice among the *Sukuma* agropastoralists of Shinyanga, Tanzania. It works by retaining areas of standing vegetation from the beginning to the end of the rainy period. Such areas, locally referred to as *Ngitili*, are usually closed to livestock grazing at the beginning of the rainy season and only made available to livestock during the dry period. The *Ngitili* thus serves to protect livestock from severe drought spells which are not uncommon in this region and at the same time serves to protect the ecology of the areas.

Apart from the strategies above, other communities of the region have other means of making a living during climate-related disasters. Such local-level coping mechanisms may include any of the following or their combination: switching to nonfarming activities, collection of wild fruits/vegetables/honey, remittances from migrant relatives and friends, and rarely selling one's assets (Conway 2002; Hellmuth et al. 2008). Nonfarming activities may include things like charcoal burning, handcrafting, casual laboring, and brick making. Although the contribution/income from such activities might be seen insignificant, it provides cushioning household to go through calamitous times like droughts and flooding. Regional lessons show that families that regularly receive remittances adapt better to climate change impacts than their counterparts who received nothing. Likewise the gathering of fruits, vegetables, and honey enables the household members to survive such times.

In the light of repeated droughts and their local experience, some societies in the region have turned into the use of local seed varieties and seed selection as a direct response to drought.

Studies have shown that some local grain varieties, for example, in Tanzania have better tolerance to drought than improved/high yield seed, and consequently farmers in drought-prone areas periodically grow local varieties. Such studies also indicate that the local varieties have longer shelf life than improved seeds.

Apart from that, some famers have replaced common crops like maize and beans with millet, sorghum, and cassava which are known to have better tolerance to drought. In addition, farmers cope with drought by including some livestock in their livelihood and establish some economic ties with pastoralists and markets and

practice other off-farm activities so as to diversify survival options (Galvin et al. 2002). Some farmers use their local skills and change planting seasons when drought is anticipated. When drought is expected, farmers have often changed the combinations in their intercropping to determine when to grow certain crops and switch between crops.

Apart from the survival strategies employed by indigenous farmers, EA pastoralists have also developed several coping mechanisms dealing with periodic droughts (Box 6). Such strategies include but not limited to economic diversification, migration to areas with better pastures, having diverse species of livestock, and intentional subjecting of herds to nutritional/drought-like stress so as to adapt them to stress period and hence increase their survival chance during disasters (Galvin et al. 2002).

Box 6: Showing Impacts of Climate Change on Sociocultural Aspects of Pastoralist Society in Tanzania and Their Subsequent Adjustments

Among the traditionally strict pastoralist societies in Tanzania include the Maasai who are entirely dependent on blood, milk, and meat from their herds for nutrition. Interestingly, the Maasai have started to practice crop farming in their means of livelihood (Grandin 1988), and non-pastoral foods like tea, corn, and sugar are increasingly becoming common. One of the reasons why the Maasai alongside other pastoralists in Tanzania have shifted to crop farming is the fact that their means of coping with climate variability to their livestock have been constrained by the current climate change pressure (Talle 1987).

Adapting Major Regional Sectors to Climate Change

Over the recent decades, the region has faced a number of climate-related calamities, namely, floods and droughts, which have crippled livelihood support systems. These have necessitated an array of adaptation strategies at various kinds of sectors including governments, private sectors, and individuals. For a long time, however, regional governments had failed to link climate change impacts on development projects. Major adaptation in this chapter will be discussed below, guided by vulnerability categories discussed above. Other specific adaptation strategies are also addressed. In recent years also, there has been recognition of the climate change challenges in regional policy issues.

Livestock Sector

Many methods have been suggested in dealing with climate change challenges on livestock sector. The most important adaptation method in practice includes reducing the number of livestock by keeping fewer healthier, more productive breeds. The latter has the potential of reducing pressure on pasture and water resources thus survive through calamitous periods like droughts (Ellis 1994). Other widely used

adaptation strategies include zero grazing and other improved methods of grazing that reduce environmental destruction (United Republic of Tanzania, URT 2007). The creation of livestock watering centers has a potential of reducing the number of livestock deaths due to shortage of water. The challenge with the latter option is on how to balance the water needs for the animals and avoid concentrating large numbers of livestock on the centers which might end up with further environmental degradation. Moreover, natural resource laws and policies especially on water and land need to be reviewed to allow pastoralists access to the resources without triggering tensions with farmers (Little and Brokensha 1987). It is under such circumstances where traditional land laws like the ones in Tanzania may be capitalized and integrated into regional strategies (United Republic of Tanzania, URT 2007). Finally, improvement of livestock extension services is vital where disaster preparedness information would easily and effectively be made to pastoralists before they occur (Hulme et al. 2001).

Health Sector

The most important means of adaptation in the health sector has been breaking breeding cycle of the disease vectors. The ongoing procedures for the control of malaria, for example, include improving drainage systems, removing stagnating water points, and bush clearance in residential areas, all of which aim at reducing mosquito multiplication (Mwandosya et al. 1998).

On the other hand, proper development and implementation of the early warning system for climate-sensitive diseases is another strategy that works better in reducing/controlling disease outbreaks. In addition, inclusion of the local skills on vulnerability, risks, and local coping options that have been used by the respective society is very important. For example, some local people within the region have well-developed skills on how to deal with both livestock and human health challenges (United Republic of Tanzania, URT 2003). Careful integration of local skills into the wider health sector may serve many lives. Tanzania's government has recognized potentials of traditional medicine and has included it in her medical research. Currently, a relatively well-advanced traditional medical center is fully operational at the Muhimbili National Hospital (Mwandosya et al. 1998).

Agriculture

Adaptation in agricultural sector probably requires the most attention as inhabitants in the region are among the global leaders in terms of food insecurity. Even more important, climate change is already estimated to have resulted in tripling food crises per year from 1980 to 2000.

Intensification of pests and diseases, changes in cropping timing, and shift in agricultural zones are consequences of climate variability that require immediate actions. Among the frequently suggested adaptation options within the region include, inter alia, the use of fast-maturing and drought-resistant crop varieties, inclusion of cover crops in the field, conservation tillage practices, and the use of green manure. However, the former strategy would require full involvement of the local people as certain farmers in the region objected certain varieties of

drought-resistant crops on grounds of their low markets and relatively high labor in their production (Mwandosya et al. 1998; Red Crescent Climate Centre, RCRCCC 2003). As climate-related failures in agriculture system intensified, agricultural sectors took the necessary steps like research in diseases and drought-resistant crops and early-maturing crop varieties. Kenya and Tanzania are leading the efforts in such researches and already promising results have been noted. In the former country, for example, 14 varieties of maize adapted to low available water are already in the field (MOENR 2002). Similar efforts are ongoing to other crops, namely, millet, sorghum, beans, and peas. In addition, different regional food security initiatives like national food reserves were created in nearly all countries in EA to help the population during times of disasters. Arguably, as a result of worsening situation, governments, nongovernmental organizations (NGOs), private sectors, and in some cases United Nations agencies are usually involved in such initiatives. Such initiatives often go down to district level so as to quickly deal with disasters when they occur. However, most of the initiatives have been hampered by lack of enough funding, high food prices, and mismanagement (Mwandosya et al. 1998).

Clean Energy and Energy-Serving Technology

In the EA region, most of the energy balance is met from biomass (Table 1). Any activity that would reduce the current rate of fuel wood consumption would thus help reduce deforestation and hence sequester more carbon. The use of fuel wood-saving stoves (efficient cookstoves) is regionally adapted as a promising strategy in dealing with energy crises. The latter is very important since land degradation, deforestation, and increase in desertification especially in arid and semiarid areas within this region have made availability of charcoal and fire wood very difficult and expensive (MOENR 2002). Interestingly, the declining biomass has necessitated regional studies on ways of consuming less biomass and higher efficiencies. Several types of fuel wood-saving stoves are in use and are proved to be very efficient. Most of these energy-saving stoves whose technology is simple and generally cheap use between 60 % and 70 % less fuel wood compared to traditional stoves (Maingu et al. 2003; United Republic of Tanzania, URT 2007; MOENR 2002). The potential of the stoves as a workable solution to reduce regional deforestation has caught the attention of nearly all regional governments, NGOs, CBOs, and other stakeholders and has been introduced to many parts of the region. As a result, the fuel wood-efficient stoves are now widely used in public institutions, hotel industry, and households. For example, a recent survey in Kenya has shown that there has been an increase in the number of households using the stoves from 4 % to 15 %. In Kenya alone, it is estimated that the increase in the use of the stoves would save about 7.7 million tons of fuel wood annually (MOENR 2002). Other countries in the region are also investing in these stoves and promising outcomes are already reported. In Tanzania, for example, efforts are being led by a nongovernmental organization called Tanzania Traditional Energy Development and Environmental Organization (TADEDO) where many stoves have been distributed countrywide (United Republic of Tanzania, URT 2007). Replication of similar efforts across the region would greatly contribute toward reduction in land degradation and deforestation since

biomass contributes over 70 % of domestic energy source in the East African region. Apart from fuel wood, other materials, namely, saw dusts, plant residuals, animal droppings, and some commercial wastes, have also been used in some of these energy-saving stoves.

In addition to the fuel wood efficiency that has a wide regional advocacy, efforts are also being made to reduce energy use and maximize efficiency in industries. Specific standards are currently operational in nearby countries regarding air quality control and generally environmental protection. Less fuel and high efficiency would all add to reduced GHGs emissions. In addition, there has been limitation in the importation of used vehicles and other machines beyond a certain age limit that have started to be implemented in most of the EA countries which in turn will contribute toward reduction in carbon emission (Maingu et al. 2003).

Other regional adaptation strategies in the energy sector include cogeneration and bioethanol production. The former mostly involves generation of electricity and heat from bagasse, a sugarcane waste product, by sugar industries. Kenya has currently one registered Clean Development Mechanism (CDM) project in this field, namely, the "35 MW Bagasse Based Cogeneration Project by Mumias Sugar Company Limited (MSCL)." On the other hand, ethyl-ethanol, a by-product of sugar processing, is relatively a clean form of energy that has multiple uses and is currently being explored by various sugar industries in Kenya. Regionally, such relatively clean energy projects are already running in Kenya and Tanzania with the potential of even further improvement to other parts (Maingu et al. 2003).

With climate change, regional cooperation in the energy sector is very important so as to compensate for potential shortfall in energy supplies. There exists a legal cooperation in the energy sector within the East African Community (EAC) member states stipulated under Article 101 of the Treaty for the establishment of the EAC. The treaty stipulates most legal issues that would ensure a smooth sharing of energy resources where member states are already sharing their energy resources (Maingu et al. 2003).

Generally, coping with climate change-related energy scarcity would require a combination of actions. The most reliable alternative to oil and biomass would be to strengthen the use of renewable energies like wind, geothermal, and solar energy. For example, geothermal energy generation in Kenya has proved to be a reliable and clean form of energy and has made a significant contribution to the national grid (Maingu et al. 2003). Further exploration of the geothermal energy into Tanzanian side would reduce the overdependence in natural forests and petroleum. Furthermore, investment into the relatively abundant supply of natural gas in Tanzania should be made central as natural gas has proved to be a relatively clean energy compared to oil and coal. Both of these attempts would additionally reduce the little regional contribution of CO_2 emission (Maingu et al. 2003).

Fight Against Disease

Because climate change has been observed to accelerate distribution and intensification of several diseases in EA, several adaptation strategies have been proposed in fighting diseases. Most regional efforts have been concentrated on malaria, the

number one global killer that has been responsible for over a million people annually. Because of the high motility rate it inflicts to people, several campaigns have been launched to eliminate the disease. Such regional campaigns range from the use of treated mosquito nets, rising awareness to the general public to the use of insecticides both indoors and in the environment. The latter strategy however needs to be taken with care so as to avoid potential environmental effects. Special attention has recently been addressed in highlands where the local inhabitants do not have the natural immunity against the disease and are thus vulnerable (Mwandosya et al. 1998). Other efforts are also addressed to other diseases such as cholera and typhoid fever. Vis-à-vis the latter case, water regional sanitation programs are threatened especially during wet seasons (World Health Organisation (WHO) Regional Office for Europe 2003). Apart from human diseases, isolated efforts are also directed toward the control of animal diseases. The latter efforts include the control of disease vectors by the use of insecticides and provision of sound breeding and extension services However, a few biological control agents of mosquitoes introduced in some areas, for example, rice-growing village of Mwea in Kenya, should be taken with care and closely monitored and controlled as cases of species invasion are not uncommon in EA (MOENR 2002) (see section "Impacts on Environment: Deforestation, Fisheries, Biodiversity, Wildlife, Ecosystems, and Sea-water Intrusion into Freshwater").

Flooding Control

With climate change, flooding calamities have been of repeated occurrence, and the latter has necessitated several adaptation strategies across the region. Among such measures include the construction of dams and dikes to prevent flooding. In Kenya, for example, such dikes are constructed on rivers Nzoia and Nyando. So as to reduce vulnerability to people, other efforts include coastal area conservation and conservation agriculture (Action Aid International 2007; MOENR 2002).

Water Harvesting, Irrigation Scheme Development, and Water-Serving Technology

Although the region is known for periodic droughts, there are periods of the year where surface runoff and flooding are common and could potentially be trapped for usage during water scarcity. The water which is most of the times wasted can potentially be trapped and used for domestic and industrial usage during drought episodes. Already efforts are being carried within the region where small- to large-scale water harvesting schemes are being done. For example, because of the increasing water scarcity in arid and semiarid regions in Kenya, rooftop rainwater collection and construction of water pans and dams are being facilitated by both the government and private sector (MOENR 2002).

In addition, East Africans have adapted to frequent droughts via irrigation development. As in the case with water harvesting, irrigation projects are well established in Kenya where recently some pastoralist societies have embarked on irrigated agriculture. The Narosura irrigation scheme run by the Maasai from the Narok district stands out to be the best example where horticultural crops are being

produced. Similar irrigation schemes are also run in Rwanda, Tanzania, and Burundi. Apart from the efforts above as climate change continued to cause water shortage in the region, water-serving technology has also became a mandatory in many of the agricultural and industrial sectors (MOENR 2002).

Environmental Conservation

As already discussed above, climate change is one of the factors for the recent environmental degradation in EA. In dealing with impacts of climate change on the environment such as soil erosion and water stress from flooding and rising global temperatures, respectively, regional governments, private sector, and other stakeholders have taken several environmental conservation steps and management of degraded ecosystems. In some parts of Kenya and Uganda, famers have adapted to farming methods that addresses both soil erosion and water loss. Increasingly, agroforestry, contour farming, and green manure are increasingly becoming common farming methods in many places in the region. On the other hand, special sectors/programs are put in place to address coastal resources in both Kenya and Tanzania (Magadza 2000). These include the Coastal Development Authority in Kenya and the integrated environmental program in Tanzania (Red Crescent Climate Centre, RCRCCC 2003). Issues of afforestation and reforestation have also been given significant emphasis in the region. For example, there is a region-wide tree planting campaign that has generally done very well. In Kenya, for example, the Green Belt Movement (GBM) led by the Nobel Prize Laureate Professor Wangari Maathai has received worldwide recognition for planting over 2,000 ha of trees. In collaborating with women groups in other parts of EA, the movement has successfully restored trees in farmlands, community lands, and even on school lands. Such local initiatives need to be assisted so as to deal with the increasing problem of regional desertification. The movement is now in the process of registering some of its afforestation/reforestation initiatives as Clean Development Mechanism projects and is already receiving financial assistance from the World Bank, among others (Patz et al. 2005).

Challenges and Opportunities for Combating Climate Change in EA

Before concluding this chapter, it would be worth to discuss something regarding regional challenges and opportunities in combating climate change.

The many opportunities available include the potential to develop reliable renewable energies within the region. As mentioned earlier, solar radiation and wind energy are not of short supply round the year (International Food Policy Research Institute (IFPRI) 2004). Potentials for geothermal energy are also very promising in Kenya and Tanzania. The former country is already producing a significant amount of electricity from geothermal energy and plans to increase its capacity even further. Albeit the region has observed a series of droughts and desertification has been reported in a number of places, it has many forests that can serve as important sink of carbon if long-term strategies regarding their sustainability would be ensured.

Because of the presence of large land cover in some countries like Tanzania, the potential of afforestation and reforestation exists with the added advantage of the geographical position which favors rapid growth of trees and hence sequesters carbon from the atmosphere (The Global Humanitarian Forum 2009; Little and Brokensha 1987). Generally, the region has the potential of being among the best beneficiaries of the UNFCCC's Reducing Emissions from Deforestation and Forest Degradation (REDD) mechanism.

On the other hand, apart from the challenges discussed so far, high above the list, poverty food insecurity and natural disasters, namely, droughts and floods, remain to be exigent. Within the region, poverty is strongly connected with deforestation and generally degradation and could thus limit the successful implementation of mitigation programs such as REDD. The challenge thus is to have effective disaster preparedness, reduce the proportion of populace that depend on rain-fed often unreliable agricultures, and have a working health-care system especially in rural areas and the provision of alternative livelihood support mechanisms (Government of Kenya Meteorological Service 1998; Patz et al. 2005; Red Crescent Climate Centre and RCRCCC 2003).

The South American Picture

A Brief of South America

South America occupies the landmass of the American continent located in the southern hemisphere, composed of 12 countries and covering 17 million square kilometers. It is bounded by Panama to the north, the Pacific Ocean to the west, and the Atlantic Ocean to the east. This region presented a population of 383 million and a gross domestic product (GDP) of 2.3 billion US dollars by 2007. The total exportations represented US$453 billion while the importations represented U$337 billion. The countries with the highest GDP per capita are Chile, Venezuela, Brazil, and Argentina (Andean Community (CAN) 2008). In this region 27,602,792 of inhabitants are indigenous (about 7.2 % of the region's population), with Peru showing the 46 %, Bolivia 21 %, and Ecuador 20 %. Additionally, for these countries indigenous population represents the 47 %, 71 %, and 43 % of the total respective national population (Roque 2005).

South America accounts for 27 % of freshwater of the world and 8 million square kilometers of forest. The region is the main global food producer and exporter and represents a hydrocarbon (oil and natural gas) offer estimated for 100 years (Comunidad 2010). The main representative organs in the political and economic agreements are the Union of South American Nations (UNASUR) which consists of all the 12 countries of South America, the Community of the Andean Countries (CAN) with the participation of the main four countries with a territory in the Andean Mountains (Bolivia, Colombia, Ecuador, and Peru), and the Common Market of the South (MERCOSUR) which consists of Argentina, Uruguay, Paraguay, Brazil, and Venezuela. Also, in the region the Amazon Cooperation Treaty

Organization was created by the countries with territory in the Amazon Forest (Bolivia, Brazil, Colombia, Ecuador, Guyana, Peru, Surinam, and Venezuela).

Climate Change Evidence in South America

The climate variability reported in the region is mainly indicated by the precipitation change, which presents an increase in Southern Brazil, Paraguay, Uruguay, Northeast Argentina, Northwest Peru, and Ecuador, while some decline is reported for Southern Chile, Southwest Argentina, and Southern Peru. The percentage of the variation in the precipitation presented a range variation between −5 and +6 in Colombia from 1961 to 1990, while in Uruguay, this tendency showed a positive variation of +20 between 1961 and 2002, which is also completely opposite to the one registered in Chile of −50 for the last 50 years (Magrin et al. 2007).

The temperature variability and its effects on climate events are not only different by region but also vary according to the season. Bolivia has showed major temperature variations in the humid months, a relationship which is also presented with the precipitation (General Secretariat of the Andean Community et al. 2007a). In the Central Andean region, the temperature variations registered between 1974 and 1998 are about 0.34 °C, which is 70 % more than the global average (General Secretariat of the Andean Community 2008), and maximum temperature variations (°C/10 years) of +0.2 and +0.2 are during the months of December, January, and February in Argentina-Patagonia for the last 50 years, with Argentina central presenting negative variations for the same periods that are presented by −0.2 to −0.8 (Tian et al. 2000).

The main climate events that have been identified in different ecosystems are strongly related to the Austral Oscillation and El Niño phenomena (General Secretariat of the Andean Community et al. 2007b; Wu et al. 2001; Jones et al. 2001). The interannual oscillation between cold and warm sea surface temperatures is known as El Niño and the Southern Oscillation phenomenon (ENSO). This phenomenon presented unusually strong warm events in 1982, 1983, 1997, and 1998, which is believed to have a relationship with global warming (Tsonis et al. 2003). This relationship has also been covered by other studies (WWF 2006) that studied data of atmospheric CO_2 concentration and the ENSO cycle to analyze the coupled climate–carbon cycle concluding that the terrestrial biosphere and the ocean carbon cycle behave in opposite senses, in which the land acts as a source while the sea acts as a net sink.

This is opposite to the dynamic described during La Niña, when sea performs as a source and land as a sink of carbon dioxide. Moreover, including decadal trend analysis, studies are showing that ENSO could be higher with warmer phases which are increasing with the global warming (Tsonis et al. 2003). On the other hand, studies have suggested that El Niño is activated to reverse positive global warming while La Niña reverses negative trends, concluding as well that ENSO could be sensitive to variation of global temperature but not at the actual value of global warming (WWF 2006).

The temperature of the surface in the Pacific is linked to the variability of the precipitations, which causes negative trends during warming events, especially in the wet seasons in the Andean region of the North of Bolivia and to the South of Peru, while in the North of the Andean, a systematic reduction is recorded in the Northeast of Ecuador and in Colombia (General Secretariat of the Andean Community et al. 2007b). Global warming can also cause a permanent El Niño state with major impacts in the Amazonia (Garcia 1999). Because of the relationship between global warming and ENSO and the influence of these events with land–climate dynamics, it is important to understand how sea sink dynamics can interact with land sources and the carbon cycle for creating mechanisms due to the protection and regulation of these cycles.

Climate Change Vulnerability in South America

The vulnerability of the region is not a linear process but a complex one related to feedbacks that increase the different risks and the vulnerability in both the natural and the human systems. In this way, the vulnerable factors described can be direct or feedback reactions resulting of the dynamic in social, natural, and/or linked human–natural systems, in which all are, associated to the climate events.

The main threats related to global warming are mainly associated with the climate variations of ENSO. This relationship causes/will cause stronger precipitation and droughts in the South American region affecting the natural hydrological cycles. The responses to the different events derived in South America are demonstrating a high vulnerability in the ecological and human systems. Because of the natural, social, cultural, political, and economical heterogeneity of the region, this vulnerability also varies through all the geography. As a result several risks are recognized for the water resources protection and supply, agriculture, health, energy security, and ecosystem protection especially in the Amazon Basin.

Ecosystem Vulnerability

The coastal area in South America is strongly exposed because the sea elevation, records show, ranges in variations over 1 mm per year for Colombia, Argentina, and Guyana and up to 4 mm/year for Brazil. In Argentina, the coastal area is already affected by the increased precipitations and landward winds (Magrin et al. 2007). Mangroves are already exposed, and risks associated with hurricanes and the sea level elevation have been recorded. Soil degradation is also worsened with climate change, estimating that more than the 20 % of the national territory could be degraded by the year 2050 in some countries like Chile, Ecuador, Paraguay, and Peru (ECLAC 2009). On the other hand, some studies estimated that the resilience of the Amazon Basin climate variations is zero, which in turn means that the conversion of this biome to a drier state threatens the key functionality of this ecosystem (representing the production of the 20 % of the global oxygen) (Thompson et al. 2009).

Some researches recognized that climate events, such as hurricanes, can expose the soil to erosion increasing the loss of nutrients. Vulnerability of these ecosystems is related to the Pacific temperature changes, to global warming, and also to local climate effects resulting from land clearing or land use change (Thompson et al. 2009). In Brazil, almost the 50 % of the country's rainforest may disappear by 2050 (Hall 2008). The effect of the long-term climatic variability has also been recognized in the northern part of the Amazonia where drier conditions have been noted since 1977 (WWF 2006). Moreover, the hydrological regime in the Amazon Basin presents more vigorous water cycles as a consequence of the increase in the evaporation and transpiration.

These specific ecosystems sustain water regimes depending on the relationships established between the sunlight, soil moisture, humidity, and cloud formation. As temperatures rise, the mountain cloud forests (also known as nebelwald which are forests with persistent wind-driven cloud) can present warming, affecting the hydrological cycles and exposing the local species to water stresses. As a result of extended dry seasons and lower water supply, vegetation is more vulnerable to fires and droughts (Foster 2001; World 2010).

With the 90 % of the Andean glaciers located in areas exposed to droughts and the 10 % in tropical humid areas, the retreating of glaciers can represent not only a loss of species but also impacts on the society and economy as energy, agriculture, and water supply, which are severally impacted for the present reduction in the ice covering (InWent 2008). Studies on glacier dynamics have included different variables to understand the impact of the climate variation and the retreat presented during the last decades. Cloud cover convection, precipitation, temperature, and humidity are related variables that have helped to monitor and estimate the past and future trends of glacier retreat. The temperature variation has increased by 0.11 °C every 10 years from 1950 (Kerven 1992), presenting a warming on the Pacific side and moderate variations in the eastern slopes (Conway 2002). Furthermore, increasing cloud cover is recognized over the north parallel 10°S in wetter seasons (December to February), while to the south of this parallel, the cover cloud is decreasing (General Secretariat of the Andean Community et al. 2007b). The cloud cover and convection have showed a decrease in the east of the Andes over the Amazon, while information analyzed for the humidity cannot be reconciled with this tendency (Vuille et al. 2003). The suppression of rainfall in the Amazon is additionally estimated as a result of changes in El Niño and weak Atlantic anticyclone (World Bank 2010).

Socioeconomic Vulnerability

The relationships of the damage ratio with the GDP show that countries like Peru, Bolivia, Ecuador, and Colombia (10 %) are more vulnerable than other countries demonstrating a direct link between GDP and vulnerability (General Secretariat of the Andean Community et al. 2007a). This social and agro-economic vulnerability is as well noted in Colombia, Ecuador, Peru, Brazil, and Bolivia by the World Bank (World Bank 2008). In addition to limited access to insurance, disparities in human development, and lack of climate-defense infrastructure, the poverty and low human

development are components that increase human vulnerability and reduce the capacity of society to adapt or respond to the climate impacts (UNDP 2007).

Driven by poverty and lack of proper planning, more population is localized on vulnerable zones. In Bolivia, the population growth rate in 1992 was 2.44 % increasing 3.47 % in the valley region by the year 2000. In the plains, the rates are higher with a growing rate of 3.89 % by 1992 and 3.26 % by 2000, with the 70 % located in the urban area (Calvo 2000). Additionally, by 1991 the homes under poverty were 78 % for the valleys and 70 % for the plains (Garcia 1999). This is a regional tendency where human settlements locate frequently on vulnerable areas, which added to extreme climate events is increasing the risk to natural threats.

Moreover, the vulnerability grows for indigenous population in the region. The major dependency of indigenous and traditional communities is on the natural resources, and because these resources could be more difficult to access or are reduced as a consequence of climate variation, these communities are exposed to negative effects (UICN 2008). Also, the location and economical activities of these communities are strongly associated to the services provided by the more affected ecosystems. Not only mountain or dry regions are occupied by different indigenous communities, but also tropical forests and some protected areas are the main zones of indigenous settlements.

It is estimated that large part of Latin Americans living in poverty are indigenous (Derruyttere 1997). The traditional and cultural backgrounds of these communities bring them to depend specially on the natural resources, creating dynamics of conservation and local development that can be threatened by the current effects of climate change. Poverty is a common factor in indigenous communities, and because of the loss and degradation of ecosystem services, the access to health systems, education, or information is more difficult for these populations.

The agricultural frontier is expanded as a result of the desertification of the ecosystems and the increasing of urban areas, causing the clearing of forests and the increase of the vulnerability by firing, soil erosion, and local climate variations as well. Although fossil fuels have been recognized as the main source of CO_2, the changes of the use of land and deforestation are the main causes of these emissions in Bolivia (83 %), Ecuador (70 %), and Peru (42 %) (General Secretariat of the Andean Community et al. 2007a). This tendency is representing a social threat because as much as 20 % of Brazilian Amazonia population depends on the region's natural resources and more than four million of rural inhabitants depend economically on these resources (ECLAC 2009).

Resulting from the glacier retreating and changes in hydrological cycles, the water resources are increasingly stressed exposing the population in South America to reduced availability of freshwater resources. Capital cities depend on high vulnerable ecosystems; 70 % of the population in Bogota is supplied with water from the Chingaza Natural Park, consisted of cloud forests and paramos, while Quito and Lima depend on water sources from important glaciers as the Antisana and Cotopaxi in Ecuador and the Chacaltaya in Peru (General Secretariat of the Andean Community 2008).

Agricultural Vulnerability

Agriculture is as well one of the main impacted components in South America. This sector is one of the most important in the regional economic development, accounting for 8.6 % of the gross domestic product (GDP) (Seo and Mendelsohn 2008). The most extensive droughts and reduction of precipitation in some areas reduce the productivity of crops. In Paraguay, decrease in cotton, wheat (by 2030), and soy (by 2050) is expected with sugarcane, cassava, and corn presenting an increase in crop yields as a result of the A2 climate scenario (climate scenarios were developed by the Emission Scenarios of the IPCC Special Report on Emission Scenarios; the A2 scenario includes a storyline and scenario family that describes a very heterogeneous world). For subsistence farms in Ecuador, 1 °C of temperature rising can increase crop yields but with retreating after temperatures reach 2 °C, and also banana, plantain, and cacao can be negatively affected with just a rise of 1 °C for intermediate farms (ECLAC 2009). In this way, it is also projected that small farmers (farms less than 30 ha) will get positive impacts for those situated in cold areas, but those located in warmer regions (Venezuela, Colombia, and the North of SA) may suffer negative consequences (Rodríguez 2007).

Some projections estimated different scenarios of temperature and rainfall variations to 2100; the first included an increase of 1.9 °C in the temperature and a 10 % increase of rainfall, and the other two estimated temperature rising of 3.3 °C and 5 °C with rainfall dropping by 5 % and 10 %, respectively. Following these projections a loss of land value of about 20 % (by 2060) and 53 % (by 2100) was calculated in the worst warming scenario and with smaller magnitudes in the other two. The study underlines the representativeness of the precipitation changes in the final values, with small household farms showing more vulnerability with higher temperature, while large commercial farms responded negatively to increasing precipitation (as these kinds of farms owned commercial livestock, what can be more affected by precipitation increase?) (Rodríguez 2007).

Impacts and Potential Risks Caused by Climate Change

ENSO has been related with malaria outbreaks in South America and childhood diarrheal disease in Peru (Siemien and Stauffer 1989). The IPCC predicts that the dry seasons can promote malaria, especially in the coast areas of Colombia, Venezuela, and Guyana, while with floods these epidemics are recurrent in the north coast of Peru. Also, prolonged droughts in Argentina, Chile, Paraguay, and Brazil increase the outbreaks of pulmonary hantavirus, while leishmaniasis, leptospirosis, and hyperthermia are outbreaks associated with the climate phenomenon (Magrin et al. 2007).

Power energy stations are presenting decreasing and suspension of the services because of the precipitation changes, increasing temperatures, and longer dry seasons corresponding to more frequent steady El Niño phenomena (see Box 7).

Box 7: News Summary

February, 2010

Paraguay faces energy shutdowns every day as result of the heat wave presented in February with high temperatures that also raise the energy consumption overcharging the capacity of the hydroelectrical system (BBC Mundo 2010).

October 21, 2009

The drought caused by El Niño has forced the energy interruptions in Venezuela. The reduction in the water levels of the rivers that supply the hydropower of different damns results in frequent electricity cutoffs in the country (IPS, Venezuela, 2009).

November, 2009

Ecuador faces the worst drought in the last 40 years that has reduced the reservoirs of the hydropower centrals and required the emergency declaration by the national government in the electricity sector. This situation has also required the increase in the energy imported from Peru and Colombia. The emergency was clear when the Paute hydroelectric plant reduced the production to 35 % of the total demand while the normal condition was of 60 % (La Hora, Ecuador, 2009).

Source: Arce, E. (2010) Paraguay also has energy crisis (in Spanish). BBC Mundo. Available on: http://www.bbc.co.uk/mundo/america_latina/2010/02/100208_1718_paraguay_energia_gz.shtml; Marquez, H. (2009), El Niño takes the water, the electricity and the water (in Spanish). Ambiente Venezuela; La Hora (2009) El Niño, El Niño is merciless with the countries of Latin America (in Spanish). Available on: http://www.lahora.com.gt/notas.php?key=58448&fch=2009-11-14

This tendency is representing a risk for the energy system in SA as electricity production is mainly based on hydroelectricity (see Fig. 2).

The present clearing rates and the agricultural frontier expansion are threatening the Amazon forest, a key global ecosystem. The increasing of evapotranspiration caused by higher temperatures will impact water cycles in the Amazon Basin. On the other hand, with the loss of vegetation and increased temperatures, a combination of lower evapotranspiration and precipitation causes a drying effect. Loss of species and ecosystem-type shifts are resulting from the global warming and increasing the vulnerability of human communities as well (WWF 2006). Furthermore, some features of the human communities settled in the Amazon region result in an increased risk for the conservation of this ecosystem and the sustainability of the human communities.

The high dependence on manual labor of small farmers in the Amazon and the information incompatibility between global and local dynamics increase the difficulty of these actors to develop adaptation and conservation measures

(continued)

Box 7: (continued)
(Brondizio and Moran 2008). As this ecosystem is one of the main regulators of the carbon dioxide and local climate and one of the main biodiversity regions in the planet, the current human and natural dynamics are generating a high risk in the loss of these functions and increasing the effects of climate variation in the region.

Adopting Climate Change Adaptation and Mitigation Measures in South America

The adaptation measures vary in different scales. In Peru, subregional strategies can be developed for the Clean Development Mechanism (CDM) or Adaptation under the National Strategy on Climate Change implemented since 2003. As a result, different actions on water management, food security, risk prevention, or hydroelectricity can be found (Patz et al. 2005). Moreover, Colombia is implementing the Integrated National Adaptation Plan (INAP): High Mountain Ecosystems, Caribbean Islands and Human Health (World Bank 2006) supported by a bilateral cooperation between the Netherlands and Japan. Additionally, many studies are still focused on the development of diagnostics, and in pilot phases, some transversal programs are found in Bolivia, where a national mechanism for climate change adaptation covering water resources, food security, health, human settlement and risk management, and ecosystems creates transversal programs in scientific research, capacity building and education, and anthropologic aspects and traditional knowledge (Commission on Climate Change and Development 2009).

Adapting to Climate Change

Information management is also part of the adaptation measures. More investments and technological development will take place as much as information is reliable and open markets as result of the people's perception on the necessity to adaptation (Commission on Climate Change and Development 2009). Counting on reliable, precise, and continuous information allows the governments to establish corrective measures for different sectors. Projects like the Community-Based Risk Screening Tool – Adaptation and Livelihoods (CRiSTAL) (to assess the systemic vulnerability) or Opportunities and Risks from Climate Change and Disasters (ORCHID) (to manage the risk, integrate adaptation, and identify opportunities to reduce vulnerability) are important developments with international support (Levine and Encinas 2008). Also, the Tropical Ocean Atmosphere Program provides observations of the upper tropical pacific from the middle of 1990 allowing the implementation of adaptive measures in agriculture planning, fire prevention, streamflow prediction for hydropower, and new applications in the health system (Magrin et al. 2007).

The Regional Role in Global Climate Change Mitigation

Mitigation actions in this region are mainly directed for the conservation and protection of forests as clue elements for sinking CO_2. In Colombia the first pilot project on adaptation by the Global Environment Facility (GEF) is being carried out, while Peru, Bolivia, and Ecuador are developing the proposal for the Andean Regional Project for Adaptation aimed at supporting pilot projects on glaciers and watersheds. Additionally, Ecuador is implementing a project through the water governance to reduce the vulnerability on climate change by an effective management of the water sources and better access to information on climate (General Secretariat of the Andean Community et al. 2007a).

On the other hand, some projects showed results on the ecosystem services demonstrating the complexity using these mechanisms. In Brazil, after 4 years, implementation of a project to pay for conservation services to small-scale farmers located in the Brazilian Amazon has presented combined results. This program developed by Proambiente has gathered about 4,200 participating families, from which the 42 % have reached payments over the R $650 (US$325) per household (Hall 2008). Also, the Juma Reserve REDD project has been established to prevent deforestation by the valuation of the services provided for the forests located in the southeastern region of the Brazilian state of Amazonas (do Planeta et al. 2008). The PES (payment for environmental services) presents a varied implementation; countries like Colombia and Ecuador count on important projects (e.g., the Face Reforestation Program for Ecuador, PROFAFOR (Spanish abbreviation), Carbon Sequestration Program, and the Pimampiro municipal watershed scheme) demonstrating advanced applications; however, Colombia presents some disadvantages in the payment to service providers, while countries like Bolivia and Venezuela show a higher skepticism and political barriers (Wunder 2007).

Otherwise, some challenges are recognized for the legal hurdles, and this aspect is observed on the Brazilian legislation for the concept of environmental services and their economic value which can be related to the water-use charges that do not place economical value on the water-conservation role of landowners (Hall 2008). Also, the complexity on the information related to the scientist and economical integration can affect the real operability of adaptation and mitigation measures. For this case, some studies have estimated that emission from both deforestation and fossil fuel combustion represents the 12 % which is 8 % less than the one estimated by the Intergovernmental Panel on Climate Change (IPCC) (Van der Werf et al. 2009).

Table 2 shows the ecological footprint for some countries in South America included in the estimations made by the Global Footprint Network (Footprint for Nations 2010) demonstrating the large biocapacity contained in the region and represented by their forests. South America counts on several advantages to develop adaptation and mitigation measures. Peru holds more than 40 projects equivalent to the reduction of about five million tons of CO_2 (General Secretariat of the Andean Community et al. 2007a). The Andean region including Venezuela and Chile has 570 million hectares of bio-productive area from which 200 million of supply goods

Table 2 Ecological footprint, ecological deficit, and main contributor of biocapacity, by country, 2006 (Elaborated based on information from Global Footprint Network (Footprint for Nations (2010) data tables http://www.footprintnetwork.org/en/index.php/GFN/page/footprint_for_nations/. Accessed September 29, 2010)

	Ecological footprint	Ecological (deficit) or reserve	Main type of biocapacity
Country name	2006	2006	2006
Argentina	3.0	4.1	Cropland (33 %)
Bolivia	2.4	16.9	Forest (82 %)
Chile	3.1	1.0	Forest (53 %)
Colombia	1.9	2.0	Forest (57 %)
Ecuador	1.9	0.4	Forest (57 %)
Paraguay	3.4	7.4	Forest (62 %)
Peru	1.8	2.3	Forest (67 %)
Venezuela (Bolivarian Republic of)	2.3	0.3	Forest (72 %)

and services absorb their own wastes, representing 370 million of global hectares valuated as 115,000 million dollars (General Secretariat of the Andean Community 2008).

The PES offers a great opportunity for countries to develop mitigation programs for the conservation of ecosystems and reforestation. For example, in Pimampiro, Ecuador, a farmer receives 12 $/ha/year for the conservation of primary forest; however, payments can vary for the same land use (a farmer in Heredia, Costa Rica, receives 57 $/ha/year for the same land use), and the implementation of PES has turned on an opportunity for farmers to develop conservation and productive activities (Kiersch et al. 2005).

The Climate Change Challenge for South America

South America's CO_2 emissions are relatively low; however, Brazil predominates the emissions of the region, while all the countries (excluding Paraguay) are presenting increase in the emissions, with Bolivia and Ecuador showing an increase of 69 % and 79 % between 1999 and 2008 relatively (see Fig. 3).

About 50 % of the $ktCO_2$ registered by 2012 belongs to energy-associated projects (see Fig. 4). This tendency is demonstrating the important participation in the Carbon Market reached by the implementation of energy projects.

Some projects in South America are demonstrating the potential of the region for implementing alternative energy and reduce CO_2 emissions (Table 3).

Despite the low participation of SA in the CDM, energy projects represent more than the 80 % of the $ktCO_2e$ registered by 2012 in all countries in the region (excluding Paraguay and Uruguay) (see Fig. 5). SA requires technological transfer to take advantage of the alternative energy potential, but better policies should be applied by participating in Global Carbon Market to achieve technology and

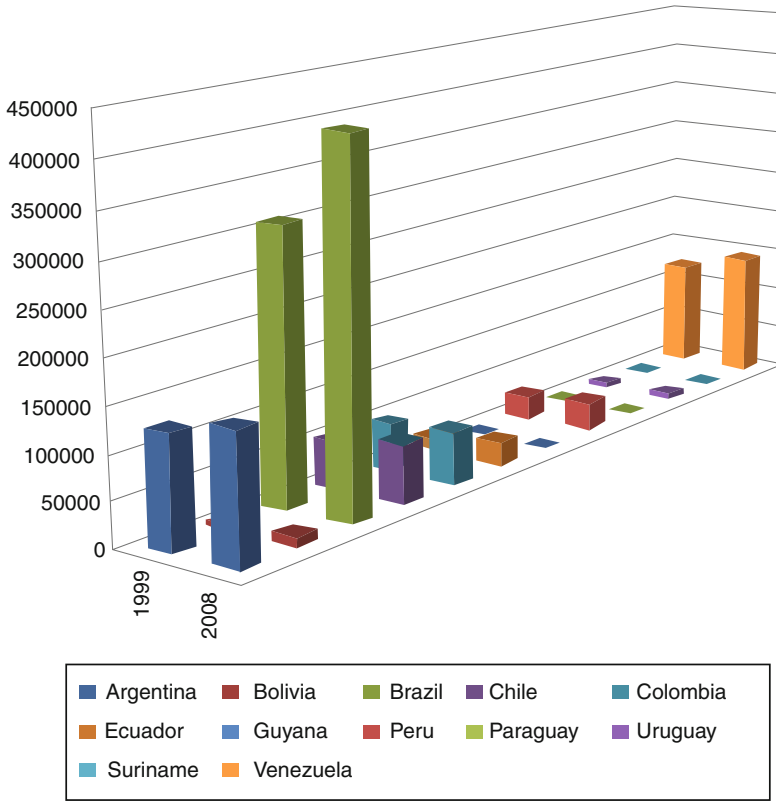

Fig. 3 CO_2 emissions (Gg) by country, 1999 and 2008. Elaborated based on the data from the Latin American Energy Organization, OLADE, 2009. Energy Statistics Report 2009. Base year 2008

resources transfer while protecting natural resources. A good example was given by Ecuador when it decided to pledge in a pioneering agreement with the United Nations to refrain from oil drilling in a pristine Amazon preserve in return for some US$3.6 billion ($4.9 billion) in payments from rich nations (Yasuni-ITT 2010).

Because of its ecological sensibility, in the sociocultural and economic context, South America is one of the main vulnerable regions in the planet facing climate change. This situation requires more accelerated and practical adaptation programs in the real scenario. Because the main natural and social characteristics bring different levels of risk, also the application of these programs should vary and be approached to different scales.

The main challenge for this region is to understand how global, regional, and local dynamics can impact the different local scenarios. At present, the main aim for combating climate change is to design more effective mitigation and adaptation measures for the specific and unique conditions, not only for the different countries, but also for the different communities and ecosystems contained within them. Policy

Table 3 CO_2 reduction potential by energy projects in South America (Elaborated based on the information from the *General Secretariat of the Andean Community, the United Nations Environment Programme (Regional Office for Latin America and the Caribbean), and the Spanish International Cooperation Agency (2007) and **Gerardo Siva Dias PR, Ribeiro WC, Sant Anna Neto JL, Zullo Jr. J (2009))

Country	CO_2 reduction potential (ton equivalent)	Kind of project
Ecuador*	307,000	Not specified
Bolivia*	17.7 million	Not specified
Colombia*	800,000	Jepirachi eolic project
Brazil**	84,165	Alta Mogiana Bagasse for electricity produced from fossil fuel energy stations by energy produced from sugarcane bagasse

integration of the countries to transform the natural resources and energy potential into operative projects is required. Regional scales, beyond national boundaries, should be integrated for designing regional actions toward the technological transfer for alternative energy development and conservation programs for vulnerable ecosystems like the Amazon, Glaciers, and forest cloud mountains.

Future Direction to Combating Climate Change in SA and EA

Vis-à-vis the present climate change impacts, it is very unlikely that the negative effects on the environment and people's livelihood will improve any time soon. The latter necessitates helping vulnerable individuals/groups cope with the adverse effects and reestablish their means of livelihood after climate disasters. Worth noting, combating climate change in the regions would require both local and extra-local efforts in a number of ways. For instance, future adaptations and mitigations to climate change vulnerability will have to be reflected in all regional polices (MOENR 2002).

Coping with climate change challenges will have to go hand in hand with major adjustments in various policies and legislations. For instance, the potential for utilization of renewable energies, namely, biomass, solar power, geothermal, wind energy, biogas, and natural gas, would require significant regional governments' commitments in terms of policy adjustments and economic sacrifices. Successful harnessing of geothermal energy in Kenya, natural gas in Tanzania, and most of the renewable in Brazil could imply that proper policy adjustments could reduce power shortages in the regions. In recent years, however, significant efforts in structuring climate change policies have been taken by nearly all regional governments. Although the efforts may be considered insufficient compared to the impacts, they do provide a fundamental framework to dealing with regional climate change challenges. These include the establishment of national bodies with full mandates

on climate change issues and environment management at large and creation of several laws and legislations on environmental issues (The Global Humanitarian Forum 2009; Red Crescent Climate Centre, RCRCCC 2003). Arguably, as a sign of worsening situation, most recent government policy documents in the regions do recognize climate change as an important impediment to their sustainable development. For instance, most climate change issues are notably defined in the regional National Adaptation Program of Action (NAPA) reports (Red Crescent Climate Centre, RCRCCC 2003). In summary, the regional bodies dealing with climate change requires an inclusion of how such projects and/or policies with potential negative impacts to the environment will be addressed before being accepted for implementation. The latter makes it mandatory for extensive environmental impact assessment (EIA) to be carried out to such projects before they would be approved for implementation (The Global Humanitarian Forum 2009; Red Crescent Climate Centre, RCRCCC 2003). However, care must be taken as some of the suggestions in the NAPA reports provide suggestion that might not work in the region. For example, some suggestions in the reports are considered too expensive in the region and require unavailable technology. Failure to fully involve local people has been experienced in the region (particularly in Tanzania) where local people objected some drought-resistant crops on grounds that they were tasteless and lacked market value (Müller 2010). The latter have resulted in poor adaptation to climate change impacts and left on agriculture a significant number of the individuals vulnerable. While some of the suggestion might work in the long run, real solutions to the challenges of climate change vulnerability would come from an inclusion of a wealth of local skills dealing with climate change and disaster management at large.

In appreciating the importance of forests in carbon sinking, forests have regionally been advocated as one of the most important gears to combat climate change. In accordance with the global move, regional efforts put a lot of emphasis on both reforestation and afforestation programs (MOENR 2002). However, renewed efforts on forest management are needed as desertification has been increasing. In addition, special consideration needs to be taken on energy sector since a significant portion of regional energy balance is met from biomass energy (International Food Policy Research Institute (IFPRI) 2004). Capitalization on the abundant potentials of renewable energy would reduce pressure on the natural forests and the amount of carbon emitted.

Alongside the suggestions above, it is worth noting that the regions lack necessary expertise and economic ability to deal with climate change and associated issues. Emphasis must thus be concentrated on training local scientists, planners, and policy makers to prepare them to deal with the worsening situation in the regions. In addition, future direction of climate change in EA and SA will have to be concentrated on land use change since major regional contribution to the GHGs comes via land use change and deforestation.

Furthermore, the EA region has an abundant supply of carbon dioxide which requires purification only to be ready for industrial use. EA countries could capitalize on the natural supply of the gas and stop importation of the gas from other places. At present, most industries in Uganda, Tanzania, and Kenya still import carbon dioxide

which is seen as a wasted regional opportunity both to control carbon and investment. As a potential investment, the Carbacid Company in Kenya has started mining the gas for commercial purposes. Thus, both regional and even neighboring countries could meet all their carbon needs from the region without requiring importation of the gas. Similar efforts need to be strengthened in other regional countries and potentially stop importation of the gas all together.

Other areas where strengthening can be done to reduce vulnerability to climate change include accurate information gathering and dissemination. The latter is important since most times when climate disasters strike many people have been caught unaware/unprepared and thus increased vulnerability. In addition to that, renewed emphasis on local capacity building and decision-making should be made central in helping vulnerable groups to adapt better to climate change impacts. Because of the poor resource base in the regions, it is very important for funds whether in the form of credit or otherwise to be available to vulnerable groups after climate change disasters. Such funds can help affected individuals or groups to restock lost animals, buy farm inputs, and/or reestablish lost business or other means of livelihoods. The best way to ensure availability of funds to such groups/individual could be via rural credit mechanisms. Governments and other stakeholders should as well help rural credit mechanisms like pastoralists and/or cooperative unions get funds from financial institutions. This is important as regional studies have shown that individuals who have financial access like remittances from relatives generally recover faster and better from disasters.

Another potential area for future strengthening includes effective early warning systems on climate change disasters and effective information gathering and dissemination. Recent regional experiences have shown that climate change vulnerability is often worsened by failures to forecast potential climate disasters and poor communication between responsible authorities and the general population (Red Crescent Climate Centre, RCRCCC 2003). In the future, it would be very helpful to have a mechanism that would ensure such information is well forecasted and the general population is well prepared for the potential effects. Vis-a-vis to the above, it will be very helpful for regional bodies like meteorological departments and disaster management units to be equipped with advanced early warning systems for potential climate disasters and effective mechanisms to spread the necessary information. Albeit governments in both regions have taken certain steps in improving their disaster management units, further effort is still needed to improve them further by purchasing more accurate meteorological equipments and proper training of staff.

Finally, careful enforcement of environmental education in school curriculums may also prove to be a reliable means of reducing causes of climate change but most importantly help in regional adaptation and mitigation strategies. Because climate change and generally environmental degradation are presently appreciated to be developmental factors, it is crucial for regional education system to effectively prepare younger generations on environmental issues. Significant efforts have been made in recent years regarding inclusion of environmental aspects in school system, and several environmental-related degree and nondegree programs are being offered in colleges (The Global Humanitarian Forum 2009). Efforts can still be done to

improve such curriculums to enable real solutions to local climate change-related challenges. Inclusions of environmental course in non-environmental programs in schools would as well help a larger part of the society become environment sensitive.

Conclusion

In SA and EA, the negative climate change impacts are no longer potential threats but rather ongoing problems that have long been underestimated. Climate variability is already affecting many development projects and even threatens to undo some of the achievements made, including some of the Millennium Development Goals (MDGs). Generally, the regional climate change vulnerability requires immediate actions as several sensitive ecosystems like the coastal resources, Eastern Arc Mountain forests, the Amazon forests, Mount Kenya, Mount Kilimanjaro, and the Andean Mountains are already affected. The negative impacts on agricultural systems, water resources, biodiversity, energy availability, infrastructures, and health issues are unmistakably clear and worsened by the fast-growing population and widespread poverty, among others. Today, ordinary people in the villages know their ways of making a living and are threatened and are left with no option but to return to their indigenous survival skills. The status quo leaves the regions with potentials of being significant contributors of GHGs in the next decades via land degradation and especially deforestation of its fast-shrinking forest resources so as to meet basic needs such as fuel wood. The use of poor often polluting technologies in the struggle for economic development and the desires to meet the needs of the fast-growing population will also add to GHG contribution in the future. As these regions near their peaks in terms of economic and industrial development, this would mean that a more net contribution in GHGs is likely because the regions will be consuming more energy, a trend that is already evident.

Most adaptations and mitigation options suggested by international bodies and which are largely reflected in the regional climate change strategies have local implementation difficulties. Since the economic base of the regions is among the world's least, implementations of such technical, expensive, and often unavailable options might prove to be difficult and could leave many people vulnerable to climate change impacts. Fortunately, the regions have rich indigenous skills and adaptation measures that require strengthening and inclusion into the regional vision for combating and/or living with climate variability. Thus, meaningful relief from climate change vulnerability will have to include existing livelihood strategies and especially recognition of the traditional resource management including on land that are well developed in the regions. However, local survival skills to the harsh conditions like droughts have in recent years been overstretched and feared not to work in the long term.

Unfortunately, governments and development planners within the regions were late to recognize that climate change was an issue of development and needed to be incorporated into all development projects. Climate change issues were for the long time not clearly reflected into the regional development plans and mistakenly treated

as a separate entity resulting to bitter lessons. Because of the severity of the challenges of climate change to the delicate livelihood system in the regions, governments, private sector, and other stakeholders were forced to take decisive steps and recognize climate change to be an integral part of regional sustainable development.

Since major contributions to climate change causes come via land use change and natural resources exploitation, land and natural resources like forests need to be central in dealing with climate change in the regions. Land and forest policies necessitate reexamining and better enforcing so as to control/reduce desertification, a trend of which has in recent years been significant in the regions.

Moreover, because both the courses and impacts recognize no regional boundaries, regions must move with the rest of the world in combating climate change. Regional governments, private sectors, individuals, and other stakeholders need to play their expected roles in both adaptation and mitigation measures to combat climate change. On the other hand, where as the international efforts do provide important generalizations regarding climate variability, they should try as much as possible to recognize special vulnerability in SA and EA where many of their frameworks dealing with the variability might not work as expected and should locally be assisted to deal with their problems in specific ways. While generalization simplifies things, specific issues in the regions, like over 70 % of the population is dependent on biomass on EA, need to be noted and treated in a special way.

Abstract

The Dodoma municipality, a semiarid region of Tanzania, is characterized by limited rains, lack of surface water sources, and a high frequency of extreme climate events, particularly droughts and floods. These disadvantaged settings make it vital to study long-term climate trends for signals and patterns of shifting climate regimes for integrity of local livelihood support systems, especially agriculture, recharge, and pasture developments. The area has fairly long climate records, some of which extend to about 100 years. This chapter presents detailed analysis of six climate parameters, namely, rainfall (R), atmospheric relative humidity (ARH), temperature (T), sunshine (S), radiation (RD), wind speed (WS), and evaporation (ET) records from three meteorological stations, namely, Hombolo Agrovet (HMS), Dodoma (DMS), and Makutupora (MMS). The parameters above were statistically and graphically analyzed in four time scales, namely, monthly, seasonal, annual, and time series. The results showed the area is characterized by slight spatial variability in R intensity and T magnitudes with HMS having higher T and rains than DMS and MMS. Further there are clear decreasing trends in ARH and R, while T, S, WS, ET, and RD parameters showed characteristic increasing trends. Thus, except for extreme rain events, particularly El Niño-Southern Oscillations (ENSO), which are characterized by abnormally increased R magnitudes, R intensity has generally decreased in which over the past 91 years, there has been a net R decrease of 54 mm out of annual rains of only about 550 mm/year. Compared to annual time step, however, monthly step reveals more silent features like shortening of the growing seasons. Similarly, the frequency and severity of drought episodes are increasing, all of which adversely impact agriculture, pasture development, and recharge. Similarly, disappearance of R in some months, shifting seasonality, and general declining R intensities and magnitudes are clearly observed. May rains have largely disappeared, while in January, February, March, and April rains have decreased and hence shortening the length of growing season. On the other hand, clear warming trends and declining ARH were also observed. Yet the area is marked by cyclic wetting and drying events where in recent years, drying cycles have been prolonged. However, there is more variability in the mean minimum temperature (MMT) than in mean maximum temperatures (MMMT) in all stations. Between 1961 and 2012, there has been a net 1.13 and 0.778 °C increases in annual MMT and MMMT in DMS, respectively. Like for R trends, silent features are more evident under monthly T data than annual time steps where it is clear that June had the highest increase in MMT (1.54 °C), while April had the least (only 0.662 °C). However, both trends have the potential of affecting major livelihood support systems particularly agriculture and pasture development, but also local groundwater recharge that is vital for the local economy. The study area therefore offers a rare opportunity to understand and manage changing climate regimes including on extent of dry spells and longevity of growing seasons. The changing climate trends consequently call for significant adaptation and mitigation strategies so that local activities adjust to the current climate regimes particularly on onset and end of rainfall seasons and recharge fluxes.

Introduction

In recent years, the augments against climate change have lost path as its negative impacts become more severe and widespread, numerous times with major socioeconomic implications (Ebi 2014; Knox et al. 2012; Omambia et al. 2012). Globally, increasing evidence have been documented showing widespread changes in climate regimes with major implications in the life support systems like food security, shifting ecological range of disease vectors (Altizer et al. 2013; Harvell et al. 2002, 2009; Lafferty 2009; Thomson et al. 2012), submergence of islands and coastal resources (Barnett and Campbell 2010; Hearty and Neumann 2001; Nicholls 1995), and exuberated vulnerability to natural catastrophes (Omambia et al. 2012), to name but a few. In addition, climate change impacts are blamed for displacement of people and livestock which have often resulted to increased conflicts in Africa (Hendrix and Salehyan 2012; Maurel and Kubik 2014; Shemsanga et al. 2010; Burke et al. 2009).

Currently, many people in rural Africa witness major changes in growing seasons, rainfall intensity and distribution (Mary and Majule 2009; Sanga et al. 2013, 2014), temperature regimes, and disappearing and/or shrinkage of the surface water bodies like rivers and lakes (Boelee et al. 2013; Conway and Schipper 2011; Faramarzi et al. 2013; Hendrix and Salehyan 2012; Mutua and Koike 2013). Further, surface water bodies in Africa are declining leading to increasing conflicts between different water uses/users, namely, pastoralists, agriculturalists, hydropower plants, and water managers (Valimba 2004). On the other hand, drought and flood episodes are becoming more frequent and severe in many places in Africa (Cooper et al. 2013; Knox et al. 2012; Paavola 2008; Simon 2010). However, irrespective of the fact that many of these impacts have been recorded in Africa (Belloumi 2014; Mutua and Koike 2013), and whereas the continent is projected to be affected more by climate variability (Solomon 2007), little has been done on the ground in the manner of observed long-term climate trends, mitigation, and adaptation options (Belloumi 2014; Cooper et al. 2013; Ford et al. 2012; Rugai and Kassenga 2014; Sanga et al. 2013). Indeed the continent has limited ability/options to adapt to climate change impacts and functional mitigation measures due to high rates of poverty, limited infrastructure, and enabling resources to cope with the changes (Cooper et al. 2013; Rugai and Kassenga 2014; Sanga et al. 2013; Simon 2010). It is plausible therefore to carefully study how long climate variability impacts affect the content and hence be better prepared for the workable mitigations and adaptation measures on various sectors.

While the entire African continent is considered more vulnerable to negative climate change impacts, semiarid regions of Africa are already more affected (Fuller and Prince 1996; Majule 2008; Mary and Majule 2009; Mongi et al. 2010; Nelson and Stathers 2009; Paavola 2006; Rowhani et al. 2011). Irrespective of this dire situation, not much is known in the Dodoma municipality, a fast growing city in semiarid Tanzania, regarding long-term climate variability in terms of relative atmospheric humidity (RH), evaporation (ET), sunshine hours (S), radiation (RD),

temperature (T), wind speed (WS), and rainfall (R) patterns. The central issue of when did the key climate parameters locally started to change and at what magnitude compared to the local and global trends also remains unknown. In addition, although many strongly agree that the world climate systems are changing, the inter-seasonal and monthly variations of these core climate parameters in semiarid regions of the developing world are not well documented. Furthermore, past climate studies did not focus on frequency of droughts and monthly and seasonal climate variations, yet these are arguably more important for the local livelihood support system than the annual or higher time scales. While simple tools can make the general climate trends more available to local players, previous regional studies used complicated science and tools that are often out of reach to locals, experts, and decision-makers, hence making it difficult to appreciate the results and most importantly their usefulness.

The geographic, climate vulnerability, and meteorological characteristics of semiarid regions of Tanzania and East Africa in general, require close monitoring of trends in key climate parameters. This is partly so because these parameters directly affect key livelihood support systems of the populace especially agriculture which is predominantly rainfed, the main source of livelihood and employment (Shemsanga et al. 2010; Omambia et al. 2012; Craparo et al. 2015). Correct understanding of these climate parameters particularly when involving smaller and varied scales (monthly, seasonal, and annual) is important in such a region often faced with chronic shortages of water needed for its rapid socioeconomic development, rainfed agriculture, pasture development, and groundwater recharge. Small variations in these climate parameters at lower monthly time step have the potential of affecting local groundwater recharge, agriculture, and pastoralism activities among others. In spite of this importance, few studies have been done locally to ascertain long-term trends, evidence of shifting climate seasonality, yet such studies were all biased toward T and R leaving other pertinent parameters in understanding local climate dynamics unstudied. For instance, limited studies have indicated that the area has observed prolonged droughts and increased crop failure as a direct consequence of decreasing R regimes. Past studies in similar locality found that agriculture and livestock-keeping sectors were severely affected by decreasing R (Majule 2008; Mary and Majule 2009; Craparo et al. 2015). Irrespective of the robust local evidence that the local climate dynamics are changing fast, past studies did not sufficiently study changes in ET, T, S, D, WS, and ARH, all of which are key in understanding of climate patterns, moisture distribution, and local water balancing.

This study intends to statistically ascertain changes and patterns in key climate parameters, namely, R, T, ARH, WS, RD, and ET in relation to livelihood support systems vis-à-vis groundwater recharge, pasture development, and agriculture among others. It is hoped that such a broad and comprehensive understanding of the local climate regimes and their impacts on local livelihood support systems in comparison with the global climate trends would enable better decision-making on adaptation and mitigation from adverse climate variability impacts.

Case Study Description

The current work focuses on the Dodoma urban district. The area is bound by latitude 5°36′59″ and 6°14′50″ S and longitude 35°36′36″ and 36°01′54″ E (Fig. 1). The faulted and tectonically active crystalline basement area of Dodoma craton underlies the area. The metasedimentary rocks are mainly quartzites, iron-stones, micaceous quartzites, quartzo-feldspathic schists, and ferruginous quartzites (Shindo 1991; Nkotagu 1996a, b). Meteorologically, the area is in a semiarid region with low (550 mm/year) unimodal rains between October and May. Temperatures are lowest in July (about 13.0 °C) and highest in November (about 30.6 °C). The semiarid nature of the area can be appreciated from very high evapotranspiration (PET) rates averaging at 2000 mm/year; this rate is roughly fourfold annual rainfall (Shindo 1991). Hydrologically, the area is notable for its lack of permanent surface water bodies and a runoff/river network that is largely seasonal, flowing only during rainy seasons and a few weeks thereafter. Hence the area is heavily reliant of groundwater. The area has a moderate population growth rate (3.3 %), and it is projected that by 2025 total population will be 689,072 compared to 410,956 in 2012. Projections show that by 2025, 94,218 m^3/day of water will be needed in the municipality compared to about 38,006 m^3/day in 2002 (URT 2003).

Materials and Methods

The methods deployed included statistical and variability analyses of climate data, namely, RH, WS, E, S, RD, T, and R. Meteorological and groundwater level data were collected from Makutupora Met station (MMS) (1921–2013), Dodoma Met station (DMS) (1961–2013), and Hombolo Agrovet Met station (HMS) (1980–2013). These were statistically and graphically analyzed under four time steps, namely, monthly, annual, seasonal, and entire time series. However, studies show that extreme events in changing climate variability are more important than averages (Katz and Brown 1992) and, accordingly, those were especially plotted and analyzed.

Data analyses were done using Instat, v. 3.37®, SigmaPlot v11®, and MS-excel, 2007. Thornthwaite monthly water balance (TWMWB®) was used to further model and understand local climate parameters based on observed data. Further, these were used to analyze long-term climate variability, droughts severity, and long-term wetting and drying events/cycles. Local drought index (DI) was developed to assess drought trends by using the following equation (Rathore 2004):

$$DI = \frac{P - x}{SD} \tag{1}$$

where P = annual precipitation, X = long-term mean, and SD = standard deviation. The DI intensity values were then categorized accordingly DI = < −0.1 light drought (LD), DI = < −0.2 moderate drought (MD), DI = < −0.5 severe drought (SD), DI = < −0.8 very severe drought (VSD) (Rathore 2004). Khronostart1.1®

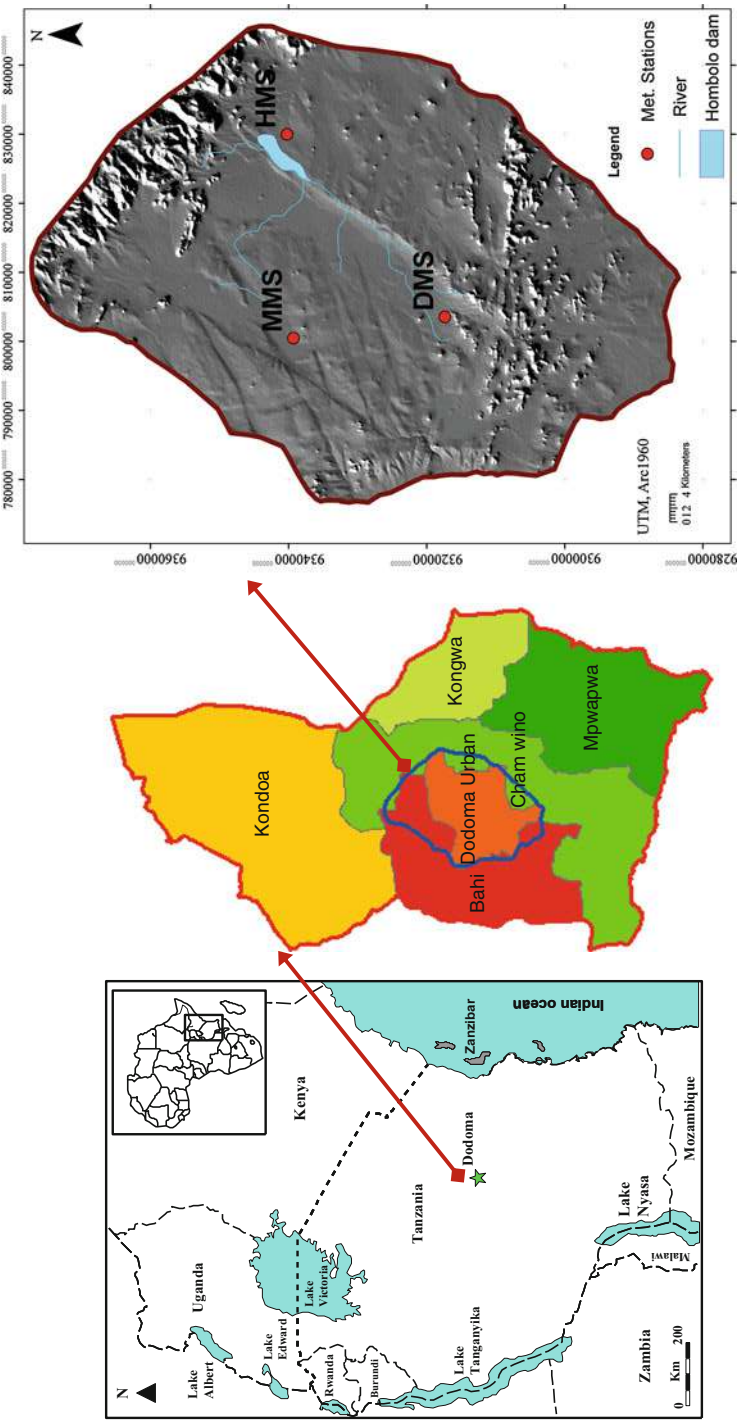

Fig. 1 Study area

software was used to determine when exactly the changes in rainfall occurred and how they varied across the entire time series, that is, when do they became significantly different from the trend. These were then compared and discussed along with the global patterns and shifts for any similarities and divergences.

In addition, extensive literature review on the current climate trend projections was performed. However, emphasis was put on simple techniques that are freely available to local experts and community with the aim that they would understand their local climatic regimes and consequently put working adaptations and mitigation measures in place. Thus, as much as possible, complicated science and expensive technologies were not employed in the current study as these are mostly unavailable to the local decision-makers and hence of little use.

Results and Discussions

Variability in Local Temperature Data

Analysis of T is important as it is a key driver for nearly all other climate parameters (Charman et al. 2009; Williams et al. 2013). Locally, T offers important climate variability signal trends with clear warming trends throughout the available time series. Figures 10 and 11 show that mean minimum temperature (MMT) and mean maximum temperatures (MMMT) have all increased over the available time series. However, these figures clearly show that there has been more significant temperature increases with the MMT than MMMT. Notice the shaper increases in MMT than in the MMMT (respectively, Figs. 10 and 11). Close observation of the T trend line and slope shows that between 1961 and 2012, there has been a net 1.13 and 0.778 °C increases in annual MMT and MMMT in DMS, respectively. Interesting to note, silent features are more evident under monthly than annual time steps where while both annual MMT and MMMT show increasing T, close observations of the monthly time step data reveal that some months had more increases in T than others (Figs. 10 and 11). The available time series suggest that June had the highest increase in MMT (1.54 °C), while April had the least of about 0.662 °C.

Similarly, the MMMT which until early 2000s had shown slow increases have recently shown much shaper increases (Fig. 11f, g, h, i, j, and l). Like for MMT, hidden and silent features are more obvious from monthly variations than annual time step in which microscale monthly variations are common with February recording the sharpest T increase (Fig. 11).

Therefore the increases in T will have important social economic consequences including on local water resources management, agriculture, and pasture developments. However, from monthly and annual average MMT and MMMT variations, it is clear that T has increased at all time scales. For instance, the MMT in 1982 and 2012 were, respectively, 18.1 °C and 19.7 °C a corresponding increase of 1.6 °C between these two points (Fig. 13b). These results correspond well with similar findings in comparable settings in Tanzania (Mary and Majule 2009; Swai et al. 2012a, b, c; Craparo et al. 2015) and recent climate downscaling and

projections. Worth noting, even minor increases in T have huge implications in the area as T is a key driver to other climate parameters like ET and the corresponding ARH (Fig. 22a, b), respectively. Thus, increases in T would in turn hamper potential groundwater recharge as more water would be involved in PET than infiltration and percolation (Calow et al. 1997, 2010; MacDonald et al. 2009, 2012; Ngongondo 2006).

Analysis of monthly average T for HMS and DMS reveals that the former has slightly higher T than the latter (Fig. 16b). Keeping other factors constant, these results mean that HMS is likely going to have slightly more PET than DMS as T is a vital driver for PET (Charman et al. 2009; Williams et al. 2013) and reiterates the role of micro-spatial T variability for local livelihood activities (Personal communication with Mr. Ntuza, Hombolo irrigation officer).

One reason why HMS has slightly higher T is to account for the fact that there are higher mountains (Chenene Mountains) in the NE which block advective winds from the depressions where HMS is located. In close connection with these findings, a recent study in the area concluded that, apart from the geology-related salinity in Hombolo Dam, high salinity in the dam was also due to excessive PET losses that is year-round higher than the R (Shemsanga et al. forthcoming). The increasing local T trend will only further exuberate the situation. Although for both HMS and DMS T are higher during the wettest month, January, hence more water losses, T is even higher for HMS during wet months; hence more water is likely to be lost via PET in Hombolo sub-catchment than in Dodoma urban sub-catchment (Fig. 16b). One can therefore plan to grow more of T-tolerant plants in HMS sub-catchment than in the DMS sub-catchment (personal communication with Mr. Ntuza, Hombolo irrigation officer).

Apart from the general warming trend in all data sets, notice that the annual MMT and MMMT have increased for up to 1.54 °C and 0.778 °C, respectively (Figs. 15 and 16). Notice also that similar warming trends are observed in the wettest month (January), driest month (September), warmest month (November), and coldest month (July) of the data set (Figs. 10, 11, and 16b). These findings are similar with current climate models that generally agree that the region is warming up fast (Cooper et al. 2013). These findings also agree with modeling and prediction results that show generalized warming trends across the continent (Mariotti et al. 2011). Further, these findings are also similar to studies from other localities in Eastern Africa with similar climatological settings (Kinh'Uyu et al. 2000). Previous studies and climate models have indicated that over the past 3 decades, there has been up to 0.6 °C in T (Omambia et al. 2012).

A study conducted at Makindu, a semiarid region of Kenya, had shown that if T is to rise by 3 °C, there would be a corresponding decrease in about 8 % in the length of growing periods (Cooper et al. 2009). By using HadCM3 model, the same study found that by 2050 the area will lose up to 5–20 % of the length of the growing season as a direct consequence of climate change. Yet increase in T has globally been associated with decreasing crop yield (Deryng et al. 2014; Liu et al. 2013; Liu et al. 2012; Deryng et al. 2014; Tao et al. 2015), and there are no reasons to think the

local increase in T will not affect the domestic agricultural sector, the largest employer in the county. For instance, it is argued that if in Tanzania T is to increase by between 2 °C and 4 °C, maize production will go down by about 33 % (Paavola 2008). Yet a recent study in northern Tanzanian highlands found that an increase in T had profound impacts in coffee yields (Craparo et al. 2015).

It is already known that T and moisture are key factors in the spread of disease vectors (Mary and Majule 2009). A recent study also modeled and linked malaria epidemic in Tanzania with increasing temperatures including in the highland where malaria was not endemic (Jones et al. 2007). This picture therefore shows that the area is very much threatened by climate variability, and adaptation measures must be considered for the local livelihoods.

Elsewhere in Africa, within the last few decades, the continent has observed widespread warming in many regions (Stocker 2014; Sabine 2014). By the end of the century, the continent's climate is further projected to have an increase of up to 2 °C in temperatures. Other projections put the continent at even higher risk (Burke et al. 2009; Hendrix and Glaser 2007; Faramarzi et al. 2013). These global projections are well translated in the current study area and would require major adaptation strategies. Such huge changes in climate dynamics are likely to impact on the local rainfed agriculture, recharge, and natural catastrophes like flooding and droughts where there has been an increase in the number of floods and drought episodes in the continent including in Tanzania and specifically in the study location as seen and discussed in the next subsection (Omambia et al. 2012; Shemsanga et al. 2010).

Rainfall Characteristics and Variability Data

Irrespective of the differences in longevity of the study, rainfall data shows similar declining trends in all three stations and at all time scales (time series, annual, seasonal, and monthly). However, the current findings show that there is high spatial and temporal rainfall variability (Fig. 3) where it is revealed that Hombolo sub-catchment receives more R (608 mm/year) than the Makutupora (548 mm/year) and Dodoma urban sub-catchments (581 mm/year) (Figs. 2 and 18b). These results also show that the annual average R is, respectively, 60 and 27 mm less in MMS and DMS than in HMS (Figs. 2 and 18b). Thus, the mountainous areas of Hombolo receive more R than the lowland areas of Makutupora and Dodoma urban (Fig. 1). These findings are similar with other local findings (Nkotagu 1996a, b, c; Rwebugisa 2008; Shindo 1994). The information on micro-scale spatial rainfall variability is important for planning types of crops to be grown and for management of groundwater in the area. For instance, from this information, it is most obvious that the shallow wells in Makutupora sub-catchment will have less recharge than Hombolo, for example, since shallow wells are mostly dependent on local rainfall (Al-manmi 2002; Cook and Herczeg 2000). Similarly, more of drought-resistant crops should be sought for Makutupora sub-catchment than for Hombolo.

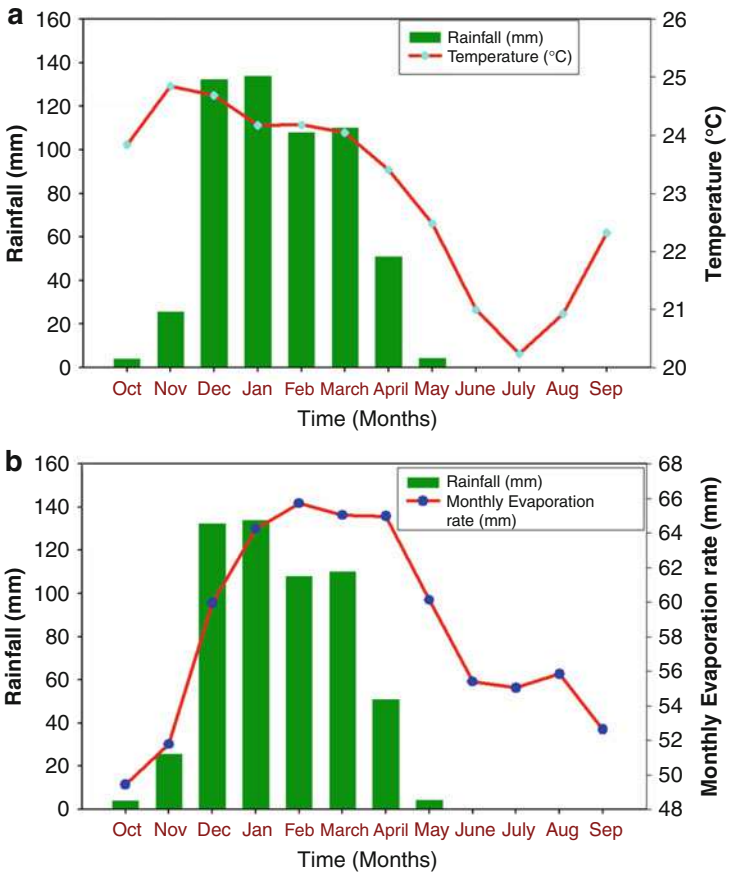

Fig. 2 (**a**) Climatograph of rainfall and temperature. (**b**) Rainfall and evaporation in the Dodoma municipality

From Fig. 3a, it is revealed that the regression of annual and May R at MMS has a slope of −0.592 and −0.556, respectively. Considering these values into account and taking the 91 years time series, this shows that there has been a net decrease in R of about 53.9 and 50.6 mm at an annual and May time step, respectively. This is a significant shift in the effective R for the area characterized by low rains (550 mm/year) that mostly come when T is highest (Fig. 16b).

Notice in the data set that all but one year that were completely with no April rains are clustered in the last 30 years. Notice also that there are significant declines in the amount of March rains from 2003 onward (Fig. 7). This may hint that April as is the case for May is no longer reliable for local livelihood support systems like agriculture and pasture development. This requires major adjustments in cropping seasonality and the choice of crops to be grown with more drought-resistant crops being the preferred choice. Similar patterns are observed for May rains for both DMS and

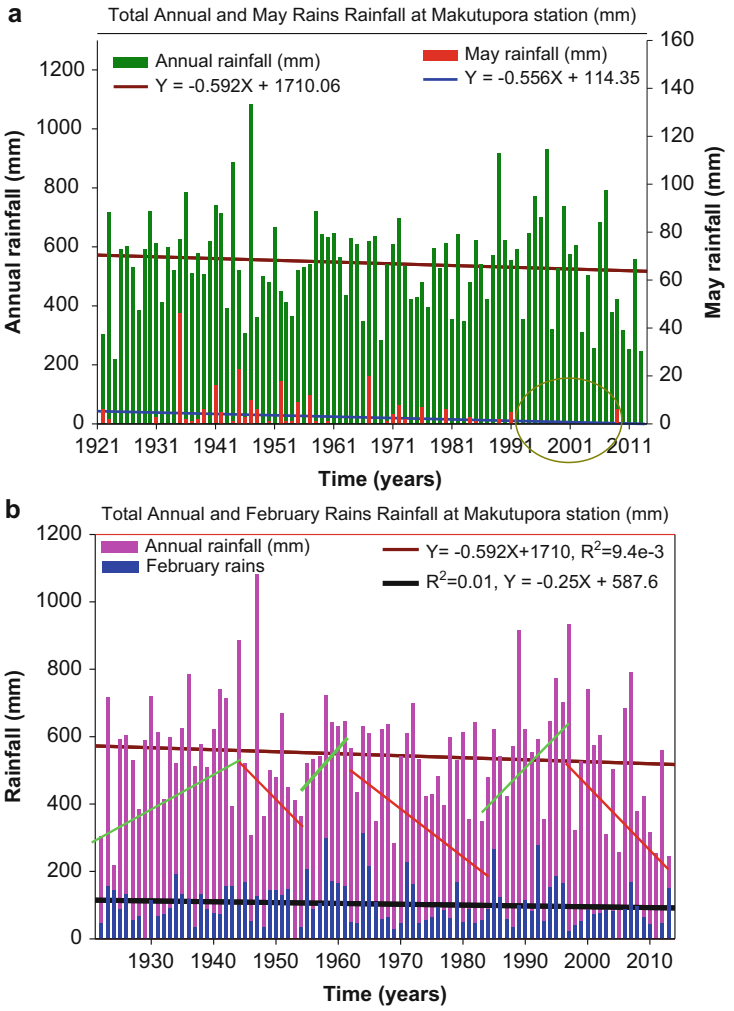

Fig. 3 (**a**) Total annual and May rains at MMS. (**b**) Total annual and February rains at MMS (mm)

HMS data sets (Figs. 4e and 5e). Further, such drops in the amount of R and the disappearance of April and May rains at Makutupora sub-catchment could adversely affect local recharge at Makutupora aquifer (well field) that supplies freshwater used in Dodoma city (the capital of Tanzania). This will further worsen the local hydrogeological balancing when already a recent study reported a decreasing dug wells yield and early drying of the well all of which were linked with decreasing R and increasing T & ET (Shemsanga et al. forthcoming).

It is interesting to note that while several years over the last 3 decades received no April rains at MMS (Fig. 7), DMS and HMS have continued to receive April rains although at a much reduced magnitude (Figs. 4d and 5d). Similarly, HMS has

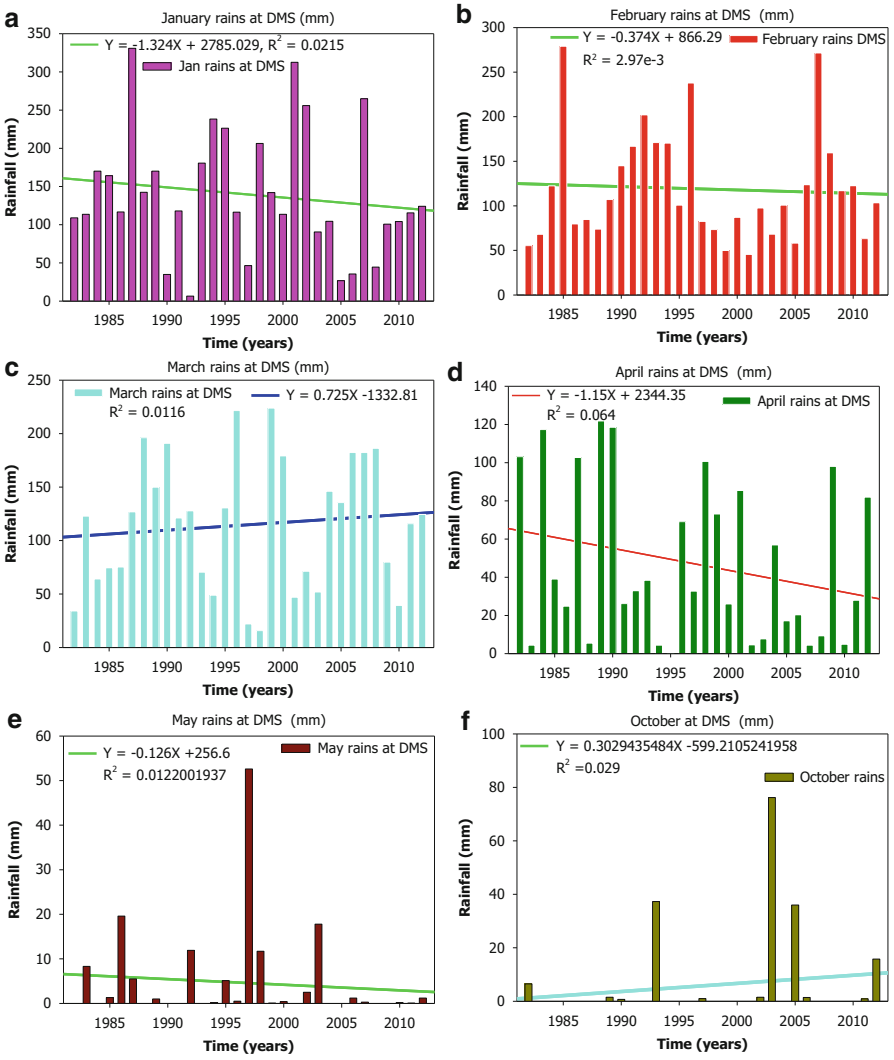

Fig. 4 Time series monthly rainfall trends at DMS

continued to receive more rains in May than DMS and MMS in that order. Such hidden and silent features are not vividly seen in annual and/or time series time step and may bring about a breakthrough in the timing of growing seasonality.

While some other local factors may play some roles, climate studies associate the widespread regional declines in R with increases in the Indian Ocean sea surface temperatures (SST) (Williams and Funk 2011). Similarly, a westward extension of the warm pole is blamed for some westward extension of the Walker circulations that dried most of EA (Williams and Funk 2011). The Indo-Pacific sea surface

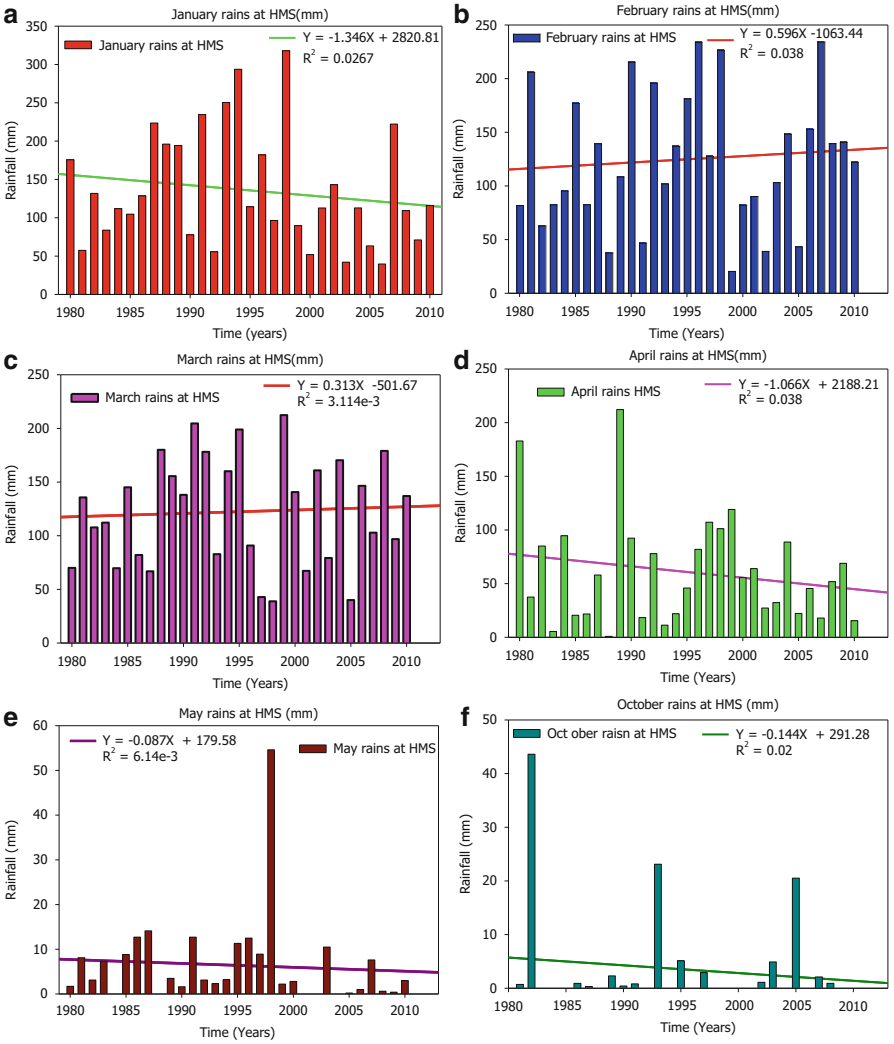

Fig. 5 Time series monthly rainfall trends at HMS

temperature plays pivotal roles in the failure of consecutive rainfall seasons in much of EA (Hoell and Funk 2014; Funk et al. 2014).

Despite the differences in longevity of the R data series from the three stations, notice that there are more or less clear and similar cyclic wetting and drying seasons. For instance, it is clear that from the early 1980s to late 1990s there were widespread wetting event seasonality (Figs. 3b, 6a, and b). The latter was followed by a drying event that is again uniformly observed in all three stations (Figs. 3b, 6a, and b). Furthermore, close observation of the pattern shows that in recent years, there have been longer drier seasons than wet seasons. This pattern however is of wide East

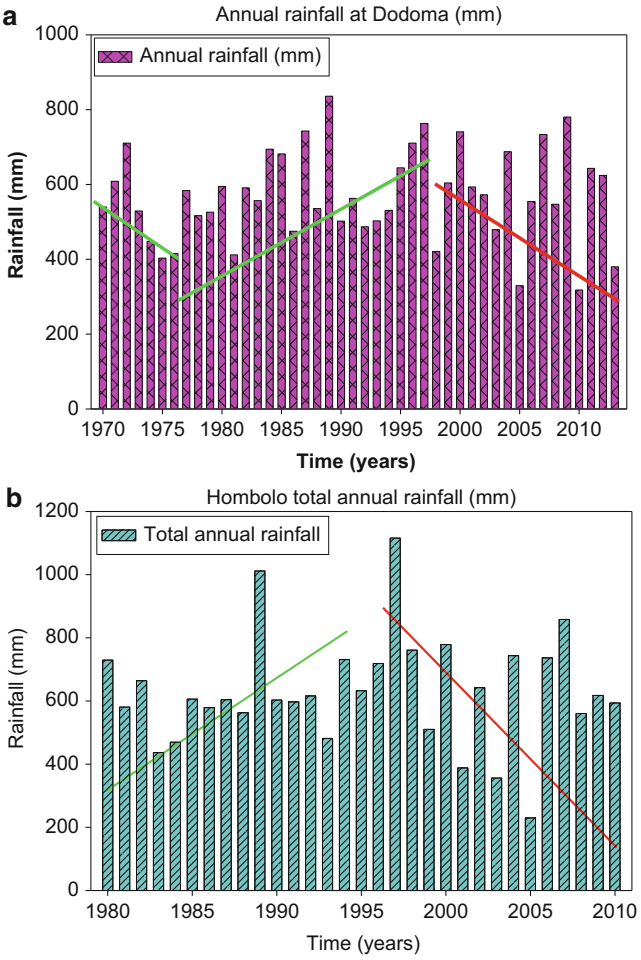

Fig. 6 Drying and wetting cycles at (**a**) DMS and (**b**) HMS

African implication and could be attributed to internal climate control parameters like thermohaline circulation, El Niño-Southern Oscillation, and changes in the ocean heat content (Cooper et al. 2008). For instance, closer similarity in the extended drier cycles can be seen in rainfall data from Kenya where in recent years there has been an extension of drier seasons in the rainfall data (Cooper et al. 2009, 2013).

Similar wetting and drying cycling was also reported in Zimbabwe between 1901 and 2007 rainfall data (Cooper et al. 2013; Hirji et al. 2002). Like already discussed, the extended drying events would therefore affect water budgeting in the area which would in turn affect groundwater recharge and availability of water for various socioeconomic activities like agriculture and pasture development.

Extreme Climate Events (Droughts and Floods)

In East Africa (EA), extreme climate events are particularly associated with floods and prolonged droughts that over the years have repeatedly cost human lives and widespread economic losses in terms of infrastructures, agricultural productivity, and domesticated and wild animal deaths, among others (Hendrix and Salehyan 2012; Maurel and Kubik 2014; Omambia et al. 2012; Shemsanga et al. 2010). According to Mr. Waziri (Tanzania Meteorological Agency TMA, central zone), recent years have witnessed more aggressive R events characterized by heavy downpours in a short time. "The rains are less evenly distributed and it is common to have a lot of R in a space of just hours leaving the rest of the season with little rains that are not productive in terms of cropping usefulness. Thus, the rains may be observed and the annual and monthly magnitude may even be the same but the bulk of the rains fall within a short time with very high force which ends up as runoff and triggering flash floods that destroy crops and infrastructure along the flow direction." Similar conclusions were reached by Valimba (2004).

In EA, the situation worsened in El Niño-Southern Oscillation events in which flash floods are very common (Valimba 2004). These years have characteristic heavy R associated with some floods. For instance, the severe ENSO-related floods of 1997/1998, the most severe in about 50 years, were specifically linked to the Indo-Pacific El Niño/Southern Oscillation (ENSO) and to sustained high sea surface temperatures (SST) in the Southwest Indian Ocean Valimba 2004). The extended 1976–1978 warm ENSO led to high R in the 1977–1979 (Fig. 18a). Generally, 2–8 years periodicity of East African Region is linked to the ENSO that is also the most rational inter-annual signal in the global climate patterns.

Evidence of Sifting Rainfall Seasonality

Close observation of time series for February, March, April, and May rains clearly shows generalized decreasing trends (Fig. 7). May being the end of rain season in Dodoma offers the best opportunity to understanding declining R variability (Figs. 3a, 4b, and 7). Notice that there have been virtually no May rains at MMS from 1992 to present except in 1999 when 6 mm of R was recorded. Thus, May rains have almost completely disappeared over the last 20 years. Specifically, no May rains were recorded from 2006 onward as opposed to previous years when up to 120 mm of R was recorded (Figs. 3a, 4b, and 7). Out of 9 years that HMS received no May rains, six were recorded in the last 15 years. Generally, in all three stations, May rains are significantly reduced and/or disappearing, a strong signal of worsening climate dynamics. Regression analysis shows that time series May rains have a slope of −0.556. Considering this value into account, it is clear that there has been a 50.6 mm of R from 1921 to 2012. This is a significant shift in the effective R for the area characterized by low rains that come mostly when T is highest (Fig. 16b).

The implications gathered here are that the useful R season is diminishing as onset of rains in October is also virtually disappearing (Figs. 5f and 7). This will affect cropping, pasture, and water resources, particularly recharge. January rains show that the rains have more or less stayed the same with no clear increase or decrease (Fig. 8). These require locals to grow drought-resistant and/or early-maturing

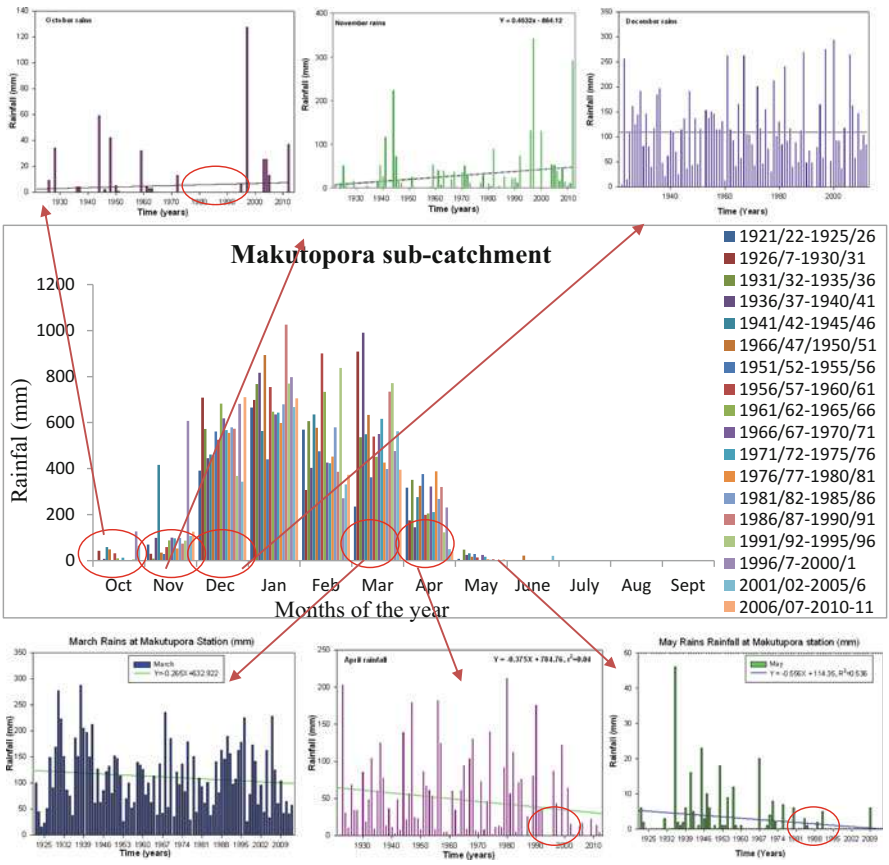

Fig. 7 Monthly temporal rainfall variability at MMS

crop varieties. Similar suggestions were given by other regional studies (Mary and Majule 2009; Swai et al. 2012a, b, c). Similarly, plans to harvest and store enough water for domestic, livestock, and irrigation should be planned as the main sources of water; dug wells have been drying early in recent years (Personal communication with Mr. Jackson in Mtumba suburb).

The area has a very high temporal variability in the amount of R received between the hydrological years (Fig. 8). For instance, going by March between 1936/1937 and 1940/1941, the area received over a thousand millimeters of R compared to only 200 mm between 1951/1952 and 1955/1956. Furthermore, considering March rains again at MMS, there has been a decrease of up to 800 mm between 1936/1937–1940/1941 and 2006/2007–2010/2011 (Fig. 8). Similarly, a close examination of the R patterns in April would reveal that between 1950/1952–1955/1956 and 2006/2007–2010/2011, there has been a decrease of up to 300 mm (Fig. 12). Similar R variability is recorded in other three stations (Fig. 9). However, high spatial and temporal R variability is typical for many semiarid regions of the country/world

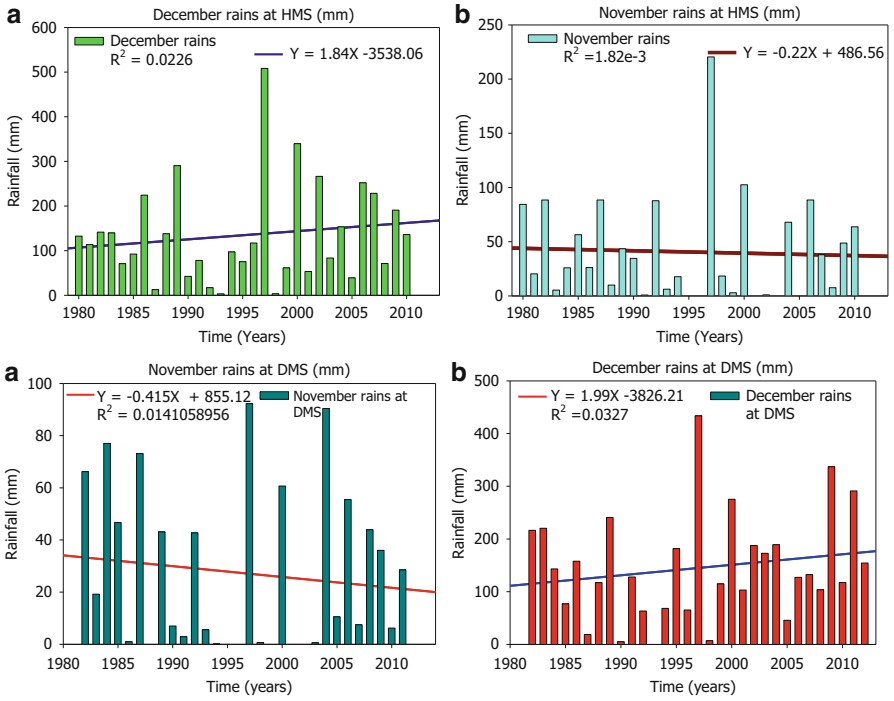

Fig. 8 Times series November and December monthly rainfall trends at DMS and HMS

(Graef and Haigis 2001; Mary and Majule 2009; Valimba 2004; Majule 2008; Rao et al. 2011). High temporal variability is also evident from the annual R data. From Fig. 7, it is evident that some years received very high rains (1947, 1989, and 1997), while others had very little R (1924, 1946, 1969, 2004, 2010, 2013). Notice that the occurrence of years with low rains has increased in recent years, whereas heavy rains are only associated with El Niño-Southern Oscillation (Figs. 3 and 7). These findings are similar to other local findings (Rwebugisa 2008; Taylor et al. 2013). Worth noting however, the high R recorded in 2004/2005 hydrological year is explained by the fact that the latter was an El Niño-Southern Oscillation. El Niño year in East Africa is known to exuberate high downpours (Cooper et al. 2013). Similar trends are also seen in other stations (Fig. 3a). The increased El Niño-Southern Oscillation events in Tanzania seem to favor surplus in which the maximum potential surplus was recorded in 1999 (Fig. 3a).

Drought Index (DI), Drying and Wetting Cycles

Close observation of the data series reveals that 47 out of 94 years from 1921 to 2014 were drought years. This means that there is a 47/94 change (50 %) of drought occurrences in the area. These show how vulnerable the area is to R stress and how R-dependent activities might be impacted. This roughly means that every second

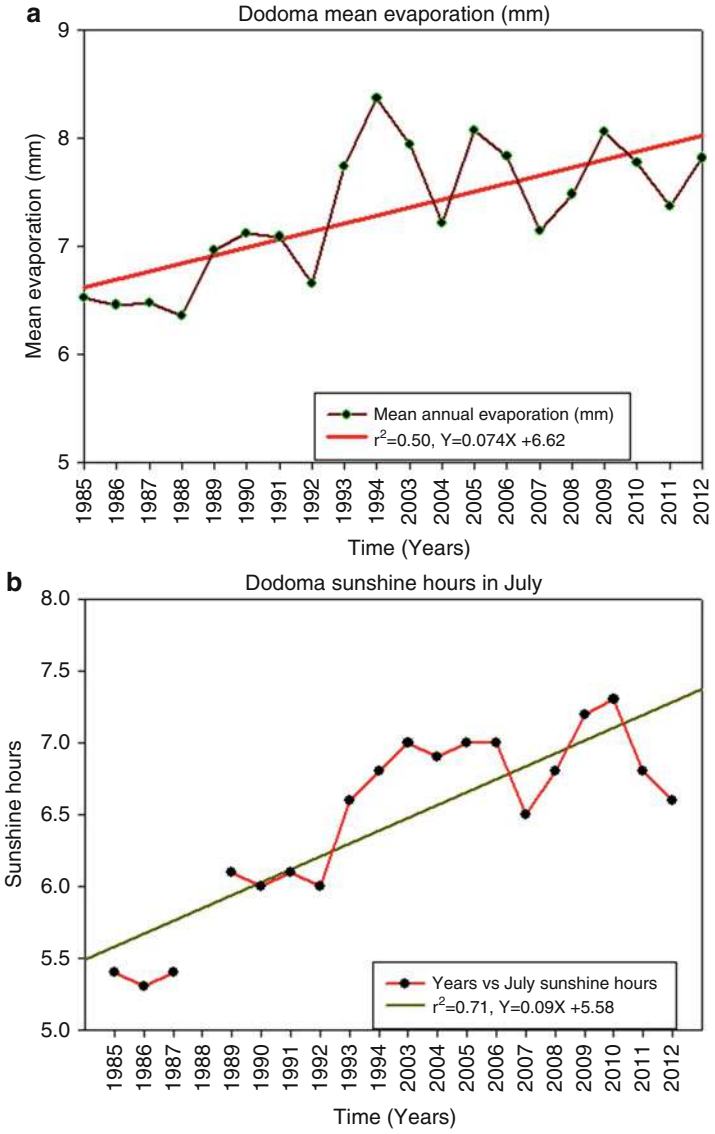

Fig. 9 Time series. (**a**) Annual mean evaporation (mm). (**b**) Dodoma sunshine hours in July

year, there has been some interference to rainfed agriculture, recharge, or pasture development. Out of 94 years, between 1921 and 2014, there were 47 years (50 %) that experienced some form of meteorological drought. Out of 20 years that experienced VSD, 10 occurred from 1977 to 2014 (a space of 37 years), while the other 11 occurred from 1921 to 1977 (a space of 56 years). In a similar way, out of 93 years of available R record, 4 and 2 and 3 and 2 years that experienced, respectively, SD

and MD were, respectively, recorded after and before 1977. Finally, out of 8 years that experienced LD, five occurred before 1997, while three followed after 1977. The bigger picture here is that lighter droughts were common in initial years of the data series, while severe droughts are more frequent in recent years; therefore, drought severity is gradually increasing, and R-dependent activities like agriculture and pasture development will continue to be adversely impacted. The increasing severity of drought is proportional with the general declining R and increasing T trends (Figs. 10, 11, 12, 13, 14, 15, 16, 17, 18, and 19). These findings support other regional studies that generally show drought is increasing (Mary and Majule 2009; Swai et al. 2012a, b, c). Studies already show that post-1970s drought characteristics in Southern Africa have been more extreme and widespread (Valimba 2004).

Although severity of drought could clearly be noticed to increase, some questions still remained, key among them being: When did the variability happen? Has it been uniform and continuous? Did we notice increasing, lengthening, and shortening wetting or drying cycles?

Thus, apart from visual assessment of R trend (Fig. 20b), the following two models were run to explain the situation more closely. Both Buishand and Pettitt models clearly show that local R is characterized by cyclic wetting and drying scenarios/cycles. Notice a prolonged drying events from 1972 to 1988 that were followed by a brief wetting event and then drying event again (Fig. 21a and b). Generally, the drying events are longer in latest time series data than in early time epoch. This drying event coincides well with the DI (Fig. 21a) suggesting worsening drought from 1977 onward. Notice also that the most recent wetting events (1957–1962 and 1987–2002) are brief compared to the earlier event in the data series (1927–1943) (Figs. 20b, 21a, and b). These results are also supported by other regional studies which concludes that the prolonged droughts from 1973 to 1976 (Fig. 20a and b) are attributed to extended 1973–1976 La Nina events (Valimba 2004; Nyenzi et al. 1999).

Relationship Between Rainfall and Groundwater Level (Recharge)

Record of groundwater head fluctuations (GHF) closely followed annual R trends with high annual R corresponding to high groundwater heads except for a few cases where high/low levels were preceded low/high R values (Fig. 5). This suggests that local R is the main source of recharge and any decreases in the R magnitudes and longevity will adversely impact groundwater resources (Shemsanga et al. forthcoming), the main sources of local fresh water for Dodoma city (Rwebugisa 2008; Kashaigili 2010). These findings are similar to previous studies in the area (Rwebugisa 2008; Taylor et al. 2013).

However, apart from the extreme R event, like 1997/1998 El Niño events in much of East African region (Valimba 2004), close analysis of the GHF trend suggests that groundwater has generally been declining as much as R trends (Fig. 22a). Figure 22a shows that, except for brief interruptions in groundwater level anomalies, there has been a prolonged groundwater level decline between 1969–1988, 1989–1994,

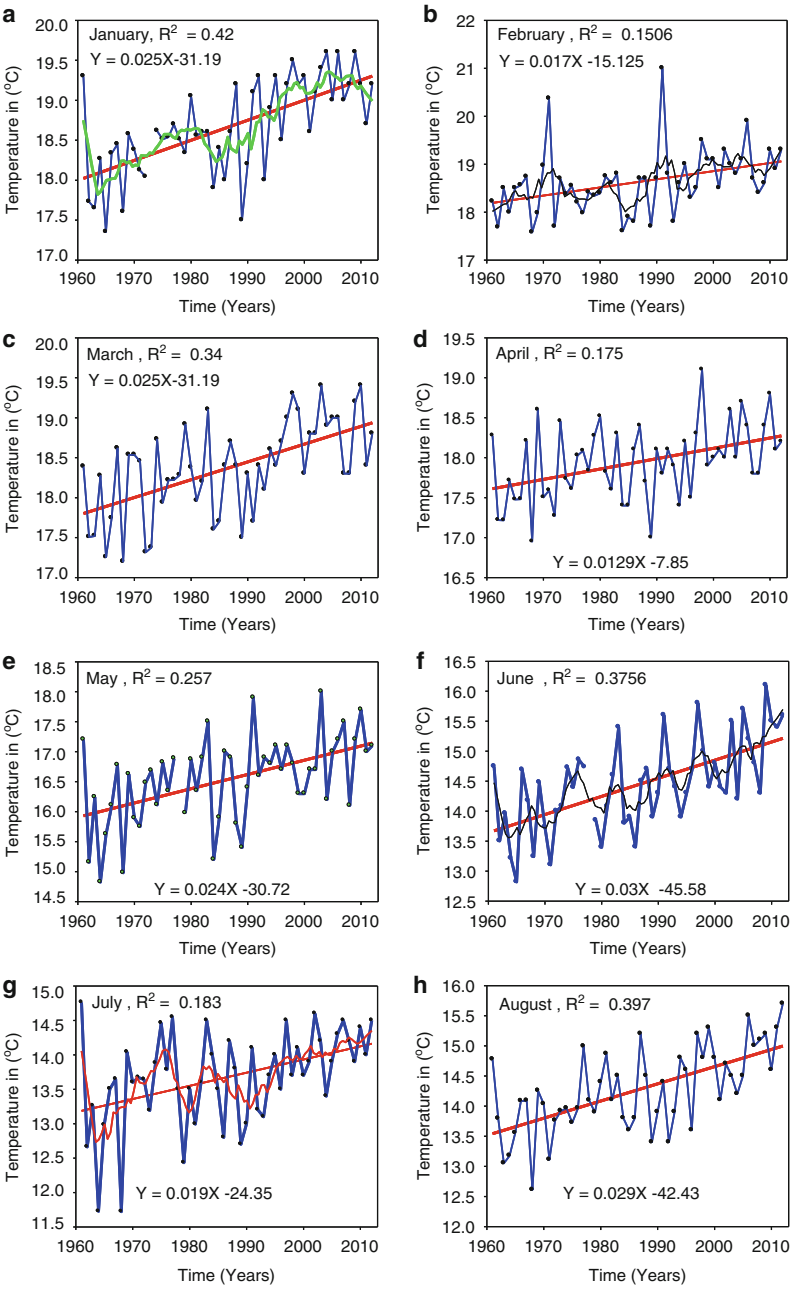

Fig. 10 (continued)

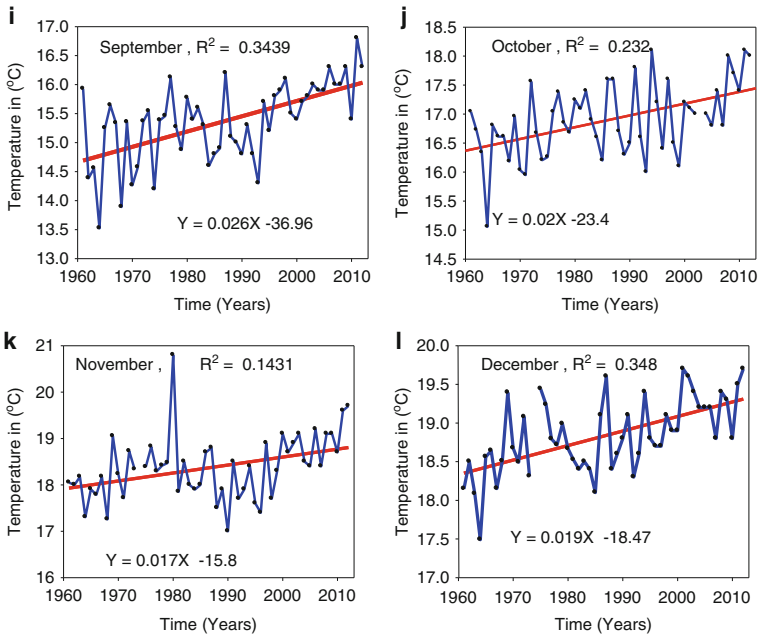

Fig. 10 Time series. Mean minimum monthly temperature at DMS

2001–2006, and 2007–present. These declines largely support epochs of the data series when R generally decreased except for a few cases. Further, this is in line with the local R trends that have been declining in much of East Africa (Omambia et al. 2012; Valimba 2004; Taylor et al. 2013). In an ongoing study, the general declining R trends have been associated with early drying up of dug wells and decreasing well yields in both shallow wells and deep wells (Shemsanga et al. forthcoming). Other regional studies also link ongoing climate variability with adverse impacts to groundwater availability and local livelihood support systems like agriculture and pasture development, especially to rural communities in semiarid regions (Calow et al. 1997, 2010; MacDonald et al. 2009; Ngongondo 2006).

Atmospheric Relative Humidity (ARH)

ARH is a useful parameter in showing potential changes in the sources of moisture for the atmosphere or changes in the dynamics of atmospheric circulations from both local and global forces (Kousari et al. 2011). The local annual mean ARH shows that there has been a steady decline in the percentage of ARH (Fig. 23a and b).

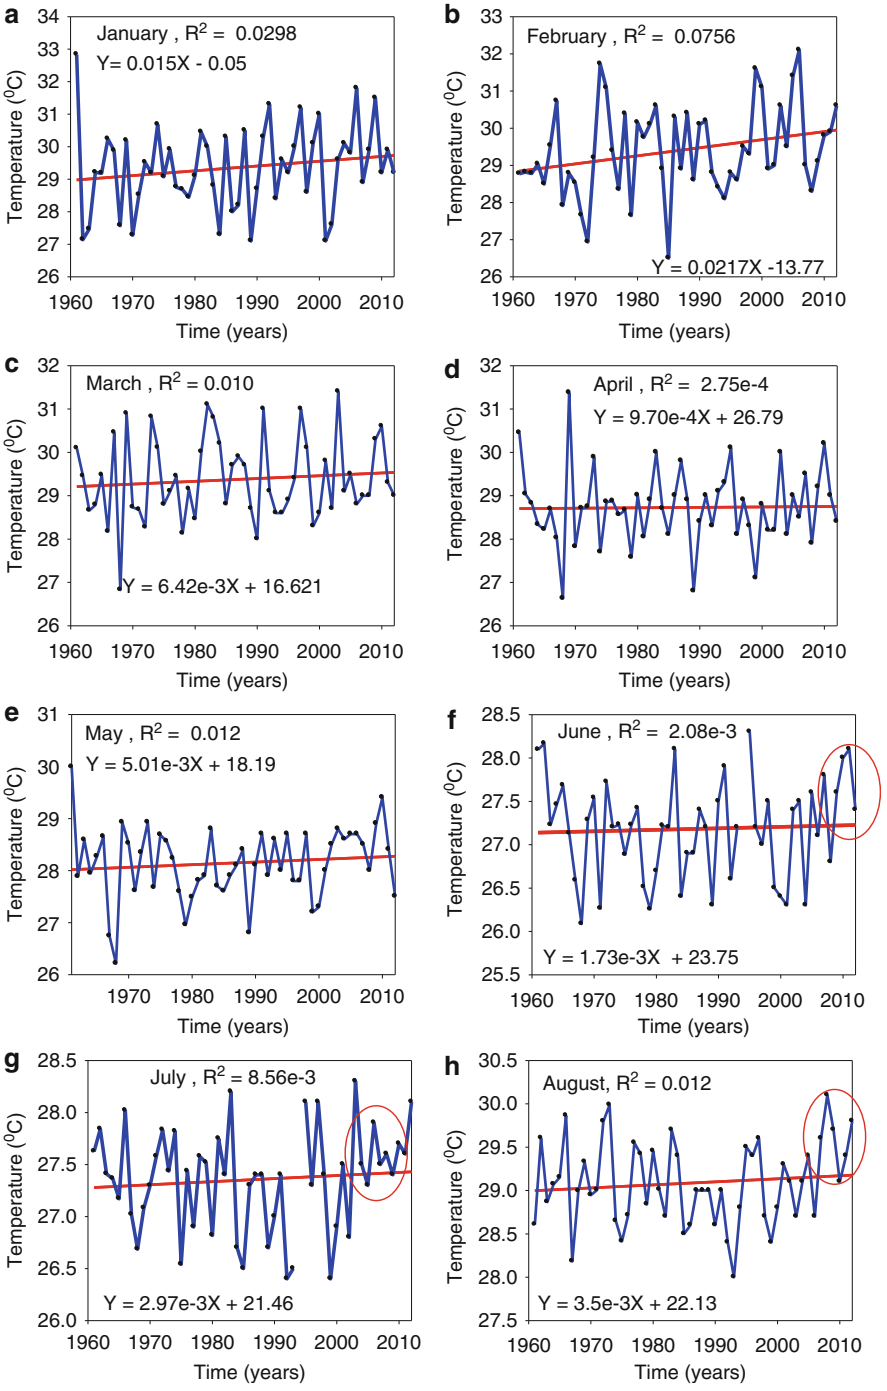

Fig. 11 (continued)

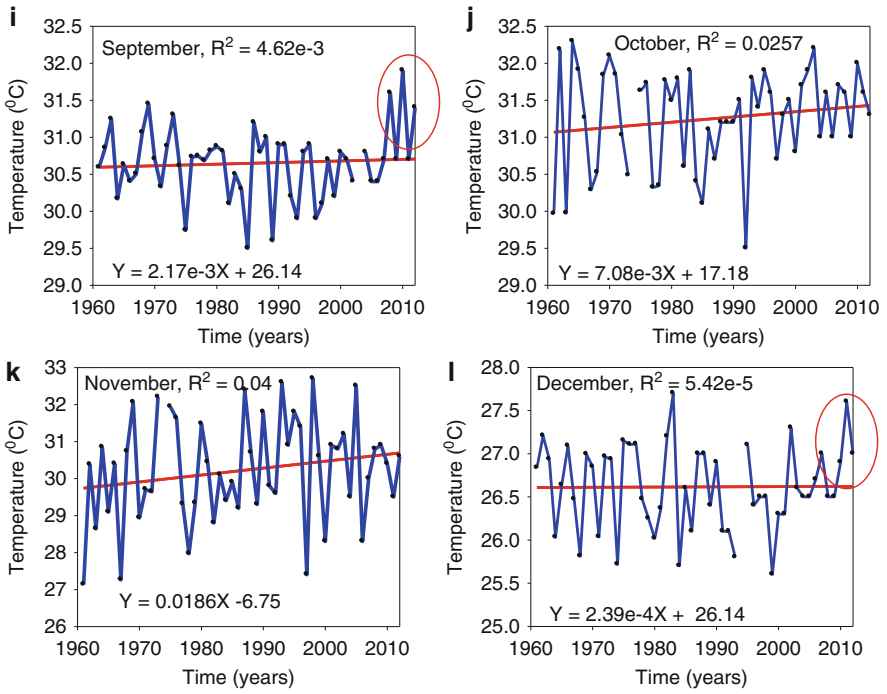

Fig. 11 Time series. Mean maximum monthly temperature at DMS

Analysis of seasonal variation in ARH shows significant decreases in wet and dry months (Fig. 23a) in which both dry and wet months (September and May, respectively) there records significant declining trends of about 7.37 % and 6.08 %, respectively, between 1982 and 2012. Considering regression for annual ARH, it is noted that the regression has a slope of −0.167. By working with the entire time series of this station (1981–2014), it is clear that there has been a 5.34 % decrease in ARH. This supports global patterns showing progressive climate-related declines in ARH magnitudes (Jung et al. 2010). Sharply declining amount of local ARH is a significant signal of changing climatic balances and/or decreases in the regional sources of moisture. These findings are similar to a study carried out in Iran where several stations had shown a decreasing ARH (Kousari et al. 2011).

The changes in sources of moisture locally could be attributed to several factors, key among them being decreasing R (Fig. 3a and b), decreasing vegetation cover and compositions (Allen 1985; Angelsen et al. 1999; Cline-Cole et al. 1990), decreasing soil moisture and shrinking water bodies (and other wet areas such as wetlands and rivers), and increasing WS (Al-manmi 2002). In line with the above, previous studies in Dodoma have recorded massive losses in vegetation cover which mostly came from high pressure on poles for construction, expansion of agricultural land, and fuelwood pressures (Allen 1985; Angelsen et al. 1999; Cline-Cole et al. 1990).

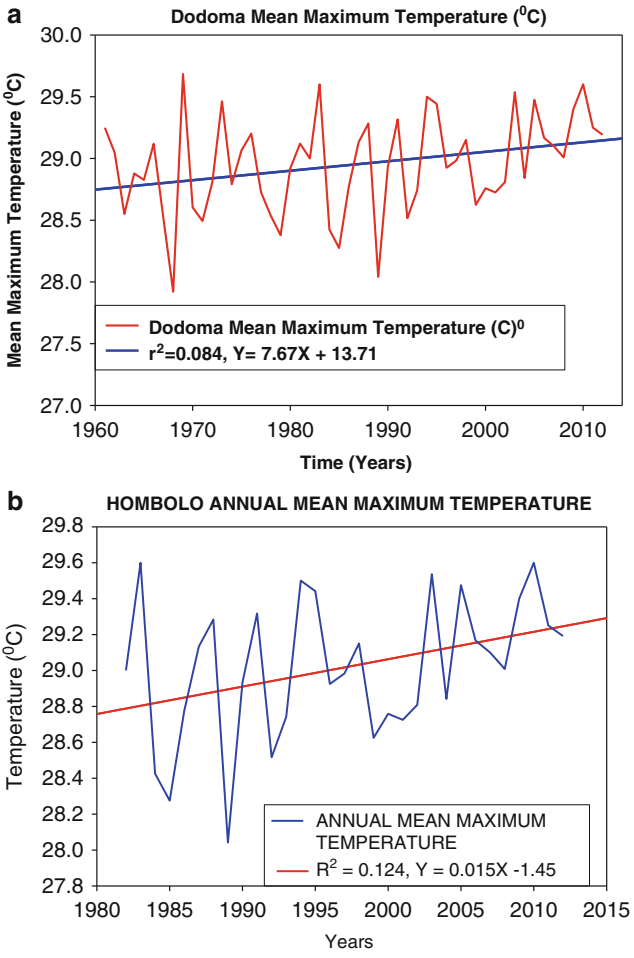

Fig. 12 Time series. Dodoma and Hombolo MMMT (°C)

In addition, increasing temperatures (Fig. 12 through 17), WS (Figs. 25 and 26), ET (Fig. 23a), radiation (Fig. 28a and b), and S (Figs. 23b to 24) could mean more water is lost immediately after rains via the process of PET leaving the rest of the year with minimum ARH. Locally, WS is at its maximum during the dry season which further blows away the available moisture and hence less detectable moisture in the atmosphere (Fig. 26a). Thus, changes in WS could also result in decreasing ARH as stronger winds blow the moisture away (Figs. 25 and 26). Notice that the mean monthly ARH at each month is higher at 9 am in the morning and relatively less at 3 pm in the evening. This relationship can explain why there has been a

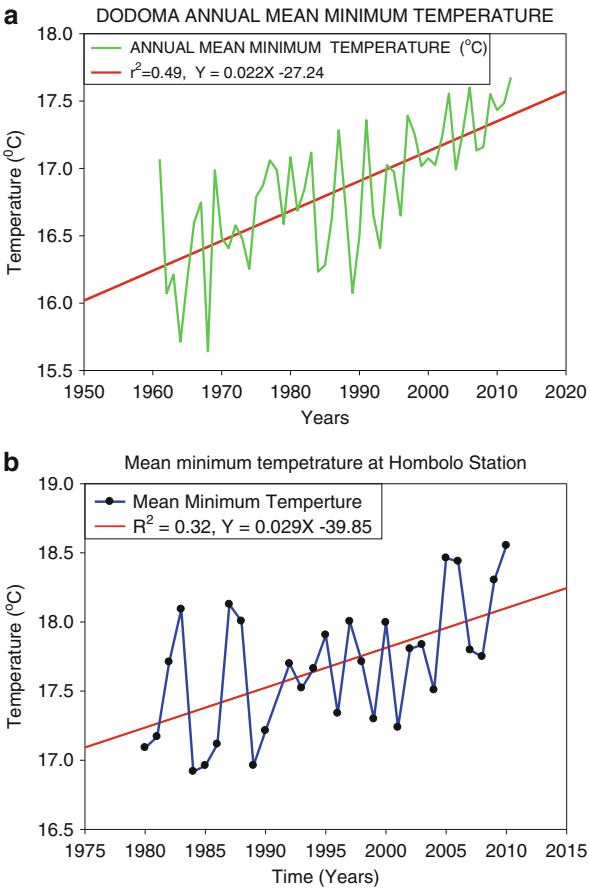

Fig. 13 (**a**) Time series MMT and (**b**) Mean MMT at DMS and HMS (°C)

general decline in percentage of ARH locally as T has been observed to increase with years (Figs. 2 and 10). Worth noting also, the minimum mean ARH is at its lowest in the peak of dry season when there is less water to be involved in PET and quickly increases as R begins in October. Thus, the declining ARH is most likely to be due to increasing T in dry, wet, coldest, and warmest seasons. This will in turn affect key livelihood support systems like local groundwater recharge and length of growing seasons.

Notice from Fig. 22 the close similarity between ARH and occurrence of R and T trends in which dry months have the lowest ARH, whereas the wettest months January and December have the highest. Indeed, T is a very important local climate driver and therefore should closely be monitored for meaningful mitigation and adaptation strategies against adverse climate impacts on water resources, agriculture and pasture development among others.

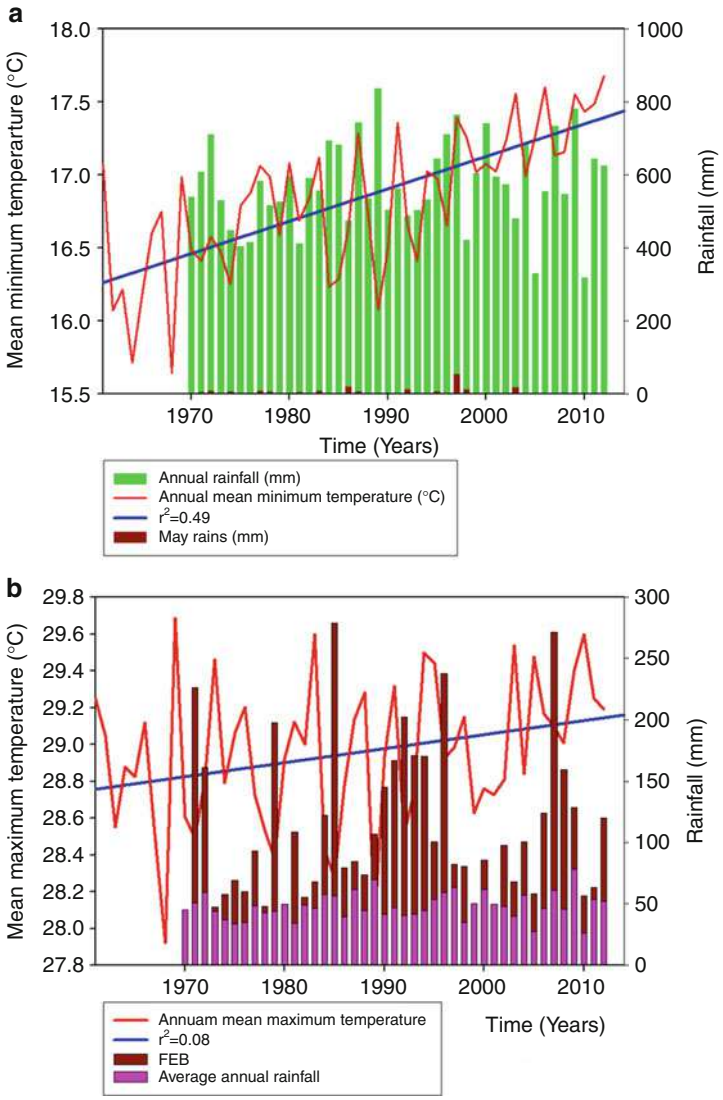

Fig. 14 Time series. (**a**) Annual and May rains and (**b**) average, annual, and February rains and MMT at DMS

Evaporation (ET) and Sunshine Hours (S)

Analysis of both S and ET data shows consistent increases in both parameters (Fig. 23a and b). The gradual increase in these two parameters suggests more water molecules are lost from the area. Thus, from the general increase in S, it is

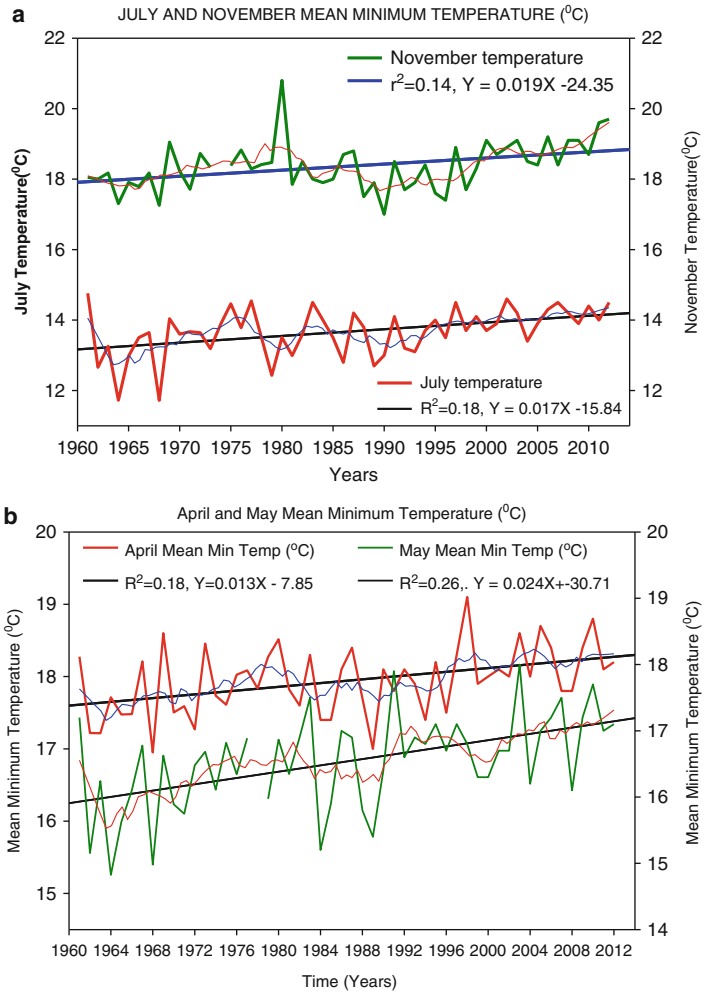

Fig. 15 (**a**) July and November MMT at DMS. (**b**) April and May MMT at DMS

not surprising to see that there has been a corresponding increase in ET rate (Fig. 23a and b). The increases in these two parameters can be explained by the proportional increases in T (Figs. 10, 11, 12, 13, 14, and 15) and (Fig. 29). The steady increases in S and ET, coupled with the decreasing amount of precipitation and ARH, could have major implications in the local water balancing. For instance, this could reduce the amount of water recharging the aquifers as the rate of recharge is inversely related to ET rate (Al-manmi 2002; Rwebugisa 2008; Shindo 1991). Past studies in the area indicated that annual PET is almost four times the amount of R leaving only a small proportion of water recharging the aquifer (Rwebugisa 2008; Shindo 1994);

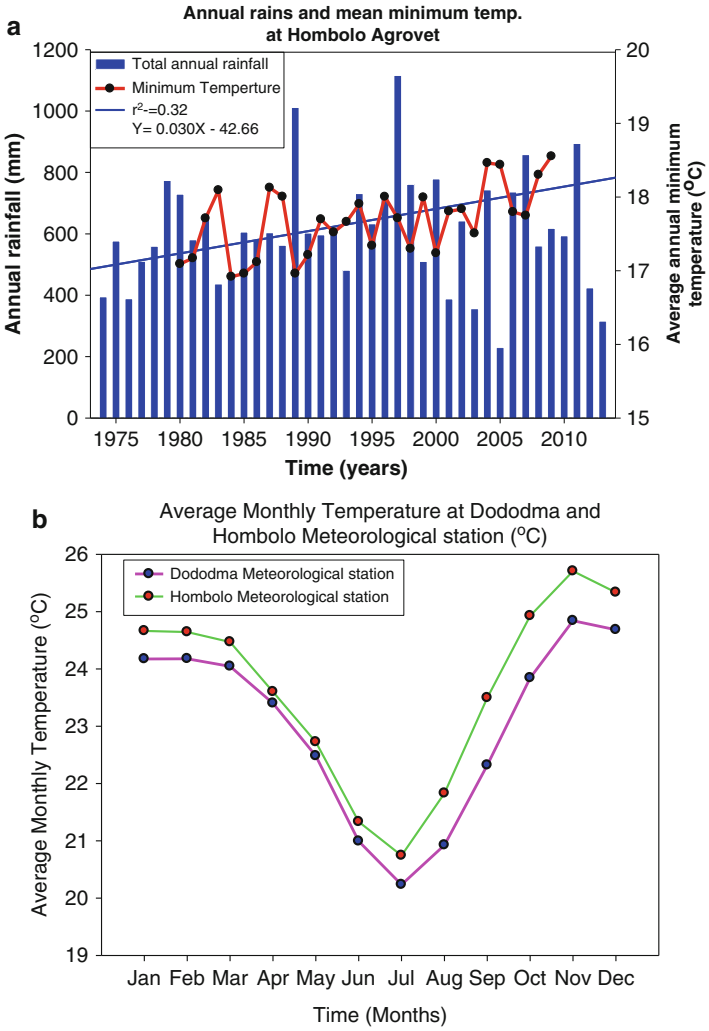

Fig. 16 (**a**) Annual average temperature and rainfall. (**b**) Mean monthly temperature in HMS (1980–2014)

therefore, the increases in these two parameters will lead to even lower proportions of water available for recharging. In addition, the increases in S and ET will both affect available water for plant growth and pasture development (Allen et al. 1998a; Stanhill and Cohen 2001; Nonhebel 1996; Wang et al. 2015; Deryng et al. 2014).

The relative higher ET in the area is also supported by modeling of the major climate data using TWMWB. The result of this model clearly shows that PET has

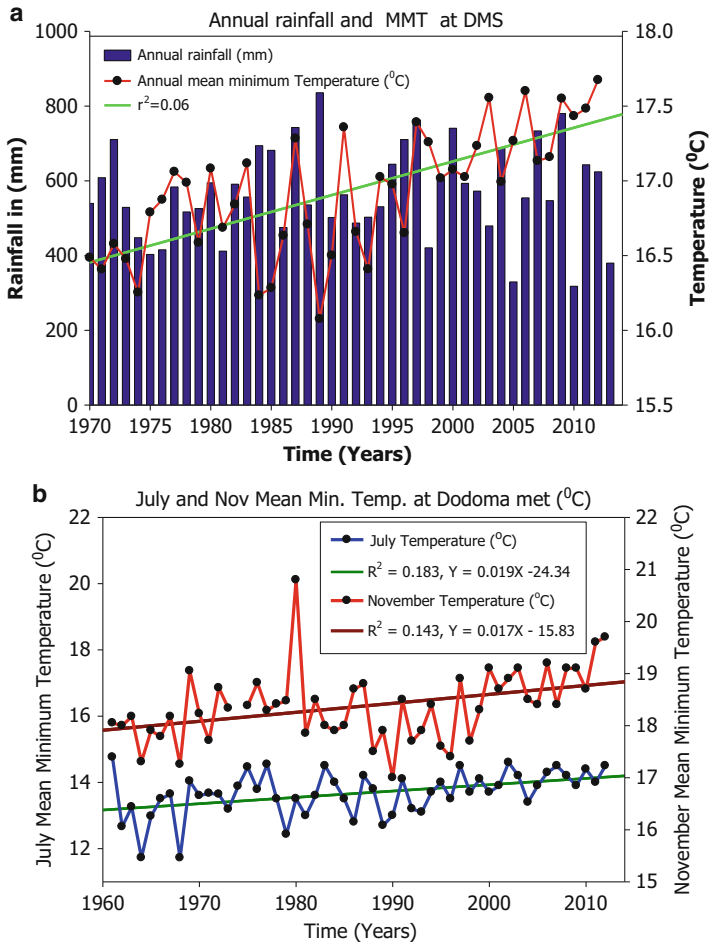

Fig. 17 Time series. (**a**) Annual rainfall and MMT at DMS. (**b**) July and November MMT at DMS

consistently been higher than that of R (Figure 26a and b). This could explain the absence of surface water bodies in the area (Shindo 1991; Rwebugisa 2008; Taylor et al. 2013). The river/runoff channels in the area only flow for a few weeks following rain events to account for characteristic high PET. Notice from Fig. 26a and b that TWMWB results support T time series data that HMS has higher T than DMS (Fig. 16b) and which leads to HMS to have higher PET than DMS (Fig. 26a and b). Past studies in the area reached similar conclusion and proposed artificial recharge schemes to be implemented to store the runoff water that often ends up to ET and flowing to the Indian Ocean and leaving the rest of the year with less water for the populace (Salama 1979).

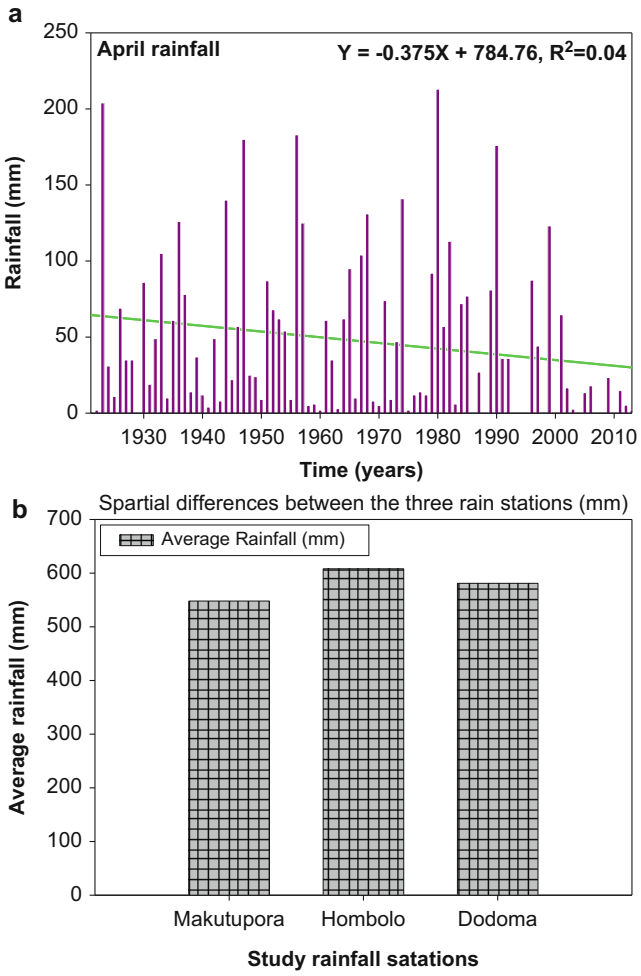

Fig. 18 (**a**) Times series April rains at MMS. (**b**) Variation of rainfall at MMS, HMS, and DMS

Wind Speed (WS)

Local wind speed parameter is marked by an increasing trend from the early 1980s that is followed by notable decreases from the early 1990s onward. Generally, the decreasing WS above was also recorded in various places of the world including in China (Jiang et al. 2010; Li et al. 2011). While changes in WS in China is partly attributed to urbanization especially uplifting of story buildings (Guo et al. 2011; Jiang et al. 2010; Li et al. 2011), locally the area around has largely remained the same, and therefore some other external forces like changes in the ocean surfaces are

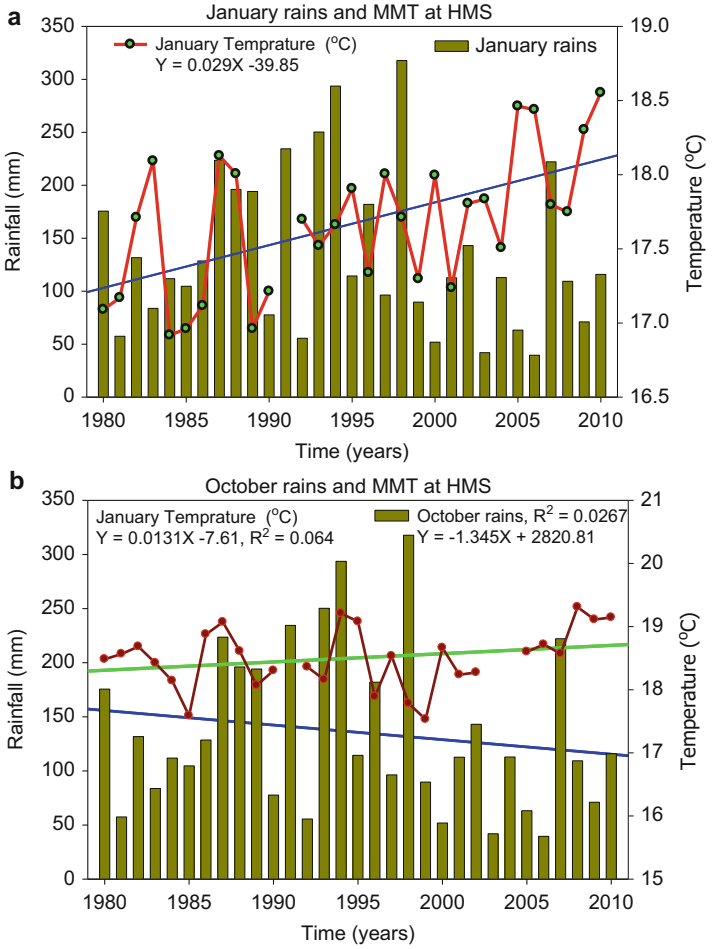

Fig. 19 January and October rains and MMT at HMS

thought to be the major cause or climate change related to lower-tropospheric pressure-gradient force (Guo et al. 2011). In Spain analysis of 67 land-based observation stations had also indicated that the WS had declined from 1961 to 2011. In these study stations, it became obvious that there were slight decreases in WS of between -0.016 m s^{-1} and -0.010 m s^{-1} per decade (Azorin-Molina et al. 2014).

Close observation of the entire data series however reveals that there has been some increases in WS (Fig. 27a and b). These dynamics will have major local implications as WS of an area is a very important parameter in many aspects including on local water budgeting between different water components

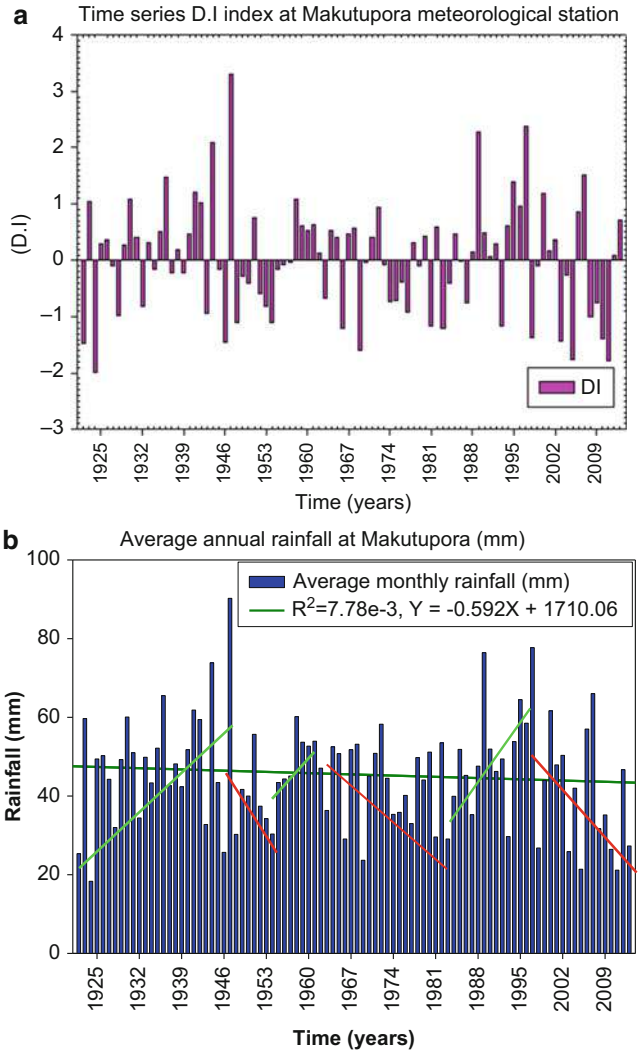

Fig. 20 (**a**) DI at MMS. (**b**) Time series average rainfall at MMS

(Allen et al. 1998b; Rayner 2007; Raz-Yaseef et al. 2012; Shenbin et al. 2006). The increasing WS has important reputations to distribution of moisture/ARH via enhanced PET (McVicar et al. 2012). Notice that the maximum WS occurs in September and October, while the average minimum WS comes in February (Fig. 29a). Similarly, there is stronger wind in the evening at 3 pm than in the morning at 9 am (Fig. 29a). This trend could explain why the area has observed an overall increase in PET following corresponding local T increases (Figs. 10 and 11).

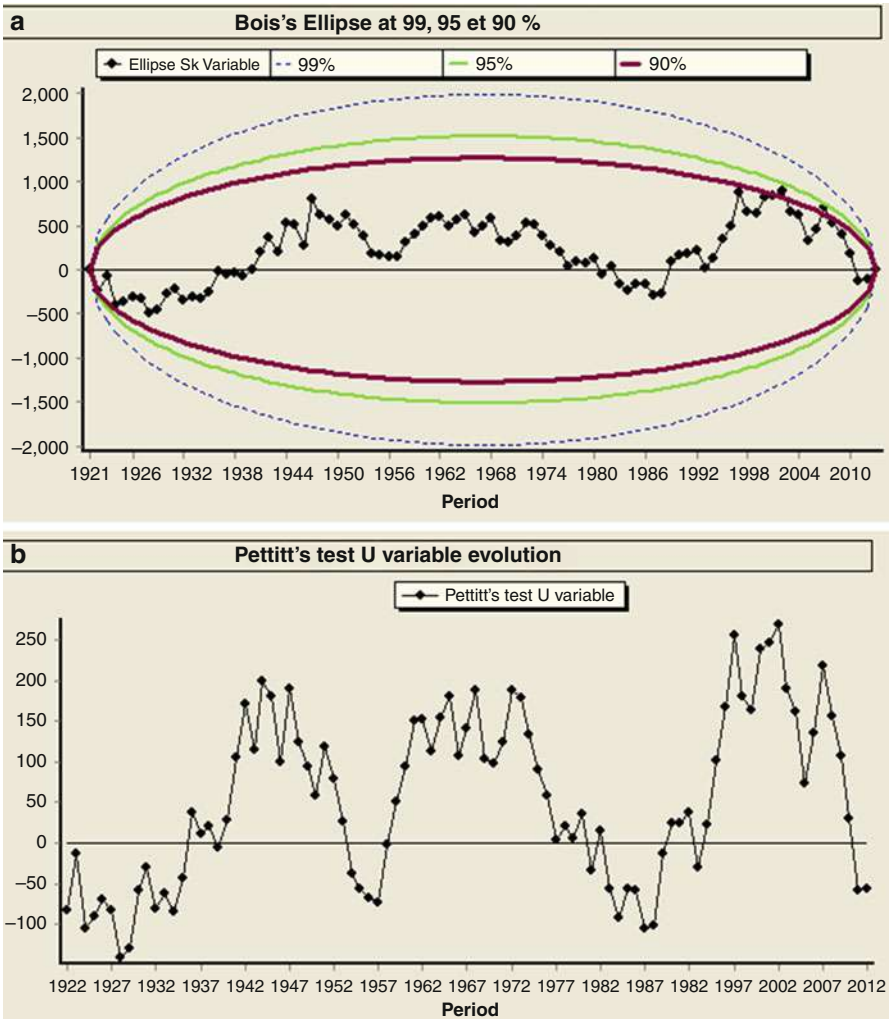

Fig. 21 Time series annual rainfall changes/fluctuation as modeled by Khronostart1.1

Thus, the maximum WS and ET occur at the hottest months of the year (November and October) which are wet months (Fig. 29a). Scholars link WS magnitudes with water resources dynamics where the windier the area is, the more the ET rate (McVicar et al. 2012); therefore these parameters must be properly monitored in the overall water resource management. Equally important, the maximum wind speed, RD, and ET all occur in October that is also the beginning of the rainy season. This relationship means that the bulk of the early rains will end up evaporating as these parameters directly favor more PET losses.

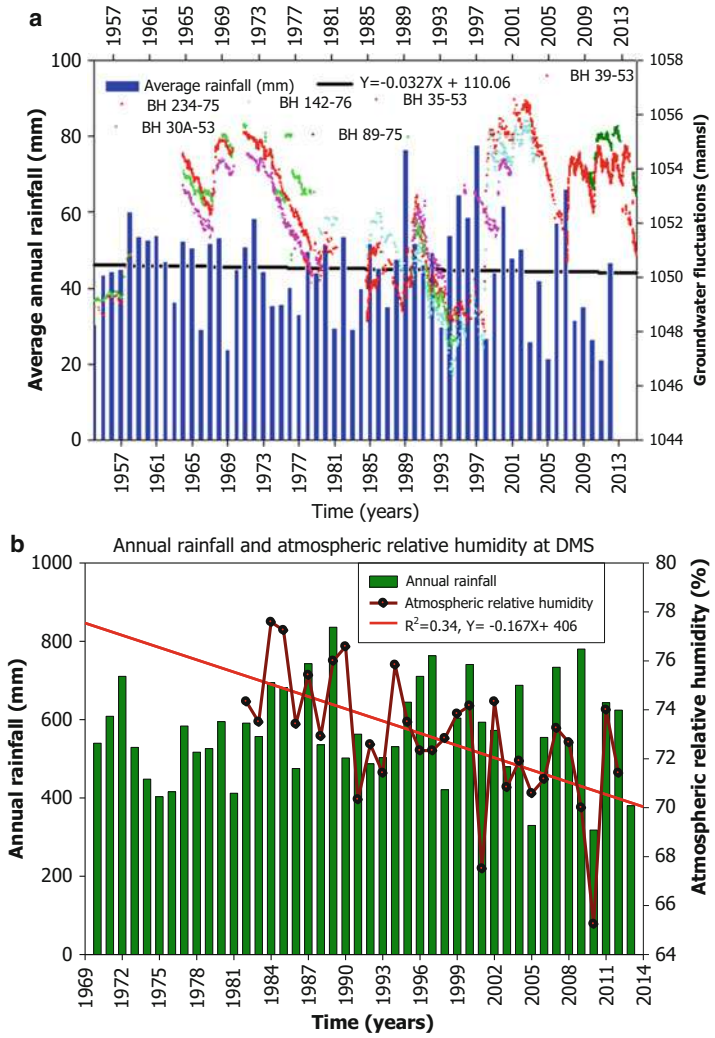

Fig. 22 Times series. (**a**) Rainfall magnitudes and hydrographs of the main observation boreholes at MMS. (**b**) Annual rainfall and ARH at DMS

Radiation (RD)

Solar radiation is one of the key parameters affecting climate and environment management strategies (Tang et al. 2011). Close observation of local SR data series suggests that like for the case of WS, the area is marked by increasing trends from the early 1980s followed by gradual decreases from 2002 onward. However, close observation of the data series suggests that over the entire time series, SR has slightly increased (Fig. 28a). Like for ET and WS magnitudes, SR has a huge effect

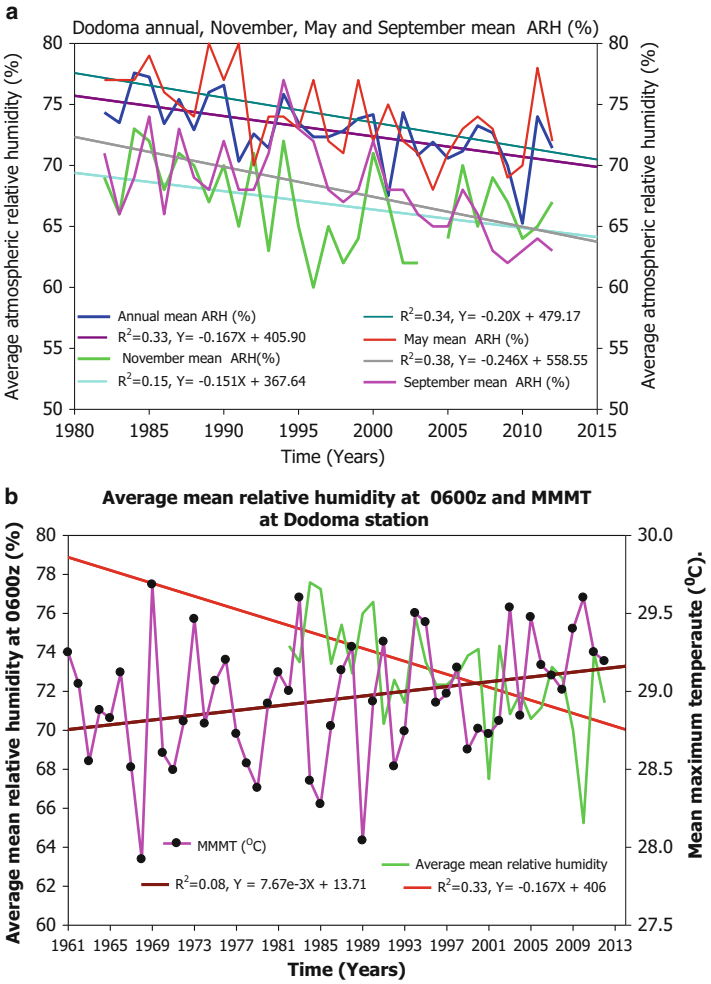

Fig. 23 Time series. (**a**) Annual, November, May, and September mean ARH. (**b**) Average ARH and MMT at DMS

on the climate dynamics including water balancing and distribution (Rathore 2004). Notice that the maximum RD occurs in October, while the minimum is in May, thus any increases in RD during wet months will adversely affect local water balancing since S trend has also increased (Fig. 29b). Thus, the highest radiation during wet months locally suggests that more water molecules would be in the vapor form and hence involved in PET losses (Fig. 28b). While analyzing radiation potentials in other Dodoma regions using 2002–2012 data series, similar findings were reached (Mking'imle 2013).

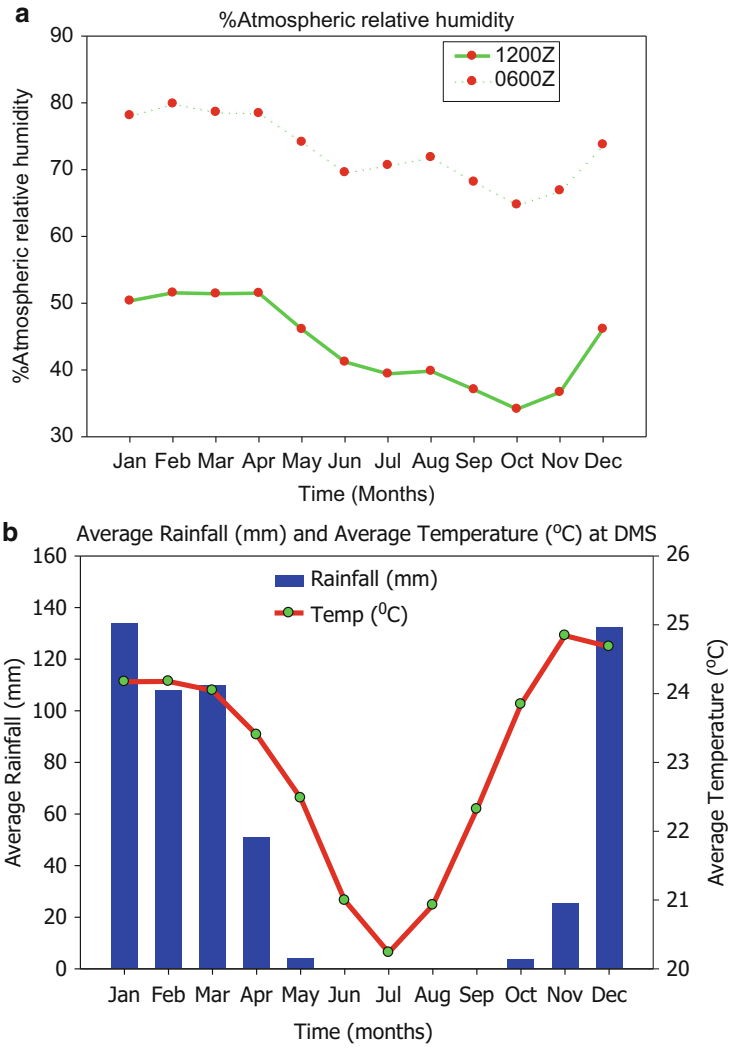

Fig. 24 Time series. (**a**) Average sunshine hours and radiation. (**b**) Sunshine hours in September at DMS (hours)

Studies across the world had indicated similar trends in SR where by using satellite observation, the decreasing trends were also observed in other parts of the world (Rathore 2004). Thus, studies show that global reduction in the amount of SR had a more global picture over the past 50 years (Stanhill and Cohen 2001). For instance, the amount of SR has observed an average decline of up to 2.7 % per decade (Stanhill and Cohen 2001). Studies in China had shown that there was widespread decline in the amount of SR in almost similar time series as recorded

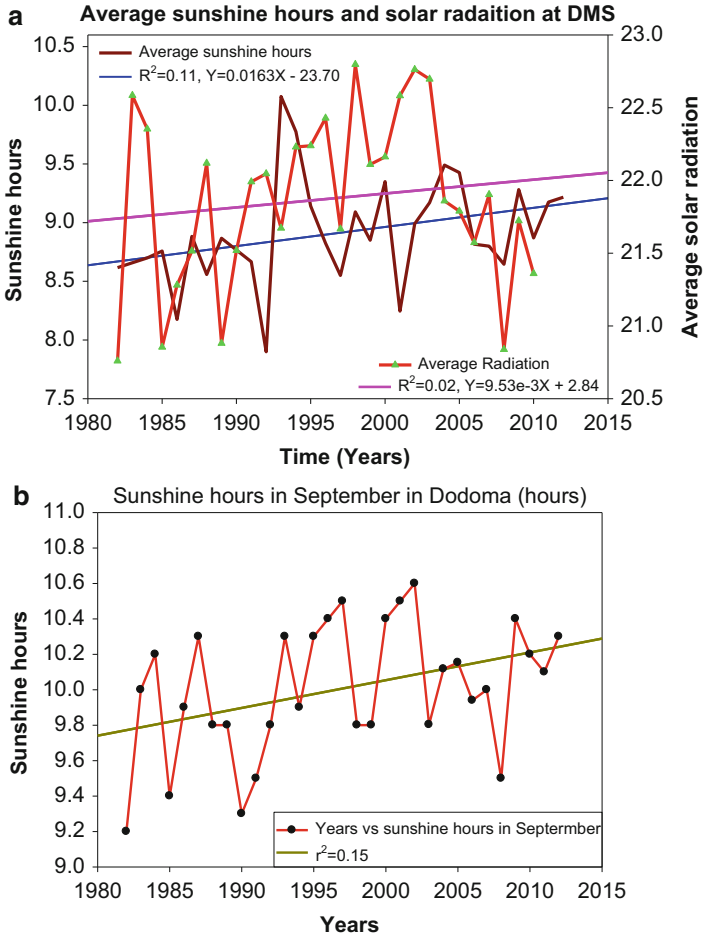

Fig. 25 Annual R and PET based on TWMWB modeling from (**a**) HMS and (**b**) DMS

in the current studies (Pavelic et al. 2012). In China the decreasing SR was further accompanied by the decreasing R which was also proportional to the amount of cloud cover. Locally, rainfall has also been declining (Fig. 3a) suggesting stronger similarities with the situation in China. The significant release of aerosol into the atmosphere from human activities and changes in land use could be one of the direct reasons to the decrease in SR (Pavelic et al. 2012). Variation in amount of SR with cloud cover is well-established science (Svensmark and Friis-Christensen 1997). Thus, the trends observed in Dodoma therefore are in agreement to similar global studies, and hence the wider causes could as well be the same. Currently, the widely accepted causes are human-related releases of aerosols; the sources and route of which do not recognize the political boundaries. These radiation dynamics will

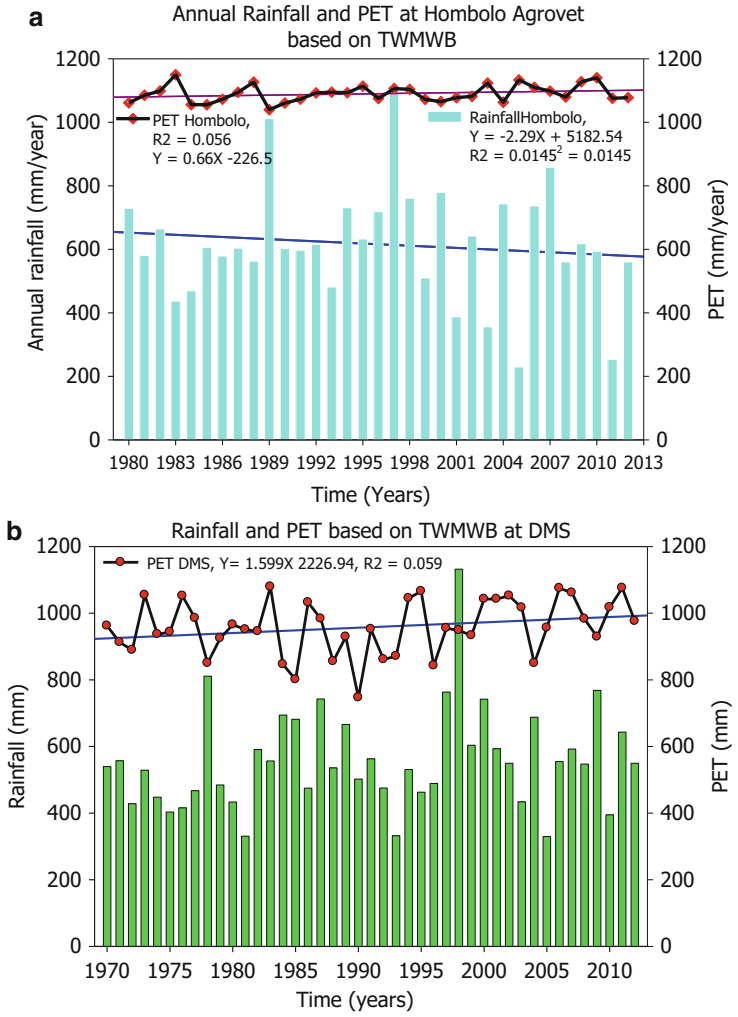

Fig. 26 (**a**) Monthly rainfall and mean ET at Hombolo Agrovet station. (**b**) Monthly rainfall and PET at DMS

inevitably adjust water, ecosystems, vegetation compositions, and primary productivity including on agricultural activities (Zhao and Running 2010). These relationships will need to be well studied in such an economy that is largely dependent on agriculture and livestock husbandry (Coulson 2011; Hella et al. 2011; Mgeni and Bangi 2014; Pedersen 2010). In Tanzania the releases of aerosols could directly be associated with the recent widespread adverse human activities, namely, deforestation activities and burning of fossil fuels (Mazvimavi 2002; Mking'imle 2013).

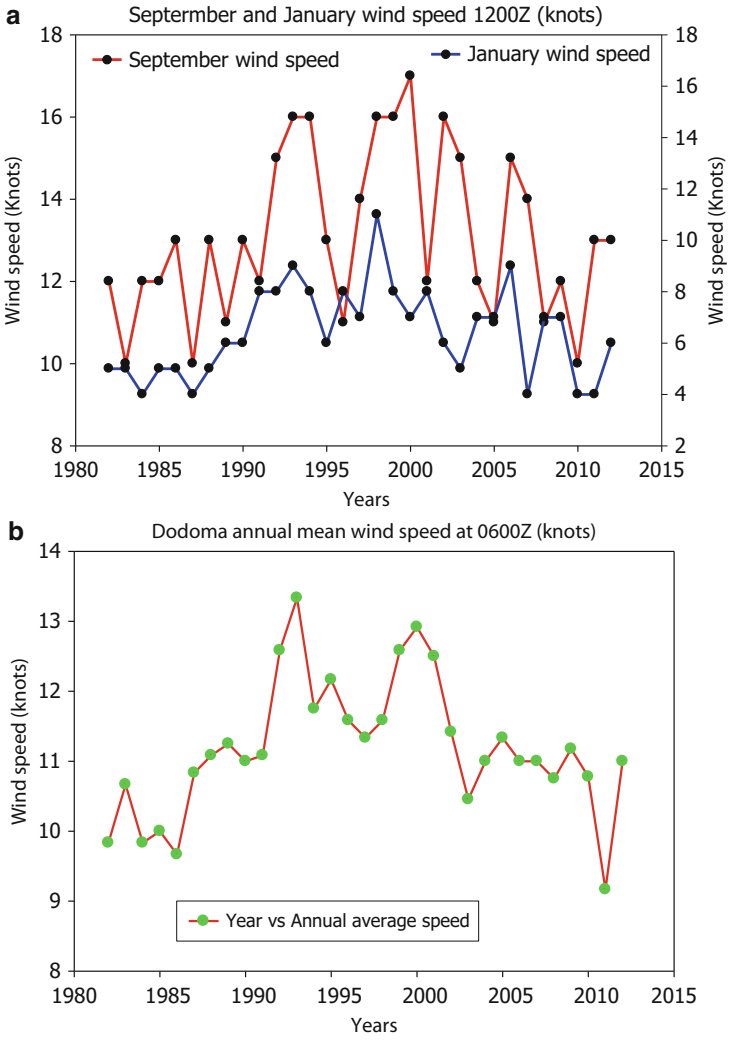

Fig. 27 Dodoma monthly mean atmospheric relative humidity (%)

Despite the fact that SR has locally decreased in recent years, the area still has a huge SR potential (Fig. 28a) that could be used for different uses including electrify generation (Mking'imle 2013) and therefore protect environment degradation (Mking'imle 2013). Worth noting, the country is still lagging behind in terms of electricity sufficiency production and supply. This remains the case when huge SR potential in Dodoma could be used to supply enough energy in Dodoma and beyond (Mking'imle 2013; Fig. 30).

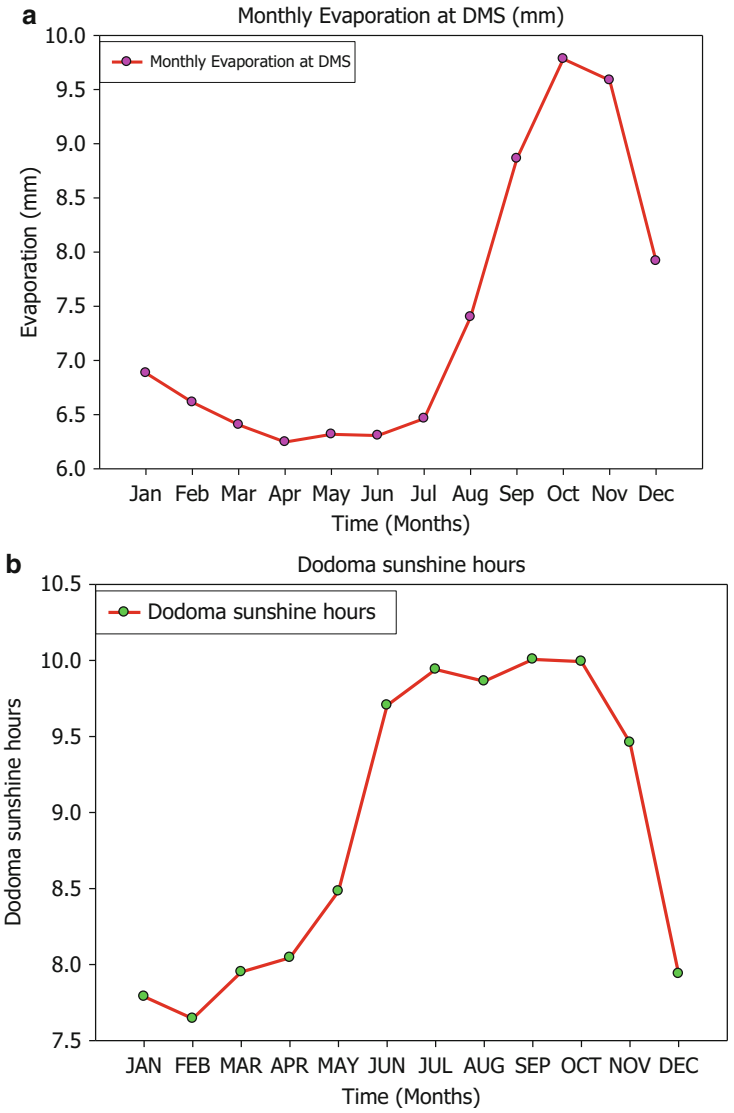

Fig. 28 (**a**) Dodoma September and January mean wind speed at 3 pm. (**b**) January and September mean wind speed at 3 pm

Conclusions and Recommendations

Analysis of major climate parameters (R, T, ARH, WS, RD, and ET) from MMS, HMS, and DMS, all located in the Dodoma municipality, a semiarid region of East Africa, was performed. The methods deployed include statistical, graphical

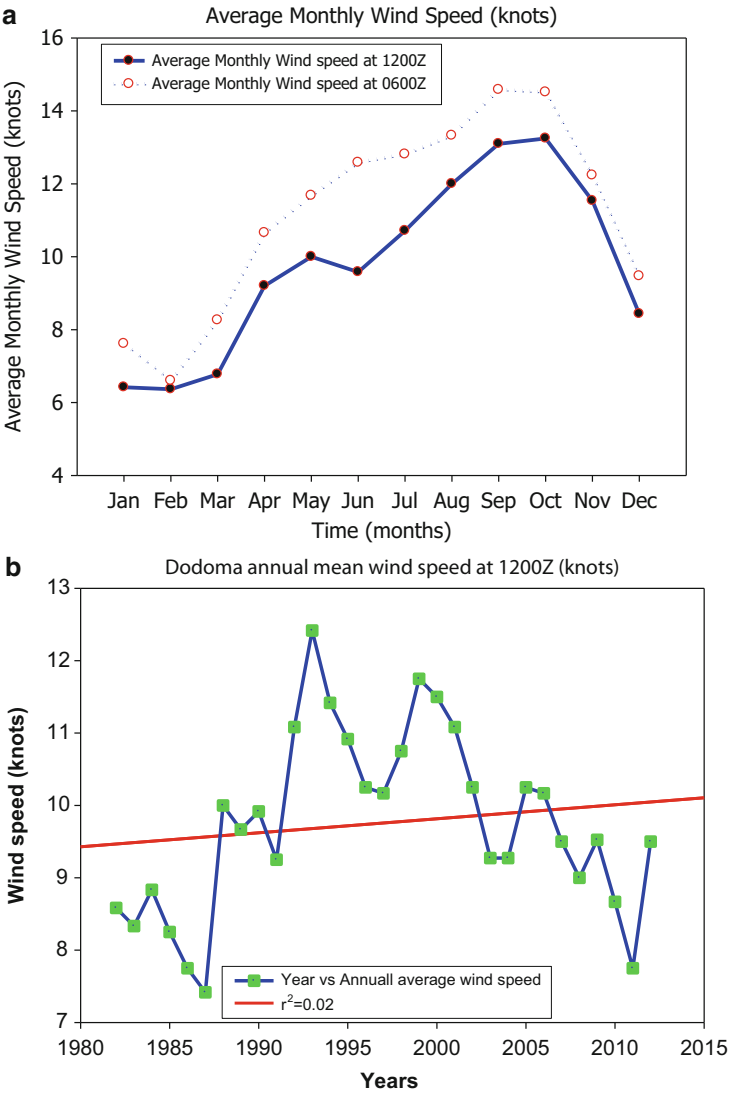

Fig. 29 (**a**) Dodoma monthly wind speed at 9 am and 3 pm. (**b**) Time series Dodoma mean monthly wind speed

modeling and extensive literature reviewing. The results show the area is not excluded from the global climate variability trends with nearly all climate parameters from the three stations showing similar trends and alterations, irrespective of the differences in their longevity. Thus, the global climate variability trends are well registered locally, offering lessons for more direct implications in terms of local

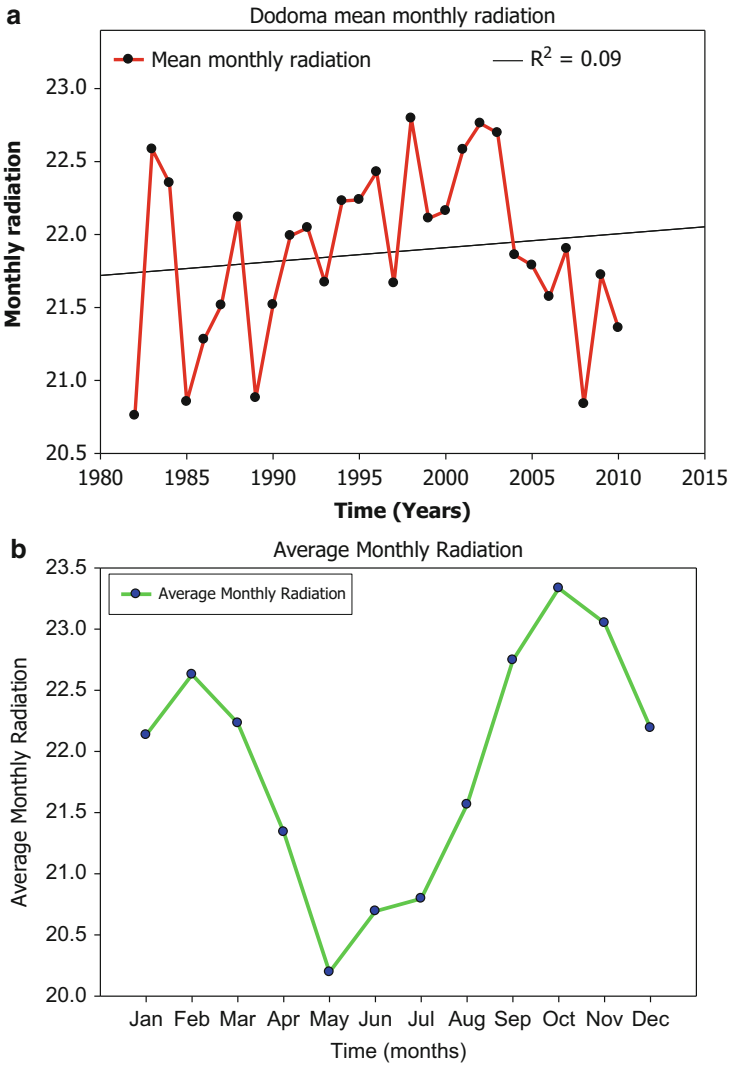

Fig. 30 (**a**) Time series Dodoma mean monthly radiation. (**b**) Dodoma average monthly radiation

livelihood support systems, namely, agriculture, pasture development, and groundwater recharge.

Locally, however, major variability is associated with T and R than with other parameters. The observed statistics clearly show that the number of rain days is diminishing and so are their magnitudes. On the other hand, it is clear that the area is getting warmer in both wet and dry seasons. Similarly, the declining ARH is likely to be linked to widespread decreases in vegetation cover and declining soil moisture and further strongly support observed R trend (the principal moisture sources), while

S and ET have slightly increased. Over the past 91 years, there has been a net R decrease of 54 mm in annual rains of only about 550 mm/year. Closer look at monthly time series reveals more hidden and silent details including strong signals of shifting R seasonality differences in the extent of decreasing and increasing climatic parameters. For instance, both May and April rains are ironically disappearing and/or significantly reduced suggesting a net reduction in the growing season and recharge cycles. Such silent features are generally not observed in annual time series.

On the other hand, like for R trends, hidden and silent features are more evident under monthly than annual T time steps where apart from the generalized warming trends, it is clear that June had the highest increase in MMT (1.54 °C), while April had the least (0.662 °C). Clearly changes in T and R (often key to the local livelihood support system like agriculture, pasture development, and groundwater recharge) will have major socioeconomic implications for the principally agrarian society. Declining R and increasing T further explain the repeated agricultural failures and livestock and wildlife deaths from shortage of pasture and water.

Furthermore, T and R are considered the most vital factors in the distributions of moisture and occurrence of disease vectors like mosquitoes. This could explain why in recent years in Tanzania malaria cases have worsened in areas where it was uncommon, like in the study area.

These findings should be reflected in adaptation and mitigation measures against the adverse impacts of climate change. These measures should include planting in accordance to the current R dates, planting early-maturing varieties, and planting drought- and high-temperature-resistant crops, among others. Measures to utilize less water should also be advocated among all water users in the area. Thus, there is a need to re-look at water allocation systems, and artificial groundwater recharge should be sought as an option as water would be protected from PET.

It is further recommended that future studies should include data from neighboring meteorological stations, satellite information and climate modeling and downscaling for a better understanding of the local climate trends in relation to a global picture. Similarly, it will be interesting to find out how the relatively well-established climate data trends and changes in land cover/use would be reflected in the surface water like river levels, sediment generation and characteristics, soil productivity, pasture development, soil moisture, etc.

Climate Change Adaptation, Mitigation, and the Attainment of Food Security in the Sudano-Sahelian Belt of Nigeria

Aishetu Abdulkadir

Contents

Abstract

Climate change and rainfall variability are evident in rainfall amount and the hydrologic growing season across the zone located between longitudes 3° and 15° east of the Greenwich meridian and latitudes 10° and 14° north of the Equator. These changes have continued to escalate the vulnerability of people's livelihood, as extreme weather conditions lead to reduction in agricultural yields which subsequently aggravate food insecurity. There is a general understanding of climate change and variability across the belt as indicated by the varying adaptation practices by individuals and communities to enable them to cope with the challenges of changing climate. Generally, in Nigeria, there are numerous crucial policies and programs aimed at addressing issues related to climate change adaptation and agricultural sustainability. However, the major concern is the level of implementation and its role in promoting, developing, and instituting effective adaptation strategies and practices that will enhance resilience of the

vulnerable communities. Consequently, bottom-up approaches should be developed and promoted to identify and document existing adaptation practices, alongside with assessing these adaptation practices for scaling up potential cost-effective practices for enhanced climate change adaptation, attainment of food security, and resilience.

The Sudano-Sahelian Belt of Nigeria

The Sudano-Sahelian belt of Nigeria is located between longitudes 3° and 15° east of the Greenwich meridian and latitudes 10° and 14° north of the Equator. However, in reality, this extends to about latitude 9° in recent times. The extreme northern part of the belt approaches the desert fringes, particularly sharing boundaries with the semiarid and arid zones of the Niger Republic. The states located in this zone are Sokoto, Kebbi, Zamfara, Katsina, Kano, Jigawa, Yobe, Borno, Gombe, Adamawa, Bauchi, and northern Kwara, Plateau, Niger, Nasarawa, and Taraba. Typical feature of this belt is land degradation in response to increase in both climate change and human activities: overcultivation and overgrazing.

The climate is characterized by alternate wet and dry seasons in response to the changes in pressure patterns. There is high variability in dates of onset and cessation of rains across the region which results in variability in length of the rainy season; this can also be attributed to the migratory patterns of the Intertropical Discontinuity (ITD). The rainy season in this belt is associated with late onset and early cessation which is associated with strong storms which destroy life and property. The rainy season in this zone has high rainfall intensity concentrated within a short period of time, thus increasing the rate and intensity of runoff. Hence, the Sudano-Sahelian zone is a moisture stress zone seen to be tending toward increased degradation. The latitudinal location of the belt also results in high temperature throughout the year, at about 27 °C. Generally, the highest temperature in the country is recorded in this zone. In addition, temperature range is highest in the northwest and northeast above 10 °C and reduces southward. The belt is dominated by savanna vegetation types: Guinea, Sudan, and Sahel savannas. The density of trees and grasses decreases northward, hence responding to climatic conditions.

Agriculture is the dominant economic activity in Northern Nigeria; crops such as groundnuts, cotton, millets, beans, Guinea corn, cassava, yam, and maize are cultivated in the region which also has the highest concentration of cattle in the country. In this belt the livelihood of rural farmers is highly tied to the availability of natural resource (land, water, and vegetation), thereby aggregating the impact and intensity of climate change on the community. A large proportion of the inhabitants depend on rain-fed agriculture. Also, irrigation scheme is employed mostly for cultivation of vegetable during the dry seasons but is characterized by low input and output.

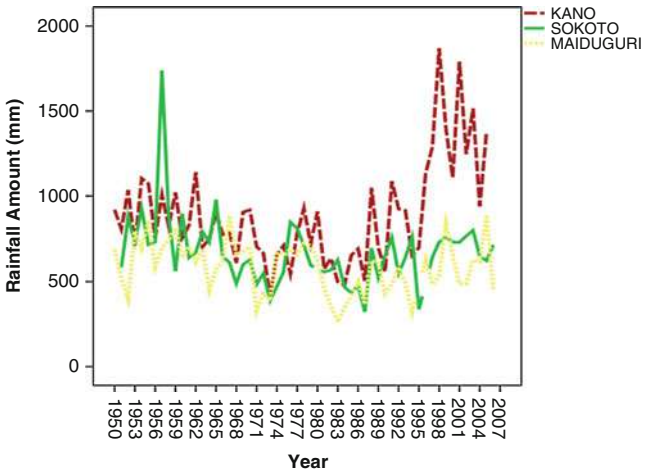

Fig. 1 Annual rainfall amount (1950–2007)

An Overview of Climate Change Impact in the Sudano-Sahelian Belt of Nigeria

The impact of climate change is already apparent across the Sudano-Sahelian zone of West Africa where a large proportion of the population engages in subsistent agriculture which is highly vulnerable to erratic weather conditions typical of the region. In Nigeria, climate changes coupled with increased human population and overexploitation of natural resources have aggravated environmental degradation which the teeming population rely on for their livelihoods. The recurring drought, desertification in the extreme Northern Nigeria, devastating flood across the riverine communities, soil erosion, and attendant loss of soil nutrients have continued to increase southward migration since the last century. Figures 1 and 2 depict the variability and gradual changes typical of the annual total rainfall amount and the hydrologic growing season in the three states across the belt. The vulnerability of developing countries and their populations to increased climate variability and change is of great concern and has attracted considerable research interest over the past decades with calls for increased funding for adaptation (Patt et al. 2010). These in addition to rainfall break, dry spell, drought, and flood during the growing season have continued to escalate the vulnerability of people's livelihood as extreme weather conditions lead to reduction in agricultural yields which subsequently aggravate individual/community poverty levels, susceptibility to climate change pressures, and food insecurity.

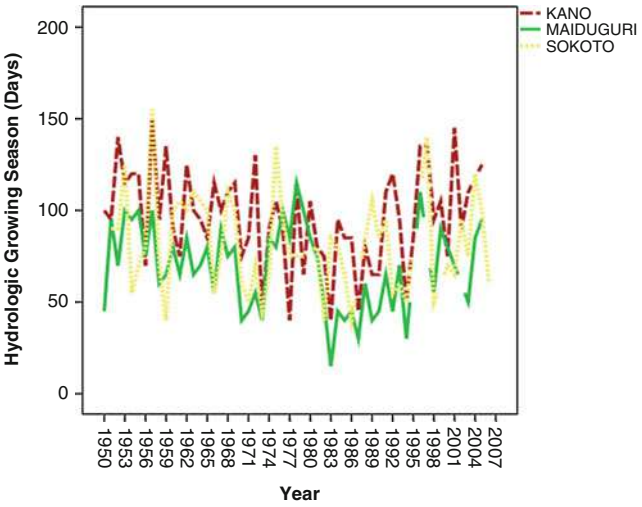

Fig. 2 Hydrologic growing season (1950–2007)

Climate Change Adaptation Practices and the Attainment of Food Security

There is a general understanding of climate change and variability across the belt as varying practices are being adapted by individuals and communities to enable them cope with the challenges of changing climate for the attainment of food security. The adaptation practices adopted are mixed farming, adoption of improved seeds that require less water and short maturing period, water conservation strategy, irrigation, and imbedding soil conservation culture through crop rotation. As such, agricultural adaptation that has always taken, and continues to take, place in Africa is responding more to perceived climate variability than climate change (Gina et al. 2008). These adaptation practices are taken to lessen the effects of climate change/variability and to increase socioeconomic well-being as well as enhance human livelihood. Adaptation to climate change is linked to sustainable socioeconomic development in the belt because large proportions of the inhabitants rely on natural resources (land and water) for their livelihood. They continue to identify measures for sustainable agriculture which is their main economic activity. Adaptation is adjusting the natural system or human system in response to actual or expected climatic stimuli or their effects (IPCC 2007). Basically, the emphasis has been on adjusting farming systems to expected climatic condition. How successful or otherwise these have been is yet to be determined. There is considerable knowledge gap with respect to climate change impact, vulnerability, and adaptation to increased climate variability and change (Molly and Brent 2011).

In recent times, the effect of climate change has forced farmers to diversify their economic activities, as most farming communities now combine crop cultivation and livestock farming or fishery. This to some extent is supported by the National Economic Empowerment and Development Strategy (NEEDS 2004) whose developmental plan is inspired by current challenges for vigorous growth. NEEDS emphasis is on job creation, strengthening the skill base, protecting the vulnerable, and promoting peace and security. This generally consists of robust plan to identify the major problems facing the various communities across the country with a view to proffering solutions using integrated economic development processes and programs across the tiers of the government (federal, state, and local government levels). However, the major concern is to what extent has the implementation of these robust plans reduced the vulnerability of the communities to climate change.

In a belt with the highest concentration of animal husbandry in the country, there is no realistic climate change adaptation practice as the existing adaptation practices are mainly reactive whereby the nomads move their animals southward for greener pastures, coupled with the fact that most of the local breed adapts to climatic stress. Livestock production in Africa and Southern Africa, especially its developing component, is vulnerable and at high risk of being severely affected by climate change (Rust and Rust 2013). This mobility will not only aggravate land, vegetation, and water degradation but also climate change as the dominance of grazing in the Guinea savanna in recent times is a potential for increased carbon dioxide emission into the atmosphere. The resultant problem of the practice is apparent in the widespread crisis between the traditional farmers and the encroaching nomads across the country. Consequently, there is an imperative need to maintain the existing grazing reserves and establish more grazing reserves to meet the growing demands of animal husbandry across the country. Furthermore, there should be capacity building for herders to enable them develop and adopt effective and affordable improved livestock management practices that will boost their adaptation to climate change.

The general approach to climate change adaptation in Nigeria has been top-down approach; usually, general policies and decisions are taken without the involvement of the communities or working together with the community groups to develop community-based climate change adaptation practices. The ministries and agencies should develop bottom-up approaches that will identify, document, quantify, and assess the existing adaptation practices for scaling up potential cost-effective practices that will enhance climate change adaptation and resilience. Integrating indigenous knowledge can add value to the development of sustainable climate change mitigation and adaptation strategies that are rich in local content and planned in conjunction with the people (Nyong et al. 2007). The community-based practices should be developed with the community by identifying their agricultural potentials and climate change challenges as well as promoting improved land and water management practices at community levels such that it will lead to the attainment of community food security in the country in general.

The Federal Government of Nigeria mandated the Nigerian Meteorological Agency (NIMET) to monitor weather and climate in Nigeria and provide meteorological information for sustainable development and safety of life and properties in the country. Hence, the agency annually gives detailed seasonal rainfall prediction (SRP) before the onset of rain so as to provide essential weather advisories and early warning to planners, decision makers, and the various operations in rainfall-sensitive socioeconomic sectors, e.g., transport, water resources, health, and agriculture. Onset and cessation dates, length of the rainy season, annual rainfall amount, expected changes in the prediction of the parameters, and socioeconomic implications are annually predicted to guide the farmers and stakeholders on the types of crops to be planted and what to expect of the growing season, dry spell, drought, and flood. Furthermore, the agency publishes agrometeorological products and services to advise the Federal Ministry of Agricultureand Rural Development and associated agencies as well as farmers to take advantage of the information contained in the two to enhance their adaptation to adverse weather conditions. NIMET – SRP (2015) predicted 3–13 days delay of onset of rains: late onset of growing season in Makurdi, Lokoja, and Enugu; early cessation of growing season in Zaria, Nguru, Kano, and Jos; shorter length of the growing season in Niger, Gusau, and Kaduna; below-normal rainfall amount in parts of the extreme southwest; and above-normal rainfall in Warri, Calabar, Bauchi, Gombe, and Nguru.

The seasonal rainfall prediction and agrometeorological products are beneficial to agriculture and other economic sectors as they contribute toward effective adaptation to the effect of climate change annually. However, considering the fact that large proportions of the vulnerable communities are uneducated, it is crucial to organize community-based sensitization programs that will enhance their understanding of these valuable information. These will reduce their vulnerability to climate-related hazards as it will enhance safe sowing and boost crop and food production. Developing countries are more exposed to experience the negative impacts of climate change owing to their fragile economic sectors and the reliance of many livelihoods on climate-sensitive sectors such as rain-fed agriculture (IPCC 2013; Stockmann et al. 2013; World Bank 2012). The relevant institutions, stakeholders, extension workers, and traditional leaders should strengthen community's capacity for climate change adaptation. Authorities, individuals, and communities' awareness will provide them with adequate capacity to act by adapting strategies for effective adaptation to the changing climate as well as facilitate the attainment of food security.

This general prediction needs to be developed into effective community- based early warning schemes that will be easily adapted by the immediate community and relevant stakeholders as cost-effective tools for climate change adaptation and attainment of food security. In the Sudano-Sahelian belt where about two-thirds of the population lives in rural areas, the starting point for the adaptation should be by promoting the culture of resilience based on existing community knowledge. In addition, the community should be well informed through dissemination of accurate and adequate information in local languages to enhance people's adaptation and resilience. Consequently, collection, compilation, and dissemination of relevant information and knowledge of climate change, vulnerabilities, and capacity at

Table 1 Agricultural research institutes in Northern Nigeria

Name of research institute	Mandate
Lake Chad Research Institute, P.M.B 1293, Gamboru Road Maiduguri, Borno State	Genetic improvement and development of production technologies for wheat, millet, and barley; the improvement of the productivity of the entire farming system in the northeastern zone
Institute for Agricultural Research, P.M.B 1044, Ahmadu Bello University, Samaru, Zaria	Genetic improvement and development of production and utilization technologies for sorghum, maize, cowpea, groundnut, cotton, and sunflower and the improvement of the productivity of the entire crop-based farming system in the northwest zone of Nigeria
National Cereals Research Institute, P.M.B 8, Badeggi, Bida, Niger State	Genetic improvement and production of rice, soybean, benniseed, and sugarcane and improvement of productivity of entire farming system of the central zone
Nigeria Stored Products Research Institute, P.M.B 1489, Km 3 Asa Dam Road, Ilorin, Kwara State	Research into improvement of major food and industrial crops and studies on stored product, pest and diseases, pesticide formulation, and residue analysis
National Animal Production Research Institute, P.M.B 1096, Shika, Zaria	Research on food, animal species, and forages
National Veterinary Research Institute, P.M.B 01, Vom	Research into all aspects of animal diseases and their treatment and control, as well as development and production of animal vaccines and sera
National Institute for Freshwater Fisheries Research, P.M.B 6006, New Bussa	Research into all freshwater fisheries and long-term effects of man-made lakes on ecology and environment throughout the country
National Agricultural Extension and Research Liaison Services, Ahmadu Bello University, Zaria	Research into technology transfer and adoption studies; overall planning and development of extension liaison activities nationally; collation and evaluation of agricultural information

community level will enhance climate change adaptation, mitigation, and resilience. The low adaptive capacity of crop farmers in Nigeria can be attributed to a variety of factors, including poverty, lack of access to resources, and poor infrastructure (Chinedum et al. 2011). Investigating the strategies for coping with current climate change will provide pointer for addressing adaption needs in Nigeria particularly in the area of food security and socioeconomic well-being.

Similarly, several agricultural research institutes are established across the zone (Table 1). Most of these institutes are mandated to conduct researches that will lead to sustainable agriculture in the zone through development of improved seed species that are today widely accepted by farmers across the zone. Ministries of agriculture have also continued to promote adoption of improved cultivation and higher-yield varieties through Agricultural Development Projects (ADP) that are widely spread across the country. The adoption of these improved species enhances community

capacity in adapting to climate change; practical adaptation initiatives tend to focus on risks that are already problematic (Barry and Johanna 2006). There are also centers like the Centre for Climate Change and Freshwater Resources (CCCFR) established in 1995 (as a linkage center of the Federal Ministry of Environment) to create awareness, educate, and train Nigeria's teeming population while conducting credible research to guide policy making. Centers like these should be empowered adequately and promoted to climate change institutes with the mandate to take leadership role in climate change monitoring, modeling, impact assessment, and development of adaptation and mitigation strategies that will enhance resilience to climate change. Generally, it is crucial to initiate polices, guidelines, programs, strategies, and projects to reduce vulnerability across the zone and help farmers adapt to the changing climate for the attainment of food security.

The National Emergency Management Agency (NEMA) in collaboration with the Federal Ministry of Education, in their contribution, has started the mainstreaming of climate change and disaster risk reduction (DRR) into basic and postbasic school curriculum. If accomplished and implemented, it will increase climate change awareness and subsequently enhance adaptation to climate change. However, it is also important to mainstream climate change into development interventions at the federal, state, and local government levels to enhance community climate change awareness and promote community-based adaptation policy such that it will lead to its incorporation into relevant socioeconomic activities at grass roots such as agriculture.

Climate Change Mitigation Strategies in the Sudano-Sahelian Belt of Nigeria

Since 1972, the United Nations General Assembly designated 5th of June as World Environment Day (WED), to stimulate awareness and understanding of the environment and the problems that besiege its sustainability; the Federal and States Ministries of Environment mark this day annually across the country with poorly planned and executed tree planting campaigns across the country. The practicality of these in climate change mitigation is still at very low level because in most cases these trees are hardly nurtured to maturity. The tree seedling should have been distributed to the endangered rural farmers that will be determined to plant and nurture them not only for climate change mitigation and resilience but also for enhanced community access to fruits, medicine, poverty reduction, enhanced livelihood, and attainment of food security.

Furthermore, the WED is generally used to encourage every Nigerian to plant trees in order to reduce emissions from deforestation and forest degradation (REDD) that is typical across the Sudano-Sahelian belt. To accomplish this, agroforestry is highly encouraged as economic tree seedlings are distributed to large-scale farmers by the ministry which not only help to mitigate climate change but also enhance community access to fruit and modify community microclimate (Plate 1). Nigeria's farmers reported that temperature and rainfall are increasing (Sofoluwe et al. 2011).

Plate 1 Large-scale agroforestry

Plate 2 Community's adaptation to climate change

This noble program should be well planned and implemented such that the rural farmers are incorporated or grassroots participation encouraged because it is a common method for rural community's adaptation to climate change (Plate 2). Through this, policy makers and environmentalists should have immensely contributed to climate change mitigation and improved standard of living as well as safeguarding biodiversity and preserving the natural environment. Furthermore, the Federal Ministry of Environment in collaboration with United Nations Development Programme (UNDP) and other partners is promoting the adoption of renewable energy across the country to promote the Nigerian Alliance for Clean Cookstoves (NACC) and is developing more efficient woodstoves to reduce consumption of biomass-based energy sources and to enhance climate change mitigation.

The agricultural management system is aggravating climate change impact as huge proportions of agricultural residue that cannot be consumed by animals are

burnt annually leading to the increased emission into the atmosphere. Crop residue burning is considered as a chief contributor of greenhouse gas (GHG) emissions in the atmosphere (Jordan et al. 2010). Thus, there is need to find appropriate methods which can enable farmers to incorporate these residues to land use practices as well as mitigate climate change and strengthen Africa's agricultural sectors to enable them to respond to growth in demand (John and Irene 2009). Improved management practice (IMP) techniques that will enhance soil organic matter storage with minimum soil disturbance through incorporation of crop residual into farming system should be promoted as its adoption will enhance climate change adaptation. Also, it will not only enhance soil fertility and crop performance but will also help in removing excess carbon dioxide from the atmosphere, thereby crucial for climate change mitigation and adaptation. In Nigeria rice straw and other crop residues are abundant; these can be incorporated into the soil as biological fertilizer in order to enhance soil sustainability and climate change adaptation and mitigation. Increasing atmosphere carbon dioxide is a dual consequence of poor management of crop residues and agricultural land practices (IPCC 2013). Thus, improved carbon sequestration necessitates adoption of improved land use management practices across the zone such that high-breed economic trees will be integrated into cultivated land for improved soil conservation, attainment of food security, and resilience to climate change.

Despite the fact that countries have ecological funds, it is not easy to determine what percentage of this goes to the climate change mitigation/adaptation. Climate change adaptation should be national priority such that it will be given its rightful place in planning for national development and supported with funds to implement adaptation strategies and enforce sustainable adaptation practices at large scale for the attainment of food security. Government at all levels, collaborative partners, and NGOs should specify certain percentage of fund for climate adaptation which should be invested in schemes and projects that will promote climate change adaption, mitigation, and resilience.

In Nigeria, available records in the Federal Department of Forestry show that Nigeria has a total of 1,160 constituted forest reserves covering over 10,752 ha of land, and this represents about 10 % of the total land area. Also, game reserves and national parks are excluded from this. However, most of these reserves only exist on paper and the Federal Department of Forestry argues that deforestation in Nigeria is now progressing at the rate of 3.5 % per annum. In Africa, for example, deforestation accounts for nearly 70 % of total emissions (FAO 2005). Furthermore, Anselm and Taofeeq (2010) stated that climate change is perhaps the most serious environmental threat to the fight against hunger, malnutrition, disease, and poverty in Africa, mainly through its impact on agricultural productivity. Hence, there is need to check the way in which people interact with these crucial resources such that it will reduce the rate of deforestation and increase biodiversity, conservation, and reforestation using introduced or indigenous species that will promote sustainability of the forest. These will not only enhance climate change adaptation and mitigation but contribute greatly toward the attainment of food security.

Future Direction

Generally, in Nigeria, there are numerous crucial policies and programs aimed at addressing issues related to climate change adaptation and agricultural sustainability. However, the major concern is the level of implementation and its role in promoting and developing institutions of effective adaptation strategies and practices that will enhance resilience of the vulnerable communities across the country. There should be an agency/organization empowered to collate, synthesize, implement, and promote climate change policies and programs at all levels of the government such that it will be widely adopted across the country particularly the vulnerable community. Bottom-up approaches should be developed and promoted to identify, document, and quantify existing adaptation practices, along with assessing these existing adaptation practices for scaling up potential cost-effective practices for enhanced climate change adaptation and resilience.

Institution and organization plans should be realistically implemented to enhance vulnerable community climate change adaptation and mitigation through such programs that will integrate environmental and natural resource development into socioeconomic development process for the attainment of food security and improved rural livelihood. Similarly, government interventions such as NEEDS should be channeled toward identifying the major problems facing the various communities across the country with a view to building their capacity in proffering solutions using integrated economic development processes and programs at community levels in job creation, strengthening the skill base, reducing vulnerability, and promoting peace and security that are today threatened across the country.

The federal, state, and local government initiatives should be proactive; the Nigerian Meteorological Agency (NIMET), NEMA, State Emergency Management Agency (SEMA), and ADP should collaborate in the development and communication of effective community-based early warning schemes as a cost-effective tool for climate change adaptation and attainment of food security. In addition to the agricultural research institutes well spread across the zone, climate change institutes should be established to take leadership role in climate change monitoring, modeling, and impact assessment, to collaborate with all the relevant agencies in the development of adaptation and mitigation strategies, and to initiate policy guidelines, programs, and projects that will enhance resilience to climate change. The institutes should identify ways of mainstreaming climate change into all developmental interventions at the federal, state, and local government levels as pathways for promoting community-based adaption policies at the grass roots. Bottom-up approaches should be enforced by identifying the varying community's agricultural potentials and the strategies of land and water management practices that will boost their adaptation to climate change.

WED should be marked by distributing tree seedlings to communities that will be determined to plant and nurture them not only for climate change mitigation and resilience but for enhanced community access to fruits, medicine, poverty reduction, improved livelihood, and attainment of food security instead of political tree planting

campaigns. Thus, agroforestry should be integrated into crop cultivation and animal husbandry by making economic tree seedlings available to small- and large-scale farmers. Renewable energy and clean cooking stoves should be promoted across the country, and more efficient stoves should be developed to reduce the use of fuel wood as source of energy as well as enhance climate change mitigation.

Furthermore, there is need to design and implement local adaptation strategies that will bridge the gap between scientific and local knowledge in order to create projects capable of increasing community adaptation and resilience. In addition to the high-breed crop varieties, relevant stakeholders should promote breeding of high-breed economic trees and make them available to farmers at subsidized rates. This will not only promote effective climate change adaptation but enhance mitigation and resilience. Diversification of the economy through provision of credit, cooperative, and micro-finance at lower interest rates should be promoted. Also, community-based organizations (CBOs), improved land and water management practices, irrigation strategies, building crop storages, developing marketing facilities, subsidizing agricultural inputs, and establishment of safe nets will enhance diversification of the economy. Generally, these are cost-effective tools for climate change adaptation, mitigation, and attainment of food security.

Understanding Climate Change Adaptation Needs and Practices of Households in Southeast Asia: Lessons from Five Years of Research

Herminia A. Francisco and Noor Aini Zakaria

Contents

Abstract

This chapter reports the main findings of research projects supported by the Economy and Environment Program for Southeast Asia (EEPSEA) over the last 5 years (2009–2013). The research projects reported focus on adaptation needs, climate change impacts, and the economics of adaptation projects as well as on efforts to link researchers with local government planners to enhance science-based adaptation planning. The lessons derived from these micro-level EEPSEA

DOI 10.1007/978-3-319-14409-2_67

studies are important because the impacts and adaptation solutions reported are often local, as they are carried out by households, communities, and local governments. Hence, these studies help in understanding how various groups are affected by climate change and what limits their adaptation choices, which are important in designing ways to increase their resilience to climate change.

Field-level assessment of impacts showed that extreme climate events (i.e., super typhoons and associated flooding) cost households more than a third of their annual household income per event. As future extreme climate events are expected to be more frequent and intense, future damage may be even bigger and will most likely drive vulnerable households toward extreme poverty. Household adaptation actions in the various study sites are generally very crude and mostly reactive (e.g., strengthening housing units, using sandbags during flooding, storing of food, evacuation) rather than preventive (e.g., relocation, building multistorey and stronger housing units). This is largely explained by the limited resources available to most vulnerable households for investment in stronger adaptation measures.

The studies also show that strengthening community ties can increase household and community resilience. It also increases the efficacy of using communities as vital conduits of climate information dissemination. Moreover, results indicate that climate communication policies and interventions should go beyond informing people of climate hazard risks; they should also provide information that would allow people to assess their capabilities as well as permit technical assessments of various adaptation options.

Local governments need support in adaptation planning. The two action research projects carried out with funding support from EEPSEA and collaborating organizations showed that local government officials are receptive to such research collaborations and are very much willing to learn from science-based adaptation planning. Research to identify efficient or cost-effective adaptation options was highly appreciated by local government units. They need support to seek climate financing for these adaptation programs however.

Introduction

The intensity and frequency of typhoons and flooding events, such as those experienced by the Philippines, Thailand, Vietnam, and Indonesia in the recent past, attest to the changed and changing climates that we all face. Southeast Asia's vulnerability to climate change is also confirmed in an Asian Development Bank report (ADB 2009) that cites the region's long coastlines, high population density and economic activity, and high dependence on agriculture and natural resources as a big reason for this vulnerability. The latest Intergovernmental Panel on Climate Change Report (IPCC 2014) affirmed these observations stating that the "risks of impacts that are severe, pervasive and irreversible is much greater if we stay on a path of continued high emissions." The areas under greatest threat are those around Manila Bay in the Philippines; in the low-lying coastal fringes of Sumatra,

Kalimantan, and Java in Indonesia; and in the Mekong (Vietnam), Chao Phraya (Thailand), and Irrawaddy (Myanmar) deltas (Handley 1992; Morgan 1993; Yusuf and Francisco 2009).

Asia as a whole is highly vulnerable to climate change. Anthoff et al. (2006) estimated that 105 million people in Asia would be at risk of having their homes inundated by a one-meter rise in sea level. In Bangladesh alone, a report by the United Nations Environment Program (UNEP 2008) mentioned that a one-meter rise in sea level would inundate 17,000 km^2 of the country's land, which is over 10 % of its total land mass.

Other parts of the world are not exempted. Countries in North America experience frequent hurricanes, often accompanied by storm surges and flooding, while others are suffering from extreme temperatures like heat waves or cold snaps. Extreme weather events like heat waves, floods, and droughts have also caused rising damage costs across Europe in recent years (Pittock 2003; Jones and Preston 2006). An increase in global temperature of 3.5 °C will result in damages worth at least €190 billion, representing a net welfare loss of 1.8 % of Europe's current gross domestic product (GDP) (European Commission 2014). Low-lying atoll countries in the Pacific such as the Kiribati, the Marshall Islands, Tokelau, and Tuvalu also face high risk from sea level rise (Garnaut 2010). The occurrence of climate change-related disasters is very likely to continue into the future (IPCC 2007).

The cost of climate change is very high. For instance, *Typhoon Haiyan* in the Philippines left more than 6,000 deaths with several thousands more missing. According to UN estimates, about 670,000 people were made homeless and 11 million people needed assistance for a long period given the extent of devastation that they suffered (Cumming-Bruce and Gladstone 2013). An article in *The Economist* placed the economic cost of Haiyan in the Philippines at USD 15 billion ("Typhoon Haiyan" 2013), which is 6 % of the country's 2013 GDP. The same article noted that the Vietnamese government averted damages by its quick and organized evacuation of 800,000 people from coastal communities (Ziervogel et al. 2013). Indeed, there are ways to prepare for catastrophes like this, but it must also be said that *Typhoon Haiyan*'s rage in the Philippines was of an unprecedented scale and intensity, which could have caught any government by surprise.

Our recent experiences with natural climate-related disasters are clearly showing us that the climate change debate is no longer about whether or not we should adapt; it is now an issue of *how* we can adapt more effectively and efficiently. Related to this is the question of how we can assist local government units (LGUs), communities, and households in improving their adaptive capacity. This chapter reports on the research findings of four (4) multi-country research projects supported by the Economy and Environment Program for Southeast Asia (EEPSEA) over the last 5 years (2009–2013). The research projects are focused on adaptation needs, climate change impacts, and the economics of adaptation projects as well as on efforts to link researchers with local government planners on adaptation planning.

The chapter is divided into five sections. The first part (section "Vulnerability to Climate Change and Impacts of Extreme Climate Events") presents an overview of the climate change vulnerability situation in Southeast Asia (SEA) based on the

work by Yusuf and Francisco (2009) and the household costs resulting from these extreme climate events based on studies in selected sites in the region. Section "Adaptation Practices and Factors Influencing Adaptation Choices" highlights the adaptation practices employed in the region and the determinants of adaptation choices. Section "Coastal Communities' Vulnerability and Adaptation Practices" expounds on adaptation by focusing on the experiences of three coastal villages in the Philippines, Vietnam, and Indonesia. Section "Working with Local Governments in Adaptation Planning" presents insights from experiences in pilot testing the EEPSEA vulnerability mapping approach as a prelude to identifying adaptation options based on a three-country grant in 2011 to the poverty-environment project, also supported by the International Development Research Centre. This section also provides insights from a 3-year grant to three research institutions in the region (the Philippines, Vietnam, and Cambodia) tasked with developing the adaptation planning capacity of LGUs and communities through participatory research. The final section (section "Lessons from EEPSEA-Funded Climate Change Adaptation Research in Southeast Asia: Future Directions") summarizes the key lessons learned from the 5-year multi-country research project carried out in countries identified as most vulnerable to climate change: the Philippines, Vietnam, Indonesia, Thailand, and Cambodia. Suggestions on how to move forward in the field of adaptation planning and economics research are advanced.

Vulnerability to Climate Change and Impacts of Extreme Climate Events

A Snapshot of Climate Change Vulnerability in Southeast Asia

In 2009, EEPSEA released the climate change vulnerability map for Southeast Asia (Yusuf and Francisco 2009). The program launched the report in the Philippines, Indonesia, and Vietnam with relevant policymakers and nongovernment organizations (NGOs) in attendance. The map (Fig. 1), which shows vulnerability to climate change at the subnational level, was well received as there was still very limited information on this at the time. While the map presents only a snapshot or a static picture of the situation using 2005–2008 information, it generated a lot of interest due to several reasons.

First, it shows how provinces or districts within a country compare with each other in terms of overall vulnerability, using the same set of indicators, namely, *hazards* (i.e., exposure to floods, drought, landslides, typhoons, and sea level rise), *adaptive capacity* (e.g., economic indicators like per capita income and poverty level, access to social services like education and health, infrastructure support like road and communication networks), and *sensitivity* (i.e., population at risk, represented by population density; ecological sensitivity, using hectares of protected areas).

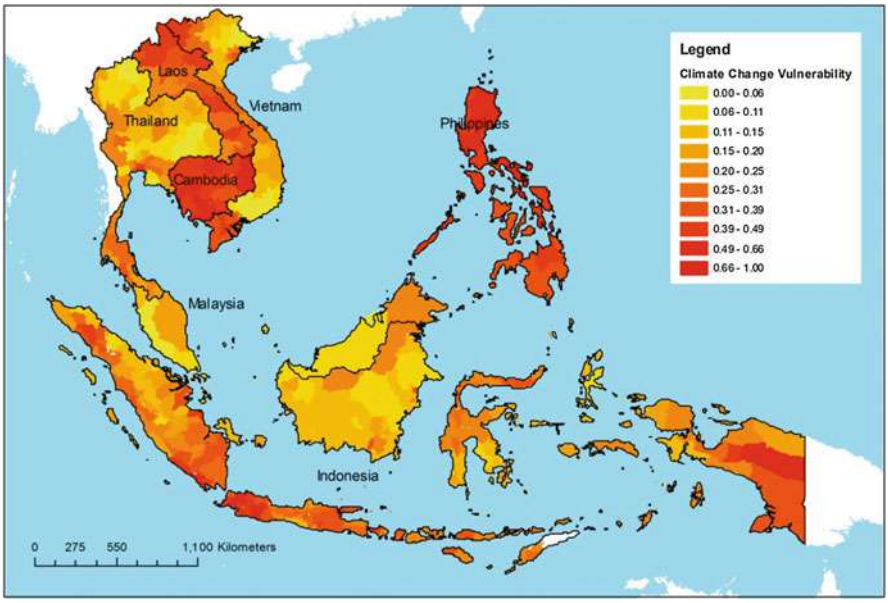

Fig. 1 Vulnerability to climate change in Southeast Asia (Source: Yusuf and Francisco 2009)

Second, the map is accompanied by a table that shows the contribution of the three elements (i.e., hazard exposure, lack of adaptive capacity, and sensitivity) to climate change vulnerability. It therefore shows areas where improvement in adaptive capacity is critical and areas where protection is a must, if exposure to hazard is the main driver of vulnerability. Likewise, it shows where vulnerability is caused by population and ecological sensitivity.

This is illustrated in Fig. 2. As shown, the main driver of vulnerability in Vietnam is exposure to hazards. Vietnam's long coastline, geographic location, and diverse topography and climates contribute to its being one of the most hazard-prone (storms and floods) countries in the Asia-Pacific region (World Bank 2011). In Indonesia, population density drives vulnerability in areas like Jakarta. Almost 230 million people inhabit Indonesia, with the majority (about 54 %) living on the island of Java (World Bank 2011). In poorer countries like Cambodia, low adaptive capacity is the dominant driver of vulnerability. The poor are the most vulnerable to the impacts of drought, floods, and landslides as they are highly dependent on climate-sensitive sectors like fisheries and forestry.

Finally, the map facilitated the active engagement of stakeholders in several countries and generated interest on how to downscale such a presentation at an even lower level of administration, such as towns and villages. Subsequently, EEPSEA provided modest funding support to pilot test the downscaling of this framework at the LGU level in several countries in the region as part of its research grants support (see section "Working with Local Governments in Adaptation Planning"

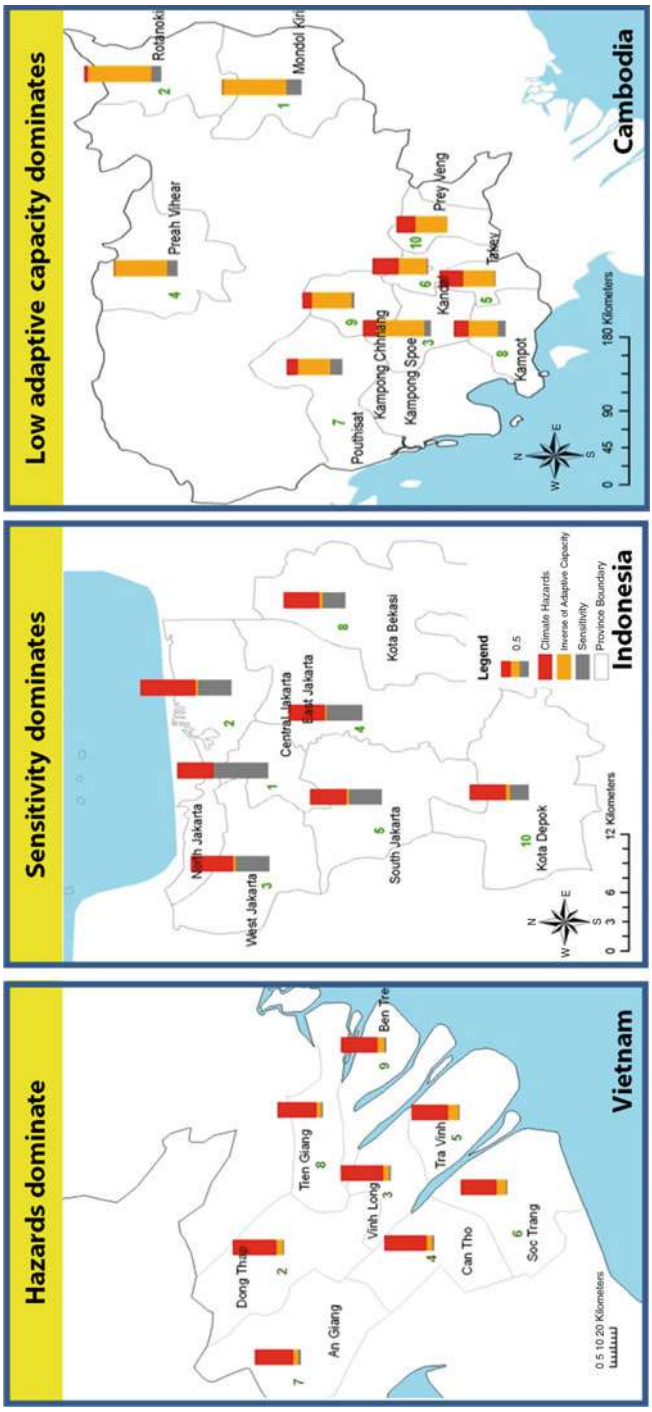

Fig. 2 Comparison of sources of vulnerability, three countries (Source: Yusuf and Francisco 2009)

discussion). The top 15 most vulnerable provinces/districts in each of the SEA countries where mapping was carried out are shown in Table 1.

Across SEA, the most vulnerable provinces and districts are found in the Philippines and Vietnam (largely from typhoons and flooding and low adaptive capacity) and Indonesia and Thailand (mostly from flooding and high sensitivity). A high degree of vulnerability can be noted for urban cities like Manila, Jakarta, and Bangkok, and this has been proven time and time again with yearly occurrences of multiple climate-related disasters like typhoons and flooding at these places. High population density, poor urban planning, and deforestation are factors that exacerbate these cities' sensitivity to climate change.

Jakarta's recent flood (Elyda and Dewi 2014) illustrates the vulnerability of urban cities to climate change. The flood affected 20,000 people (with seven reported dead) in 48 subdistricts where inundation of up to 6 m was experienced. While losses from this event were already big, the flood that took place in Jakarta in February 2007 remains unsurpassed. In the 2007 flood, nearly 60 % of the city was inundated, displacing 320,000 people and causing the death of 50.

The 2011 Thailand flooding is another example of the massive economic loss associated with climate change-related disasters. That was, by far, the worst flooding in 50 years that affected not only Bangkok but neighboring provinces as well. From July to December 2011, the Geo-Informatics and Space Technology Development Agency (GISTDA 2011) reported the inundation of 69 provinces covering 41,381 km^2. There were 815 reported deaths and damage to about 13 million rai (2.08 million hectares) of agricultural lands. This had a profound impact on food security in SEA as Thailand is a leading exporter of rice, a region staple (Loo et al. 2014).

Clearly, urban centers' high population density and high hazard exposure partly explain the high cost of damages from climate change, but other causes such as poor urban planning, clogging of waterways, and forest denudation are also partly to be blamed.

How Much Does a Household Suffer from Extreme Climate-Related Disasters?

The figures on losses and damages from any disaster could appear like mere statistics to most people, but to those on the ground, these numbers translate to economic loss and other forms of social loss or discomfort. We take a closer look at flooding damages and at how these had influenced those living in the affected areas of two studies most recently supported by EEPSEA (i.e., Wijayanti et al. 2014; Nabangchang et al. 2013) as well as of the five cross-country adaptation projects carried out in 2011.

Flooding Damages

Wijayanti et al. (2014) looked into the damages from the January 2013 Jakarta flooding that inundated houses and merchandise shops for about 3 days. It analyzed what factors influenced the level of damages using a flood damage model. In addition, it looked closely into the role of women in dealing with the flooding

Table 1 Top 15 vulnerable provinces/districts per country based on EEPSEA 2009 vulnerability mapping

Country	Top 15 vulnerable provinces/districts (2008 data)
Cambodia	Mondulkiri, Ratanakiri, Kampong Speu, Preah Vihear, Takev, Kandal, Pursat, Kampot, Kampong Chhnang, Prey Veng, Koh Kong, Svay Rieng, Stung Treng, Kampong Thom, and Battambang
Philippines	Manila, Benguet, Batanes, Ilocos Sur, Rizal, Bataan, Batangas, Bulacan, Abra, Albay, Quezon, Nueva Ecija, La Union, Aurora, and Mountain Province
Thailand	Krungthep, Samut Prakan, Nonthaburi, Samut Sakhon, Trang, Chachoengsao, Nakhon Si Thammarat, Surat Thani, Satun, Pattani, Ranong, Nakhon Nayok, Nakhon Pathom, Phatthalung, and Yala
Vietnam	Lai Chau, Dong Thap, Vinh Long, Can Tho, Tra Vinh, Soc Trang, An giang, Tien Giang, Ben Tre, Thai Binh, Minh Hai, Long An, Kien Giang, Thua Thien Hue and Son La
Lao PDR	Phongsali, Houaphan, Luang Namtha, Oudomxay, Saravan, Bokeo, Hammouan, Luang Prabang, Attapeu, Xekong, Borikhanxai, Xiangkhoang, Savannakhet, Viangchan, and Xaignabouri
Indonesia	Central, North, West, East, and South Jakarta, Kota Bandung, Kota Surabaya, Kota Bekasi, Kota Bogor, Kota Depok, Kota Palembang, Tangerang, Kota Tangerang, Kota Malang, and Jayawijaya
Malaysia	Sabah, Pulau Pinang, Kelantan, Terengganu, Perlis, Pahang, Kedah, Kuala Lumpur, Johor, Sarawak, Perak, Selangor, Melaka, Negeri Sembilan

situation. Specifically, a survey was conducted in two districts of South Jakarta (i.e., Pesanggrahan and Kebayoran Lama) covering three villages (i.e., Ulujami, Kebayoran Lama Utara, and Cipulir) and in two districts in West Jakarta (i.e., Kebon Jeruk and Cengkareng) covering three villages (i.e., Kedoya Selatan, Sukabumi Selatan, and Rawa Buaya).

As shown in Table 2, the nature and cost of the damages to households over a 3-day flooding event included damage to house structure and its content, cleanup cost, evacuation costs, loss of income (foregone income), and cost of illnesses.

The study found that the average loss to a household from the 3-day flooding is about USD 309.00. With a minimum daily wage of USD 5.00, this damage cost is huge. Inundation depth and duration, household income, and house area are positive and significant predictors of the level of flood damage based on the regression analysis carried out in the study.

For households engaged in small-scale trading or commercial enterprise, losses were three times higher than that of nonbusiness households. For this group, the losses took the form of damage to goods or merchandise, structural damage, and cleanup costs (Table 3).

The average flood damage to the business shops in the affected area over the 3-day flooding event was valued at USD 858. Consistent with the findings from nonbusiness household data, the main predictors of damages to the business group are inundation depth and duration, total floor area occupied by the business, and income, measured by turnover or sale per day.

Table 2 Average flood damage per house resulting from the January 17–19, 2013, flood event

Damage		Value (IDR)	Value (USD)	Percentage (%)
Direct	Structural damage	423,395	42	14
	Content damage (inside and outside)	1,881,703	188	60
Indirect	Cleanup cost	241,186	24	8
	Loss of income	290,345	29	9
	Evacuation and temporary house	117,383	12	4
	Cost of illnesses	142,252	14	5

Table 3 Average flood damage per unit business resulting from the January 17–19, 2013, flood event

Damage		Value (IDR)	Value (USD)	Percentage
Direct	Structural damage	564,800	56	7
	Content damage	1,543,060	154	18
Indirect	Turnover loss	5,252,704	525	61
	Temporary quarters	56,000	6	1
	Labor cost	383,667	38	4
	Cleanup cost	786,633	79	9
Total		**8,586,864**	**858**	**100**

Cf: Wijayanti et al. (2014), Table 7 in the original report

The second study was carried out in Bangkok, Thailand, by Nabangchang et al. (2013). In 2011, Thailand was hit by the worst flood experienced in 50 years. From July to December 2011, 69 provinces were affected, with a total inundation area of 41,381.8 km^2 (GISTDA 2011). The death toll reached 815, with three persons missing. Nearly 2.08 million hectares of agricultural land were damaged and the transportation of goods and services, particularly food supplies, was crippled because major roads were flooded and impassable.

The study looked at the damages incurred by households as a result of this long period of flooding. It surveyed some 500 households from the following districts: Bang Bua Thong district (in Nonthaburi province located west of Bangkok), Klong Luang district (in Pathum Thani province located north of Bangkok), and Don Muang district (northern Bangkok). The flooding in these districts was about 2 m at its highest level, with a flooding duration of 2–3 months. The households were interviewed twice with the first done immediately once the flooding begun to subside and the second done a year later. The intent of the second survey was to capture a more accurate estimate of flooding damages since most repairs and cleanup activities would have been completed by then. At the same time, some questions on the preferences for flooding insurance were asked.

Table 4 Mean household damages (in THB) by nature of damages and comparison of study results to World Bank 2012 estimates

	Bangkok		Nonthaburi		Pathum Thani

Source: Nabangchang et al. (2013)

Table 4 shows the damage estimates based on field interviews carried out in the three study areas. For comparison, it also shows the World Bank damage estimates provided immediately after the event. Nabangchang et al. (2013) estimated Bangkok residents' household losses at USD 6,598; USD 5,937 for Nonthaburi residents; and USD 3,531 for Pathum Thani residents. These numbers are three to five times higher than the estimates provided by the World Bank, showing that quick estimates can understate the extent of climate change impacts.

The big source of underestimation comes from the estimate of losses to the housing unit itself and damage to furniture and household appliances soaked underwater for a long time. This number is huge (38–67 % of total losses), most particularly for those residing in Bangkok and Nonthaburi. Nabangchang et al. (2013) also captured other losses that were not included in the World Bank estimates. These include, among others, expenditures to prevent water from coming into the house (e.g., use of sandbags and motor pump to get water out) and household contributions to community efforts to protect the village.

The cost to the households took the form of repair or replacement costs for damaged properties, cleanup costs, relocation costs, and foregone income during the disaster period. In terms of proportion to annual household income, the flood damages accounted for 44 % of annual household income in Nonthaburi, 30 % in Bangkok, and 29 % in Pathum Thani.

Typhoon Damages

Damages can take other forms, depending on the climate hazard. In the case of strong typhoons, production losses (crops, livestock, and fisheries destroyed by the typhoon) constitute a huge part of the overall damage cost.

The Philippines, Vietnam, and China are highly prone to natural disasters (i.e., earthquakes, volcanic eruptions, tropical cyclones, and floods) making them among the most disaster-prone countries in the world (Nhu et al. 2011; European Commission 2007). The Philippines is hit by an average of 20 typhoons per year as a result of its location along the Western Pacific Basin, the world's busiest typhoon belt (Heijmans and Victoria 2001). Vietnam is also highly vulnerable to climate change, especially its coastal areas (European Commission 2007) as well as Central Vietnam, which is likely to be hit by at least two typhoons per year (Tuan et al. 2012). An average of six typhoons hit China annually (Horiguchi 2014).

A team of researchers from the Philippines, Vietnam, and China looked into the damages caused by super typhoons that hit their respective countries from 2006 to 2007 (Table 5). *Typhoon Xangsane* hit Quang Nam province with intensity level 13 (134–149 kph) and was accompanied by heavy rains that led to flooding in Dai

Loc (Dai Loc People's Committee 2007 cited in Phong et al. 2010). The total damage was estimated at VND 578 billion (USD 27.5 million) (Phong et al. 2010). The same typhoon (locally named *Milenyo*) hit the Philippines on September 25–29, 2006. It was a category 4 super typhoon with a maximum speed of 230 kph. It affected 277 municipalities with the Southern Luzon provinces of Laguna, Cavite, and Batangas hit badly. Total damage was placed at PhP 6.6 billion (USD 137.5 million) (Peñalba and Elazegui 2011). *Typhoon Saomai* hit China in 2007 and was considered as the country's worst typhoon since 1951 (Yueqin et al. 2011). It caused substantial damages to property and livelihood and caused people to lose income for a short time due to flooding.

The losses that farming villages hit by super typhoons took the forms of: damage to houses and other properties; crop, fishery, and livestock production losses; and foregone income during and a few days after the event. The higher damage inflicted by *Typhoon Xangsane* in the Philippines compared to those from Vietnam reflects the fact that, historically, typhoons hit the former with greater intensity before it enters the latter. Vietnam's higher level of preparedness also helped lower the damage cost. The average damage from *Xangsane* in the Philippines was placed at USD 1, 341/household whereas this number is only USD 391/household in Vietnam. In the case of China study sites where a large number of small-scale household factories are found, the bigger percentage of household losses came from foregone income (Yueqin et al. 2011).

As a share to household income, the typhoon damages from one extreme typhoon could wipe out 34 % of the annual household income in the Philippines, 12 % in Vietnam, and 33 % in China. The average damage cost of USD 1,140/typhoon event across all sites amounted to about a third of the yearly household income, a significant amount particularly for communities with very low income to start with.

With the increasing frequency of super typhoons hitting the region in the last 5 years, those dependent on agriculture are facing serious threats that could drive people to extreme poverty. They would need to diversify their income sources, build stronger houses, or move to areas that are less vulnerable to climate change. They would need support from government and nongovernment development workers to enhance their adaptation capacity. The next section will discuss the results of several EEPSEA studies that aimed to understand the adaptation needs of communities in selected villages in the region.

Adaptation Practices and Factors Influencing Adaptation Choices

Adaptation to climate change is a complex, multidimensional, and multi-scale process (Bryant et al. 2000 cited in Tiwari et al. 2014). According to Tiwari et al. (2014), household adaptation choices are not only influenced by environmental variables but also by household socioeconomic characteristics. Supporting this notion, several studies found that farming experience, socioeconomic position, and access to resources and credit increase the probability of uptake of adaptation measures to climate change (Maddison 2007; Nhemachena and Hassan 2007).

A question that we want to answer in this section is "how have people been adapting to extreme climate events?" The five-country research that EEPSEA supported in 2007 looked specifically into this question. It identified adaptation practices of households, communities, and LGUs in selected study sites in Indonesia, Vietnam, Thailand, the Philippines, and China. The study sites in China, the Philippines, and Vietnam (Hue) were affected by typhoons and flooding while those in Thailand, Indonesia, and Vietnam (Hanoi) had to contend with riverine flooding. The study also analyzed what factors influenced their adaptation choices. A total of 2,005 households from nine villages in these five countries were interviewed (Table 6).

What Climate Change Adaptation Practices Were Being Practiced?

The cross-country researchers found that, for most countries, the proportion of households who were doing either behavioral or "structural" adaptation measures is less than half of the respondents. The behavioral adaptation practices included moving properties to safer places, evacuating when the warning is received, and storing 3–5 days worth of food and drinking water before the disaster hits. It is worth noting that majority of the Thai respondents (88 and 96 % of urban and rural respondents, respectively) knew the drill of moving their properties to safer places during flooding season (Table 7).

Those who engaged in soft structural adaptation measures were even fewer. These measures included reinforcing farmhouses with heavy objects or tying them to trees and using more durable housing materials where available and use of sandbags to protect the houses from flooding. Relatively well-off households have managed to build mezzanine or second floor areas to keep them protected during flooding, but these practices were carried out by less than 10 % of the household respondents. In Thailand, it was a common practice to use sandbags to protect the houses from the inflow of floodwater (Table 7).

In general, the survey on climate change adaptation (CCA) practices in the five countries demonstrated that in 2007–2009, CCA at the household level was still

Table 6 Type of ecozone and number of sample households

relatively low and, if done at all, was of the form that was considered "soft" and thus could hardly help mitigate impacts from climate change-related disasters.

Clearly, these adaptation measures, while needed, are not sufficient to protect the affected households from extreme events. Three options that were considered by experts as potentially having a bigger impact in reducing damages are (1) relocating households currently in flood-prone areas to safer places, (2) building a community safe shelter where people can evacuate to during disasters, and (3) buying disaster insurance for property or crop losses. The study teams asked the respondents if they will support these adaptation options and results are given in Table 8.

As shown in Table 8, building a community safe shelter is favored by majority of the respondents in all countries. This was not given as an option in the Philippine study sites as most villages considered the town's public schools as evacuation shelters. A good number of the respondents pointed out though that building a dedicated community safe shelter is constrained by limited financial resources available to the community.

Getting disaster insurance, if it becomes available, is favored by a third of the respondents. Those who did not support it said that the main constraint for getting insurance is the lack of knowledge on how it works and where it can be secured. This is something that a better information and outreach campaign could easily solve.

Relocation is, of course, not that popular for almost all study sites, except those from Indonesia where about 65 % expressed openness to this option. Those who refused this option considered the financial difficulty of doing this and the loss of social and economic ties as the main constraints.

What Determines Adaptation Practices?

An analysis of the factors affecting households' adaptation choices in this cross-country project was carried out and reported in Francisco et al. (2011). The authors used the data from four countries: the Philippines, Vietnam, Thailand, and China with a total sample size of 1,711 households. The households' adaptation practices were classified as either reactive or proactive. Those that were carried out when the disaster is about to happen or has begun to happen are reactive measures. This would include evacuation and practices like reinforcing housing structures. Proactive measures are those carried out long before the event happens, usually, in anticipation of the rainy season or typhoon months. These measures include monitoring information sent through the early warning system, constructing elevated housing units, and building concrete walls or dikes to prevent flooding. Sixty-four percent (64 %) of the households did some form of reactive measures and about 31 % undertook proactive measures. About 6 % did not do anything (Table 9).

Using a multinomial linear (MNL) regression analysis, the authors found that households where members had received training on disaster preparation are less likely to just perform reactive adaptation measures and are more likely to opt for

Table 8 Recommended adaptation action by experts and why some households do not take them

Adaptation strategies	Percentage of households willing to adapt each strategy and main reason of those not willing to adapt (in parenthesis)

Adaptation choice	Frequency	Percentage
No adaptation (Y = 0)	99	5.8
Reactive measures (Y = 1)	1,090	63.7
Proactive measures (Y = 2)	522	30.5
Total	**1,711**	**100.0**

Source: Francisco et al. (2011)

proactive ones. Those with permanent types of houses and have more than a one-storey house are also likely to adopt proactive adaptation measures as well (Table 10). These variables are reflective of the higher economic status of the households, indicating that wealthier households would be more likely to take proactive adaptation measures.

Social capital (inferred from households seeking outside help) was also found to significantly influence household adaptation decisions. Those who sought help from outsiders (positive sign) would more likely use reactive measures. In contrast, those who found no need to seek help from others (negative sign), which is probably an indicator of economic independence, were more likely to opt for proactive measures (Table 10).

The adaptation choice analysis also reveals that increasing the number of information channels that provide news about extreme climate events will decrease the probability of undertaking reactive measures. This potential for rural climate information to support adaptation and climate risk management points to the need to make climate information more accurate, accessible, and useful for households (Roncoli et al. 2002; Ziervogel et al. 2005; Hansen et al. 2007 cited in Asfaw and Lipper 2011).

In terms of socioeconomic characteristics, a bigger household size is found to positively and significantly affect the probability of a household undertaking reactive adaptation measures. This indicates that with strength in number, people tend to be complacent about taking a more proactive stance to climate change. Moreover, the more educated households were more likely to implement proactive adaptation strategies than reactive ones. This is supported by Tiwari et al. (2014) who stated that households with more knowledge and information can be proactive in their response toward climate change. Other studies (Maddison 2006; Nhemachena and Hassan 2008) found that the age of the household head, which represents experience, positively correlated with the uptake of adaptation measures.

Finally, the analysis revealed that households were more likely to undertake reactive rather than proactive measures if they perceived the risk of future extreme climate events to be more severe than what they had previously experienced. This is unexpected and should be further investigated as this seems to imply the existence of an attitude of resignation to fate to climate change disasters.

This attitude of resignation was indeed expressed by some of the respondents. Their thinking is that since nature wills it, it cannot be controlled and is something we just have to live with. Surely, there are ways to reduce damages and this is the essence of undertaking effective adaptation measures to protect lives, property, and

livelihood from extreme climate change disasters. In fact, everyone should also be thinking of mitigation because while it is true that our generation is already committed to climate change, there are efforts that can be done to slow down climate change for future generations.

Coastal Communities' Vulnerability and Adaptation Practices

Coastal areas in Asia face "an increasing range of stresses and shocks," which are intensified by climate change (Cruz et al. 2007). This is supported by a 170-country assessment by Harmeling (2011) on the impacts of extreme weather-related events such as storms, flood, and extreme temperatures. The assessment showed six Asian countries to be among the most vulnerable, namely, Bangladesh (rank 1), Myanmar (rank 2), Vietnam (rank 5), the Philippines (rank 7), Mongolia (rank 9), and Tajikistan (rank 10).

That coastal communities are highly vulnerable to climate change is widely recognized (IPCC 2007, 2014; ADB 2009, 2014). Their vulnerability comes from the rising sea level that accompanies the overall warming of temperature as well as the storm surges that accompanies the increased frequency and intensity of typhoons. Low physical and financial capacity for disaster preparedness also contributes, to some extent, to these areas' vulnerability to extreme climate events (Ward and Shively 2011; Adger 1999); wealthier countries typically suffer lower social losses than poorer countries (Kahn 2005).

The threat from sea level rise has been in the radar of climate discussions during the last few years, but the threat from storm surges became real only with the Philippines' experience during super *Typhoon Haiyan* in November 2013. In just less than an hour, the 13 ft storm surges with strong current experienced during *Haiyan* left a death toll of 6,300 with 1,785 left unaccounted for. A few months after the super typhoon, more than 52,000 families are still living in tents in the danger zone in Tacloban City as the local government struggled to find a 100-hectare relocation site for these people (Lowe 2014; Stevens 2014).

Given the critical situation that coastal communities face as a result of the changing climate, EEPSEA also supported several research projects on CCA in coastal areas. This effort was done in collaboration with the WorldFish Philippine Country Office (WF-PCO) and came in two sets of projects. The first project focused on understanding the adaptation practices and assessing the vulnerability of selected coastal communities in the Philippines, Vietnam, and Indonesia. The various studies part of this first project looked into the impacts and adaptation practices used in dealing with typhoons/flooding, coastal erosion, and saltwater intrusion at the household, community, and local government levels. Several planned adaptation options were then evaluated using cost-effectiveness analysis (CEA).

The second project, which is still ongoing, looks into intra-household impacts of climate change, how the various members are affected, and how they can be engaged to generate a stronger household adaptation plan. Table 11 shows the

Table 11 Summary of climate change hazards, impacts, and compounding issues in the study sites

Batangas, Philippines	Palawan, Philippines	Jakarta, Indonesia	Ben Tre, Vietnam
Hazards	***Hazards***	***Hazards***	***Hazards***
Sea level rise	More frequent and intense typhoons	Coastal erosion and seawater intrusion	More frequent and intense typhoons
Confounding environmental issues	Floods	Coastal or tidal flooding	Destructive flood and tidal surges from 1996 to 2008
Coastal erosion	***Confounding environmental issues***	Sea level rise	***Confounding environmental issues***
Sand quarrying	Mangrove cutting for charcoal, housing, and fencing materials	***Confounding environmental issues***	Sand mining
Illegal charcoal making from mangroves	Weak enforcement of coastal management laws	Loss of most of mangrove and coastal ecosystems	Salinity intrusion
Illegal fishing using blasting and cyanide	Illegal fishing	Large population	Heavy traffic of sea vessels
Fishing with fine mesh net and superlight	Burning of some upland areas for rice farming (*kaingin*)	Pollution that affects water quality, soil erosion	***Impacts***
Impacts	Expansion of private beachfront property	Absence of strong fisheries policy and overlapping jurisdictions	Loss of shelter and livelihood from typhoons
Damage to property (hotels, resort, houses, and boat) during typhoon	Inadequate protection of the fish sanctuary	***Impacts***	Land encroachment
Coral bleaching and increasing number of crown of thorns	***Impacts***	Land subsidence, coastal inundation, and coastal abrasion	Saltwater intrusion during the dry season leads to a shortage of freshwater for domestic and production uses
Impacts to livelihood and tourism in vulnerable coastal areas	Change in the fish species caught	Seawater intrusion has reached the National Monument	
House relocation due to coastal erosion	More houses and boats destroyed by typhoons	Increased turbidity of water affecting photosynthesis	
Mangrove areas, coral reefs, marine protected areas, and beaches now at risk	Coral bleaching	Decreasing water quality	
	Decreased land area due to coastal erosion	Change in the pattern of flow, bathymetry, and coastline	
	Loss of traditionally gleaned shells along the coastline	Sediment accumulation in the entrance of harbor lanes increases dredging costs	
	Seawater is hotter during the 3–4 pm gleaning activity		
	Bangus fry collected for the past 5–6 years declined significantly		

Cf: Perez et al. (2013), shown as Table 3 in the original study

climate change impacts considered in the different study sites and the compounding environmental stresses that those communities face in addition to climate change.

In particular, most communities had to deal with coastal erosion, sand quarrying, deforestation of forests and mangroves, and rampant illegal fishing, all of which could compound the impacts of climate change. What Table 11 further tells us is that efforts to address the development needs of these coastal communities need to be holistic since theirs is a complex environment that is not necessarily affected only by their coastal location. Instead, it is important to note that coastal communities live in an environment that traverses several ecosystems, some of which are linked to one another. They are also affected by an economic and governance system that influences their livelihood and hazard vulnerability, be it climate change or other hazards. Moreover, they are also assisted by the government and other development agencies in how they cope with climate change impacts. These coping measures are further discussed in the next section.

Adaptation Practices in Selected Coastal Villages

In the Philippines, it is noticeable that all local governments have formed a municipal disaster risk management council (MDRMC) that is funded using 5 % of the 20 % Development Fund (Table 12). This fund is used to provide disaster victims with food, particularly those who stay in evacuation centers during disaster events. The fund is also used to undertake information, education, and communication (IEC) campaigns on disaster risk reduction (DRR). In addition, local governments conduct dredging and river widening activities to reduce the flooding threat as well as to rehabilitate mangroves, which are now widely believed to provide protection from coastal erosion and flooding.

The same efforts are reported in the Indonesia and Vietnam study sites. In addition, Vietnam reports of technological support to farmers in the form of drought/flood-tolerant varieties and modified farming systems to suit the new climate (Table 12). Vietnam is also doing more structural measures, in the form of dike and pond system, to support livelihood. Indeed, as noted by Francisco (2008), there are a lot that countries in the region could learn from Vietnam on how they have been living with flooding.

Adaptation practices at the community and household levels were also obtained during the study. It is worth noting that most local government initiatives involved the community. Community folk participated in mangrove replanting, dike repairs and construction, and in other activities to improve their environment and help prepare for disasters. At the household level, adaptation practices included relocating and strengthening of houses, putting up defense structures like cement dikes, engaging in alternative livelihood activities to enhance financial security, and shifting fishing/farming practices to suit new and changed environments, particularly in Vietnam.

Table 12 CCA and disaster mitigation strategies in the study sites, 2012

Government-led initiatives	Community-based initiatives	Autonomous household adaptation practices
San Juan, Batangas, Philippines		
Organized MDRMC, which is financed by 5 % of the 20 % Development Fund Gave out cash support (e.g., PhP 1,000–2,000 to affected fisher folk) River dredging and widening to prevent flooding Regular IEC campaigns Maintenance of Marine Protected Areas, mangrove replanting, and engagement in "Billions of Trees Project" in 400 ha of upland, lowland, and beach side areas	Aquaculture and fish processing projects Mangrove replanting Crown-of-thorns starfish removal, as spearheaded by resort owners Typhoon warning system improvement and preparation for emergency evacuation Cleanup of drainage and flood control structures	Relocate or strengthen house structures Plant and sell mangrove seedlings Temporarily remove light structures in beach areas Join savings/credit cooperative Modify planting schedules
Honda Bay, Palawan, Philippines		
Passed an ordinance to conserve, protect, and restore (CPR) the Puerto Princesa City's sources of life Flood control project implementation and construction of breakwaters Mangrove reforestation Established a barangay disaster risk management council (BDRMC) with fund allocation	Establishment/ maintenance of fish sanctuary Participation in riverbank bioengineering projects (e.g., sea dike construction, mangrove reforestation) to reduce erosion and siltation Establishment of community-based early warning system and provision of temporary evacuation center	Use of indigenous materials to strengthen housing structures Use of cement and rocks to build dikes
Jakarta Bay, Indonesia		
Implemented measures related to watershed management and coastal and marine resources protection Conducted capacity building and community empowerment activities to implement watershed and marine and coastal resources management Promoted policies that integrate environmental concerns in economic development Encouraged institutional strengthening for river basin management and coastal and marine bay management	Community involvement in various initiatives to protect watershed and coastal and marine resources Construction of permanent embankments Drainage improvement and river dredging Mangrove planting	Clean the beach fronting their houses

Cost-Effectiveness Analysis of Selected Adaptation Options

The results of a CEA of selected adaptation options, which were identified by LGUs as priority projects, are presented in Tables 13, 14, and 15. For the analysis, the researchers selected a common denominator, such as cost per unit of area protected or per household saved or protected. However, this is a very crude comparison as multiple types of benefits may be delivered by each of the adaptation options. For instance, a mangrove protection project will produce other types of benefits than what can be "produced" by installing a dike to protect a given area. As such, the comparison should be interpreted with caution. The last column in each of the next three tables provides some additional information regarding the interpretation of results.

For San Juan, Batangas, in the Philippines, sea wall construction and mangrove reforestation were compared, and results showed that it is a lot cheaper to prevent a kilometer of shoreline erosion using mangrove reforestation (Table 13). In addition,

Table 13 Cost-effectiveness analysis results for San Juan, Batangas, Philippines

Objective	Planned adaptation strategies	CE ratio	Notes
Protect the coastline from erosion	Sea wall construction	USD 0.16 M/ linear km of erosion prevented	Mangrove reforestation is not only more cost-effective but also offers other co-benefits like additional sources of income and marine biodiversity preservation
	Mangrove reforestation	USD 0.01 M/ linear km of erosion prevented	
Increase the number of households safe from typhoon/flooding	Zoning provisions and relocation	USD 0.07 M/ HH saved	The changing zoning provisions need to be accompanied by the removal of communities from areas they currently occupy, a very costly and socially unattractive option

Source:

this option produces other forms of benefits from the mangrove resources, both in terms of provisioning and regulating functions; if valued, these benefits will make this measure even more attractive.

The use of early warning system and the provision of evacuation shelter were also compared with improvement of zoning regulation and relocation. As expected, the latter was a lot more costly to implement as a way of protecting households from the negative impacts of flooding and/or typhoons. The early warning system is being put in place in many parts of the country.

A similar analysis was carried out for the Palawan, Philippines, study site (Babuyan in Honda Bay). Several options were evaluated: to protect households from storm surges (i.e., breakwater construction, dike construction, and mangrove reforestation), to protect them from inland flooding (i.e., upland reforestation, IEC with provision of temporary evacuation shelter, and household relocation), and to protect production areas (i.e., dike construction, riverbank rehabilitation, and river dredging). The results show the superiority of mangrove reforestation over structural measures, the cost-effectiveness of river dredging and riverbank rehabilitation, and support for an effective early warning system supplemented by IEC as part of DRR strategies (Table 14).

For the study sites in Jakarta Bay, Indonesia, several options with varying objectives were compared as shown in Table 15. River dredging[1] was found to be more cost-effective than the construction of new canals or embankment and even

[1]Note: The study did not indicate how often this has to be done.

Table 14 Cost-effectiveness analysis for Honda Bay, Palawan, Philippines

Objectives	Planned adaptation strategies	CE ratio	Notes
Protect households from storm surges and loss of property and minimize sand erosion	Breakwater construction	USD 0.276 M/HH	Mangrove reforestation is cost-effective in protecting households and properties and in minimizing sand erosion where mangroves are seen to thrive well
	Dike/levee construction	USD 0.032 M/HH	
	Mangrove reforestation	USD 0.019 M/HH	
Prevent river overflow and minimize siltation, which damage coconut plantations and fishponds	Riverbank rehabilitation using vetiver grass	USD 0.004 M/ha	The discussion on the planned options and cost-effectiveness (CE) ratios focused on prioritizing riverbed dredging together with riverbank rehabilitation using vetiver grass alone
	Riverbank rehabilitation using vetiver grass combined with mechanical method	USD 0.034 M/ha	
	Dike construction	USD 0.032 M/ha	
	River dredging	USD 0.002 M/ha	
Protect households from inland flooding	Upland reforestation	USD 926/HH	IEC is cost-effective but success depends on the maturity of the residents to react accordingly
	IEC/early warning system establishment and provision of temporary evacuation area	USD 120/HH	
	Household relocation	USD 2,234/HH	

Source:

mangrove rehabilitation. The high cost of mangrove rehabilitation is attributed to the need to purchase land from private landowners who already have rights over the areas previously occupied by mangroves. However, mangrove restoration is likely to make an even bigger contribution to the local economy in the face of climate change and the resulting increase in typhoon frequency and intensity (Tuan and Duc 2013). Mclvor et al. (2012) suggested that mangroves can potentially play a significant role in coastal defense and DRR.

Overall, one can see that the CEA results tend to favor mangrove reforestation over structural measures and river dredging in order to increase flood control function. The scientific basis for this claim was found in the study by Mazda

Table 15 Cost-effectiveness analysis for Jakarta, Indonesia

Site	Objectives	Planned adaptation strategies	CE ratio	Notes
Rorotan	Reduce the no. of HH affected by flooding	Construction of East flood canal	USD 307 M/ HH	The cost-effective option suitable in this area is the dredging of Sunter river
		Dredging of Sunter river	USD 0.695 M/ HH	
Marunda	Reduce the no. of HH affected by flooding and coastal flooding	Construction of permanent embankment	USD 2.5 M/ HH	The cost-effective option is planting mangroves
		Mangrove rehabilitation	USD 13.37/ HH	
Kalibaru	Reduce the no. of HH affected by flooding, coastal flooding, and saltwater intrusion	Road elevation	USD 2.64 M/ HH	The more cost-effective solution is to dredge Cakung river
		Dredging of Cakung river	USD 2.09 M/ HH	
Kamal Muara	Reduce the no. of HH affected by flooding and coastal flooding	Dredging of Pesanggrahan river	USD 2.09 M/ HH	The more cost-effective solution is to dredge Pesanggrahan river. A large portion of the cost of planting mangroves is the value of coastal land owned by private individuals or groups
		Mangrove rehabilitation	USD 2.43 M/ HH	
Muara Angke	Reduce the no. of HH affected by flooding and coastal flooding	Road elevation	USD 0.311 M/ HH	The more cost-effective solution is to elevate roads. Like in Kamal Muara, a large portion of the cost of planting mangroves is the value of privately-owned coastal land
		Mangrove rehabilitation	USD 2.07 M/ HH	

Source: Agus et al. (2013)

et al. (2006) and cited in Andrade et al. (2010). Moreover, the early warning system supplemented by evacuation shelter provision was found to be quite cost-effective compared with the other options evaluated. This finding is consistent with other studies' findings which validate the use of an early warning system as one of the most cost-effective measures to reduce damage cost (Hallegatte 2012; Linham and Nicholls 2010).

The next section describes efforts to link research with local government adaptation planning based on the experience from two cross-country projects implemented from 2011 to 2013.

Working with Local Governments in Adaptation Planning

Climate change will affect everyone. Differences on the impacts felt will depend on the locality's hazard exposure, the people's adaptive capacity, and the LGU's level of preparedness. This means that adaptation planning has to be locale specific to suit the conditions and capability of different local governments.

In order to bring research to the level where it can have impact, EEPSEA supported two multi-country projects to engage local government planners in adaptation planning in 2011–2013.

CBMS-EEPSEA Project

The main funding source of EEPSEA, the International Development Research Centre (IDRC), also supports a Community-Based Monitoring System (CBMS), a global project with presence in the Philippines, Vietnam, and Indonesia. The CBMS-EEPSEA partnership was carried out to pilot test the application of the EEPSEA framework on climate change vulnerability assessment and mapping at the local level using CBMS data and supplemented by data from other government sources. There are two outcomes that were expected from this initiative: (1) LGU level capacity building on understanding how to assess climate change vulnerability and (2) identification of adaptation strategies based on research done on this topic.

The study sites included (1) Vietnam, Kim Son district of Ninh Binh province in the North, Nghia Lo municipal of Yen Bai province in the North Mountainous Region, and Tam Ky town of Quang Nam province in the Central Region; (2) Indonesia, two villages in the province of Kota Pekalongan (Pasirsari village, Kecamatan Pekalongan Barat, and Panjang Wetan village, Kecamatan Pekalongan Utara); and (3) the Philippines, municipality of Carmona in Cavite province and Marinduque province.

Experience in pilot testing the climate change vulnerability framework shows that its main advantage is its simplicity, which allows local government decisionmakers to understand what factors they should consider when doing such an assessment. The ability to map information that allows government officials to immediately see how they fare relative to their neighbors was also found attractive.

Experience in using vulnerability mapping to aid in identifying suitable adaptation strategies varies across the participating country teams. The Philippine teams managed to bring the discussion to the point that they were able to identify the adaptation practices that need to be strengthened and those that need to be implemented as listed in Table 16 (Reyes 2012). The Vietnamese team shares that the process helped them understand the location and the sources of vulnerability but that these were not sufficient to assess what the community needs in order to adapt to the changing climate.

In a way, identifying the adaptation practices that the community or the local government could undertake is indeed only the first step. Given limited resources

Table 16 Adaptation strategies identified in the Philippine CBMS-EEPSEA project

Study site	Adaptation strategies identified
Carmona, Cavite	Strengthen current efforts in: river cleanup, solid waste management, and de-clogging of canals and waterways Conduct more orientations on DRR management, enhance DRR communication capability and early warning system with new equipment and strengthen flood forecasting, and upgrade evacuation and health facilities Install diversion canals, dams, and reservoirs to protect industrial and agricultural lands
Marinduque province	Review/update and enhance the provincial DRR management plan Strengthen the rehabilitation of watershed areas and reforestation projects through the National Greening Project (NGP), Bamboo Greenbelt Project, and other forest rehabilitation projects Build LGU and community capability and capacity on the various facets of DRR (i.e., warning, search and rescue, emergency relief, logistics and supply, communication and information management, emergency operation management, evacuation planning and management, health emergency education, and post disaster management) Establish/construct evacuation centers in safe areas and improve and construct roads and feeder roads, drainage facilities, footbridges, spillways, and floodways in priority areas Produce and disseminate natural hazard and geographic info system susceptibility maps and IEC materials and install Integrated Warning/ Communication and Response System Install automatic weather station in major critical areas such as Boac and Sta. Cruz

Source: Reyes (2012)

and varying capacity, an assessment of the economics of these measures and their technical and social acceptability must be carried out as well; these are not within the scope of the CBMS-EEPSEA project.

In the case of the Indonesian team, the adaptation policies and programs of the national and local governments were discussed and analyzed as a separate activity from the vulnerability mapping. The analysis revealed that current adaptation planning is largely addressing the hazard component of vulnerability, which they pointed out is a major limitation on account of the findings of the project. In particular, the CBMS-EEPSEA project showed clearly that adaptive capacity and sensitivity are equally important sources of vulnerability and should therefore be addressed as well.

All the project country teams recommended that similar efforts be done to assist other LGUs to better understand their vulnerability situation and to help them identify adaptation practices. To help evaluate the economic viability and acceptability of these identified strategies would require a longer time and a different set of skills, as demonstrated in EEPSEA's project with IDRC's Climate Change and Water program, which is discussed in the next section.

CCW-EEPSEA Project

In February 2011, EEPSEA and the IDRC program on climate change and water (CCW) awarded three 3-year research grants to institutions based in the Philippines, Vietnam, and Cambodia. The project, entitled "Building Capacity to Adapt to Climate Change in Southeast Asia," aimed to enhance the capacity of university researchers, provincial officials, LGU representatives, and other mass organizations in selected SEA countries by equipping them with knowledge on how to assess climate change causes and impacts and how to undertake an economic analysis of selected adaptation options.

Specifically, the collaborating partners were expected to undertake vulnerability analysis, prioritize adaptation options, and develop sound and feasible project proposals for funding. Based on the highly vulnerable sites identified in Yusuf and Francisco (2009), the project selected the following study sites: Kampong Speu in Cambodia (highly vulnerable to drought), Laguna in the Philippines (highly vulnerable to flooding), and Thua Thien Hue in Vietnam (exposed to flooding and typhoons).

The project adopts a multidisciplinary and participatory approach. Each country research team is composed of researchers with backgrounds in natural science, sociology, and economics. Their mandate was to work with their study site's local government officials in undertaking vulnerability assessment, in identifying and evaluating adaptation projects, and in developing the CCA proposal/plan for submission to donor agencies.

During project implementation, the research team implemented a series of training courses, joint field visits, and dialogues with community members. The key skills that the training courses addressed are vulnerability assessment and mapping following the framework used in Yusuf and Francisco (2009), evaluation of climate change impacts, economic analysis of adaptation options, and proposal development for adaptation funding support. Interestingly, many of the team members are now being involved in providing consultancy services on these areas in their own countries – a sure offshoot of their engagement in this project.

The engagement of the local government people in the project had brought about several benefits, namely, (1) greater awareness on climate change risks; (2) generation of risk maps, which were used to develop agricultural production plans for three subregions in Thua Thien Hue; (3) integration of climate risks in the socioeconomic development plan; and (4) improved knowledge on how to conduct vulnerability assessment and economic analysis of adaptation options as well as proposal development. They were also able to network with government people from other countries as the project hosted sharing and training meetings as part of the capacity building activities designed for the collaborators.

A post project survey was implemented to assess changes in knowledge and skills of the people involved in the project. All team members across the three countries demonstrated improved understanding of the climate change problem and a higher level of knowledge on the various tools that were used by the team. The

biggest improvement was noted among the research team members from Cambodia.

In terms of concrete actions taken up, local government partners in Thua Thien Hue have developed agricultural production plans based on the results of the climate change vulnerability map that was prepared through the project. The Thua Thien Hue LGU staff developed proposals to raise funds for the construction of local CCA measures, particularly better use of water in rice production.

The LGU partners in Laguna, Philippines, now have better appreciation and knowledge on how to implement vulnerability assessment and mapping and how to package proposals, but they acknowledged that they may not be able to carry these out on their own. Their reservation regarding their independent implementation/conduct of such activities is not due to perceived capacity constraint but more as a result of their busy schedules as they are responsible for multiple projects at the provincial office.

The project research findings also affirmed the findings of previous studies. First, that vulnerability to climate change is quite high and that it varies across areas. In Thua Thien Hue, Vietnam, households living in delta communes had higher adaptive capacity compared with households living in coastal and upland communes. The social capital was found to be generally high but limited infrastructure support, access to technology, and lower financial resources contributed to lower adaptive capacity for many households.

In Laguna, Philippines, higher vulnerability was noted among coastal communities compared with agriculture-based households. Interestingly, it was found that a big proportion of the vulnerable households are not knowledgeable about the threats posed by climate change. The most vulnerable households are often the most poor as well and so it probably makes no difference where their poverty stresses are coming from. In terms of experience with climate-related hazards, majority identified typhoons and flooding as the hazards posing the greatest threat based on experienced damages over the years, most intensely in the last few years. The biggest losses/damages come in the form of damages to houses and furniture. About 16 % of the households regularly experience evacuation, and a tenth of those interviewed had experienced permanent relocation as supported by the local government of Sta. Cruz, Laguna. The important role played by social capital, particularly those involving women's organizations, in accessing DRR programs was also highlighted in the Philippine study site.

The study site in Kampong Speu, Cambodia, is predominantly a farming community and is threatened mostly by drought, with flash floods occurring in certain areas only. Vulnerability was found highest in the eastern and central western regions of the province on account of the highest concentration of vulnerable communes in these areas. Farming households in lowland areas have been coping with drought conditions by shifting to short-duration crop varieties. Those in mountainous areas were found less willing to shift to new varieties, but they generally have more resources to cope with the impacts of a changing climate. For both sites, other adaptation strategies included: constructing and renovating canals, selling household assets, and migrating to

work outside the village (e.g., work in a garment factory, as household help, and in construction).

The teams also packaged adaptation proposals, which the LGUs can then submit for funding support: (1) a technology-based flood early warning system for the Sta. Cruz River Watershed in Laguna, Philippines; (2) improved irrigation system for Kampong Speu, Cambodia; and (3) upgrading of the An Xuan tributary banks and river dredging in Thua Thien Hue, Vietnam. These projects were found to be the most economically efficient option for the three sites based on the economic analysis of several alternative projects.

Lessons in Action Research: Working with Local Government Units

The researchers of the two projects considered working with the local governments both rewarding and productive. They are able to immediately share and discuss with local government planners their research results as the study progresses. The local government collaborators were involved more deeply in data analysis and presentation as they were engaged all throughout the project. Hence, there is joint ownership of the research reports, which was linked to adaptation planning more directly, unlike in the traditional research process. More importantly, there is improvement in the knowledge and skills of not only the researchers but also of their collaborating local government partners. All these are expected to result in a better understanding of the problem and a higher capacity to assess, evaluate, and decide on how it can be addressed.

Nonetheless, it must be mentioned that the heavy workload of the local government partners prevented them from being more engaged in the research process. They are only engaged in the project part time with DRR/climate change being only one of their many other responsibilities in their capacity as local government staff. The same can be said of the university researchers who are only working part time with the research. They meet and work with their collaborators only during meetings or major activities.

Perhaps, the project duration for the CCW-EEPSEA project is too long (i.e., 3 years), and that of the CBMS-EEPSEA project (i.e., 1 year) is too short. The CCW-EEPSEA project differs from the CBMS-EEPSEA project in that it is longer and thus has more resources. Its idea is to fully understand the various aspects of vulnerability by forming three teams (i.e., economic, social, and mapping teams) and to analyze and characterize who are the most vulnerable sectors in the locality. The team is comprised of university researchers, LGU representatives, and representatives from NGOs working in the community. On the second year, the potential and existing adaptation practices were identified and evaluated. An economic analysis of those options was carried out. In the last year, the team assisted the LGU in developing a proposal to seek support from donor organizations to fund their adaptation plans. This 3-year project completely contrasts with the 1-year duration of the CBMS-EEPSEA project, both in terms of depth of analysis and resources.

From a program point of view, it will appear that having 2 years for both projects will be a Pareto improvement. The CBMS-EEPSEA project would have more time to expand its adaptation analysis. On the other hand, 3 years may have been too long for the CCW-EEPSEA team as the members managed to do multiple assignments that took them away from a more concerted, focused analysis of the problem on hand. Somewhere in between these two project durations could result in a more intensive interaction between researchers and their local government partners as well as richer data collection and analysis.

Lessons from EEPSEA-Funded Climate Change Adaptation Research in Southeast Asia: Future Directions

Climate change is here to stay and is likely to get worse given that serious commitment to reduce greenhouse gas (GHG) emission will only happen starting 2020 *if*, *and only if*, the 2015 International Agreement with significant GHG reduction commitment will be signed by all countries in Paris. The prospect of having such a stronger agreement in place does not look good given how previous talks have failed on this front. We can only hope that our global leaders will come to their senses and put in place serious efforts to reduce GHG emission to slow down climate change.

On the positive side, it is good to hear about various countries' efforts to move toward a green economy by using more efficient technologies, building high energy savings, and investing on ecosystem reforestation or protection. However, these efforts cannot be done at a microscale – we need government commitment to pass stronger measures to reduce carbon emission. Surely, a carbon tax supplemented by programs to reduce impacts on the poor is a step in the right direction but is opposed in many countries because of strong lobbying pressure by those sectors who will be hit by this measure.

With the exception of climate deniers, everyone agrees that climate change poses a real threat to people, with some countries facing (and in fact, already experiencing) more serious challenges than others and the poor being more vulnerable to it. The various research supported by EEPSEA on CCA in SEA proved that the impact of extreme climate events on those affected is huge with an extreme event costing households up to 44 % of their annual household income. Depending on the number of extreme climate events (which unfortunately is expected to be more frequent and intense in the future), future damage can be even bigger and will most likely drive vulnerable households to extreme poverty.

Despite the severity of the situation, adaptation actions by SEA households are generally very crude and mostly in the form of reactive measures (e.g., strengthening housing units, using sandbags during flooding, storing of food, evacuation) rather than preventive ones (e.g., relocation, building multistorey and stronger housing units). Largely, this is explained by the limited resources available to most vulnerable households for investment in stronger measures. Moreover, in

many cases, there is still the hope that extreme events will not occur that often in the future or that they are used to this condition already and will be able to manage.

This complacency is now being addressed by enhanced IEC campaigns that most governments are launching toward DRR/climate change. A lot of this effort needs to be done more widely and intensely, but stronger adaptation investments need to be made if adaptation capacity or resilience is to be enhanced in areas most vulnerable to climate change. The financial resources available to these communities are undoubtedly small in relation to needs and efforts must be done to provide more resources and/or use more wisely the limited resources available. Hopefully, developing countries in the region will be able to access some of the adaptation funds available, and the economic analysis done on some of these measures was found to be economically viable.

Local governments need support in adaptation planning. The two action research projects carried out with funding support from EEPSEA and the collaborating organizations (IDRC's CBMS and CCW) showed that local government officials are receptive to such research collaborations and are very much willing to learn science-based planning. With more resources provided to free up some of their time during the conduct of such action research projects, a higher-level and more fruitful engagement can perhaps be expected from them. In addition, our experience shows that there are existing programs (e.g., CBMS, WorldFish, etc.) in most communities that researchers can tie up with so that synergy can be achieved in getting more resources and technical expertise in the action research.

Finally, given the urgency of the situation and the relatively higher level of research information now available from different organizations working in SEA, it is high time to move toward research that feeds directly into concrete actions, to not simply come up with plans and proposals but with adaptation projects/measures that can be readily implemented on the ground. This calls for action research with some funding available to pilot test adaptation projects that will be evaluated as part of the research. This is not going to be easy as there seems to be a dichotomy between research and development. In most cases, research organizations just do research while development organizations focus on development projects. This is so unfortunate in this instance since concrete actions supported by science are what we need to help prepare local governments, communities, and households to better adapt to climate change. Research alone oftentimes translates to *just pure talk*; action research is *walking the talk*.

Impact of Climate Change, Adaptation, and Potential Mitigation to Vietnam Agriculture

Trinh Van Mai and Jenny Lovell

Contents

Abstract

The Institute for Agricultural Environment of Vietnam conducted a research to study climate change impacts on agriculture, develop climate change adaptation measures, and identify mitigation options. Climate change impacts were

assessed through past, current, and future conditions. Past information showed damages due to extreme weather events. Current production and climate conditions showed potential vulnerability. Future climate change scenarios and crop growth modeling predicted long-term impacts on crop production. The impacts of many adaptation measures and mitigation options were evaluated to reduce risks and losses from climate change and to reduce greenhouse gas emissions. Results showed that climate change has caused strong impacts on agriculture in Vietnam. It has caused severe damages in the past, and it is likely to cause high vulnerability and heavy crop production losses in the future. Flat lands experience stronger impacts than highlands, with the Mekong River Delta suffering the strongest impacts, followed by the Coastal Central area and Red River Delta. As a country strongly impacted by climate change, it has suffered many extreme events and disasters. The agricultural sector has developed suitable adaptation measures to cope with the extreme events. Vietnam maintains a high agricultural productivity not only to feed more than 70 million people but also to export a high amount of food and foodstuffs. Vietnam is the leading cashew nut exporter, second highest rice exporter, and third highest coffee exporter in the world. However, with extensive areas of rice paddy production and high animal populations, Vietnam's agriculture contributes substantial greenhouse gas (GHG) emissions. As a result, the Vietnamese agricultural sector is developing and implementing many mitigation options, such as alternative wetting and drying irrigation, biogas digestion, composting, and converting rice land to non-rice land. These policies target a 20 % GHG emission reduction by 2020 in comparison to the "business-as-usual" scenario.

Introduction

Climate Change in Vietnam

Climate change is projected to impact human and ecosystems health at global, regional, country, and local scales. Due to human-induced greenhouse gas (GHG) emissions to the atmosphere, climate change will cause a cascade of environmental changes. These effects will particularly impact agricultural production.

The main causes of climate change are the accelerated increase of GHG-emitting activities, combined with the exploitation of carbon sinks, such as forests, and the destabilization of natural carbon sequestration mechanisms, such as oceans. The Kyoto Protocol aims to prevent and stabilize the emission of six main GHGs including carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrochlorofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF6). Of these GHGs, the most abundant and concerning is CO_2, which originates primarily from anthropogenic fossil fuel combustion of coal, oil, and gas. The second most important GHG is CH_4, which is emitted from landfills, enteric fermentation, air-cooling systems, coalmines, and natural gas.

These emissions increase GHG concentrations in the atmosphere, causing global warming and higher temperatures; glacial melting leading to the loss of lowlands and islands; shifting borders between ecological and agroecological zones that have existed for thousands of years; altering atmospheric, hydrologic, and biogeochemical cycles; and altering the functional components and quality of the hydrosphere, biosphere, and geosphere. These impacts ultimately result in profound changes in natural and human system productivity.

Because Vietnam is considered one of the countries most strongly impacted by climate change Dasgypta et al. (2007), the Government of Vietnam has paid a lot of attention to this issue. Climate change and sea level rise scenarios were developed for Vietnam as a foundation for assessment of impacts on sectors and regions in order to take proper responsive actions.

Extreme Events in Vietnam

Temperature

Changes in annual temperature over the past 50 years in Vietnam have been inconsistent in different regions. Overall, the average annual temperature increased by approximately 0.5 degrees Celsius (°C). The maximum temperature change ranged between −3.0 °C and 3.0 °C, and the minimum temperature change varied between −5.0 °C and 5.0 °C compared with the historical average (MONRE 2012), similar to the global temperature trends.

Rainfall

During the past 50 years, rainfall tended to decrease in northern regions but increased in southern regions. In the northern climate zones, rainfall has changed insignificantly in the dry season (from November to April) but decreased between 5 % and 10 % in the rainy season (from May to October). In the southern climate zones, rainfall decreased dramatically in the dry season but increased from 5 % to 20 % in the rainy season (MONRE 2012). However, the overall trend of average annual rainfall is to decrease in north and to increase in the south. In particular, rainfall increased by about 20 % in the southern central region compared to other regions (Table 1).

Typhoon

Annually there is an average of 12 typhoons or tropical depressions that affect Vietnam. Of these storm systems, 45 % originate from the Eastern Sea and 55 % originate from the Pacific Ocean (MONRE 2012). The Central Coastal areas of Vietnam, lying between 16°N and 18°N, and the Northern regions above 20°N, have the highest frequency of typhoons and tropical depressions.

Drought

Drought, including monthly water scarcity and seasonal scarcity, has increased overall but inconsistently. Drought impacts shift depending on the region and weather station within the same climate zone. Overall, the number of hot days

Table 1 Increase of temperature and changing of rainfall during 50 years in agro-climate zones of Vietnam

Agro-climate zone	Temperature (°C)			Rainfall (%)		
	January	July	Year	Period November–April	Period May–October	Year
Northern West	1.4	0.5	0.5	6	−6	−2
Northern East	1.5	0.3	0.6	0	−9	−7
Red River Delta	1.4	0.5	0.6	0	−13	−11
North Central	1.3	0.5	0.5	4	−5	−3
South Central	0.6	0.5	0.3	20	20	20
Central Highlands	0.9	0.4	0.6	19	9	11
Mekong River Delta	0.8	0.4	0.6	27	6	9

Source: IMHEN (2010a)

increased significantly across the country, especially in the Central and Southern regions.

Sea Level Rise

Satellite data from 1993 to 2010 indicated that the sea level in the Eastern Sea is rising at a rate of 4.7 mm per year. This translates to an average sea level rise along Vietnam's coastline of 2.9 mm per year. However, the coastal areas in the Central regions and the Southwestern region have higher sea level rise than other coastal areas.

Climate Change and Sea Level Rise Scenarios in Vietnam

In 2009, the Ministry of Natural Resources and Environment (MONRE 2009) published the first edition of Climate Change and Sea Level Rise Scenarios. The report included low-resolution forecasting for the seven climatic zones of Vietnam. MONRE designated the Vietnam Institute of Meteorology, Hydrology and Environment (IMHEN) as the leading agency on detailing and updating climate change and sea level rise scenarios for Vietnam. In collaboration with other research institutes, government agencies, and departments, the team prepared updates in 2010 and developed climate models and selective statistical tools specialized for Vietnam. Through this collaborative work, MONRE published the second edition of higher-resolution climate change and sea level rise scenarios for Vietnam in 2012 (MONRE 2012). The report included details at regional scales and an additional climatic extreme section.

Vietnam Agricultural Production

Although the agricultural sector only accounts for 20 % of Vietnam's gross domestic product (GDP), the industry plays a crucial role in Vietnam's economy. The sector is

responsible for feeding more than 70 million people. While Vietnam has seen a substantial increase in industrial production, the agricultural production has continued to increase at a slower rate over the past 10 years. The average annual growth rate of agriculture remained at about 3.5 % but has decreased in recent years due to the severe effects of climate and soil conditions. For example, in 2005 it accounted for 19.3 % of the GDP, and in 2012 it had only increased to 19.67 % of the GDP.

The makeup of Vietnam's agricultural outputs shows no significant change in recent years. Food crops are the biggest proportion of Vietnam's agricultural sector, accounting for 74.6 % of the total production. Crops are followed by livestock production, which accounts for 23.8 %, and agricultural services makes up the remaining 1.58 %. Crop production still plays the biggest role by far. There was a very slight decrease of the proportion of crop production between 2005 and 2012, from 76.39 % to 73.81 %. During this time livestock production filled that gap with an increase from 21.95 % to 24.65 %.

Crop production is dominated by annual crops, which account for 83.4 % of the area under production, and perennial crops, which account for 16.6 %. Most of the annual crops are cereals such as rice, maize, and soybeans, which make up 78.5 % of the annual crop production area. The remainders are commodity and annual industrial crops, covering about 9.4 % of the annual crop area. Because Vietnam's agricultural sector is dominated by annual crops, it is a highly important resource for food and economic security. Annual crop systems are highly vulnerable to weather and will be strongly impacted with a more variable and changing climate (Table 2).

Impact of Climate Change on Agriculture

Agriculture Vulnerability

According to Patnaik and Narayanan (2005) and Iyengar and Sudarshan (1982), agricultural vulnerability can be calculated using an index based on three factors: exposure to a hazard, sensitivity, and adaptability. This index approach is shown in Table 3.

Damages in Agriculture Production Associated with Climate Change

Damages Due to Natural Disaster, Drought, and Flood

Vietnam is located on the eastern seaboard of Southeast Asia, an area frequented by natural disasters. Climate change adds complexity to this system, increasing the frequency of typhoons and extreme hot and cold weather, droughts, landslides, and flooding. According to historical meteorological data, an average of 6.96 typhoons hit Vietnam annually between 1950 and 2008. The number of typhoons increased over the years, and, more importantly, these typhoons occurred later in the rainy season between 1990 and 2008. Between 1950 and 1990, typhoons would normally

occur in August. However, between 1990 and 2008, they appeared regularly in October and November, much later in the season. There are also more extreme typhoons with higher intensity affecting the whole country. Historically, the highest typhoon speed was between 118 and 133 km per hour (km/h), which is an intensity of 12 on the typhoon Beaufort scale. In recent years typhoons have reached speeds of between 134 and 183 km/h, an intensity of 13–15. As a consequence of these more extreme events, there have been stronger impacts on agriculture production.

Data in Table 4 indicates that the average annual damage to agriculture during the period between 1995 and 2007 was 781.74 billion VND (equivalent to 54.9 million USD). This accounts for 0.67 % of agriculture's GDP (comparing to the 1.24 % GDP loss of all sectors caused by natural disasters). While agricultural production is a small portion of the country's income, the industry feeds more than 71.41 % of the population. Any damages to agriculture caused by natural disasters resulted in severe impacts on poor people, for whom it is very difficult to recover from a shock (Table 5).

Damages Due to Sea Level Rise

Without major action such as dyke reinforcements and improved drainage systems, a 1 m rise in mean sea levels along the coastline of Vietnam would cause an estimated threat of inundation to 17,423 km^2 (km^2) or 5.3 % of Vietnam's total land area (IMHEN 2010a). Specifically, it would threaten 39 % of the Mekong Delta, 10 % of the Red River Delta, and over 2.5 % of the Central Coast provinces. Moreover, 33 out of 63 provinces and municipalities, or 5 out of 8 economic regions, are threatened by severe inundation (IMHEN 2010a). The effects of sea level rise on saline water intrusion are significant, especially for the Mekong River Delta. In the period between 1980 and 1999, the 4 % salinity level reached 22.0 kilometers

(km) inland on the Red River. With 1 m mean sea level rise, by the end of the twenty-first century, the 4 % contour line will penetrate 4.5 km further inland into the Red River (IMHEN 2010b; Table 6).

Based on projected impacts due to sea level rise scenarios developed in 2009 and updated in 2012 by MONRE (2009, 2012), potential loss in rice production (rice equivalent) of the Mekong Delta will be about 7.6 million tons per year, equivalent to 40.52 % of the total rice yield toward 2100. If climate change and sea level rise happen as predicted in the scenarios and if the average annual yield of rice production remained unchanged, Vietnam would face serious problems of food shortages in 2100 with a 21.39 % rice yield lost.

Damages Caused by Changes in Climate Factors on Crop Production

For this damage, the impact of climate change on crop production was determined using crop growth models performed by the Institute for Agricultural Environment (Mai Van Trinh and Nguyen Hong Son 2011). The model used long-term climate factors such as maximum temperature, minimum temperature, rainfall, sunshine hour, humidity, and evaporation as the data inputs for the model. Potential rice, maize, and soybean yield in the spring and summer seasons, as well as yield changes due to altered climatic parameters, were determined in seven different ecological regions. Two provinces were selected for each region (Table 7).

Table 6 Forecast of rice yield loss according to 1 m sea level rise scenarios in MDR

*Compare to 2008 production

IAE simulated crop yield for the years 2030 and 2050 under climate change conditions compared with normal climatic conditions. The simulation showed that rice yield will be reduced by 8.18 % and 15.06 % in 2030 and 2050; maize yield will be reduced by 18.71 % and 32.91 %; and soybean yield will be reduced 3.51 % and 9.03 %, respectively (Mai Van Trinh and Nguyen Hong Son 2011).

Quantify the Impacts Through Calculating Indexes

Vulnerability Index

Vulnerability indices of the agricultural sector for seven ecological zones were calculated following Patnaik and Narain (2005) and Iyengar and Sudarshan (1982). Results (Fig. 1) show that agricultural production in the Mekong River Delta and the South Central region are the most impacted by climate change with the highest vulnerability score. Their vulnerability is due to high annual rainfall, high average annual temperatures, high unemployment rate, long coastal exposure, and a large proportion of agricultural land.

Damage Index

Table 5 shows impacts of extreme events on agriculture, and Fig. 1 shows a damage index from 2001 to 2008. From these estimates, IAE concluded that South Central, North Central, and the Mekong River Delta were the most damaged by climate change. The Central Highlands, Northern Midlands, and Mountainous Areas are less affected. Particularly, in 2010 and 2011, there were 10 and 6 typhoons, respectively. These typhoons hit the North and South Central regions, causing extreme property damage, human injuries, and deaths.

Impact on Crop Production

Based on climatic changes such as temperature and rainfall under the scenarios from 2020 to 2025 and crop yields under regular cultivation conditions, a crop production impact index for seven ecological zones in Vietnam was calculated and presented in Fig. 1. The Red River Delta, Mekong River Delta, and North Central areas are the top three regions that scored the highest on the impact index.

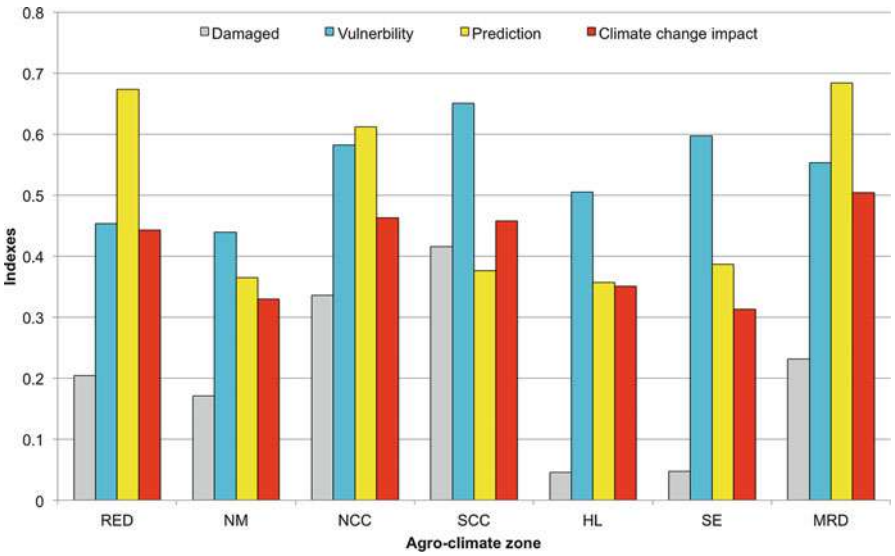

Fig. 1 Vulnerability indices, damages, crop yield prediction, and climate change impact

Indicators for Climate Change's Impact Assessment on Agricultural Sectors

An average of three indices were used as indicators to calculate impacts of climate change on different agricultural zones: a damage index, potential impact index (vulnerability), and forecasted impact index (impact of crop production). According to these indices, climate change will impact the Mekong River Delta the most, followed by the North and South Central Coast regions, and the Red River Delta. This result is also in line with the historical documentation of climate change in the regions. It can be used as a validated model to fully understand the impact of climate change and to develop adaptation measures and mitigation options for that region.

Climate Change Adaptation for Crop Production

Experiences in Climate Change Adaptation in Vietnam

In Vietnam, agricultural production is widely distributed in all ecological zones with climatic, geographic, soil, and crop characteristics. Because of this diversity, it is necessary and important to develop climate change adaptation measures for sustainable agricultural production in each region.

– *Northern Midlands and mountainous areas*: Rainfed crops that demand less water (such as sugarcane, cassava, and edible canna) are recommended to replace paddy rice. Additionally, upland rice and other crops that demand less water are

recommended for sloping land with the purpose of reducing dependence on the irrigation system and preventing soil erosion and degradation. In specific microecological zones in the high mountain areas with temperate climatic condition, Mai Van Trinh et al. (2014) recommend that farmers plant high-value medicine and herbal plants, such as black cardamom. This approach allows growers to gain the economic benefits of agricultural production while reducing impacts of extreme weathers, such as freezes and droughts, on perennial industrial crops. Farmers can also apply soil conservation methods on sloping land such as terrace farming, contour farming, windbreak, shading plants, and agro-forestry (Ha Dinh Tuan 2005). These valuable experiences can be transferred to other regions with the same conditions, facing the same climate change impacts.

- *Red River Delta*: The key crops of this region are paddy rice and annual industrial crops. Regarding climate change adaptation, changing the crop rotation, crop type, cropping calendar, and water supply are among the most popular methods to reduce risks from extreme events such as, drought, flood, and salinization. Specifically, for paddy rice production in the Red River Delta, the crop calendar can be changed with late transplanting of spring rice to avoid cold weather and increase rice yield. More importantly, changing of the crop calendar for an earlier summer season allows winter crops after the double rice crop. The farmers can achieve a better harvest with this modified crop calendar.
- *Central Coastal areas*: Adaptation measures in the Central Coast areas mainly focus on drought and desertification prevention for high water demand crops. Drought-tolerant crops are introduced to suitably grow in limited water supply conditions. New water sources, new farming methods, and modified cultivation techniques have also been introduced and implemented successfully in the region. For example, there is a new crop rotation including an annual rice, sweet potato, and cassava crop (Binh Dinh PPC 2010).
- *Southeast region:* As a semiarid ecological zone, adaptation measures in the Southeastern region mainly focus on changing the crop pattern and preventing drought for key crops such as cashew, peanut, sesame, sugarcane, and other annual industrial crops. IAE-ICRISAT (2010) showed that farmers in this region also want to reduce the rice production area and introduce other upland crops with lower water demand and higher profit values. These new crops, such as grapes and apples, improve grower's incomes and are more sustainable in drought conditions.
- *Central Highlands*: The main crops of the Central Highlands region are coffee, pepper, rubber, tea, and fruit tree. Most of adaptation measures aim to reduce water stress for these crops. In the same time, legume cover crops, fruit trees, and intercropping between annual crops and perennial crops should be implemented. These techniques increase income while maintaining soil moisture, protecting soil from erosion, and saving irrigation water.
- *Mekong River Delta:* As the most agriculturally productive region of the country, many adaptation measures, tools, and techniques are transferred to farmers in the Mekong River Delta. For example, extension workers promote suitable crop

selection, changing crop patterns or rotations, and integrating crop management to optimize crop production and reduce investment cost (Pham Quang Ha 2013).

Climate Change Adaptation Technologies

Prioritized Climate Change Adaptation Technologies in Agriculture

Plant Breeding

Using annual data on key crops between 1995 and 2008, IAE notes that rice, cassava, soybean, and sugarcane yields increased significantly (Table 8).

Yield increase under climate impact is a sign of strong adaptability in terms of food security. With the exception of a reduction in sweet potato production, yields from rice, maize, soybean, and peanut increased greatly between 1995 and 2008. Specifically, annual yields of rice, maize, and cassava production increased by 13.8, 3.3, and 5.0 million tons, respectively. The side benefits from yield improvements include increased photosynthetic biomass production, and therefore increased carbon sequestration in belowground biomass.

Climate change also causes changes in the frequency and severity of precipitation surplus and deficits. For example, Vietnam is experiencing a high number of rainfall events during the rainy season, which can lead to flooding and flash flooding. Conversely, less rainfall is associated with drought and salinization and works to increase the effects of sea level rise and saltwater intrusion. Observed data shows that saltwater intrusion moved inland from approximately 20 to 30 km from the shoreline in the Northern coastal line and between 50 and 70 km in the Southern coastal line (Mai Van et al. 2014). For this reason, the government encourages farmers to introduce and implement flood-, drought-, and salt-tolerant varieties. Many of rice varieties were introduced and successfully implemented in practice,

such as rice varieties of OM5464 (Tran Thi Cuc Hoa 2011), OM5629, OM5981, and OM7368 (Lang et al. 2011).

Water-Saving Irrigation (WSI)

One of the impacts of climate change on agriculture is reducing available irrigation water. Many reservoirs in the upland areas tend to run out of water before the rainy season comes, causing drought late in the dry season. Hence, water-saving irrigation helps to save water, better contribute water resources for the whole season, and secure crop harvesting in the dry season.

System of Rice Intensification (SRI)

SRI was first introduced in Vietnam in 2003 in three provinces (Hanoi, Hoa Binh, Quang Nam). SRI uses the following practices: (i) using young seedlings (2.5 leaves or 8–15 days old); (ii) transplanting one plant per hill (instead of three or four); (iii) irrigating with a minimum of water (a thin water layer of 1–2 cm deep); (iv) applying more organic fertilizers and reducing nitrogen fertilizer; and (v) hand weeding (Uphoff 2002). These practices could be modified to suite local conditions. SRI practices were highly recognized and accepted by farmers and local authorities in the Northern region. The Ministry of Agriculture and Rural Development (MARD) officially adopted SRI as a good farming package by issuing Decision Number 3062/QĐ-BNN-KHCN on October 15, 2007. In 2011, 21 of 33 provinces in the Northern region applied and implemented SRI with total area of 185,065 ha and 1,070,384 participant farmers (PPD 2011).

Produce Compost from Crop Residues

Previously, crop residues or by-products were mostly used as fuel for cooking, roofing material, animal fodder, or tilled back into the fields. Recently, because rural areas are urbanizing, the traditional rice straw roof is being replaced by brick and concrete; wood cooking stoves are being replaced by gas, electricity, and coal; and crop residues are becoming obsolete. Burning these residues after harvesting is becoming popular practice but causes a serious air pollution and GHG emission problem. One of the suitable solutions is to produce compost using effective microbials.

Rice straw is shown to have many positive effects when used as a crop residue. Pham Thi Nhung (2006) carried out field experiments during the winter maize seasons of 2004 and 2005 with fertilizer application of 8 t manure per hectare (ha); 150 kilograms (kg) of nitrogen (N), 90 kg of phosphorus pentoxide (P_2O_5), and 90 kg of potassium oxide (K_2O) per ha; and 5 t of dried rice straw per ha. Results indicated that rice straw increased rice yield by 6–8 % compared to the control of no rice straw application. Rice straw supplementation with 10 % N, 10 % P2O5, and 10–20 % K_2O increased maize yield by 7–8 % above the control treatment. Increasing the supplement to 30–40 % K_2O does not change the maize's yield, and at 50 % the maize's yield's reduced 4 %. This illustrates that rice straw is a nice complement to input supplementation, increasing the efficiency and reducing the amount of nitrogen, potassium, and phosphorus needed.

Reduced Tillage

On sloping land: Tillage is one important field activity for cultivating maize, cassava, pachyrhizus, and edible canna in the central and mountainous provinces. Adoption of reduced tillage has significantly expanded with labor-saving benefits and introduction of better fertilizer and herbicide use (CYMMIT 1991). For example, in Son La Province (Northwest region), over 23 % of the area under production applied reduced tillage. This includes more than 30,000 ha out of total 130,000 ha of maize production. Farmers were interested with this farming technique, and they learned to practice it. The technique has also been widely implemented in five other mountainous provinces.

On flatland: No till is mainly applied in the winter crops after a double rice crop. For example, no till is used in soybean, potato, and maize by directly sowing the seeds on soil surface after harvesting of the summer rice and then covering the seed with rice straw. This farming technique has gradually expanded and is implemented in between 25 % and 60 % of the total winter soybean and potato crops in the Red River Delta (MARD 2009).

Biochar Application

Biochar, or charcoal, is produced by pyrolysis of biomass under the absence of oxygen or oxygen-limited conditions. Many scientists *consider* biochar "black gold" in agricultural production. Biochar contains carbon in stable pools with slowed decomposition that transforms to active forms (CO_2, CH_4, and other GHGs) recommend to use (Feng et al. 2012; Liu et al. 2011). Therefore, biochar has high potentials in improving soil properties by increasing the soil's water- and nutrient-holding capacity and protecting soil microorganisms and in improving yields. More importantly, biochar is considered an effective approach to carbon sequestration by storing carbon permanently in the soil. The agricultural sector of Vietnam produces huge amounts of crop residues which can be pyrolyzed to become biochar. With an annual production of 61 million tons of rice straw and other annual crop residues (IAE 2012), there is a large source of inputs for biochar production in Vietnam.

Soil Surface Cover

Farmers cover soil surface in well-drained land (on terraces); high-evaporative, arid land; and sandy land with low water-holding capacity. The materials for covering include rice straw, tree leaves and trunks, and nylon. The technique is widely applied in the Central region of Vietnam. The area is characterized by large areas of sandy soil with low soil organic matter, nutrient content, high vulnerability to drought, and low crop yield. Surface cover helps seeds to germinate more fully and faster, prevents weeds from emerging, maintains soil moisture, and reduces nitrogen volatilization. Soil cover is most often used on peanut, soybean, and sugarcane fields (Le Duy Thanh 2004).

Change Land Use from Rice to Fruit Tree

In many areas, rice is not the most suitable crop for the conditions. For example, in areas where land is elevated and unfavorable for irrigation infrastructure, soil fertility

is low, or soil is waterlogged due to a depression or sea level rise, usually rice yields are very low. One of the effective measures is converting rice to fruit tree orchards, especially in Mekong River Delta. Large areas of lowland paddy rice were shifted into fruit-fish systems, sculpting the land into alternating bunches of fruit trees and ditches for fish ponds.

Change Intensive Rice to Rice and Aquaculture

(i) *Paddy rice and fish/shrimp system*
Fish/shrimp systems are a growing trend in Mekong River Delta as an option for breaking away from solely rice farming. The old systems include an annual triple rice crop (three rice seasons per year) or double rice crop (two rice seasons per year). Because of changing climate and hydrological conditions, the low-elevation areas were deeply flooded and could not support the triple crop. Rice crops that are flooded at harvest time maintain low and unstable yields, usually in the rainy season in mid-September. In the fish/shrimp systems, the flooded land is used for raising fish or shrimp instead of growing rice in the late rainy season (third or second rice season). This land use is growing quickly in Mekong River Delta. As of 2008, there were 120,000 ha under fish/shrimp production. This trend is in line with the MARD policy to expand this land use type in Mekong River Delta to adapt to climate change and diversify production.

(ii) *Rice/duck system*
The rice/duck system has been implemented for a long time in the Mekong River Delta. The duck populations in the region as of 2010 reached 20 million (GSO 2011–2014), 70 % of which was released into the rice fields to seek food left after harvesting. However, in recent years, as the severe impacts of bird flu, field-free duck breeding is not recommended. It is recommended that ducks be raised in planned areas to reduce disease outbreaks (Table 9).

Climate Change Mitigation

GHGs Emission in Crop Production

Because agriculture is a leading sector for GHG emission reduction, MARD issued a plan for reducing GHG emissions by the year 2020 (Decision No. 3119, 2011). The plan focuses on the following solutions:

(i) *Applying advanced farming techniques.* This set of practices is aimed at rice production and includes water-saving irrigation such as SRI. Another part of the advanced farming techniques program is the “three reductions and three gains” program, which includes a reduction of seed, nitrogen fertilizer, and other chemical inputs and gains of crop yield, product quality, and economic

Table 9 Potential prioritized mitigation practices in agriculture

#	Practice	Properties	Prospect
1	Genetics	Increase carbon sequestration, increase biomass and yield Increase flood tolerance, salt tolerance, and drought tolerance	High
2	WSI (water-saving irrigation)	Water saving and reduction in irrigation Increase fertilizer use efficiency Reduce CH_4 emission	High
3	SRI	Reducing costs on seeds, fertilizers, pesticides, and irrigation Reduce CH_4 emission	High
4	Production of organic fertilizers from agricultural residues/by-products	Replacement of inorganic fertilizers Reduce emission of N_2O (from dry land) and CH_4 (from flooded land) Reduce environmental pollution from burning agricultural residues or agricultural waste	Medium
5	Biogas	Prevent environmental pollution from livestock production Reduce N_2O emission Collect biogas to replace other fuels (wood, coal, gas, etc.)	High
6	Minimum cultivation	Reduce soil erosion, soil run-off, and carbon loss Reduce costs on tillage and plowing	Medium
7	Biochar	Recovery of 50 % carbon in crop biomass Stabilized carbon in soil for long time and reduce emission Significantly improve soil properties including fertility Increase fertilizer efficiency, reduce N_2O emission Use as alternative fuel	Medium
8	Soil cover	Reduce soil erosion and carbon loss Reduce N_2O emission Save irrigation, fertilizers, and weeding labor Reduce using pesticides	Low
9	Conversion from rice production to fruit tree plantation	Reduce CH_4 emission	Medium
10	Conversion from three rice season system to two combined rice/fish/shrimp system	Increase efficiency and bring more benefit of lowlands	Medium

benefit. This strategy is nicknamed the "3R3G." Another campaign is called the "1M5R" and focuses on reducing adoption of one standard seed variety and reductions of overall seed inputs, nitrogen fertilizer, chemicals, water, and postharvest loses. Alternate wetting and drying irrigation (AWD) is also encouraged to save water and reduce GHG emissions.

AWD application has been shown to reduce the global warming potential (GWP) of rice production. Pandey et al. (2014) reported that AWD irrigation reduced methane emissions by approximately 67–71 %. While there is a slight increase in nitrogen oxide, overall, there is a 62–67 % reduction in CO_2 emissions.

(ii) *Change land use type from rice to short-duration industrial crops*

The total area of rice cultivation in Vietnam was 7.89 million ha (about 4.1 million ha rice land) in 2013 (GSO 2011–2014). However, according to development planning for the agricultural sector Mard (2010), rice cultivation will see a reduction to 3.8 million ha (about 7.0 million ha of cultivated rice land). Firstly, 0.266 million ha of rice cultivation will be converted to higher value annual industrial crops to reduce GHG emissions. This transition is expected to decrease emissions by 1.29 million tons of CO_2e (2.27 %).

(iii) *Change low yield/benefit rice land to high-value aquaculture (shrimp, fish)*

The main advantages of rice and fish/shrimp farming systems include obtaining higher economic benefits, reducing pesticide costs by 48–56 %, and increasing income by approximately $1375 per ha. According to MARD, in the Mekong River Delta, more than 600,000 ha of rice cultivation area could be converted to rice and fish/shrimp systems in order to reduce GHGs emission by 5.37 %, equivalent to a reduction of 3.06 million tons of CO_2.

(iv) *Effectively use rice straw*

Rice straw is increasingly going unused after the harvest, which poses a problem for disposal. However, the unused straw could represent a potential source for efficient reuse of waste materials and a reduction in GWP for crop production. It is reported that straw compost has also shown potential for maintaining N_2O emissions at a low level (Yao et al. 2010).

Pandey et al. (2014) carried field experiment in Red River Delta of Vietnam and found that the reuse of composted rice straw can reduce methane emissions by about 25–29 %, reduce nitrogen oxide by 5–20 %, and reduce CO_2 emissions by 24–28 %. In addition to compost, biochar that is pyrolyzed from rice straw Yanai et al. (2007) can improve soil fertility and crop yield (Table 10).

Identify and Analyze Technologies to Reduce GHG Emission in Agriculture

GHG reduction technologies are primarily applied in rice cultivation, in livestock breeding, and in altered fertilizer application on arable land.

Table 10 Potential GHG emission reduction from some crop production (Gg of CO_2e)

			Crop			
Measure	Rice	Maize	Soybean	Peanut	Cassava	Sugarcane
Business as usual (BAU)		1.020	0.177	0.239	0.089	1.270

Rice Production

Rice production is the most important agricultural subsector in Vietnam. According to Mai Van et al. (2014), GHG reduction technologies in rice cultivation should meet the following requirements: (1) increase rice yield, (2) increase economic benefits for farmers, (3) decrease investment costs, and (4) be sustainable.

Currently, two promising GHG reduction technologies in rice cultivation are being studied: irrigation management and nutrient management.

Irrigation management includes irrigating less, draining the soil, and keeping the soil humid during rice growth stages. The key stage to keep the soil humid is after top tillering until just before flowering and after ripening. By using this combination of irrigation management, experiments have shown a decrease in CH_4 emissions from rice as well as increased soil aeration and, hence, increase plant available nutrient. This option could be easily applied in lowlands with sufficient irrigation.

There are several options for mitigating GHG emissions using nutrient management techniques. Results of studies on emissions from rice fields indicate that both organic manure and nitrogen fertilizers increase CH_4 and N_2O emissions. Thus, increasing manure application needs to be paired with draining the soil to reduce CH_4 emission and increase N fertilizer use efficiency. By applying the correct N fertilizer amount to meet plant requirement in each growing stage, studies show reductions in N_2O emissions. Other mitigation options include changing the land use type from rice to upland crops; introducing drought-, flood-, and salt-tolerant crops; shifting the crop calendar; and implementing SRI. Farmers can also combine N fertilizer management and crop management to practice integrated crop management (ICM). Based on the program of integrated pesticide management (IPM), ICM aims to optimize water, soil, and solar conditions to optimize potential yield, reduce yield gaps, and lower GHG emissions.

Irrigation management is considered the most important approach for reducing CH_4 emissions from rice fields. Approaches can be implemented by mid-season drainage, AWD irrigation, and field expose-shallow irrigation (Table 11). All these

Table 11 Prioritized climate change mitigation technologies in agriculture

No.	Technology	Description	Prospect
1	Suitable nitrogen fertilization rate	Establish nitrogen formula suitable for soil property and crop characteristics; deep fertilizing, plant winter crops for better use of nitrogen residues from previous season	
2	Field water drainage during rice growth stages	Drain field water out during two stages: tillering and ripening in order to reduce CH4 emission and increase rice yield	
3	Surface expose drying and irrigation	Application cycle of shallow irrigation and water drain out (20–25 day/cycle) after transplanting in order to reduce CH4 emission and increase rice yield	
4	Application of short duration varieties	Application of short-term rice varieties (approximate 100 days of growth duration) with high yield and high disease and pest resistance to replace long duration varieties (more than 140 days of growth duration)	
5	Nutrient improvement by oriented additions of animal's feed	Oriented addition of nutrients in animal's feed (BMU cakes, urea, etc.)	
6	Application of stimulants in livestock production	Applying stimulants such as bovine somatotropin (BST) and anabolic steroid to improve and increase meat and milk quality and yield as well as reduce CH4 emission	
7	Biogas	Store livestocks' wastes under anaerobic condition to generate CH4 (biogas) for fuels. By-products from biogas are used as fertilizers or animal's feed	
8	Crop rotation to reduce soil organic carbon (SOC) loss	Applying conservation farming to maintain soil's water content. Planting legumes to increase soil's nitrogen fixation. Applying crop rotation suitable for soil properties and climate conditions	
9	Plant cover crops on sloping land to reduce soil erosion and maintain soil moisture	Planting different cover crops following contour line on sloping land. Digging holes to prevent soil erosion and recover soil from water run-offs	
10	Nutrient improvement by mechanical and chemical processes	Processing animal's feed through mechanical methods (grinding and blending) and chemical methods (fermentation, compost, micro-nutrient increase, etc.) in order to increased iggestiverate and meat yield	
11	Gene modification for livestocks	Apply gene engineering to create new livestock varieties with ability of rapid growth, high disease resistance	

mitigation options are suitable with local conditions but prioritized following the technology needs assessment (TNA) procedure (Quach Tat Quang et al. 2012).

Fertilization

The emission of N_2O is related to nitrogen in the soil and N fertilizer. Nitrogen is the key element in creating and increasing crop yield, making it both essential and potentially harmful in agricultural management. Fertilizer management can include many techniques. Farmers can perform a soil quality assessment in order to identify soil potential supply. Yield modeling can be used to identify the rate and amount of fertilizers to apply, based on soil properties and crop characteristic. Simple nutrient budgets and N testing can be used to identify the rate and time of fertilizer application. Farmers can also calculate their N balance from crop uptake, absorption, run-off, and emissions. Efficient use of manure and organic wastes used as fertilizers can reduce N emissions. Growers can also use winter crops to sequestrator remaining nitrogen from previous seasons or apply deep fertilization. Finally, growers can implement proper irrigation techniques and management to avoid fertilizer loss and check the soil's pH and acidity.

Cropland, Noncultivated Land, and Bare Land

Cropland

On actively cultivated croplands, farmers can conserve the soil by using alley cropping, contouring, terracing, crop residues to cover soil surface, reduced tillage, or no tillage. Mulching is practiced widely in sloping land areas to protect the soil from rain and wind erosion, limit evaporation, maintain water content in the soil, and prevent organic matter degradation. It also returns organic carbon and nutrients into the soil and reduces the costs of chemical fertilizer.

Fallow Land and Bare Land

Fallow and bare lands usually occur where there are unstable rainfall conditions, poor irrigation regimes, unfavorable transportation conditions, and poor humus. These lands occupy about 23 % of the nation. In these unfavorable soil conditions, many pedological processes lead to continued soil degradation and GHG emissions. Improvement and rehabilitation of these lands will improve ecological conditions, control soil erosion, reduce leaching, and reduce GHG emissions.

It is recommended to apply the following techniques to reduce GHG emission for noncultivated and bare lands:

- Plant green manure or grasses along the contour lines to prevent surface flows and retain sediment during high rainfall. Simultaneously, these buffers make terraces and soil traps along the contour lines to trap soil and prevent sedimentation from gently sloping surfaces.
- Apply intercropping, agro-forestry, and mix planting of annual crops and perennial crops. These practices have been implemented widely in hilly and mountainous areas. They were especially promoted as a key activity of the National Project

(Project 327) of regreening noncultivated and bare lands to protect against natural disasters, flash floods, and droughts in highlands
– Application of Sloping Agricultural Land Technology or SALT. SALT has certain advantages over both the traditional techniques of slash-and-burn (swidden agriculture) and conventional terrace farming. SALT enables farmers to stabilize and enrich the soil and to grow food crops economically. There is also a reduced need for expensive inputs like chemical fertilizers. In addition, SALT also conserves soil moisture and reduces pests and diseases. But most importantly, to a financially harried farmer, the technology can increase his or her annual income to almost threefold after only a period of 5 years.

Conclusion

Climate change strongly impacts Vietnam's agricultural sector. Damages have been documented in the past, the existing environment is highly vulnerable, and projections show high crop losses in the future. Flatlands are more strongly affected than highlands, in which the Mekong River Delta shows the most impacts. The Coastal Central area and Red River Delta follow the Mekong Delta. Vietnam experiences many extreme events and disasters each year. Climate change is projected to increase the frequency and severity of these weather events, damaging agricultural outputs. The agricultural sector has developed suitable adaptation measures to cope with climate change and keep production ongoing, not only feeding over 76 million people but also exporting a high amount of food and foodstuffs. Vietnam is the leading cashew nut exporter, second rice exporter, and third coffee exporter in the world. With a large area of paddy rice land and a large livestock sector, production processes in Vietnam have high GHG emissions. Thus, the agricultural sector is striving to implement many mitigation options such as AWD irrigation, composting, and converting rice land to non-rice land. With these mitigation measures, the sector plans to reach the target of reducing GHG emission by 20 % by 2020.

Potential Impacts of the Growth of a Mega City in Southeast Asia: A Case Study on the City of Dhaka, Bangladesh

A. K. M. Azad Hossain and Greg Easson

Contents

Abstract

Megacities with populations of more than ten million people in compact urban areas are the most vulnerable environments on the earth. The impacts of climate change on these megacities will be multi-faceted and severe, especially in developing countries, due to fast growth rate and inefficient adaptation. It is very important therefore to understand the contributions of the growth of megacities to climate change, especially in the developing countries. Dhaka, the capital of Bangladesh, is one of the fastest-growing megacities in the world; its population

increased from 6.621 million (in 1990) to 16.982 million (in 2014). Today, Dhaka is the 11th largest megacity in the world and is projected to be the 6th largest megacity in the world with a population of 27.374 million by the year 2030.

Remote sensing technology has been successfully used for mapping, modeling, and assessing urban growth and associated environmental studies for many years. This research investigates how the intensity of the urban heat island (UHI) effects correlates with continuous decrease in the greenness of the city of Dhaka, as measured from satellite observations. The results of this study indicate that Landsat imagery-derived normalized difference vegetation index (NDVI) can be used to investigate the changes in greenness in the city of Dhaka from 1980 to 2014. The changes in greenness can be correlated with the increase in the intensity of UHI effects in the city of Dhaka as determined using Landsat thermal data from 1989 to 2014.

Introduction

Urban populations grew rapidly throughout the nineteenth century, more by migration from the rural areas to the cities and manufacturing centers than by absolute population growth. Throughout the twentieth century, the number and sizes of cities grew, along with the percentage of the total population living in the cities (Schubel and Levi 2000). Since 1950, the worldwide urban population has grown from 746 million to 3.9 billion in 2014, 54 % of the total global population (United Nations 2014). Continued population growth and urbanization are predicted and it is projected to add 2.5 billion more people to the world's urban population by 2050 (United Nations 2014).

A large percentage of the urban growth is concentrated in the developing world, where the average urban growth rate for developing countries is 3.5 % per year, compared with a rate of less than 1 % per year for the developed countries (United Nations 1997; WRI 1998). Asia, despite its lower level of urbanization, is home to 53 % of the world's urban population. By 2050 it is projected that 90 % of the world's urban population will be in Asia and Africa (United Nations 2014).

The past several decades have seen the emergence of megacities, a metropolitan area with a total population in excess of ten million people (New Scientist Magazine 2006). A megacity can be a single metropolitan area or two or more metropolitan areas that have converged. The concept of megacities was initiated in 1987 to combine both theory and practice in the search for successful approaches to improve urban management and the conditions of daily life in the world's largest cities. The megacities concept was based on a collaborative effort among government, business, and community leaders of these megacities, in an attempt to shorten the time between the introduction of innovative ideas and their implementation and diffusion. The idea was coined not simply to identify, distill, and disseminate positive approaches but to strengthen the leaders and groups who are evolving the approaches and find sources of

support to multiply their efforts. The idea promotes a dual strategy that functions simultaneously at the practical and theoretical levels: (1) sharing "best practices" among the cities and putting the lessons of experience in the hands of decision makers and the public and (2) gaining a deeper understanding of the process of innovation and the consequences of deliberate social changes in the cities.

In 1950, New York and London were the world's only megacities (Schubel and Levi 2000). In 1990, the number of megacities had increased to 10, with a population of 153 million people, representing less than 7 % of the global urban population. By 2014, the number of megacities had nearly tripled to 28. The urban population in these megacities has grown to 453 million, and these areas now account for 12 % of the world's urban residents. The number of megacities is projected to increase to 41 by 2030 (United Nations 2014). Since most of the recent urban growth is concentrated in the developing world, the majority of the megacities are expected to be located in the developing world (Schubel and Levi 2000). Currently, 15 out of the 28 megacities are located in Asia, with the number projected to increase to 23 in Asia by 2030 (United Nations 2014). Table 1 shows the list of the current and projected megacities in the world.

The most vulnerable environments on the earth are the urban areas, especially the megacities. It is increasingly recognized that airborne emissions from major urban and industrial areas influence both air quality and climate change on scales ranging from regional to continental and global. The viability of important natural and agricultural ecosystems in regions surrounding highly urbanized areas is severely affected by the deteriorating urban air quality. Megacities also influence regional atmospheric chemistry. This situation is particularly acute in the developing world where the rapid growth of megacities is producing atmospheric pollution at unprecedented severity and extent (Gurjar et al. 2014).

The impacts of climate change due to urbanization are multi-faceted and severe. The impacts differ dramatically among the megacities in the developed and in the developing countries. The impacts in the developed countries are already adapted or being adapted with efficient technologies/policies/regulations, whereas in the developing countries, due to fast growth rate and inefficient adaptation, the impact is imminent and severe. There are also no signs that the governments in the developing countries will prove to be more capable in the future. These swarming, massive urban areas will continue to grow and should concern the world (Liotta and Miskel 2012).

It is very important therefore to understand the impacts of the growth of megacities on climate change. Studies on megacities at different spatial and temporal scales using various models will be required to understand their local-to-global impacts and implications (Gurjar et al. 2014). Lawrence et al. (2007) employed a global model to examine the outflow characteristics of pollutants from megacities. That model demonstrated the trade-offs between pollutant buildup in the region surrounding each megacity versus export to downwind regions or to the upper troposphere. Unfortunately, the coarse resolution of global atmospheric models and source inventories still presents difficulties to capturing the details of the impact of megacity emissions temporally and spatially (Gurjar et al. 2014).

Dhaka, the capital of Bangladesh, is one of the fastest-growing megacities in the world; its population increased from 6.621 million (in 1990) to 16.982 million (in 2014) (Table 1). Today, Dhaka is the 11th largest megacity in the world and is projected to be the 6th largest megacity in the world with a population of 27.374 million by the year 2030 (United Nations 2014).

The urban heat island (UHI) effect is an important impact of urbanization. Urban and suburban areas experience elevated temperatures compared to their surrounding rural areas (EPA 2015). The annual mean air temperature of a city with one million people or more can be 1.8–5.4 °F (1–3 °C) warmer than the surrounding area (OKe 1997). On a clear, calm night, this temperature difference can be as much as 22 °F (12 °C) (OKe 1987). The UHI effect for the city of Dhaka has already been recorded by several reports and articles (Ahmed et al. 2013). It is not yet however completely understood how the intensity of the UHI effect changes with the continuous growth of the city.

Remote sensing technology has been successfully used for urban growth and associated environmental studies for many years. This research investigates how the intensity of the UHI correlates with continuous decrease in the greenness of the city, as measured from satellite observations and using digital image processing techniques. The specific objectives include: (1) evaluating the changes in greenness from 1973 to 2014 using Landsat imagery-derived normalized difference vegetation index (NDVI), (2) estimating land surface temperatures (LST) using Landsat thermal imagery, and (3) investigating the potential of the Landsat-derived LST to evaluate the changes in the UHI effect.

Research Data

A time series of ten Landsat images covering Dhaka, Bangladesh, acquired from 1973 to 2014 were used in this research. The time series of imagery includes data acquired by Landsat 1 and Landsat 3 Multispectral Scanner (MSS), Landsat 4 and Landsat 5 Thematic Mapper (TM), Landsat 7 Enhanced Thematic Mapper Plus (ETM+), and Landsat 8 Operational Land Imager (OLI) and Thermal Infrared Sensor (TIRS). Table 2 lists the imagery acquisition dates and corresponding sensors and their characteristics. All ten data sets were used for visual analysis, but only selected imagery were used for vegetation and land surface temperature (LST) analysis. Table 3 shows the data usage matrix.

The spatial distribution of vegetation in Dhaka was mapped to evaluate the changes in greenness over time. A normalized difference vegetation index (NDVI) was used to detect the changes in greenness. NDVI was calculated for the imagery acquired in 1973, 1980, 1989, 2000, 2010, and 2014. The thermal sensor of the Landsat series became available with the launch of Landsat 4. The earliest thermal data available for this region was acquired in 1989, started the time series of LST data for 1989, 2000, 2010, and 2014 (Table 3).

The gradual changes in land use and land cover in and around the city of Dhaka from 1973 to 2014 are shown in Fig. 2. Figure 3 shows the net change in land cover and land use between 1973 and 2014.

Table 2 Satellite data acquired

Date	Sensor	VNIR bands	Spatial resolution (m)	Thermal bands	Spatial resolution (m)
Dec. 05, 1973	Landsat 1 MSS	4,5,6, and 7	60[a]	NA	NA
Feb. 20, 1980	Landsat 3 MSS	4,5,6, and 7	60[a]	NA	NA
Jan. 28, 1989	Landsat 4 TM	1,2,3, and 4	30	6	30[b]
Feb. 28, 2000	Landsat 7 ETM+	1,2,3, and 4	30	6	30[c]
Mar. 24, 2003	Landsat 7 ETM+	1,2,3, and 4	30	6	30[c]
Jan. 16, 2005	Landsat 5 TM	1,2,3, and 4	30	6	30[b]

Methods

This research is based on the hypothesis that satellite observation-based normalized difference vegetation index (NDVI) and land surface temperature (LST) can monitor changes in urban greenness in a megacity and the changes in the intensity of urban heat island (UHI) effect. Data acquired by Landsat satellites would be the best available option to achieve these results due to the extensive archive of imagery and consistency of the sensors.

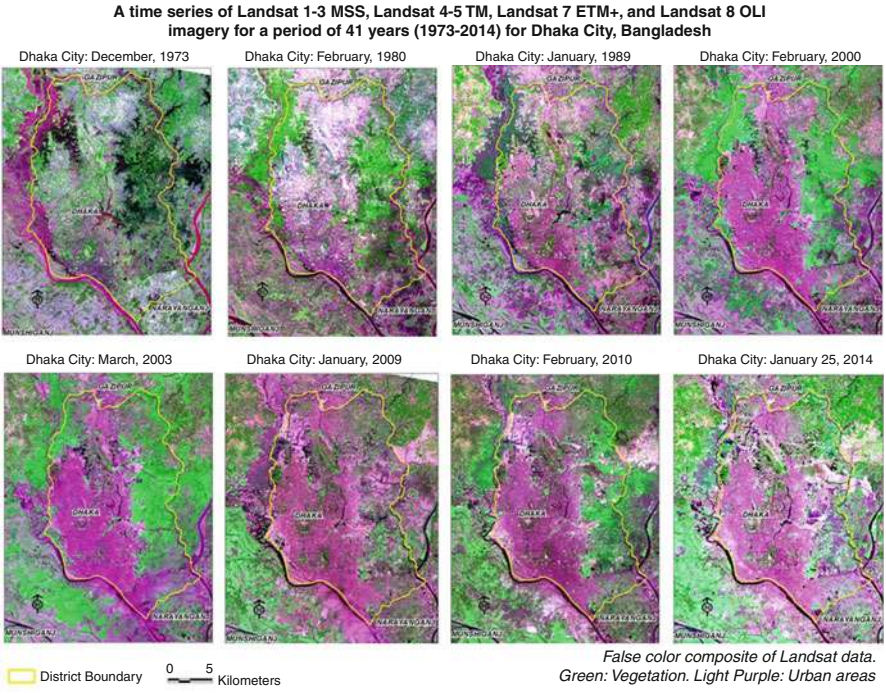

Fig. 2 Changes in land cover in Dhaka City

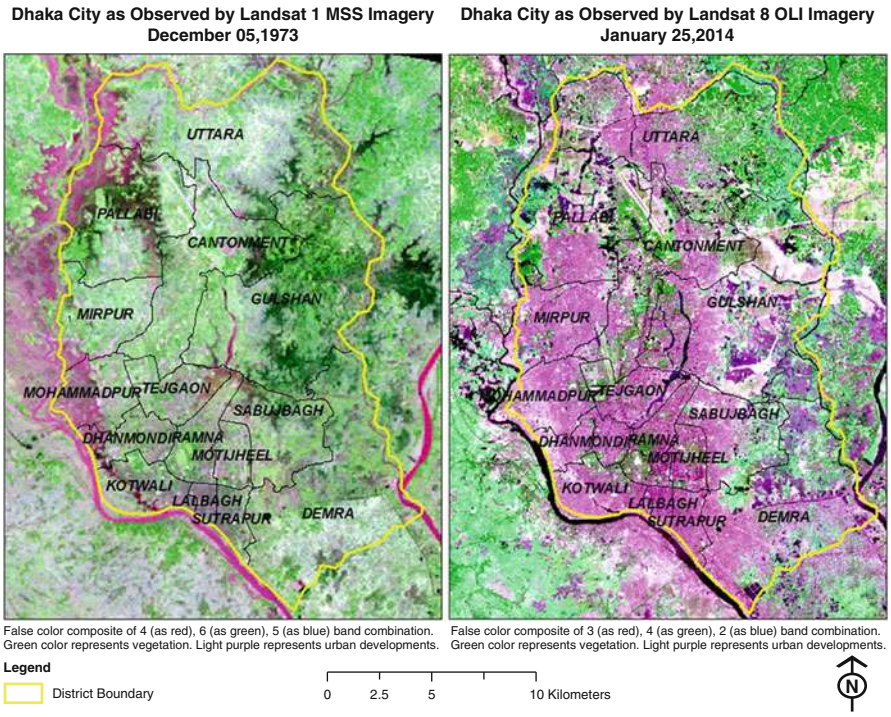

Fig. 3 Land use and land cover changes as observed by Landsat data

Normalized Difference Vegetation Index (NDVI)

The normalized difference vegetation index (NDVI) is an image enhancement technique, which can be used to describe the greenness or relative density and health of vegetation in an image. It is one of the most widely accepted and widely used vegetation indices. NDVI was first attributed by Rouse et al. (1973), but the concept was discussed by Kriegler et al. (1969). NDVI is commonly used as an indicator of relative biomass and greenness (Boone et al. 2000). The calculation of NDVI is based on the nature of the variation of reflectance values obtained from vegetated surfaces in the near-infrared (NIR) and red regions of the electromagnetic spectrum (EMS). The reflectance values of vegetation in the near-infrared (NIR) region are higher than that in the red region. NDVI provides a ratio of the NIR and the red bands (Eq. 1), eliminating any discrepancies that may occur in the imagery due to sensor differences or image quality issues, such as brightness and other interference (Hossain and Easson 2011). The NDVI can be computed for a wide variety of sensors depending on the availability of measurements in the NIR and red bands.

$$\mathrm{NDVI} = \frac{(\mathrm{NIR} - \mathrm{R})}{(\mathrm{NIR} + \mathrm{R})} \tag{1}$$

where NIR and R are pixel values of NIR and R bands, respectively.

Landsat data has been used for vegetation studies for many years. Since all the sensors used in Landsat data acquisitions consist of both visible and near-infrared (VNIR) channels (Table 2), it is possible to calculate NDVI using image data from all Landsat sensors. In this study, NDVI was calculated using imagery acquired by Landsat 1 MSS, Landsat 3 MSS, Landsat 4 TM, Landsat 5 TM, Landsat 7 ETM+, and Landsat 8 OLI satellites (Table 3). The NDVI calculation equations are as follows:

$$\mathrm{NDVI}_{\mathrm{Landsat1\_MSS}} = \frac{(\mathrm{Band7} - \mathrm{Band4})}{(\mathrm{Band7} + \mathrm{Band4})} \tag{2}$$

$$\mathrm{NDVI}_{\mathrm{Landsat3\_MSS}} = \frac{(\mathrm{Band7} - \mathrm{Band4})}{(\mathrm{Band7} + \mathrm{Band4})} \tag{3}$$

$$\mathrm{NDVI}_{\mathrm{Landsat4\_TM}} = \frac{(\mathrm{Band4} - \mathrm{Band3})}{(\mathrm{Band4} + \mathrm{Band3})} \tag{4}$$

$$\mathrm{NDVI}_{\mathrm{Landsat5\_TM}} = \frac{(\mathrm{Band4} - \mathrm{Band3})}{(\mathrm{Band4} + \mathrm{Band3})} \tag{5}$$

$$\mathrm{NDVI}_{\mathrm{Landsat7\_ETM+}} = \frac{(\mathrm{Band4} - \mathrm{Band3})}{(\mathrm{Band4} + \mathrm{Band3})} \tag{6}$$

$$\mathrm{NDVI}_{\mathrm{Landsat8\_OLI}} = \frac{(\mathrm{Band5} - \mathrm{Band4})}{(\mathrm{Band5} + \mathrm{Band4})} \tag{7}$$

Land Surface Temperature (LST)

Land surface temperatures (LSTs) in and around the city of Dhaka were estimated using the Level 1 thermal data acquired by Landsat 4–5 TM, Landsat 7 ETM+, and Landsat 8 TIRS sensors. The unitless digital number (DN) values of the thermal bands were digitally processed to corresponding radiance values. The processed radiance values were then used to calculate LST.

Conversion of DN to Radiance

Landsat 4–5 TM and Landsat 7 ETM+

During the generation of Level 1 data, pixel values from raw unprocessed imagery (Level 0 data) were converted to units of absolute radiance using 32-bit floating-point calculations. These absolute radiance values were then scaled to 8-bit values representing calibrated digital numbers (Q_{cal}) before output to the distribution media. Conversion of these calibrated digital numbers (Q_{cal}) in L1 products back

to the "at-sensor spectral radiance" (L_λ) requires knowledge of the original rescaling factors. The following equation (Eq. 8) was used to perform a radiance conversion for the Level 1 Landsat 4–5 TM and Landsat 7 ETM+ imagery (Chander and Markham 2003; Chander et al. 2009).

$$L_\lambda = \left(\frac{LMAX_\lambda - LMIN_\lambda}{Q_{calmax} - Q_{calmin}}\right)(Q_{cal} - Q_{calmin}) + LMIN_\lambda \tag{8}$$

where

L_λ = spectral radiance at the sensor's aperture in W/(m^2.sr.μm)
Q_{cal} = quantized calibrated pixel value in DNs
Q_{calmin} = minimum quantized calibrated pixel value corresponding to $LMIN_l$ (DN = 0)
Q_{calmax} = maximum quantized calibrated pixel value corresponding to $LMAX_l$ (DN = 255)
$LMIN_\lambda$ = spectral radiance that is scaled to Q_{calmin} in W/(m^2.sr.μm)
$LMAX_\lambda$ = spectral radiance that is scaled to Q_{calmax} in W/(m^2.sr.μm)

The required parameters were obtained from the Level 1 product metadata to process the acquired thermal data using Eq. 8. Equation 8 was modified to Eqs. 9, 10, and 11 and was used to obtain the at-sensor radiance values for the imagery acquired in 1989, 2000, and 2010, respectively.

$$L_{\lambda(L4\ TM\_1989)} = \left(\frac{15.303 - 1.238}{255 - 1}\right)(DN_{Band6} - 1) + 1.2378 \tag{9}$$

$$L_{\lambda(L7\ ETM\_2000)} = \left(\frac{12.650 - 3.20}{255 - 1}\right)(DN_{Band62} - 1) + 3.20 \tag{10}$$

$$L_{\lambda(L5\ TM\_2010)} = \left(\frac{15.303 - 1.238}{255 - 1}\right)(DN_{Band6}) + 1.238 \tag{11}$$

Landsat 8 TIRS

Landsat 8 TIRS data has two different thermal bands (Band 10 and Band 11), unlike Landsat 4–5 TM and Landsat 7 ETM+. The center wavelength and bandwidth of Band 10 are 10.9 and 0.6 μm respectively, whereas the center wavelength and bandwidth of Band 11 are 12.0 and 1.0 μm, respectively. In this study, Band 11 was used to estimate LST to be more comparable with Landsat TM and ETM+ thermal data. As proposed by USGS (2014), the conversion of DN values (Q_{cal}) to the "at-sensor spectral radiance" (L_l) was done using different approaches (comparing to Landsat TM and ETM+). Equation 12 was used in this case. This approach was also used in several recent research projects (e.g., Sameen and Kubaisy 2014).

$$L_\lambda = M.Q_{cal} + B \tag{12}$$

where

M is the radiance multiplier
B is the radiance add

The values of "radiance multiplier" and "radiance add" were obtained from Landsat 8 TIRS metadata (Table 4) for Band 11. These values were used in Eq. 12 to obtain Eq. 13, which was used to estimate LST for 2014 imagery acquisition date.

$$L_{\lambda(L8\ TIR_{2014})} = M * DN_{Band11} + B \tag{13}$$

Conversion of Radiance to LST

The obtained radiance values for all Landsat thermal data were converted to land surface temperature (LST) using Eq. 14. Since the obtained radiance values are of top of the atmosphere (at-sensor radiance), Eq. 14 was modified by adding an emissivity factor ($\mathcal{E}$) to minimize the influence of atmospheric distortion in the calculation (Eq. 15). Table 4 provides the values of K1 and K2 for Landsat 8 TIRS (Maher and Kubaisy 2014). Table 5 provides the values of K1 and K2 for Landsat 4–5 TM and Landsat 7 ETM + (Coll et al. 2010).

$$T_k = \frac{K_2}{\ln\left(\frac{K_1}{L_\lambda}\right) + 1} \tag{14}$$

$$T_k = \frac{K_2}{\ln\left(\frac{K_1.\varepsilon}{L_\lambda}\right) + 1} \tag{15}$$

where

T_k = effective at-satellite temperature in Kelvin
K_2 = calibrated constant 2 in Kelvin

Table 4 Landsat 8 TIR parameters

	TIR parameters			
			Thermal constants	
			K_1	K_2
TIR bands	Radiance multiplier (M)	Radiance add (B)	W/(m^2.sr.μm)	Kelvin
Band 10	0.0003342	0.1	774.89	1,321.08
Band 11	0.0003342	0.1	480.89	1,201.14

Table 5 Landsat TM and ETM+ thermal band calibration constants

	Constants	
	K_1	K_2
	Units	
Sensor type	$W/(m^2.sr.\mu m)$	Kelvin
Landsat 4 TM	671.62	1,284.30
Landsat 5 TM	607.76	1,260.56
Landsat 7 ETM+	666.09	1,282.71

K_1 = calibrated constant 1 in $W/(m^2.sr.\mu m)$
L_λ = spectral radiance at the sensor's aperture
e = emissivity (typically 0.95)

Equation 15 was then modified to form Eqs. 16–19 to calculate LST, in degrees Kelvin, for each different Landsat sensor by using corresponding values of L_λ, K_1, and K_2. After calculating LST in absolute temperature, the values were converted to degrees Celsius, using Eq. 20.

$$T_{k(L4\ TM_{1989})} = \frac{1260.56}{\ln\left(\frac{607.76 * 0.95}{L_{\lambda(L4\,TM\_1989)}}\right) + 1} \tag{16}$$

$$T_{k(L7\,ETM_{2000})} = \frac{1282.71}{\ln\left(\frac{666.09 * 0.95}{L_{\lambda(L7\,ETM\_2000)}}\right) + 1} \tag{17}$$

$$T_{k(L5\,TM_{2010})} = \frac{1260.56}{\ln\left(\frac{607.76 * 0.95}{L_{\lambda(L5\,TM\_2010)}}\right) + 1} \tag{18}$$

$$T_{k(L8\,TIR_{2014})} = \frac{1201.14}{\ln\left(\frac{480.89}{L_{\lambda(L8\,TIR\_2014)}}\right) + 1} \tag{19}$$

$$T_c = T_k - 273.15 \tag{20}$$

Results and Analysis

The processed NDVI and LST data were subset for Dhaka metropolitan area for analysis of changes in greenness and land surface temperature. The time series of Dhaka NDVI data was used to study the changes in greenness since 1980. The time series of Dhaka LST data was used to evaluate the changes in the intensity of urban heat island (UHI) impact since 1989.

Changes in Greenness

On the basis of the minimum and maximum values of NDVI, the lookup table of the entire time series data was scaled from −0.5 to 0.65 to visualize the changes in greenness over time. Figure 4 shows the NDVI time series for Dhaka city from 1980 to 2014. In Fig. 4, it is clearly seen that the average NDVI values decreased continuously from 1980 to 2014. The most dramatical change occurred between 1989 and 2000. The net change in greenness from 1980 to 2014 is also substantial as seen in Fig. 5.

Changes in the Urban Heat Island (UHI) Effects

The variation in the intensity of urban heat island (UHI) effects due to the changes in greenness in the city of Dhaka was evaluated by determining the changes in the nature of spatiotemporal distribution of land surface temperature (LST) over time. The Landsat satellite observed LST time series data were used in different ways to study the changes in the nature of spatiotemporal distribution of LST over time.

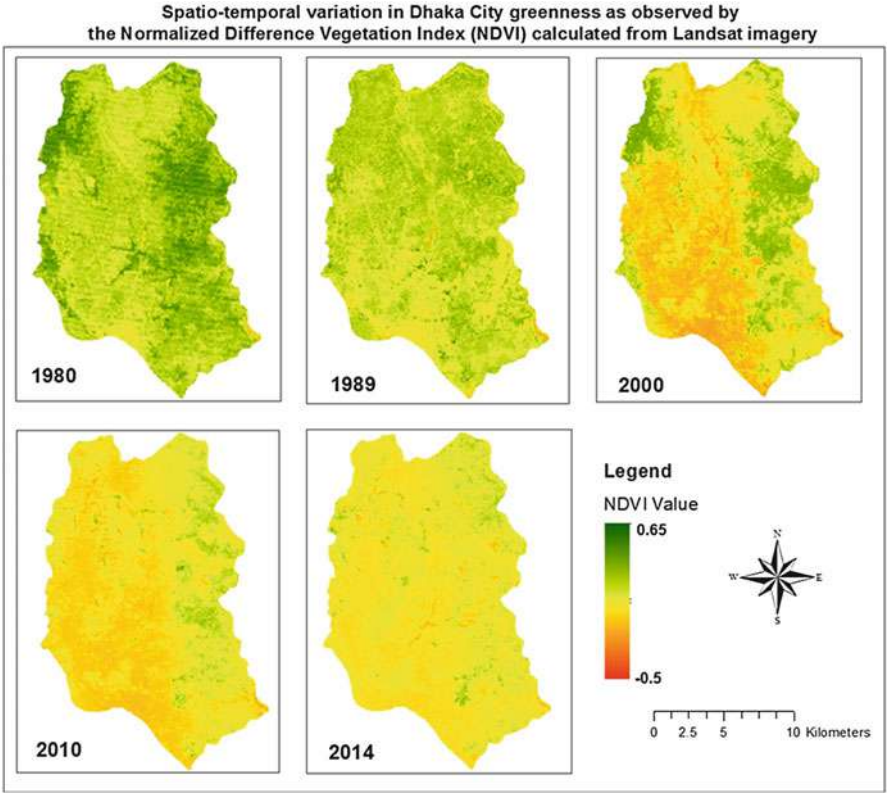

Fig. 4 Changes in greenness from 1980 to 2014 as observed by the Landsat data

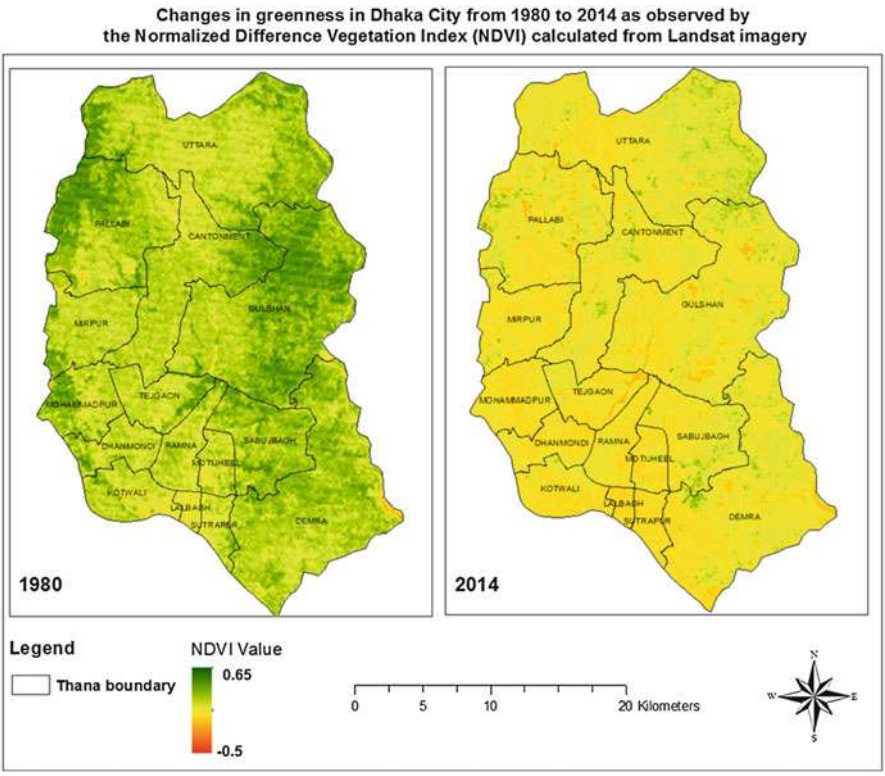

Fig. 5 Detailed changes in greenness from 1980 to 2014 as observed by the Landsat data (Thana is a kind of local administrative boundary like county)

At first, the LST distribution was visually analyzed by stretching the data lookup table from red to green. The red and green ends represent the maximum and minimum temperatures for each date. The areas covered by yellow represents approximately mean temperature for each date. Figure 6 shows the spatiotemporal distribution of Landsat observed LST in the city of Dhaka from 1989 to 2014. The LST imagery time series in Fig. 6 clearly shows that the areas characterized by high temperature extended substantially from 1989 to 2014, with significant increase from 1989 to 2000. Since the satellite imagery used in this study were acquired in different seasons of different years, it was not found reasonable to determine the absolute changes in LST variation by detecting the net changes in LST values.

The second approach focused on the variation in LST along specific cross-section profile. A cross-section line A-B was selected in the east-west direction on each LST data set to extract the temperature values along the line (Fig. 6). The extracted LST values along line A-B were plotted and compared with the mean LST value for the corresponding data acquisition dates. Figures 7, 8, 9, and 10 show the variation in LST along A-B in 1989, 2000, 2010, and 2014, respectively. This analysis supports

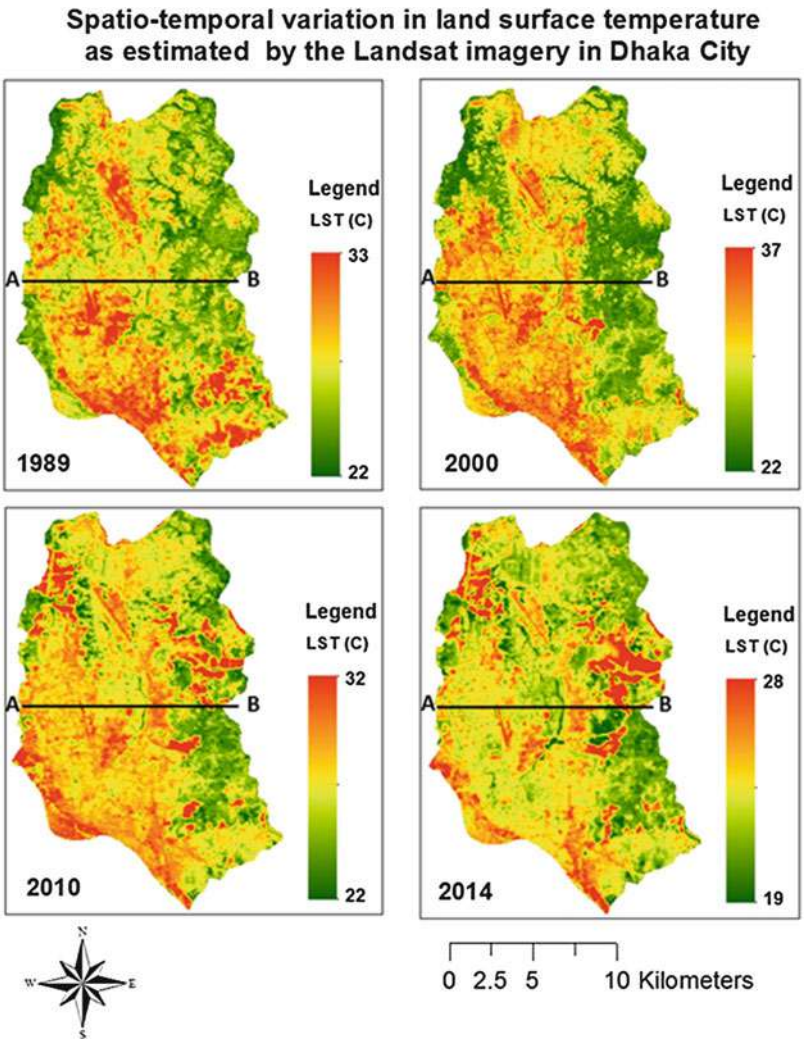

Fig. 6 Land surface temperature (LST) from 1989 to 2014 as observed by the Landsat data

the visual analysis performed earlier and also provided a more quantitative understanding of how the LST values changed over time in reference to the mean values.

The changes in the LST distribution pattern observed along line A-B provide a good quantitative evaluation of the changes in the intensity of UHI effects over time. However, the observation is limited in a particular direction and areas. The potential of image classification techniques was therefore evaluated to extend the quantitative analysis. The classification was performed based on the statistics of the satellite-observed LST imagery (Fig. 6) as shown in Table 6 and Figs. 11 and 12.

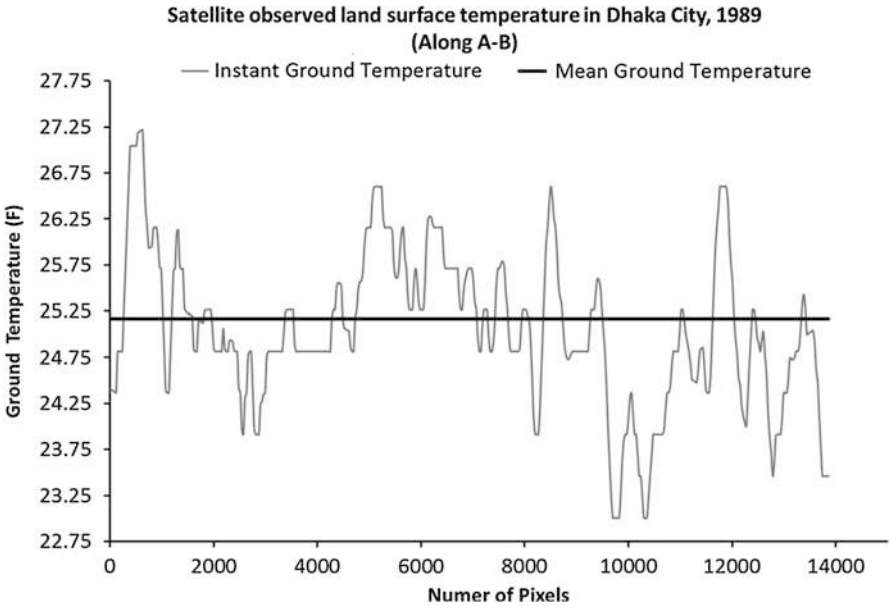

Fig. 7 Variation in LST along A-B in 1989

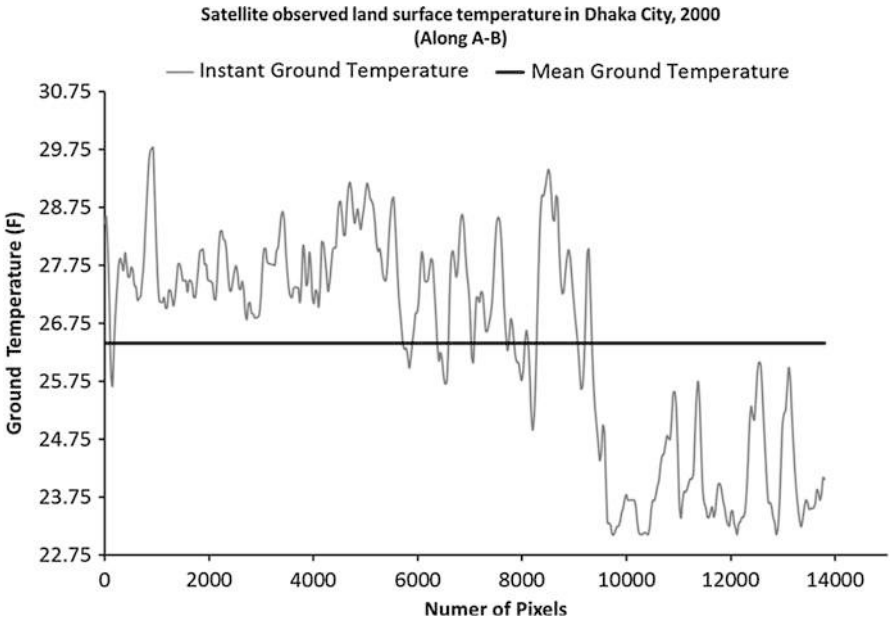

Fig. 8 Variation in LST along A-B in 2000

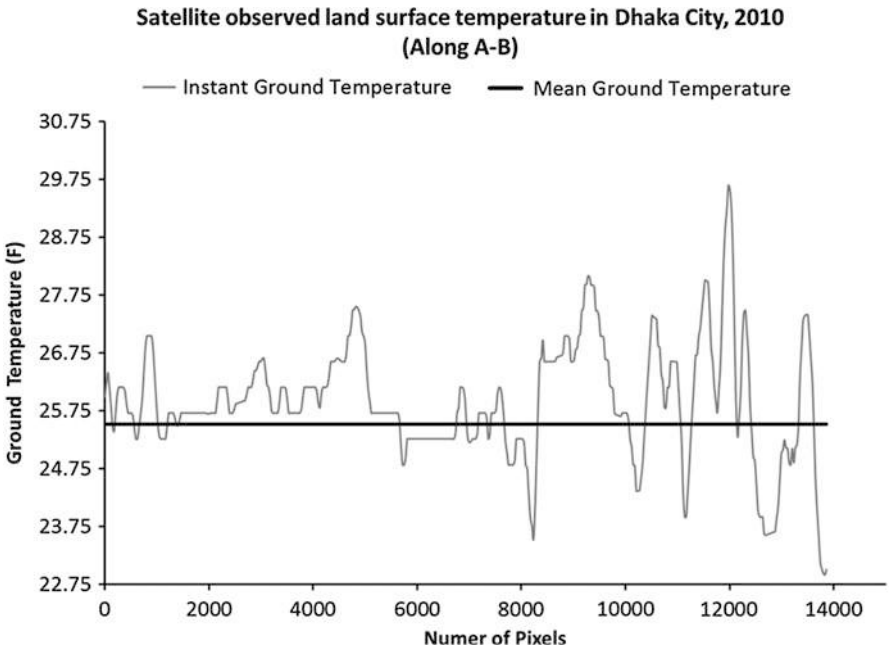

Fig. 9 Variation in LST along A-B in 2010

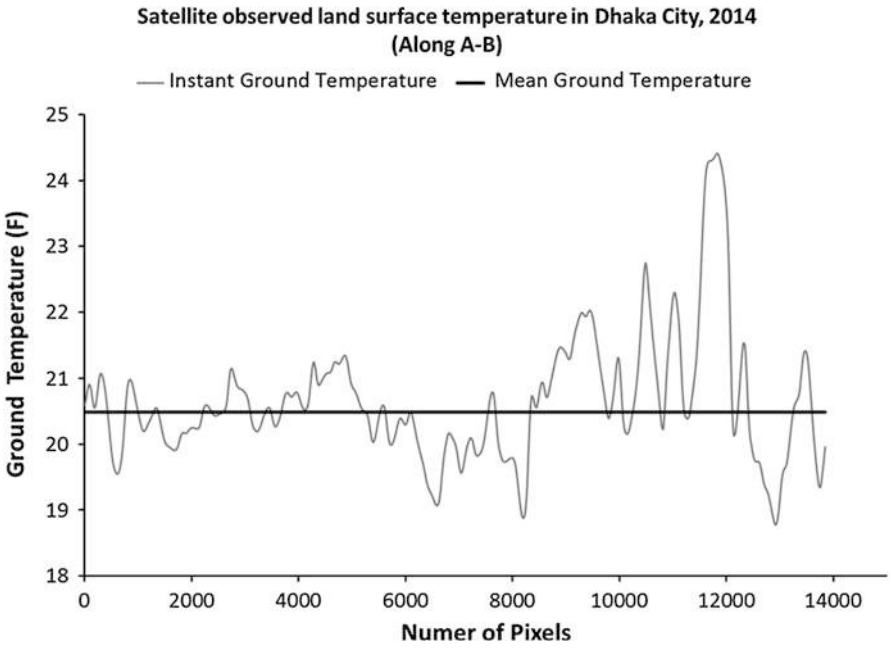

Fig. 10 Variation in LST along A-B in 2014

Table 6 Temperature statistics

Date	Sensor	Temperature statistics (°C)		
		Min	Max	Mean
1989	Landsat 4 TM	22.09	32.66	25.17
2000	Landsat 7 ETM+	21.61	36.63	26.41
2010	Landsat 5 TM	21.63	31.81	25.52
2014	Landsat 8 TIR	17.47	25.38	20.49

Each LST imagery was classified into five classes around the mean temperature to map the spatiotemporal distribution of the areas characterized by different levels of above mean temperature. The classes are as follows:

- Class 1: Areas with temperature equal or less than mean
- Class 2: Areas with temperature 1° higher than mean
- Class 3: Areas with temperature 2° higher than mean
- Class 4: Areas with temperature 3° higher than mean
- Class 5: Areas with temperature >3° higher than mean

Figures 13, 14, 15, and 16 show the distribution of LST pixels above mean LST in the city of Dhaka as observed in 1989, 2000, 2010, and 2014, respectively. The classified raster LST data were converted to vector data and polygons were simplified. The vector data with simplified polygons were used to calculate the areas covered by each LST regime (class).

The area calculations were plotted for different classes to compare them graphically. The area comparison plots improve the understanding of the changes in the intensity of UHI effect over time.

Figure 17 shows the comparison of the size of the areas characterized by total above mean temperature in the city of Dhaka from 1989 to 2014. The total size of the areas where LST remained above the mean increased continuously from 1989 to 2010 but decreased in 2014. Figure 18 shows the comparison of the size of the areas characterized by 1° above mean temperature in the city of Dhaka from 1989 to 2014. The total size of the areas where LST remained 1° above the mean decreased from 1989 to 2000, but increased since then continuously. Figure 19 shows the comparison of the size of the areas characterized by 2° above mean temperature in the city of Dhaka from 1989 to 2014. The total size of the areas where LST remained 2° above the mean increased from 1989 to 2000, but decreased since then. Figure 20 shows the comparison of the size of the areas characterized by 3° above mean temperature in the city of Dhaka from 1989 to 2014. The total size of the areas where LST remained 3° above the mean increased significantly from 1989 to 2000 and remained above 1989 since then.

Discussion and Conclusions

The number and size of megacities are increasing with the majority of the growth occurring in developing countries, especially in Asia and Africa. Understanding the potential impacts of the growth of megacities on the climate in Southeast Asia will

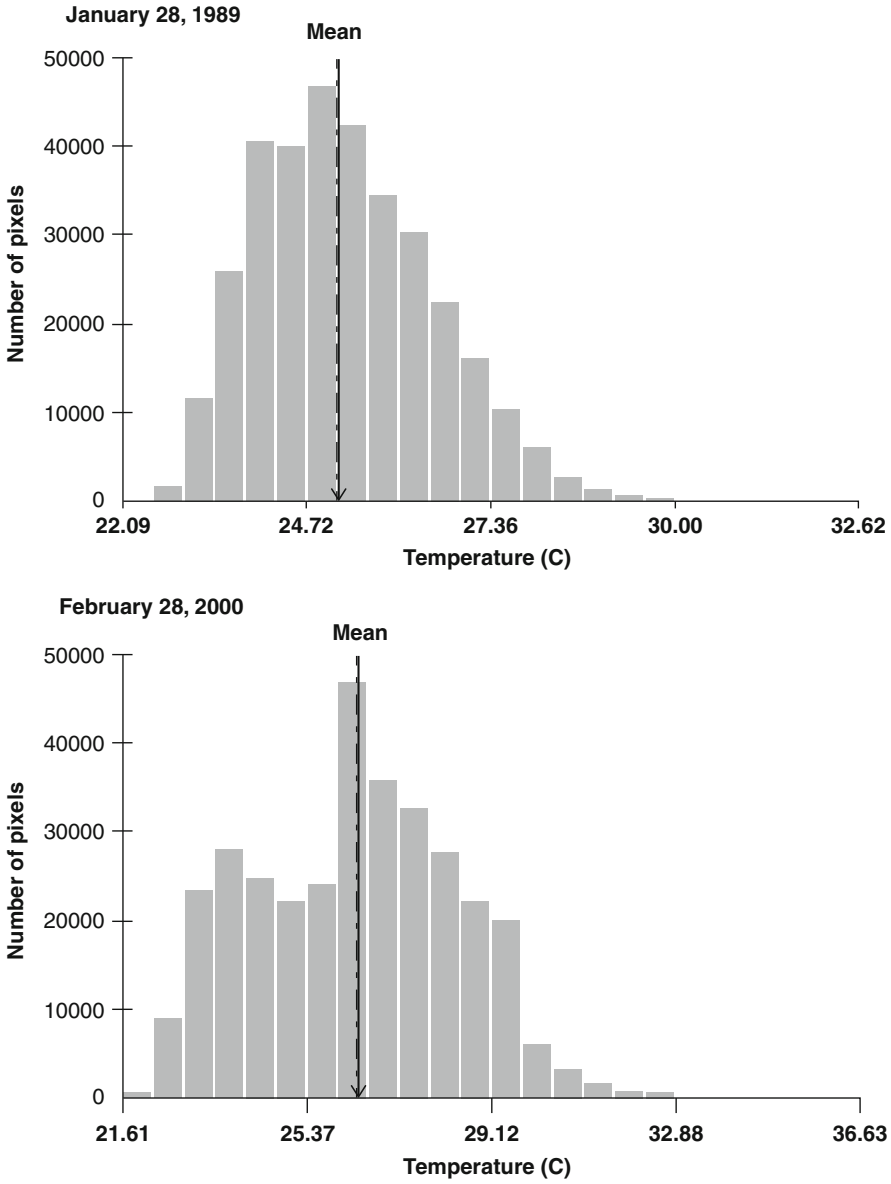

Fig. 11 LST mean for 1989 and 2000

provide insight for understanding the relationship between climate change and urban growth in the developing world. The analysis of the results obtained in this research for Dhaka, Bangladesh, shows that:

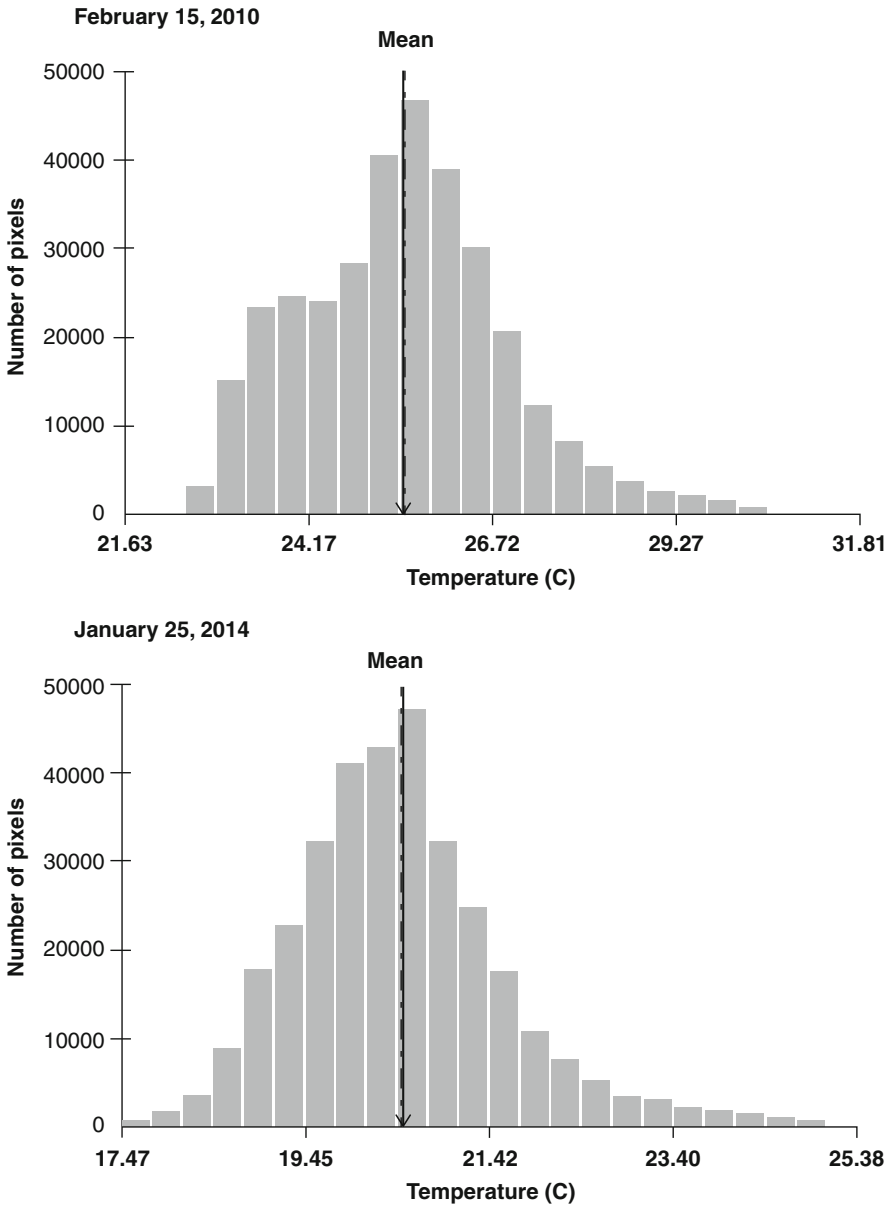

Fig. 12 LST mean for 2010 and 2014

- The land use and land cover change due to urban growth and development can be mapped and quantified using time series data acquired by the Landsat satellite programs from 1973 to date (Landsat 1–3 MSS, Landsat 4–5 TM, Landsat 7 ETM+, and Landsat 8 OLI and TIRS).

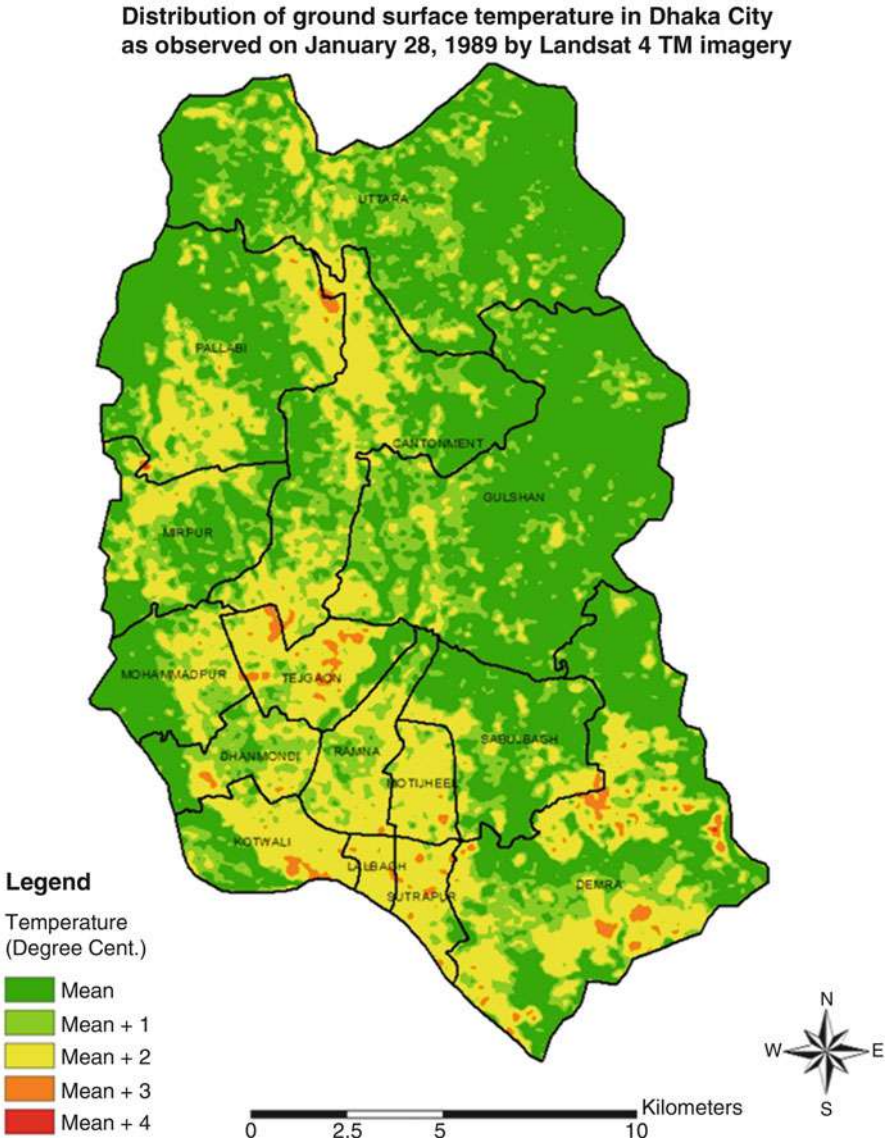

Fig. 13 Distribution of above mean temperature on January 28, 1989

- Landsat imagery-derived NDVI can be used to map and monitor the changes in greenness in growing megacities. It was observed that the average NDVI values in Dhaka decreased continuously from 1980 to 2014 with a significant change between 1989 and 2000.
- The changes in the land surface temperature (LST) can be used to determine the changes in the intensity of urban heat island (UHI) effect as a result of the growth

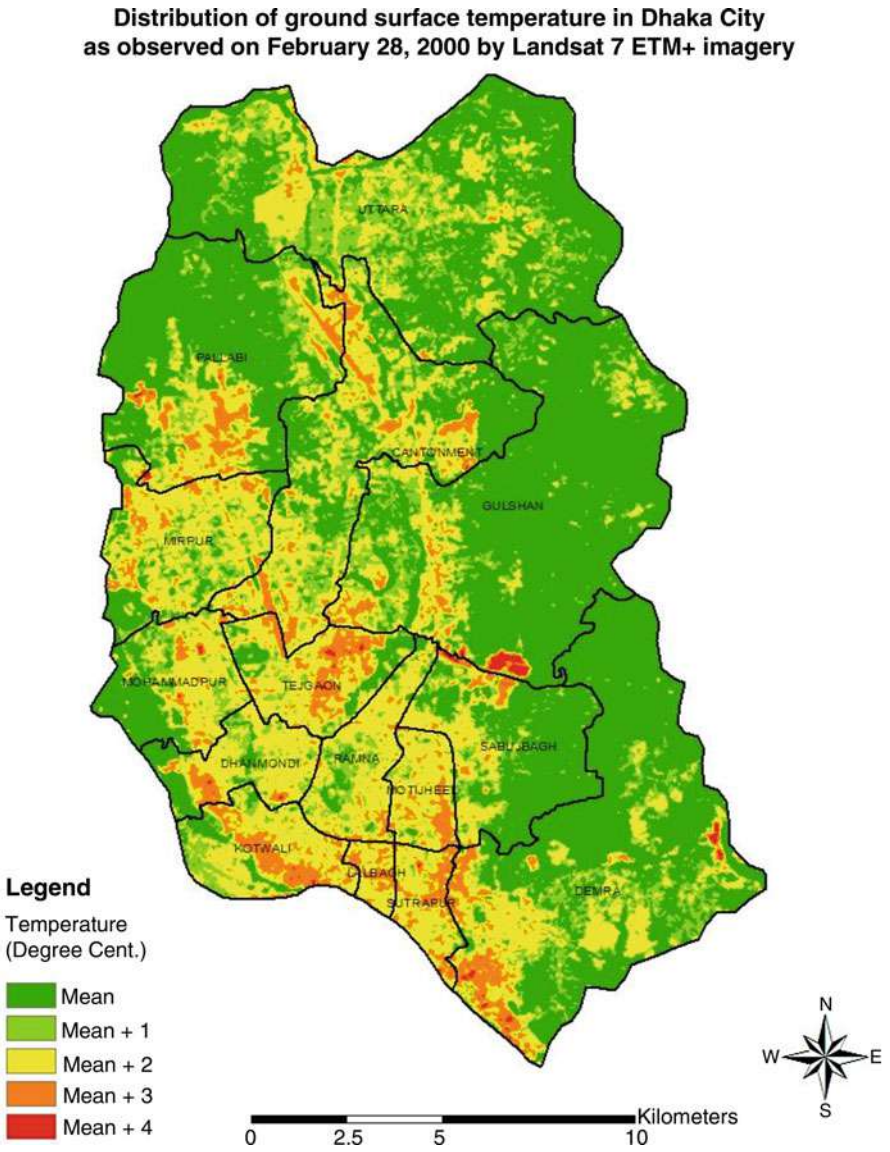

Fig. 14 Distribution of above mean temperature on February 28, 2000

and development in a megacity. The Landsat satellite-observed thermal data can be used to estimate continuous LST at 80–30 m spatial resolution from 1980 to date.

- It is possible to study the changes in the intensity of UHI effects in megacities, such as Dhaka, using the thermal data acquired by Landsat 4–5 TM, Landsat 7 ETM+, and Landsat 8 TIRS from 1989 to 2014. Visual inspection of the

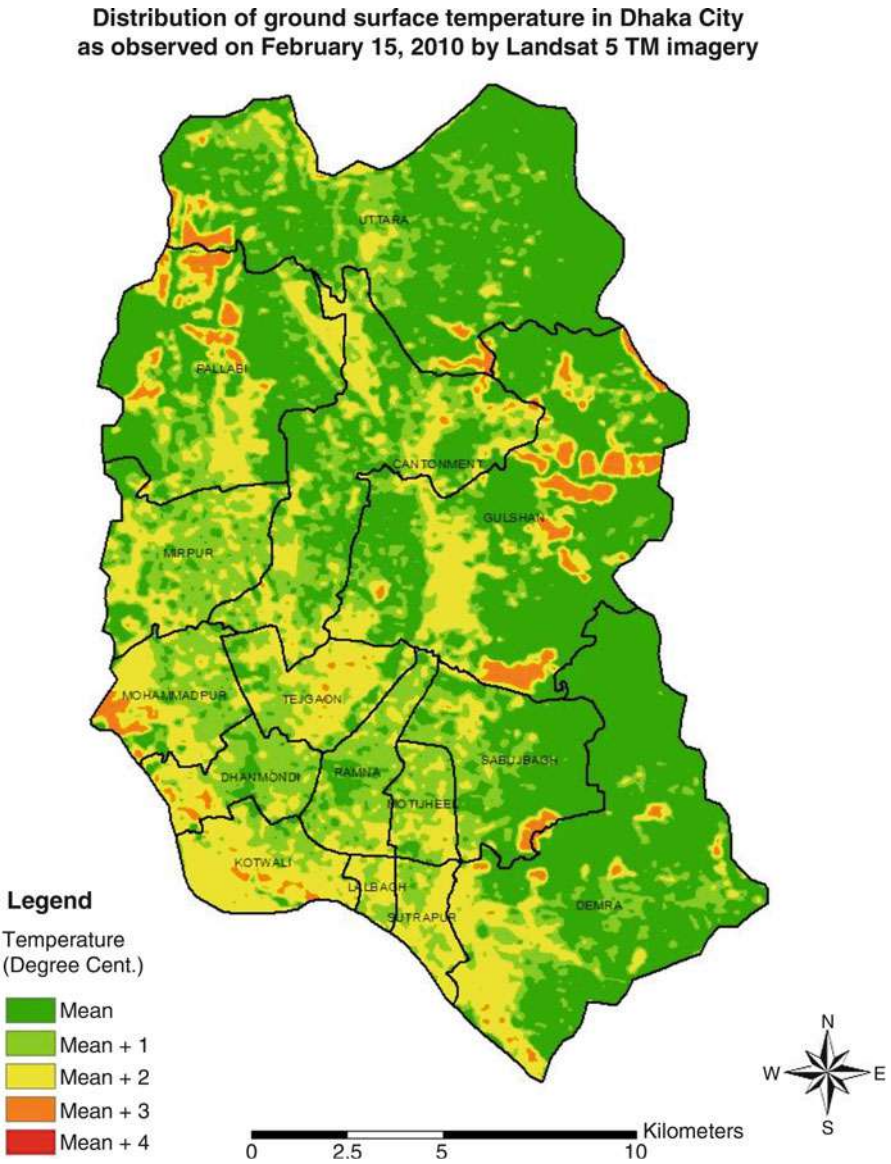

Fig. 15 Distribution of above mean temperature on February 15, 2000

Landsat-derived LST estimation can be used to interpret the changes in the intensity of UHI effects. However, a quantitative assessment of the changes in the spatiotemporal distribution of the LST over time is necessary to quantify the changes in the intensity of UHI effects. Image classification technique of the LST distribution can provide a reasonable solution in this regard. A five-class image classification scheme based on mean LST and 1, 2, 3, >3° above mean LST

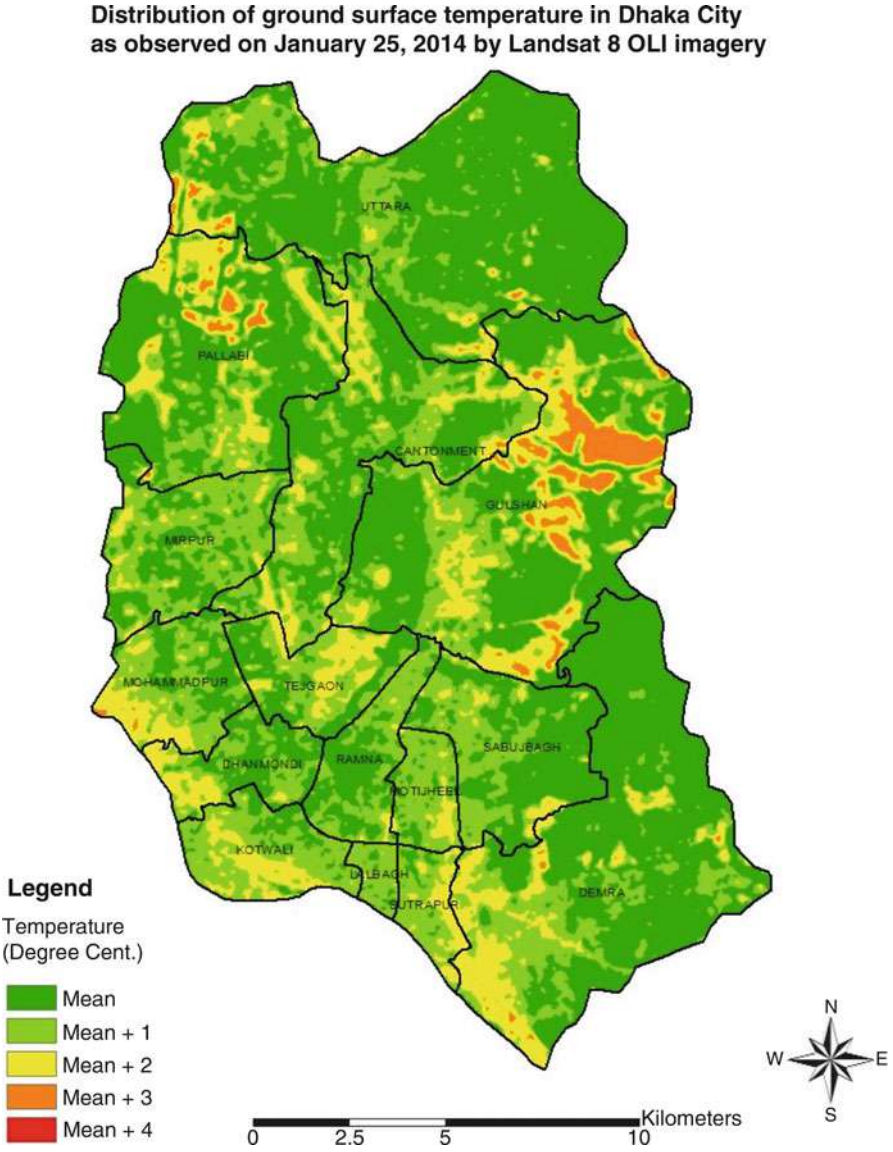

Fig. 16 Distribution of above mean temperature on January 25, 2014

provided a good understanding of the spatiotemporal variation of the above mean LST in Dhaka from 1980 to 2014.

- The imaging technology of LST (thermal data) by the Landsat 8 TIRS is different from that of the other Landsat sensors. The Landsat 8 TIRS data calibration approach used by NASA is also different. More research is needed to make the

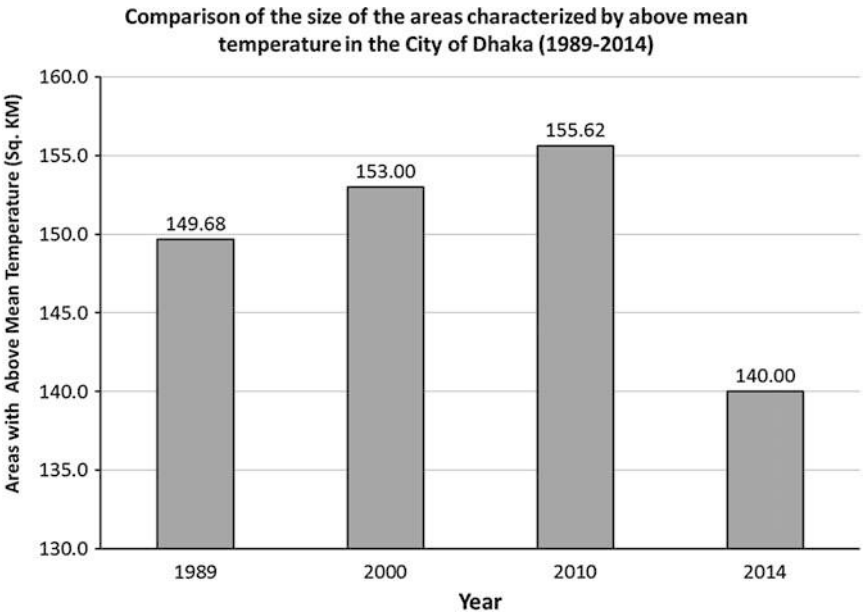

Fig. 17 Comparison of the size of the areas characterized by above mean temperature in the city of Dhaka (1989–2014)

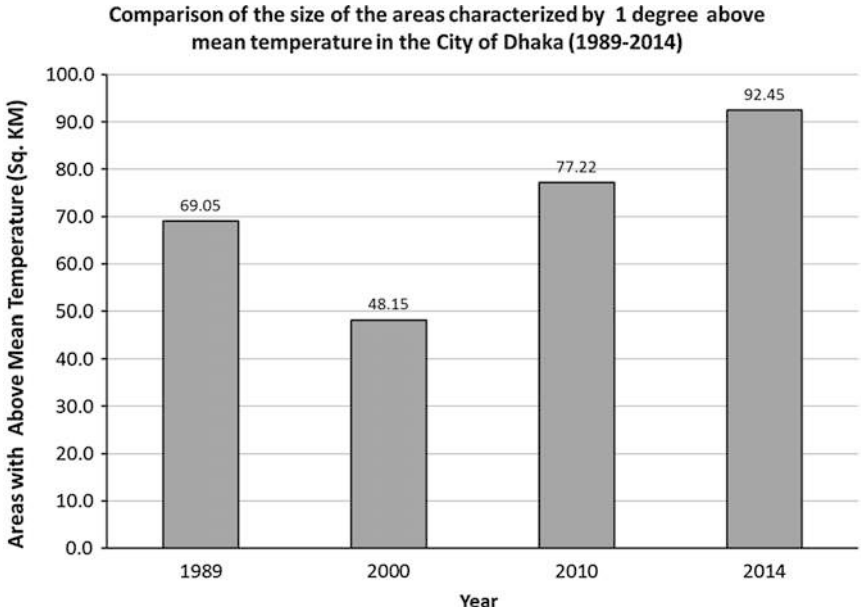

Fig. 18 Comparison of the size of the areas characterized by 1° above mean temperature in the city of Dhaka (1989–2014)

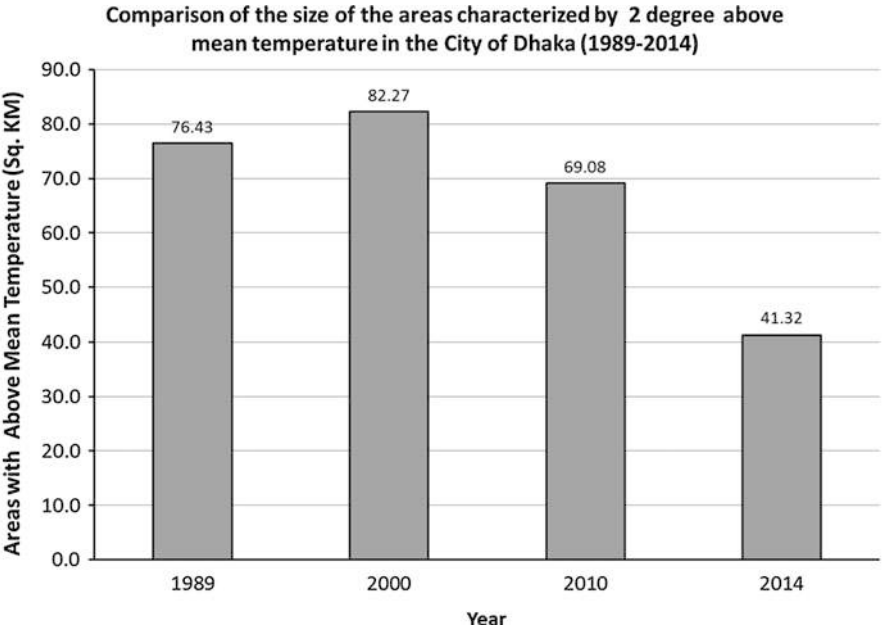

Fig. 19 Comparison of the size of the areas characterized by 2° above mean temperature in the city of Dhaka (1989–2014)

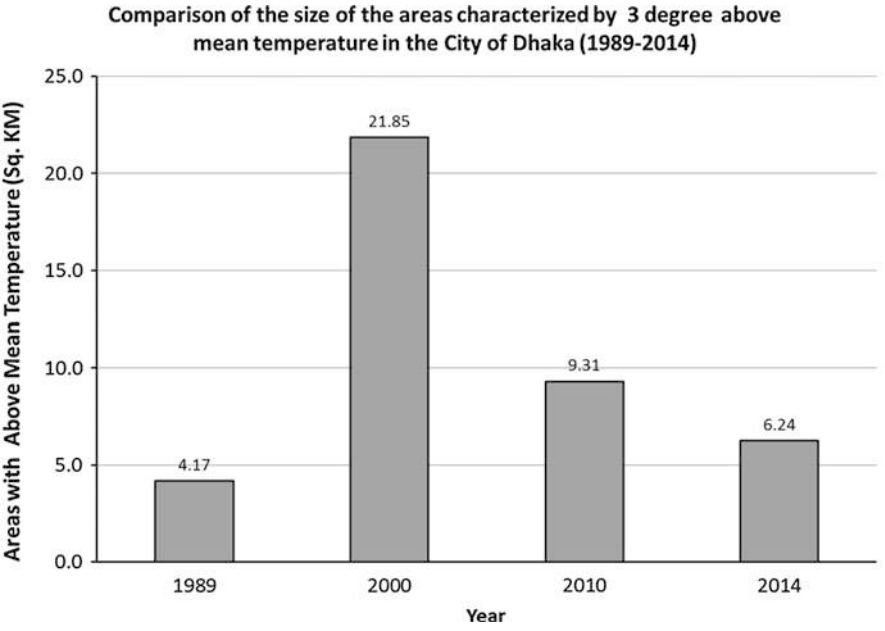

Fig. 20 Comparison of the size of the areas characterized by 3° above mean temperature in the city of Dhaka (1989–2014)

thermal data acquired by Landsat 8 TIRS and other Landsat sensors (TM and ETM+) comparable and reduce uncertainty.
- The interpretation of the changes in the greenness in the city of Dhaka was qualitative in nature in this study. It is recommended to use the surface reflectance-based NDVI calculation for the quantitative change detection studies.

Future Research Directions

The research presented in this chapter shows the potential of remote sensing data and image processing techniques to improve our current understanding about the impact of the growth of megacities in Southeast Asia on climate change. This study provides a good platform for future research to contribute in climate change studies following the emerging "bottom-up approach" (Hossain 2013). As part of this approach, initiatives are underway to extend the current research in the following directions.

- Categorize the NDVI and LST data for specific seasons and months so that the seasonal and monthly variations in land use and land cover and LST are minimized.
- Develop more statistically based methods to determine the changes in the intensity of UHI effects over time by normalizing the seasonal and monthly variations of LST.
- Extend this study to selected other megacities in both developing and developed countries to investigate if the developed methods/techniques work globally to determine the changes in the intensity of UHI effects due to urban growth.

Acknowledgments Thanks are due to NASA and USGS for providing all the Landsat data used in this research at free of charge. Thanks are also due to the National Center for Computational Hydroscience and Engineering (NCCHE) and Mississippi Mineral Resources Institute (MMRI) at the University of Mississippi for providing all the logistics and computing facilities for conducting this research.

Abstract

The issue of waste management is now a global problem because it is not only damaging soils but also deteriorating the natural state of air and water. This chapter focuses on two important aspects of solid waste in Pakistan, i.e., domestic solid waste and agricultural solid waste. The industrial and commercial activities are contributing heavily in large quantity of solid waste. Solid waste comprises of heterogeneous substances. The most common substances may belong to paper, aluminum, plastic, glass, ferrous materials, nonferrous waste, yard waste, construction and demolition wastes, etc. The issue of management of solid waste in Pakistan is a major environmental problem. Various research findings indicate that solid waste generation in Pakistan varies from 0.283 to 0.612 Kg/capita/day, while various studies indicate that the waste generation growth rate is 2.4 % per year. As a general practice, solid waste is commonly dumped on low-lying land or open vacant land area. Then, it is burned by sanitary staff to reduce its volume so that the life span of the dumpsite can be enhanced. However, the dumped solid waste does not burn completely but rather produces clouds of smoke that can be seen from miles away. This causes obnoxious smell and creates a breeding ground for flies and rats.

Various findings indicate that currently, about 60,000 t/day of solid waste is generated in Pakistan. No weighing or segregation facilities are located at any disposal sites. The wastes generated from hospitals and industrial activities are simply treated as ordinary wastes. They are jointly collected and shifted to the dump sites. The research findings indicate that common composition of solid waste in Pakistan contains plastic, rubber, metal, paper, cardboard, textile waste, glass, food, animal waste, leaves, grass, straws and fodder, bones, wood, stones, and fines to certain extent. Out of this the food wastes are 8.4–21 % of the total solid waste; paper waste 15–25 %; leaves, grass, straw, and fodder 10.2–15.6 %; fines 29.7–47.5 %; and recyclables 13.6–23.55 %. Keeping in view this proportion of solid waste, a sustainable and viable management of solid waste may be adopted by recycling, composting, and waste to energy.

In the other part of the chapter, focus is on agricultural waste which is actually agricultural biomass. Being an agricultural country, huge quantity of biomass is generated and remains unutilized or burned in the agricultural fields causing air pollution. It can be observed from Tables 6, 7, 8, and 9 the biomass residue of

various crops such as wheat straw, rice husk, rice straw, cane trash, bagasse, and cotton stalk is in different ratios. These ratios are wheat and wheat straw ratio 1:1, 20 % rice husk found as waste in paddy, paddy and rice straw ratio 1:1, 23 % cane trash found as waste in sugarcane harvest, 30 % wet bagasse found as waste in sugarcane industry, and cotton and cotton sticks ratio 1:3.

Keeping in view the availability factor, the different agricultural residue biomass is used as animal feed and also as a raw source of energy at local level; hence, we theoretically consider 40 % availability of total average amount of agricultural residue biomass, i.e., 5354.73 × 103 t/year. Theoretically considering average calorific value of agricultural residue biomass 3500 KCal/Kg, then the theoretical energy content = 3500 k Cal/Kg × 5354.73 × 10^6 Kg = 1.91 × 10^{13}KCal (heating value) if this amount of heat energy is multiplied by 4.81 for converting K Cal into KJ = 7.97 × 10^{13} KJ or KW-S. Hence, the power plants of about 10,000 MW are possible to be installed in the province of Sindh with the use of only 40 % of single source by agricultural residue biomass of only major crops.

This step will help in reducing air pollution in the region as a whole, and on larger scale it will help in restoring the climatic changes occurring around the world.

Part A: Solid Waste and Its Management in Pakistan

Solid Waste

Solid waste can be explained as the waste that is discarded by the society as unwanted material with the understanding that it is of no any productive use and has passed through its ultimate use. Mostly it is in solid, semisolid, or liquid state and is thrown out from residential, commercial, or industrial premises. The Basel Convention defines wastes as, "substances or objects which are disposed of or are intended to be disposed of or are required to be disposed of by the provisions of the law" (Basel Convention 1989).

With the advancements, solid waste generation has increased enormously and consequently has started to cause environmental problems. In the past whatever the small quantity of solid waste used to be produced by the society, it was thrown in the open environment and the nature was capable to absorb it slowly and gradually without causing any significant harm or effect to the natural environment and the valuable environmental components of it. But the situation changed over time with the generation of large quantities of solid waste, and nature turned unable to replenish the damaging environment as the quantities of waste started to be disposed of in larger quantities. The issue of waste management is now a global problem because it is not only damaging soils but also deteriorating the natural state of air and water.

The large quantity of generation of solid waste is taking place due to changing lifestyles; increasing use of disposable items and excessive packaging are all adding to an increase in the quantity of solid waste being generated. The industrial and commercial activities are contributing heavily in large quantity of solid waste. Solid waste comprises of heterogeneous substances (APO 2004). The most common substances may belong to paper, aluminum, plastic, glass, ferrous materials, non-ferrous waste, yard waste, construction and demolition wastes, etc. (UNEP 2005).

The issues associated with solid waste management are complicated because of the quantity and diversity of the nature of waste as well as financial limitations in large cities. It is due to this reason that nowadays the authorities of municipal organizations, planners, and managers are concentrating on proper management of the solid waste so that it does not cause any adverse problem to the environment in general and human society in particular. The municipal solid waste management (MSWM) is generation, segregation, collection, transferring, transportation, and final dumping to the designated place. By this way it succeeds in addressing public health concerns, economics, conservation, aesthetics, and the environment.

For proper management it is essential to understand sources and types of solid waste (Hoornweg and Thomas 1999). These are given in Table 1.

Composition of Solid Wastes

Waste composition is used to describe the individual ingredients present in solid waste stream and their relative distribution. Knowledge of composition of solid wastes is important in evaluating and assessing the equipment needed, system and management programs, and plans needed for solid waste management. The municipal and commercial portion adds up about 50–75 % of total municipal solid waste generated in a society. The actual percentage distribution depends on the extent of the municipal services provided, location, season, economic conditions, population, social behavior, climate, market for waste materials, and other factors.

Solid Waste Issue in Pakistan

Like the rest of the world's urban areas, the issue of management of solid waste in Pakistan is a major environmental problem. Various research findings indicate that solid waste generation in Pakistan varies from 0.283 to 0.612 Kg/capita/day, while various studies indicate that the waste generation growth rate is 2.4 % per year. As a general practice solid waste is commonly dumped on low-lying land or open vacant land area. Then, it is burned by sanitary staff to reduce its volume so that the life span of the dumpsite can be enhanced. However, the dumped solid waste does not burn completely but rather produces clouds of smoke that can be seen from miles away. This causes obnoxious smell and creates a breeding ground for flies and rats.

Table 1 Sources and types of solid waste

S. no.	Sources	Locations from where solid waste is generated	Types of solid waste
1	Domestic	Single or multifamily housing units	Food waste, paper, cardboard, plastic, textiles, leather, yard waste, wood, glass, metals, ashes, special waste bulky items, consumer electronics, goods, batteries, oil
2	Factories	All locations where light and heavy manufacturing takes place, construction sites, power and commercial plants	Manufacturing process waste, scrap materials, construction and demolition wastes, rubbish, ashes, and special wastes
3	Commercial	Departmental stores, hotels, restaurants, markets, office buildings, etc.	Paper, cardboard, plastics, wood, food wastes, glass, metals, special wastes, hazardous wastes
4	Institutional	Schools, hospitals, prisons, government and private offices	Paper, cardboard, plastic, wood, food wastes, glass, metals, special waste
5	Construction or demolition	New construction sites, road repair, renovation sites, demolition of buildings, broken pavements	Wood, steel, concrete, dirt, etc.
6	Municipal services	Street cleaning, landscaping, parks, beaches, recreational areas, water and wastewater treatment plants	Street sweepings, landscape and tree/plant trimmings, general waste from parks, beaches, and other recreational areas, sludge
7	Agricultural	Crops, orchards, feedlots, agricultural farms, etc.	Spoiled food wastes, agricultural waste, rubbish, hazardous wastes

Source: Solid Waste Management in Asia Urban Development Sector Unit

This soil may have been used for more useful purposes and most important is that the possible recyclable materials are lost (ESMF 2009).

There is no proper waste collection system in any urban area at all. The solid waste is dumped on the streets. Different types of waste are not collected separately. There are no controlled sanitary landfill sites. Citizens are not aware of the relationship between ways of disposing of waste. As a result the overall natural environmental and public health problems emerged frequently. Figures 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, and 17 given below reflect the solid waste dumped in an improper way in an open area (Pakistan's garbage disposal 2001).

Current Status of Solid Waste Generation in Pakistan

Various findings indicate that currently, about 60,000 t/day of solid waste is generated in Pakistan. No weighing or segregation facilities are located at any

Fig. 1 Improper dumping of solid waste in the vicinity of vacant residential area

disposal sites. The wastes generated from hospitals and industrial activities are simply treated as ordinary wastes. They are jointly collected and shifted to the dump sites (Wastes in Pakistan 2006). The estimated waste generations in different cities of Pakistan are given in Table 2.

Dumping of solid waste at abandoned open places and then its burning are the common practice. This thrown away waste has got lot of potential for recycling and is lost away easily. The total collection varies from 51 % to 70 %, while the rest of the solid waste stays behind on the streets. No relevant disposal facilities exist anywhere. It is unfortunate that no any city in Pakistan has acceptable solid waste management system right from generation of solid waste up to its final disposal. All such uncollected waste poses certain risk to the human health as well as results in clogging of drains and formation of stagnant pools of dirty water. This situation provides breeding ground for mosquitoes and flies that result in spreading malaria and cholera.

Common Composition of Solid Wastes in Pakistan

The research findings indicate that the common composition of solid waste in Pakistan contains plastic, rubber, metal, paper, cardboard, textile waste, glass, food, animal waste, leaves, grass, straws and fodder, bones, wood, stones, and fines to certain extent. Out of this the food wastes are 8.4–21 % of the total solid

Fig. 2 Improper dumping of solid waste in the low-lying area

waste; paper waste 15–25 %; leaves, grass, straw, and fodder 10.2–15.6 %; fines 29.7–47.5 %; and recyclables 13.6–23.55 % (UNEP 2005).

Environmental Problems Due to Solid Waste

Ground Pollution

As water whether surface or rain infiltrates deep down through solid waste, it causes leachate that comprises organic matter and may contain metallic substances like iron, mercury, lead, and zinc from discarded batteries and appliances. The leachate may also contain paints, chemical substances, pesticides, detergents, printing inks, etc. Such polluted water may cause serious impact on all living beings, including humans, and on an ecosystem.

Air Pollution

When solid waste is burned away in such an open place, heavy metals like iron and lead and harmful gases spread over the populated areas and result in air pollution. The blowing of wind also transfers finer solid waste substances, dust particles, and gases to the far-flung areas. The disintegration of solid waste in sunlight results in obnoxious smells and reduced visibility.

Fig. 3 Scavengers searching and collecting valuable items from improperly dumped solid waste

Health Hazards

The open dumping of solid waste initiates skin and eye infections and turns common in the prevailing area. Finer dust particles in the ambient air at or in the vicinity of dumpsites can cause respiratory problems in children and elders. The insects like flies breed on openly dumped waste and spread diseases like diarrhea, typhoid, all types of hepatitis, and cholera. Mosquitoes' bites transfer many viruses and parasites that cause diseases like malaria and yellow fever. Stray animals like dogs, cats, and rats staying and wondering around the dump site turn carriers of a variety of diseases including plague and fever. Even the sanitary staff engaged in handling and transferring of solid waste suffers from intestinal and skin diseases.

Major Constraints in Solid Waste Management in Pakistan

The proper management is missing in Pakistan because of numerous problems and issues. They include lack of infrastructure, inadequate budgetary allocations, lack of clear roles and responsibilities, uncontrolled disposal of solid waste (dumped in suburb and city boundaries), threat to public health and sanitation, and environmental pollution. In all such circumstances, solid waste solutions are not only with the engineers but can equally be distributed in between 50 % engineering and 50 % social – policy and institutional lack of participation and involvement (UNEP 2005).

Fig. 4 Scavengers intentionally burning the dumped solid waste and collecting exposed metallic items

Integrated Solid Waste Management Practices

Integrated solid waste management (ISWM) can be explained as a comprehensive waste prevention, recycling, composting, and disposal program through which the generated solid waste is managed in an environment-friendly way. A successful ISWM system focuses on prevention, recycling, and managing solid waste in such a way that it effectively protects human health and the natural environment. ISWM concentrates on sustainable solid waste management and involves in examining local needs and conditions. After this it selects the most suitable solid waste management methodologies for their strategies. Each and every activity needs careful collection and transportation of the waste to the final disposal point (Landfill design, U.S 1993).

Waste Prevention

Waste prevention is a term used for "source reduction" under which efforts are launched to prevent waste from being produced. The methodologies for waste prevention are the use of less packaging material, designing and manufacturing such items that can stay longer, and reusing repeatedly the products and materials which are once produced. Waste prevention supports in reduced handling, reduced treatment, and minimized disposal costs and in the end reduces the generation of methane.

Waste Recycling

Waste recycling may be defined as a process of collecting, reprocessing, and recovering certain waste substances, e.g., metals, glass, plastics, and paper, to

Fig. 5 Improperly dumped solid waste and its burning cause smoke and air pollution

Fig. 6 Improper dumping of solid waste causes damage to water and soil resources

produce new items. After collection, substances are segregated and forwarded to facilities that process them to manufacture new products and items and are made available as new products for their use. Recycling is the excellent option to resolve solid waste management issues. This technique of recycling exists in most cities. However, the recycling system differs from developing countries and developed countries. The advanced countries have established well-organized at-source segregation and recycling system, while in the developing countries, the system of recycling is not effective.

Fig. 7 Solid waste skip fully filled with waste and dropping down on the ground

Recycling converts materials into valuable raw materials that otherwise would have become useless waste and initiates a host of environmental, financial, and social benefits (Environment Protection 2011). There are at least five benefits for recycling of solid waste and they are as under:

(a) **Economic**
Possible economic benefit of waste prevention includes reduced waste disposal fees as the waste is not usually disposed free of cost; rather, substantial charges are to be paid by the producer. On the other hand, revenues can be earned from recycling commodities by selling the recyclable substances.

(b) **Environmental**
The environmental advantage lies in reduced energy consumption, reduced pollution, conservation of natural resources, and extension of valuable landfill capacity, which stimulate the development of greener technologies and prevent emissions of many greenhouse gases and water pollutants.

(c) **Employee Morale**
Employees' morale improves when they see the company taking steps to reduce waste through recycling. This enhanced morale certainly increases employee interest, productivity, and more waste prevention measures. Some companies use recycling revenues for employee recreation (i.e., picnics, holiday parties, etc.).

(d) **Corporate Image**
When customers and the surrounding neighborhoods see that the company is environmentally conscious, it creates a favorable image of the company. An enhanced corporate image might attract customers. It is noted from various surveys that more consumers now give preferences to a firm's environmental record when making purchasing decisions.

Fig. 8 Improperly dumped waste material alongside a wall of a residential house

(e) **Compliance**
Reducing solid waste through recycling means compliance with local or state solid waste regulations. Some stakeholders and organizations restrict the quantities or types of waste accepted at solid waste management facilities. By implementing an extensive and sustainable recycling program, the business can help ensure compliance with these requirements.

Waste Composting

Composting is the term used for degradation of organic materials under controlled conditions. This practice results in a marketable soil amendment or mulch. It is in fact a natural process that can be carried out with very simple human efforts. It can be systematically executed by reducing the composting time and space required and by minimizing the objectionable smells. The stabilized end products obtained after composting are rich in organic matter. These end products can act as a fine soil conditioner. But the concentrations of key nutrients such as nitrogen, phosphorus, and potassium are typically low in comparison to commercially manufactured fertilizers.

In the simplest composting systems, yard wastes are stacked in long, outdoor piles called windrows. A typical windrow might be 2 m high, 3 or 4 m wide, and tens of meters long. Their length is determined by the rate of input of new materials, the length of time that materials need for decomposition, and the cross-sectional area of the pile. The composting process is affected by temperature, moisture, pH, nutrient supply, availability of oxygen, bacteria, and fungi. These are principal players in the decomposition process. But microorganisms such as nematodes,

Fig. 9 Animals like dogs contract pathogens from the dumped solid waste material which spreads within the human settlements

mites, bugs, earthworms, and beetles also play a key role by physically breaking down the materials into smaller bits that are easier for microorganisms to attack (Integrated Agricultural Systems 2002).

A number of nutrients must be available to the microorganisms that are attacking and degrading the compost pile. The most important nutrients needed are carbon for energy, nitrogen for protein synthesis, and phosphorus and potassium for cell reproduction and metabolism. In addition, a number of nutrients are needed in trace amounts, including calcium, cobalt, copper, magnesium, and manganese.

Disposal (Landfilling and Combustion)

The landfilling and combustion activities are adopted to manage that solid waste which cannot be prevented or recycled. Under the method of landfilling, the solid waste is placed in properly designed, constructed, and managed landfills. In the landfills the dumped solid waste is safely contained permanently. The other method to handle this waste is through combustion. Combustion is the controlled burning of waste, which helps reduce its volume, and the burning process is called as incineration.

The Three Rs (Reduce, Reuse, and Recycle)

In today's world, reduce, reuse, and recycle, commonly referred as the three Rs for waste management, are effective measures that serve as alternatives to disposing

Fig. 10 Open dumping practice of solid waste in huge quantity on a large area

waste in landfills. Nowadays, various methods are available for properly managing the solid waste that is produced. The relevant municipal authority introduces an integrated approach to manage the generated solid waste along with combination of substitute options. The strategies of three Rs assist in reducing down the quantities of waste disposed away. The strategies of three Rs presently are helping out in conserving natural resources, landfill capacities, and energy. In addition to this, the three Rs save land and money. Choosing a new landfill has become complicated and more costly due to environmental bindings and opposition from the public living in the vicinity (Margaret Cunningham 2010).

(a) **Reduce**

The concept behind the option of reduce is not to produce the solid waste. This option can be practiced by purchasing carefully and being familiar with few guidelines like purchasing products in bulk quantity. Larger, economy-size items or those products that are confined in less packaging may be opted, avoiding overpackaged products, especially those which are packed with several materials such as foil, paper, or wooden boxes. Avoid disposable goods, such as paper plates, cups, napkins, razors, and lighters as their disposal contributes to the problem. Additionally, they are expensive because they are replaced again and again. Purchase long-lasting products that are durable or that carry good warranties. They will be long-lasting, save money in the long run, and save landfill capacities. At the office environments, make two-sided copies whenever possible. Maintain one master file instead of using several files.

Fig. 11 Scavenger is busy in openly burning the solid waste

Adopt the practice of using electronic mails or maintain a bulletin board for correspondence and communication. Also, adopt the practice of usage of cloth napkins instead of paper napkins.

(b) **Reuse**

The concept behind reuse is using again and again the products that are capable to do that. By adopting this practice, the paper material and plastic bags can be saved in larger quantities. More importantly, the broken appliances like furniture and toys can be repaired and made ready for reuse. Similarly, use a coffee can to act as a lunch box. Reuse successfully plastic microwave dinner trays as picnic dishes. Sell old clothes, appliances, toys, and furniture in garage sales or donate them to charities. Use resealable containers rather than plastic wrap. Use a ceramic coffee mug instead of paper cups. Reuse grocery bags or bring your own cloth bags to the store. Avoid taking any a bag from the shops until and unless they are really needed.

(c) **Recycling**

Recycling practice may be explained as a series of steps in which the used materials are processed and converted into raw material again and new products are remanufactured. These remanufactured items are sold as it is as a new product. The concerned organizations advise to purchase products made from recycled material. The remanufactured products are identified by a symbol called a recycling symbol. The recycling symbol indicates out one of the two things –

Fig. 12 Smoldering smoke coming out from dumped solid waste

either the product is made of recycled material or the item can be recycled. For instance, many plastic containers have a recycling symbol with a numbered code that indicates out the type of plastic resin it is made from. The users of the relevant plastic product can check out collection centers and curbside pickup facilities to see what they accept and start collecting those materials. Most commonly, the recyclable materials may include metal cans, newspapers, paper products, glass, and plastics. Preferences must be given to buying recycled materials at work when materials for office supply, office equipment, or manufacturing are needed. Speak to store management and ask for products and packaging that help in reducing down the solid waste. Prefer purchasing those items made from substances that are collected for recycling in the local area. Adopt practices for recycled paper for letterhead, copier paper, and newsletters.

Solid Waste Collection

Solid waste collection is the first operation of the solid waste management stream. More significantly, three parties play an important role in this operation, i.e., the producers of the waste, the municipal authority, and the sanitary staff. In order to execute this system, all the three parties have to work in close coordination; else, it will be difficult to yield the success. The producers must be familiar with their roles

Fig. 13 Improper dumping of solid waste and emerging smoke in the vicinity of vacant residential area

and responsibilities, and then there come the responsibilities of the municipal authorities and then the sanitary staff. For better performance the collection system can be classified in residential refuse collection systems, commercial waste collection, and recyclable material collection.

In executing waste collection system, there may be some influence of prevailing climate, topography, available transportation systems, traffic, roads, types of wastes, and population density. However, they can be managed by adopting best waste collection practices.

Waste Management Through Source Reduction

The solid waste that is not produced does not have to be collected is a simple concept. That is not the case in many other advanced countries in the world – especially those with modest domestic resources and limited land space for disposal, such as Germany and Japan. In such circumstances, strategies like good green design practices can be considered successful in reducing solid waste.

Green Product Design Strategies

The design that reduces the environmental impacts associated with the manufacture, use, and disposal of products is an important part of any pollution prevention

Fig. 14 Improper dumping of solid waste in the vicinity of vacant residential area

strategy. Companies that engage in such green product design are finding products that combine environmental advantages with good performance and price. The Office of Technology Assessment, USA, identifies two complementary goals of green design:

(a) Waste prevention
(b) Better material management

Waste prevention can be achieved by reducing the weight, toxicity, and energy use of products along with increasing the useful life of products. Better material management facilitates remanufacturing, recycling, and composting along with enhanced energy recovery opportunities.

Product System Life Extension

Products that do not wear out as quickly do not have to be replaced as often, which usually means that resources are saved and less waste is generated. Sometimes, products are discarded for reasons that have nothing to do with their potential lifetime. For example, computers become obsolete and clothing fashions change, but many products can continue to remain in service for extended periods of time if they are designed to be durable, reliable, reusable, remanufacturable, and repairable. Extending product life means consumers replace their products less often, which translates into decreased sales volume for manufacturers. Market share in the future may be driven to some extent by

Fig. 15 Improper dumping of solid waste and exposure of pollutants to the passersby

consumer demand for greener products. Consumers, of course, must make that happen.

Material Life Extension

Once a product has reached the end of its useful life, the materials from which it was made may still have economic value, and additional savings can result from avoiding disposal. The key design parameter for extending the life of materials is the ease with which they can be recycled. Products that have been designed to be recycled easily are becoming especially common in Germany. For example, Germany's requirement that automakers take back and recycle old automobiles has stimulated green design in companies such as BMW and Volkswagen. BMW already sells cars with plastic body panels that have been designed for disassembly and that are labeled as to resin type so they may more easily be recycled.

Material Selection

A critical stage in product development is selection of appropriate materials to be used. In green design, attempts are made to evaluate the environmental impacts associated with the acquisition, processing, use, and retirement of the materials under consideration. In some cases substituting one material for another can have a modest impact on the quality and price of the resulting product but can have a considerable impact on the environmental consequences.

Fig. 16 Large number of scavengers busy in searching valuable items from solid waste

Process Management

Manufacturing products requires raw materials and energy inputs. Both of which often can be managed more efficiently. The energy required to manufacture a product is an important component of a life cycle assessment. Process improvements that take advantage of waste-heat recovery, more efficient motors and motor controls, and high-efficiency lighting are almost always very cost effective.

Efficient Distribution

Methods of packaging and transporting products greatly affect the overall energy and environmental impacts associated with those products. Transportation costs are affected by the quantity and type of material shipped, which is in turn affected by packaging, trip distance, and type of carrier. The type of carrier is constrained by the terrain to be covered as well as the speed required for timely arrival. In general, shipping by boat is the least energy-intensive option, followed by rail, truck, and then air, which is fastest but requires the most energy per ton-mile transported.

Policy Options

Germany has shifted the burden of packaging disposal from the consumer back to manufacturers and distributors. Germany's Packaging Waste Law requires manufacturers and distributors to recover and recycle their own packaging wastes. The concept may even be extended to large durable goods, such as household appliances and automobiles. Germany's take-back policy is one of many examples of approaches that governments can take to encourage reduction in the environmental costs of products.

Fig. 17 Open transportation of collected solid waste and the sanitary staff involved in loading activity without relevant safety measures

Table 2 Estimated waste generation in different cities of Pakistan

S. no.	Name of city	Population	Waste generation rate Kg/capita/day	Daily waste generation (tons/day)	Annual waste generation (tons/year)
1	Karachi	1,66,31,255	0.613	10,195	37,21,160
2	Hyderabad	14,96,163	0.563	842	3,07,454
3	Peshawar	13,44,967	0.489	658	2,40,056
4	Faisalabad	28,08,982	0.391	1098	4,00,883
5	Quetta	6,57,788	0.378	248	90,755

Labeling

Surveys have consistently shown that American consumers purchase products that are environmentally superior to competing products, even if they cost a bit more. Attempts by manufacturers to capture that environmental advantage have led to an overuse of poorly defined terms such as recyclable, recycled, eco-safe, ozone friendly, and biodegradable on product labels. Unfortunately, without a uniform and consistent standard for such terms, these labels are all too often meaningless or even misleading. For example, all soaps and detergents have been "biodegradable" since the 1960s. Aerosols "CFC-free, ozone friendly" have been the norm in the USA since the banning of CFCs for such applications in 1978.

Landfill Operations for Municipal Solid Waste

The properly designed landfills for disposal of municipal solid waste have brought a revolution in the place of traditional dumping of waste in the outskirts of residential settlements. The traditional waste dumping used to develop a variety of environmental pollution problems, viz., emergence of large number of flies, rats, airborne diseases, obnoxious smells/odors, and a black cloud of smoke.

The term landfill refers to physical facilities adopted for the final placement of solid wastes in the ground. There are few more terms which are used in this exercise of solid waste dumping. For example, **sanitary landfill** refers to engineered mechanism for the dumping of domestic solid wastes into the ground to reduce the public health and environmental impact, while the term **secure landfill** refers to the engineered facility for the dumping of hazardous wastes.

When the waste is placed in the landfills, biotransformation of organics takes place, and landfill gases and liquids are generated. The aerobic process starts to take place; then, it is followed by anaerobic processes. The aerobic processes produce and release carbon dioxide (CO_2) and liquid (H_2O), while the anaerobic process produces carbon dioxide (C_2O), methane (CH_4), and trace amounts of ammonia and hydrogen sulfide (Landfill manuals 1993).

Nowadays, the proper dumping of municipal solid waste in the properly designed and constructed land areas is referred as municipal solid waste landfills.

The term landfill refers to physical facilities adopted for the final placement of solid wastes in the ground. There are few more terms which are used in this exercise of solid waste dumping. For example "**Sanitary landfill**" refers to engineered mechanism for the dumping of domestic solid wastes into the ground to reduce the public health and environmental impact. While the term "**Secure landfill**" refers to the engineered facility for the dumping of hazardous wastes.

When the waste is placed in the landfills biotransformation of organics take place and landfill gases and liquids are generated. The starting take place aerobic process, then it is followed by anaerobic processes. The aerobic processes produce and release carbon dioxide (CO_2) and liquid (H_2O). While the anaerobic process produces carbon dioxide (C_2O), methane (CH_4) and trace amounts of ammonia and hydrogen sulfide (Environment Protection 2011).

Solid Waste Management Landfill Methods

There are various landfill methods which are discussed as under:

(a) **The trench method**
The trench method of landfills is used in level terrain. The trenches are dug by excavation in the ground. Solid waste is filled in the trenches and dirt is replaced on top of the buried material. After completion the trench is compacted.

(b) **The area method**
The area method is the most popular landfill method. In this method a side of a hill or a sloped area is found out. Then, refuse is dumped on the side of the slope and then covered with dirt. It continues until the entire slope is leveled.

(c) **The valley or ravine method**
The valley or ravine method is commonly used where large quantities of waste are generated by large cities. This method is used in an area with large depression or slope such as a valley or ravine. Usually, an area naturally developed is considered most suitable. Refuse is dumped in the depression and filled with dirt. The area is then compacted and built up.

Landfill Operation Classification

There are three classifications of landfills:

(a) **Class I landfills or secure landfills**
These landfills are designed for dumping of hazardous waste.
(b) **Class II landfills or monofills**
These landfills are designed for dumping of designated wastes, which are particular types of wastes such as incinerator ash or sewage sludge that are relatively uniform in characteristics.
(c) **Class III landfills or sanitary landfills**
These landfills are designed for dumping of municipal solid waste.

Though landfills remain the primary means of municipal solid waste disposal, three Rs of reduce, reuse, and recycling are beginning to have greater attraction in the waste management system.

Landfill Site Construction Requirements

The construction of a landfill site requires a step-by-step approach. The landfill activity planners and designers are basically concerned with the viability of a suitable site (Pak EPA 2011). In order to construct commercially and environmentally feasible landfill site, specific requirements must be kept in consideration. The specific requirements are discussed below:

(a) **Location**
The landfill site should be in easy access to transport the solid waste by road. The transfer stations may be established if the haul distance is far away or rail network is used for solid waste transportation. In addition to this, land value (cost of land), cost of meeting government requirements, and prospects of overall community served through the operation may also be considered before making any final decision. Types of construction, i.e., more than one landfill, may be used at a single site in order to enhance the life of the planned site for a very long time.
(b) **Stability**
It is the complete study of underlying geology at the planned landfill site, by studying the nearby area for earthquake faults or any such weak strata, underground water table, and location of nearby rivers, streams, and flood plains so that the landfill site stays intact.
(c) **Capacity**
Capacity refers to the quantity of solid waste that is to be dumped in the landfill area. The calculation of solid waste capacity is based on quantity of the wastes,

amount of intermediate and daily cover applied to it, and amount of settlement that the waste will undergo following tipping. The thickness of capping the landfill operation is considered along with construction of lining and drainage layers when it is completely filled at its end.

(d) **Protection of soil and water**
The solid waste is permanently dumped in the landfills. This permanent placement of solid waste needs installation of liner and collection systems. In addition to this arrangement for storm water control, leachate management and landfill gas migration may be seriously considered.

(e) **Nuisance and hazard management**
The overall operation of solid waste landfills is of critical nature. The solid waste is transported from one place to its final disposal. It is ensured that it does not cause any nuisance as there is a chance of it falling down from the loaded vehicle on its hauling path. The waste may possibly emit odor that is again a nuisance for the residents living on the haul-way path or near the landfill site. In some cases the solid waste may be infectious or hazardous in nature, and in that case special attention must be given while collection is performed.

Basic Features of Landfills

Moisture or water content in a landfill is important if the wastes are to decompose properly. The initial moisture contained in the wastes themselves is quickly dissipated, so it is water that percolates through the surface, sides, and bottom that eventually dominates the water balance in the landfill. Water percolating through the wastes is called leachate. Its collection and treatment is essential to the protection of the local groundwater.

Municipal solid waste landfills require composite liners and leachate collection system to prevent groundwater contamination. The composite liner consists of a flexible membrane liner (FML) above a compacted clay soil. Leachate is collected with perforated pipes that are situated above the FML. A final cover over the completed landfill is designed to minimize infiltration of water (BC Ministry of Environment 2013).

During waste decomposition, methane gas is formed so completed landfills need collection and venting system.

Sources of Methane: Landfill

On a global scale the methane gas emissions from landfill activities are estimated to be in between 30 and 70 million tons each year. It is believed that major releases of this landfill methane presently come from developed countries, where the levels of waste tend to be highest and no comprehensive methane recovery mechanism is adopted.

Landfills provide most suitable conditions for methanogenesis, with huge quantity dumping of organic material and prevailing anaerobic conditions. The larger quantities of waste which are dumped in landfills can produce methane for years to come after the closure of the landfills, as the waste passes through slow decay under the ground.

The municipal solid waste landfill activities are the largest human-related methane emissions. This landfill gas is easily captured and redirected if relevant

arrangement is made. Firstly, the commercial landfill gas energy (LFGE) recovery project was started in 1975 in Los Angeles. Gases are released during decomposition in landfills. When captured and converted to an alternative energy source, LFG is called biogas. The municipal solid waste decomposition releases methane ~50 %, $CO_2 \sim 45$ %, and $N_2 \sim 5$ % (Ahmed et al. 2013).

Methane release takes place from landfills either directly to the air or by diffusion through the soil cover and causes impacts on the natural environment.

Infectious Waste

Infectious waste is a waste that possesses potential risk of diseases or illness to human beings or a waste that is capable of causing infectious diseases. Segregation and labeling of infectious waste is carried out at its source of generation. When performing handling of infectious waste, it should be ensured that it must be carefully managed. The intactness of the packaging must be maintained and quicker bacterial growth and putrefaction is repressed. The containers in which sharps are placed must be impervious, rigid, puncture resistant, leak resistant, and sturdy so that they can sustain the risk.

Infectious waste may include human blood, body fluids, separated or removed away body organs through surgical operation, syringes, sharps, glassware, or all items used during the treatment activity on an infected patient.

Training for Handling Infectious Waste

Persons working with blood may be trained about blood-borne pathogens. The engaged staff working with animal contact may be trained with relevant training. The staff working with any waste that carries a potential risk of transmitting illness or disease to humans may be trained with infectious waste management. The staff engaged with infectious organisms having risk to cause illness or disease in healthy people, animals, or plants may be trained in biosafety.

Personal Protective Equipment for Handling Infectious Waste

The people who are engaged in handling infectious waste must be advised to wear relevant personal protective equipment (PPE), for example, wearing impermeable gloves for handling infectious waste. For splashing risk, wearing of eye protection or wearing shoe covers for walk-through hazards is advised.

Infectious Waste Storage

The noninfectious waste must be kept separate from infectious waste. If infectious waste is mixed by mistake with noninfectious waste, then it must be considered as infectious waste. Efforts should be made to minimize storage time duration. The area where infectious waste is placed must only be accessible by authorized personnel. The infectious waste storage area must be ventilated to outdoors. The area must be labeled with a warning sign in a clear and visible manner. The area must thwart exposure to common people, animals, and insects and disclosure to

weather. Red- or orange-colored bags are generally used for putting the infectious waste and are also called biohazard bags. The colored bags must be correctly sealed when filled. For leakage or seep hazards, leak-proof bins or bags should be used.

Labels for Infectious Waste

The universal biohazard symbol must be displayed at the place where infectious waste is placed. The biohazard symbol should be understandable from at least seven meters away from the placed bags containing infectious waste. A written message like "biohazard" or "biohazardous," "infectious waste," or "biomedical waste" must also be displayed.

Hazardous Waste

Wastes containing harmful components that are too dangerous to be handled in ordinary manner and sent to the landfill, dumped into the sewer system, or released into the atmosphere are hazardous substances. These can be in a form of a solid, liquid, contained gas, or sludge. Improper release of hazardous waste may seriously threaten the environment and human health. Hazardous waste is regulated from the moment it is created through the time of final disposal. Identification of listed hazardous wastes:

F-Listed Wastes
- Wastes from nonspecific sources
- Solvents from cleaning and degreasing operations
- Wastewater treatment

K-Listed Wastes
- Created from specific sources
- Chemical or pesticide manufacturing

P-Listed Wastes
- Acutely hazardous discarded commercial chemical products
- Arsenic trioxide

U-Listed Wastes
- Less hazardous discarded commercial chemical products

Future Changes in Solid Waste Composition

In terms of solid waste management planning, knowledge of future trends in the composition of solid waste and quantities is of great importance. As the time is passing, we are experiencing new lifestyles and for that we too adopt many practices; some of them are pointed as under:

(a) **Food waste**
The quantity of kitchen food waste collections has been changed significantly with the passage of time as a result of technological advancements and change in public health. Food processing and packaging industry and the use of kitchen food waste have affected the quantity of food waste. The proportion of food waste, by weight, has decreased as it is preserved or refrigerated for some time and used later on.

(b) **Paper and cardboard**
The proportion of paper and cardboard found in municipal solid waste stream has increased greatly over the past 50 years. All this happened due to excessive use of paper in offices and newspaper publications. This is expected to increase further in coming times.

(c) **Yard wastes**
The proportion of yard waste has also increased significantly, primarily due to passage of the relevant legislations that prohibit burning of yard wastes. By weight, yard waste currently accounts for about 16–24% of the waste stream.

(d) **Plastics**
The proportion of plastics in solid waste has increased significantly during the past 50 years. It is anticipated the use of plastic will continue to increase, but at a slower rate than during the past 25 years.

Future Directions

The way in which currently the solid waste is being managed is not an environment friendly. The incomplete collection of generated waste, lack of awareness from the common person to the chain of municipal authority, and ignorance toward segregation and open burning of waste are few issues out of many which need engineering and administrative approaches. The improper disposal has started causing numerous problems. The air is being polluted by addition of air pollutants in the atmosphere due to this open burning. The sewerage system is clogged and starts malfunctioning due to fallen down solid waste material. The freshwater bodies including canals and lakes as well as ocean water are heavily polluted, and its aquatic life and ecosystem are damaged. The receiving soils lose their fertility and deteriorate the landscaping. The scattered waste causes nuisance and foul smells in the prevailing area.

The solution lies in systematic approach of integrated solid waste management (ISWM). The individuals, the authorities of health-providing facilities, commercial areas, institutions, manufacturing facilities, etc. all need awareness and have to play participatory roles in order to perform their due responsibilities. The most important responsibility no doubt is on the part of municipal authorities. The municipal authorities should introduce separate waste collection system for recyclable waste for recycling, organic waste for composting, combustible waste for incineration, and the left out waste for properly maintained landfills. This will certainly help in properly managing the solid waste problem in Pakistan to a greater extent, and resultantly, the overall environment will be saved.

Fig. 18 *Mohenjo-daro*: Renowned place of archeological importance (Source: http://www.mohenjodaro.net)

Part B: Agricultural Biomass of Major Crops Produced in the Province of Sindh, Pakistan

Introduction

The province of Sindh, Pakistan, is historically important due to one of the oldest civilizations of the world, the Indus Valley Civilization, and the archeological site of Mohenjo-daro (Fig. 18). Since histories back the Indus Valley Civilization grew agriculture with Indus River as the source, agriculture is the backbone of our economy. In Sindh the major crops of wheat, rice, sugarcane, and cotton are on average annually grown on **2,41,22,600** ha, which produce an average of **1,87,98,930** t of major crops; as a result there is **1,36,34,340** t of average agriculture residue biomass annually. If only 40 % of this biomass residue is utilized for power generation, there will be more than **10,000 MW** of power plant generation capacity which is almost **81 %** replacement of fossil fuel power generation and **52 %** of overall generation capacity of Pakistan with Sindh province as the only source, while, if **35 %** of agricultural biomass residue of only major crops of Pakistan is utilized, there would be almost **double** of the installed capacity of Pakistan up to 2013 (Installed Capacity of Pakistan 19,360 MW).

Though there is a huge potential available in this region, if it is properly utilized, there could be double of our crop yields resulting double amount of agricultural

biomass residue, hence more poverty reduction and more environment-friendly energy generation for the future needs and development of the country at large.

Historical Background

History is evident about the emergence of the world's oldest civilizations, most of these civilizations born and flourished on the banks of the rivers – they needed freshwater to drink, to grow grains to feed, and to sail as a way of transportation. The first ancient civilizations arose in the Middle East, the Mesopotamia (land between two rivers Tigris and Euphrates); Egypt (Nile River); modern-day Pakistan, the Indus Valley Civilization (Indus River); and China, the Huang He (Yellow River) Valley.

The common factors of flourishing of these civilizations among all these were water and agriculture. The Indus Valley remained the host of ancient civilization of the world's human history; it is learned that the cloth used for the mummification in Egypt was exported from Mohenjo-daro. After the extermination of the Indus Valley Civilization, the new settlements grew slowly in the region (especially in the "doabs," the region lying between and reaching to the confluence of two rivers). Most of today's irrigation systems we have were an effort of the British authorities in the middle of the nineteenth century who managed the already existing system of low irrigation occurrences which evolved much earlier before the British rule; such systems were the small dams and inundation canals (*Ghar Wah*, the famous inundation canal constructed by the then Kalhora rulers of Sindh before the British in the region now known as Larkano District of Sindh). The British authorities expanded and modernized the whole irrigation water supply system of the Indus Basin known as Indus Basin Irrigation System (IBIS).

On the part of the British, they constructed in 1932 AC one the most famous barrages on the Indus River near Sukkur city of Sindh (known as Lord Lloyd or Sukkur barrage with seven canals taking from it) in the Sindh irrigation system (Sindh irrigation system is a part of IBIS). The Sindh irrigation system with three barrages, one pre-independence and two post-independence, and 14 main canals is one of the world's largest irrigation systems; the agricultural area of the province is irrigated by these 14 main canals.

The size of the area irrigated by the irrigation system in Sindh province is more than the area irrigated in Egypt, and it is one-and-a-half times the area irrigated in Mexico (van Steen Bergen 2014). The economy of the province is of dual nature; on the one side it has the country's biggest metropolitan city with Bin Qasim seaport and capital of Sindh province Karachi, which accounts for about 40 % of the population of the province and is the economic hub of the country as a whole. The rural population and area on the other side is mostly agricultural.

The rural Sindh is the most poverty stricken with huge manpower still with 35 % of the population below poverty line in 1999; one of the causes of this

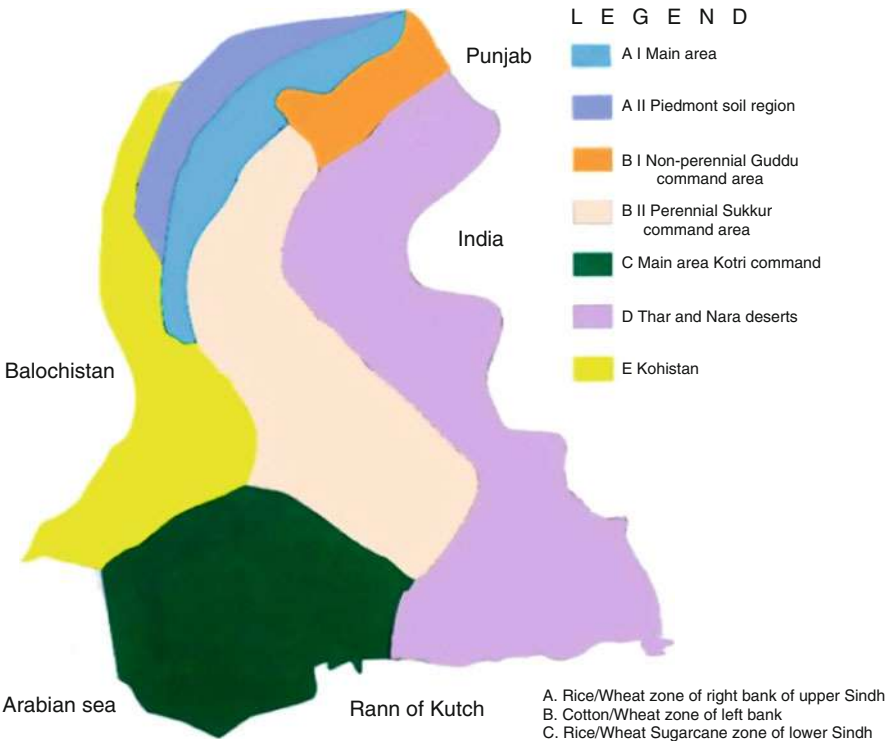

Fig. 19 Agricultural and ecological zones of Sindh province. Source: PARC

poverty is the great extent of inequity in land distribution. Big landlords with large farm cultivate their land through the tenants and land laborers and with mechanized equipments; mostly these equipments are tractors. Officially classified small farms are only 33 % the area of the size less 8 hectares (ha) (van Steen Bergen 2014).

Almost the entire agricultural area of the Sindh province is irrigated with 14 canals except limited areas in the west with spate irrigation, and agriculture in Tharparkar desert is rain fed. Rice, wheat, cotton, and sugarcane are the major crops mostly grown in the province; Fig. 19 gives the detail of command area and crops grown and includes desert area (van Steen Bergen 2014). The yield compared to the rest of the world which is much below is graphically shown in letter pages of this write-up. Mango and banana orchards are in districts of Hyderabad and Sanghar, guava is grown in Larkano District, and date palms are grown in Khairpur District. All are limited but high-valued horticulture, while mango and date palms are exported too.

The agricultural production of the province has increased more or less at the pace of population increase at a rate of 2–3 % a year, over the last 15 years (van Steen Bergen 2014).

Table 3 Barrages on Indus River in Sindh province

1. Guddu barrage	
(i) Left bank canals: one canal	01. The Ghotki Feeder (non-perennial)
(ii) Right bank canals: two canals	01. Desert Pat Feeder and 02.The Begari Sindh Feeder, (both are non-perennial canals)
2. Sukkur/Lord Lloyd barrage	
(i) Left bank canals: four canals	01. Khairpur West Canal, 02. Rohri Canal, 03. Khairpur East Canal, and 04. Eastern Nara Canal
(ii) Right bank canals: three canals	01. North West Canal, 02. Rice Canal, and 03. Dadu Canal
3. Kotri barrage	
(i) Left bank canals: three canals	01. The Akram Wah (Lined Canal), 02. The Fuleli Canal, and 03. The Pinyari Canal
(ii) Right bank canals: one canal	01. Kalri Baghar Feeder

The Irrigation System

The three gigantic barrages (namely, Guddu, Sukkur, and Kotri) on the Indus River in Sindh province (Table 3) supply irrigation water; the Sukkur barrage construction was completed in year 1932 pre-independence, while the other two barrages Kotri barrage construction completed in 1955 and Guddu barrage construction completed in 1962 both are post-independence barrages. Figures 20, 21, and 22 show the view of these three barrages.

The 14 main canals are fed by the above three gigantic barrages; further, the larger canals are subdivided into branches. Through the branches, distributaries, and minors, irrigation water is supplied to the agricultural lands through water courses. In the province of Sindh, there are 109 branch canals, 509 distributaries, and 902 minors (**Courtesy**: Sindh Irrigation Department).

Rohri Canal, and Eastern Nara Canal these off take from Indus river at Sukkur barrage on the left bank, both these serve command near about 1 million ha such is the huge size of Sindh irrigation system, these are one of the largest single Canal in the world (van Steen Bergen 2014). Out of these 14 main canals, some are non-perennial larger canals which flow seasonally (in summer season only when the river is in its high flows), and others are perennial which flow year-round (only closed in month of January for maintenance purpose).

The IBIS network for agriculture of our country Pakistan (Fig. 23) provides 90 % of fiber and food needs, while 10 % is provided through rain-fed (locally called barani) area. The IBIS has three dams, of which Tarbela Dam is a mega dam of Pakistan; the system also contains 19 barrages on river, 12 inter-river link canals, 45 big canal commands, and more than 1 million tube wells, including disposal network of agricultural effluent about 18,000 km length, with one drain carrying much part of agricultural saline effluent direct into the Arabian Sea known as Left Bank Outfall Drain (LBOD). The drainage network is still not connected as the

Fig. 20 Guddu barrage (Courtesy: Sindh Irrigation Department)

Fig. 21 Sukkur/Lord Lloyd barrage (Courtesy: Sindh Irrigation Department)

irrigation network is, resulting in such a large irrigated agricultural system that has not achieved the objective of poverty reduction. Further to the effect, the system even more deteriorated as time passes; the causes are detached management of different sectors (irrigation system, agriculture, environment, and social), as there is

Fig. 22 Kotri barrage (Courtesy: Sindh Irrigation Department)

deficiency in coordination among various water-related stakeholders and dearth of linkage of systemic process between economic, social, and environment; deficiency in execution of modern water management technologies; deprived water polices, especially in groundwater management; and poor maintenance and operation of the system as a whole (Lashari and Mahesar 2012).

As about 60 % population of the Sindh province of Pakistan is rural and their source of income is almost agriculture, so the economy of Sindh is agriculture dependent. The major crops are rice, wheat, cotton, and sugarcane; these crops make use of 68 % of area under crop, though in Sindh some horticulture crops are grown too, such as dates, bananas, and mangoes, including vegetables almost of all kinds seasonally. Total gross command area (GCA) of Sindh is 5.76 million hectare (Mha), and it is estimated that production of major crops in Sindh is reduced by 40–60 % as about 37.6 % of the total GCA is under waterlogging and salinity problems (Lashari and Mahesar 2012).

On the other hand, Table 4 shows the detail of 14-year data, where the net production of major cops and net cropped area vary from year to year depending upon availability of surface water and other factors such as to some extent introduction of modern techniques of hybrid seeds.

The contribution of Sindh province in overall national production of major agricultural crops from the 14-year data (i.e., from financial years 1997–1998 to

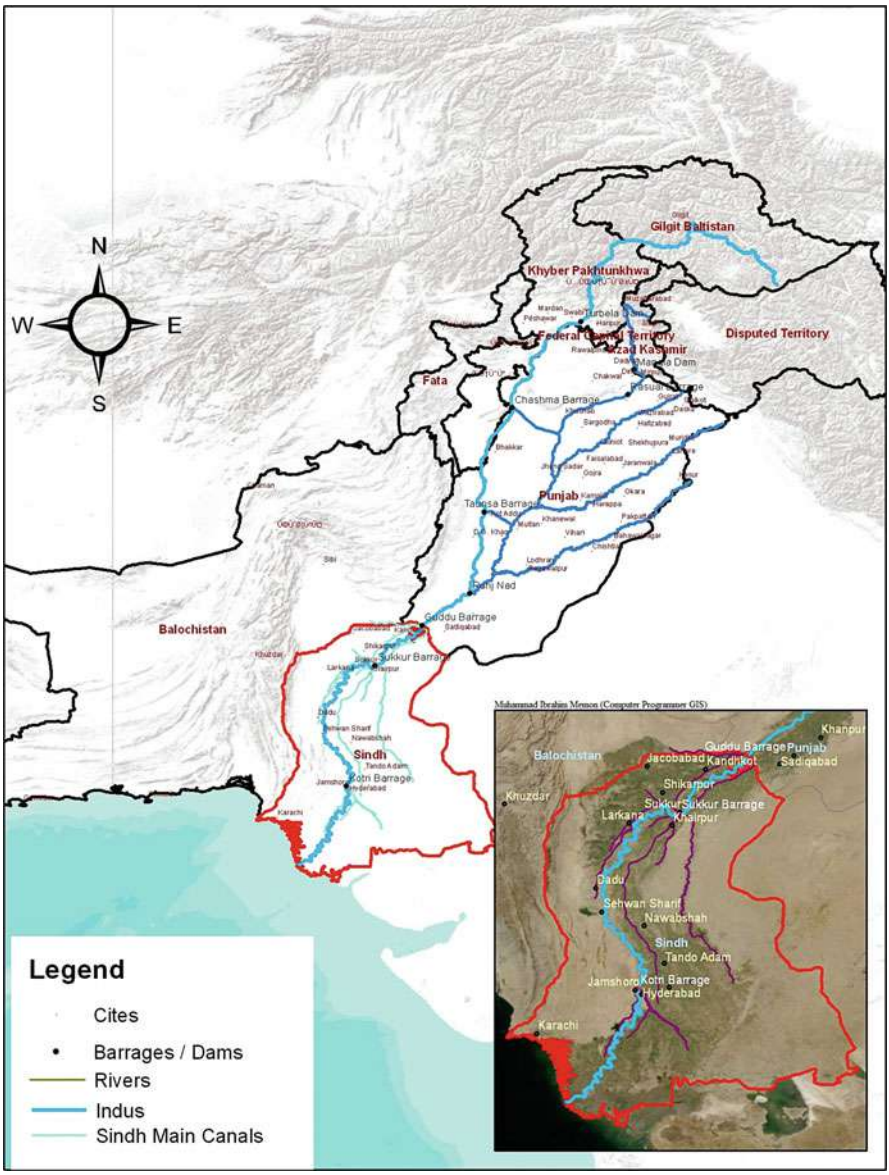

Fig. 23 Map of Pakistan and Sindh province showing IBIS (Source: SIDA.org.pk)

2010–2011) shows an average of 14 % to maximum 17 % in 2010–2011 in wheat, average of 34 % to maximum 36 % in 2008–2009 in rice, average of 27 % to maximum 29 % in 2007–2008 in sugarcane, and average of 23 % to maximum 33 % in 2009–2010 in cotton (*Pakistan Statistical Year Book of 2008 and 2011*).

Table 4 The production of major agricultural crops in Sindh province 14-year data

	Wheat		Rice (paddy)		Sugarcane		Cotton	
Cropping year	Area ha. (000)	Production (000) ton	Area ha. (000)	Production (000) ton	Area ha. (000)	Production (000) ton	Area ha. (000)	Production (000) bales (375 lbs each)
1997–1998	1120.2	2659.4	689.3	1840.9	261.6	15,999.6	600.3	2335.5
1998–1999	1123.7	2675.1	704.1	1930.3	270.8	17,050.7	630.2	2134.1

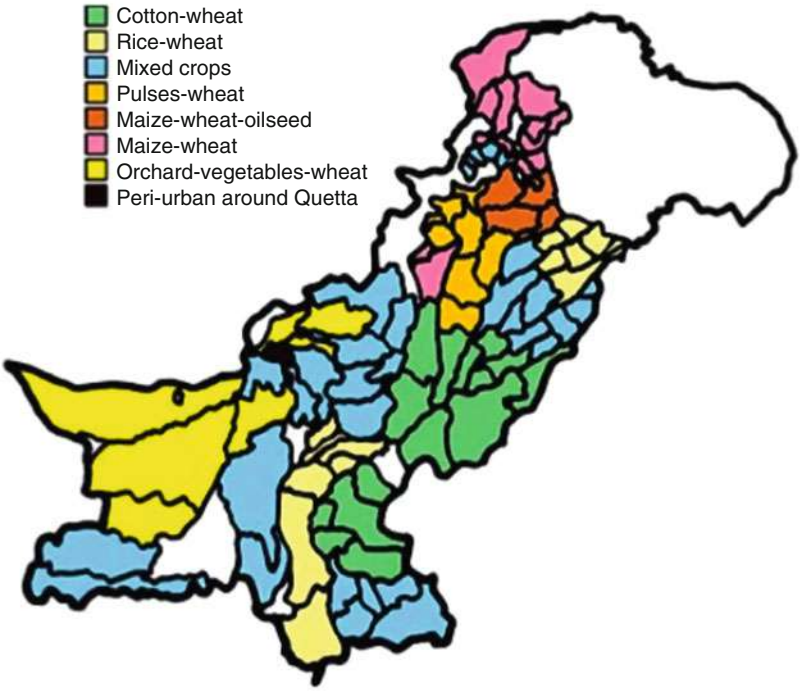

Fig. 24 Crop production regions (Source: FAO of UN)

The province of Sindh is the second largest province of Pakistan in terms of population and economy and is also known as the "Valley of Mehran." Mehran and Sindhu are the two well-known names of the Indus River. The name of province Sindh is also derived from word Sindhu – the Indus River – and it is the third largest province in terms of area which is 54,407 sq-miles (1,40,914 sq-km).

The total gross command area (GCA) of the province is 5.76 million hectares (Mha), and its culturable command area (CCA) is 2027Mha. The major crops grown are wheat, rice, sugarcane, and cotton; these major crops are cultivated on 68 % of total cropping area, and the rest is the horticulture crops. The irrigation network provides 48.76 million acre foot (MAF) of surface water to irrigate the command area, though the availability is generally 10–12% less than the above quantity of surface irrigation water. 5 MAF is the groundwater availability that is too unregulated, while the rainwater has good potential, but it is also not properly explored (Lashari and Mahesar 2012).

In horticulture, Sindh produces 88 % of chilies, 34 % of mangoes, and 73 % of banana grown in Pakistan. Others are the fodder crops, pulses, oil seeds, condiments, fruits, and vegetables (Kiani 2008).

Fig. 25 (**a**, **b**) Image of paddy crop sowing (Source: SARSO Sindh, Pakistan)

Figure 24 gives the detail of the entire Pakistan including the Sindh province region-wise major crops grown. In addition to this, in different regions various vegetables and other horticulture crops are also grown (Figs. 25, 26, 27, 28, 29, 30, 31, 32, 33, and 34).

Fig. 26 Image of grown paddy crop (Source: SARSO Sindh, Pakistan)

Fig. 27 Image of cotton crop sowing (Source: SARSO Sindh, Pak)

Pattern of Cropping and the Yield of Major Crops

Figure 35 gives the detail of cropping pattern of the entire country and Sindh province district and region wise; Table 4 shows the yield of major crops and area of each cultivated crop per year (wheat, rice, sugarcane, and cotton), while Fig. 36 and Table 5 show yield in kg/ha of different major crops for each year of Sindh province.

From Table 4, Table 5, and Fig. 36, it is very clear that all major crops from last 14-year data are in increasing trend in terms of cropping area, yield, and especially the average yield per hectare; the increase of average yield per hectare predicts the

Fig. 28 Image of grown cotton crop

future of agricultural production of the province on the positive side. For example, the cropping pattern and yield of major crops for the last 6 years (i.e., from 2004–2005 to 2010–2011) have remained worth noting as under:

Wheat in 2004–2005 area under crop was 887,400 ha and yield was 2827 Kg/ha, and in year 2010–2011 area under crop was 11,44,400 ha and yield was 3747 Kg/ha; cropping area increased by 22 % and yield per ha increased by 25 %.

Rice in 2004–2005 area under crop was 5,43,900 ha and yield 2757 Kg/ha, and in year 2010–2011 area under crop was 3,61,200 ha and yield 3406 kg/ha; cropping area decreased by 51 % (*the reason is Sindh province was the most affected region due to floods of cropping year 2010–2011*) even though yield per ha increased by 19 %, and if we compare cropping year 2008–2009 with that of 2004–2005, then the area under crop was 7,33,500 ha and yield 3459 Kg/ha; here cropping area increased by 26 % and yield per ha increased by 25 %.

Cotton in 2004–2005 area under crop was 6,35,100 ha and yield 808 Kg/ha, and in year 2010–2011 area under crop was 4,57,000 ha and yield 1316 Kg/ha; cropping area decreased by 39 % (*the reason is Sindh province was the most affected region due to super floods of cropping year 2010–2011*) even though yield per ha increased by 39 %, and if we match cropping year 2008–2009 with 2004–2005, then the area under crop was 651,500 ha and yield 902 Kg/ha; here cropping area increased by 2.5 % and yield per ha increased by 10 %.

Fig. 29 Image of ready cotton crop (Source: SARSO Sindh, Pakistan)

Sugarcane in 2004–2005 area under crop was 2,14,900 ha and yield was 43,543 Kg/ha, and in year 2010–2011 area under crop was 2,26,500 ha and yield 60,779 Kg/ha; cropping area increased by 5 % and yield per ha increased by 28 %.

From Table 5 it is clear from colored data and from Fig. 36 that the yield of major crops has gone under speedy increase in the last 6 years. The yield of wheat was 3747 Kg/ha and the yield of rice was more than 3400 Kg/ha.

However, it is also observed through data that some of the districts of Sindh Nawabshah and Khairpur were receiving the yield wheat around 4000 Kg/ha, while from field visits and meeting with progressive *zamindars* (land growers), the maximum was around 6000 Kg/ha. It is also observed through data and field visits that some of the paddy-growing districts of Sindh, Larkano, Shikarpur, Jacobabad, and Kandhkot, Kashmore, were getting paddy (using hybrid seed) yield around 5930 Kg/ha on average and some of the progressive *zamindars* (land growers) of the same area get yield maximum around 7907 Kg/ha.

From Figs. 37 and 38, evaluating the yield of wheat and rice in Sindh with the rest of the world's most advanced in yield of wheat and rice, the province of Sindh is 3747 Kg/ha, France 7280 Kg/ha, Germany 7750 Kg/ha, and the USA 8250 Kg/ha of wheat. Likewise, the yield of rice crop in Sindh is 3406 Kg/ha, the USA is more than 8000 Kg/ha, and Egypt is even more than 10,000 Kg/ha. But it is worth mentioning here that Sindh province has the capability to yield wheat of

Fig. 30 Image of grown wheat crop (Source: SARSO Sindh, Pakistan)

4000 Kg/ha to 6000 Kg/ha and rice about 6000 Kg/ha to 8000 Kg/ha as mentioned in the above paragraph regarding progressive land growers.

The province of Sindh has the capability of improving its yields as the trend shows in Fig. 36; the only requirement is the proper management of irrigation system and utilization of modern technologies and machinery while educating the farmers, tenants, and land growers.

The Rain-Fed (Nonirrigated) Area of Sindh

There are three prospective areas in Sindh where rain feed can be achieved; these are Thar desert, Khirhar hills, and Ubhan Shah hills; as shown green areas are canal-irrigated lands, while white areas are the rain-fed areas in Fig. 39 (Lashari and Mahesar 2012).

From Fig. 36, it is clear that the yield of major crops is on increasing trend but it is still low at national levels as of some progressive land growers are getting even more than the yields shown in Fig. 20, it means there is a potential gap that should be filled to increase the yield. Another point of focus is the rain-fed areas which are almost ignored and less considered which require more consideration that will result in significant growth in the production and yield. The sustainable irrigated agriculture is under threat from a number of issues which include increasing need of

Fig. 31 Image of wheat crop harvesting (Source: SARSO Sindh, Pak)

Fig. 32 Image of wheat grain (Source: SARSO Sindh, Pakistan)

water to meet raising population demand; poor maintenance of canal system causing inefficient service; waterlogging and salinity problems; excess use of groundwater resources resulting in exhausted groundwater aquifers, thus leaving large areas not viable for the poor farmers; insufficient field drainage system (even the existing field drainage effluent network not properly connected) which could dispose of agricultural effluent in due time; improper pricing or valuation of water; and scarce participation of consumers. Therefore, for the optimum production and crop yield, these areas need to be focused: competent and resourceful management including conservation of present water resources, equitable distribution of water in different areas and canal commands (from head to tail users), efficient drainage effluent interventions with well-connected networks for the maximization of crop

Fig. 33 Image of grown sugarcane crop

production, and reforms to be introduced within institutions to make the managing organizations more responsive, efficient, and dynamic (Lashari and Mahesar 2012).

The distribution and supply of irrigation water from head to tail has not remained reliable; people at the head get more water than the water users at the tail. As a result the set targets and objectives of irrigated agriculture are not being achieved, so the productivity is much lesser in quantity than it should have been. If reforms in irrigation sector are executed wholeheartedly, then farmers can play their important role to improve the productivity. Poor working of irrigation system since the 1960s is mainly due to water shortage which resulted into defective and unreliable supply, distribution, and finally inefficient use of irrigation water (Lashari and Mahesar 2012).

Biomass Residue of Agricultural Crops in the Province of Sindh

It can be observed from Tables 6, 7, 8, and 9 in columns from a to f that the biomass residue of various crops such as wheat straw, rice husk, rice straw, cane trash, bagasse, and cotton stalk is in different ratios, which is given below. These ratios are verified on-site and from research studies (Cerqueira et al. 2010; Figs. 40, 41, 42, and 43).

(a) Wheat and wheat straw ratio 1:1
(b) 20 % rice husk found as waste in paddy
(c) Paddy and rice straw ratio 1:1

Fig. 34 Image of harvested sugarcane crop (Source: SARSO Sindh, Pakistan)

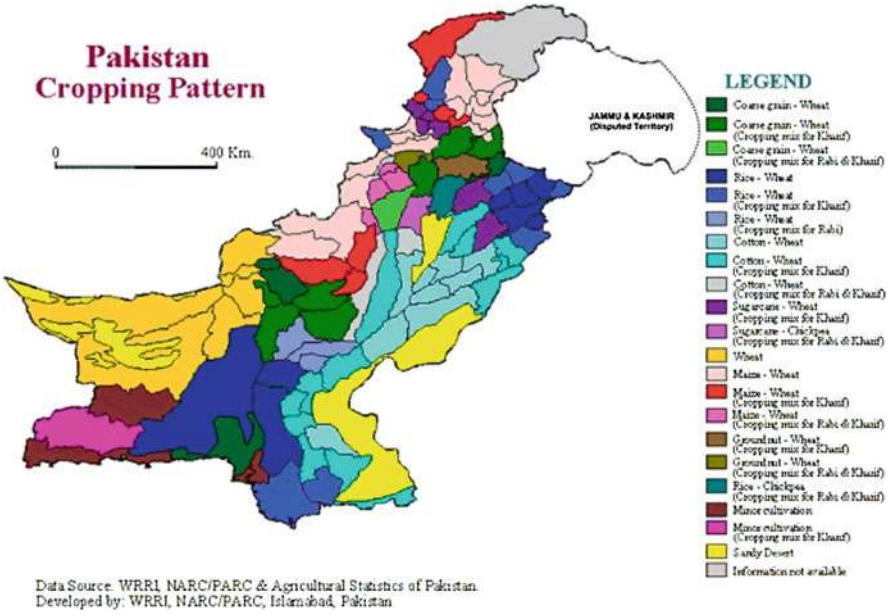

Fig. 35 Cropping pattern (Source: PARC)

(d) 23 % cane trash found as waste in sugarcane harvest
(e) 30 % wet bagasse found as waste in sugarcane industry
(f) Cotton and cotton sticks ratio 1:3

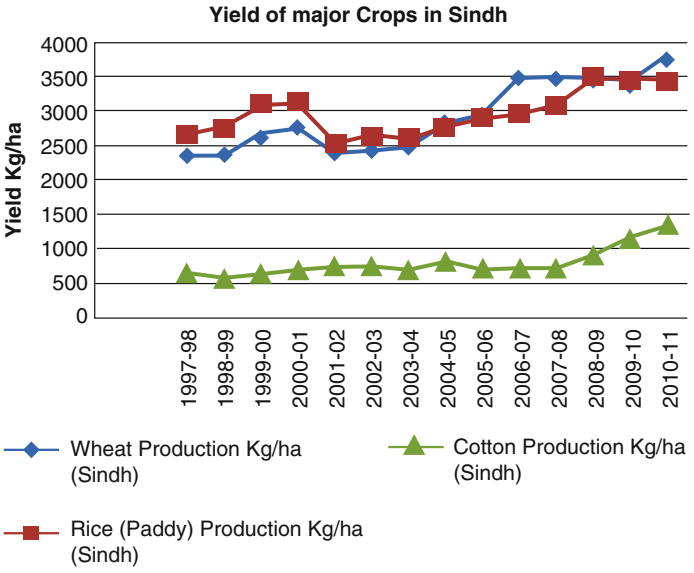

Fig. 36 Yield of major crops in Sindh

Table 5 Yield of major crops in Kg/ha of Sindh province

Cropping year	Wheat production Kg/ha	Rice (paddy) production Kg/ha	Cotton production Kg/ha	Sugarcane production Kg/ha
1997–1998	2374	2671	662	61,161
1998–1999	2381	2742	576	62,964
1999–2000	2623	3075	638	61,972
2000–2001	2746	3115	696	50,459
2001–2002	2401	2514	759	47,430
2002–2003	2442	2662	756	53,355
2003–2004	2473	2599	680	56,221
2004–2005	2827	2757	808	43,543
2005–2006	2947	2901	707	61,372
2006–2007	3471	2946	716	58,357
2007–2008	3446	3060	710	60,861
2008–2009	3432	3459	902	50,414
2009–2010	3390	3423	1145	57,740
2010–2011	3747	3406	1316	60,779

It may be observed from Tables 6, 7, 8, and 9 that annual average production of various agricultural major crops based on 14 years of data is a huge quantity which is given as under in Table 10.

From Tables 6, 7, 8, and 9, the total biomass residue of various agricultural major crops of 14 years and its average production are given as under in Table 11.

	Pak	France	Germany	U.K
Area (1000)ha	1144.4	5400	3320	1940
Yield kg/ha	3747	7280	7750	8250

Fig. 38 Rice crop production and yield in the world

Total average amount of agricultural residue biomass of Sindh = **13,634.34** × **10^3t/year.**

Energy Content of Biomass Residue of Agricultural Crop in the Province of Sindh and Pakistan

Keeping in view the availability factor, the different agricultural residue biomass is used as animal feed and also as a raw source of energy at local level; hence, we theoretically consider 40 % availability of above total average amount of agricultural residue biomass, i.e., 5354.73 × 103 **t/year.**

Theoretically considering average calorific value of agricultural residue biomass **3500 KCal/Kg,** then the theoretical energy content = 3500 KCal/Kg×5354.73 × 10^6

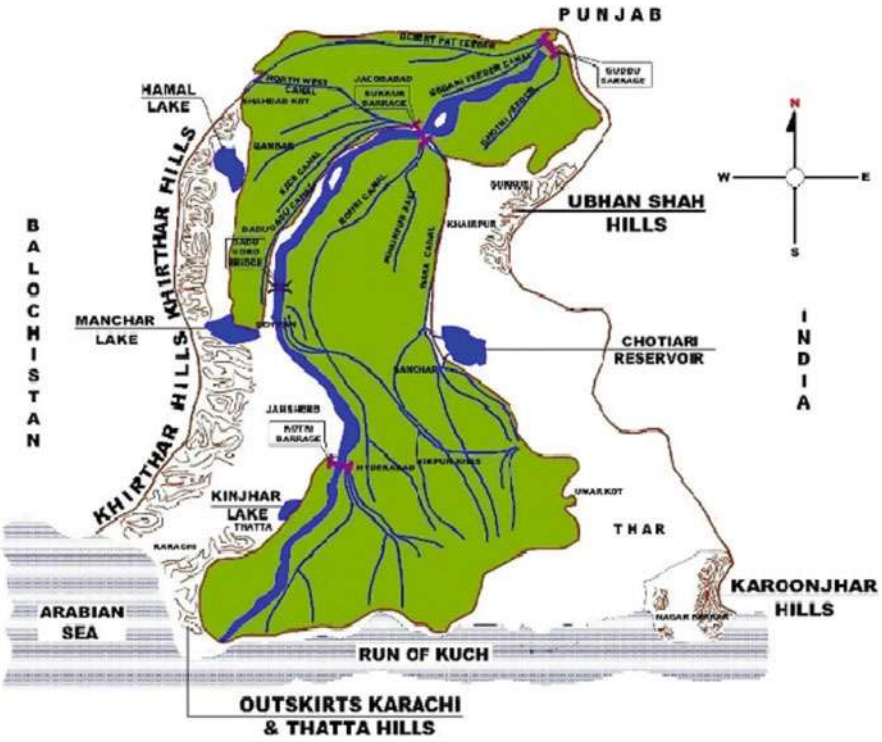

Fig. 39 Rain-fed and canal-irrigated lands (Source: Lashari and Mahesar (2012))

Kg = 1.91 × 10^{13}KCal (heating value) if this amount of heat energy is multiplied by 4.81 for converting K Cal into KJ = **7.97 × 10^{13} KJ or KW-S**.

With this theoretical heat content if converted into electrical energy with **40 %** overall power plant efficiency, then we have **3.2 × 10^{13} KW-S (el energy)**. Converting this for power plant to be installed, we'll have **8.9 × 10^{10} KWh = 10,120 MWYear.**

Hence, the power plants of about **10,000 MW** are possible to be installed in the province of Sindh with the use of only 40 % of single source by agricultural residue biomass of only major crops. By the end of the year 2013, the installed capacity of Pakistan is given in Table 12.

Then, the **10,000 MW** through agricultural residue biomass of major crops of Sindh province only will be 52 % of total installed capacity and 81 % of total fossil fuel installed capacity of Pakistan.

As already mentioned, that the *province of Sindh contributes significantly toward* overall national production of major agricultural crops from the 14-year data (i.e., from financial years 1997–1998 to 2010–2011) shows an average of 14 % to maximum 17 % in 2010–2011 in wheat, average of 34 % to maximum 36 % in 2008–2009 in rice, average of 27 % to maximum 29 % in 2007–2008 in sugarcane,

and average of 23 % to maximum 33 % in 2009–2010 in cotton (*Pakistan Statistical Year Book of 2008 and 2011*).

Production of agricultural residue biomass in Pakistan is shown in Table 13 (by the production of major crops data of major crops *Pakistan Statistical Year Book of 2008 and 2011*) *on same considerations as* Table 11 for Sindh agricultural residue biomass.

Total average amount of agricultural residue biomass of Pakistan = **60,088.05**$\times$**10^3 t/year** as shown in Table 13. If the 35 % above total biomass agricultural residue produced in Pakistan could be utilized, about **39,026 MW** can be produced, which is very near to about 200 % of total installed capacity of all power plants in Pakistan.

This shows that there is huge potential of biomass that is available in Pakistan which could be utilized to meet the energy requirement and can overcome the energy crisis problem. At present, Alternative Energy Development Board Ministry of Water and Power Government of Pakistan has planned two power plants based on biomass waste in the province of Sindh; the details are given as under:

1. 12 MW biomass to energy power plant at Mirwah Gorchani Town, Mirpur Khas, Sindh
2. 9 MW biogas power plant at Pak Ethanol, Matli, Sindh. Letter of interest (LoI) issued to Pak Ethanol (Pvt) Ltd. for setting up power plant

Rice (paddy)	1746.99
Sugarcane	13,694
Cotton	2676.5(000 bales, 375 lbs each)

Future Directions

Pakistan is bestowed by God with such great potentials which need to be exploited properly; it has such a climate with temperatures ranging from −50 °C to +50 °C; though we are facing difficulties with modernizing our agricultural and irrigation systems with the world today, still it has sufficient food to feed its population and to export, but there remains huge gap to be filled.

Our irrigation system is one of the largest systems of the world, and our agricultural command area is so expanded and large that it can also be compared to the huge agricultural commands of Egypt and Mexico.

Our agricultural lands have capability to produce yields to the world's best producing countries; to get such yields we have to improve all our systems related to agriculture as it is the backbone of our economy. To achieve such targets of which our agricultural lands and irrigation system are capable of, we must interlink various sectors which are helpful and beneficial to our agroeconomy. For this task, the irrigation department, agriculture department including farm water

management, revenue department, and finance department should be interlinked starting from union council level by a focal person from each department to resolve related issues and to report to the higher authorities; every complaint must be recorded online and weekly progress-based reporting should be submitted, and to tackle the issue related to water with proper and well-connected agricultural drainage effluent networks, modernizing agriculture with farm water management and farm power machinery while at the same time educating the farmers, tenants, and land growers and revenue collection should be made accordingly while financing the growers and the tenants for better yields and proper pricing of the crops. As our economy is agrobased, hence research and development must be carried out in

every sector to improve our irrigation system, effluent drainage system, and agriculture at large.

Better yields will result in more production of agricultural residue biomass; consequently, we will have better economy at grassroots levels and poverty reduction, and we will be able to cater our energy requirements by utilizing some portion of agricultural residue biomass which is our own resource; this will further improve our economy.

The Advanced Recycling Technology for Realizing Urban Mines Contributing to Climate Change Mitigation

Tatsuya Oki and Toshio Suzuki

Contents

Abstract

Coping with sustainable civilization and utilization of renewable energy, climate change mitigation is one of the big challenges. Obtaining metal resources from urban mines (waste) for supporting the civilization of human races will contribute not only to support sustainable development of civilization society to the future but also to mitigate climate change. Urban mines are one of the promising resources especially for poor natural metal resource countries such as Japan. Fortunately, Japan is one of the major rare metal consumers and also is capable of smelting rare metal by its own. Japan's urban mine will be more practical with top class recycling technology. In addition to these technological developments, it

is necessary to reform the society system in order to realize productive and economical urban mines which overcome the natural mine. Furthermore, in order to continue a steady development of rare metal recycling, it is necessary to conduct well-planned technology development based on the prediction of the future material usage. In this chapter, the authors show the technical subjects for realizing total circulating usage of metal resources including rare metals and an attempt currently tackled in Japan.

Introduction

Huge metal resources are needed to support the civilization of mankind. Not only developed countries but also the remarkably developing Asian region has been consuming metal resources. In the past time, a lot of metal resources have been acquired from natural mines. Although a true depletion of the resources may be in the far future, the metal content of mines continues to decline gradually, and the amount of associated heavy metals and radioactive substances tend to increase. Total material requirement (TMR) which indicates the total amount of material usage to produce 1 ton of metal is usually utilized to compare the material consumption for production (Yamasue et al. 2009). For example, copper ore grade is decreasing year by year worldwide; as a result, the TMR of copper is increasing. This means that total energy consumption involved in the copper production increases. TMR increases especially for minor metals, which nowadays are very important for supporting advanced industries. Japan is being the world's largest minor metal-consuming country (in Japan, 47 species of minor metal are called "rare metals," as shown in Fig. 1), while the production of rare metals tends to be monopolized by certain countries and the world production volume of each rare metal is small. Therefore, the access to these metals can be easily restricted by the control of the production. In addition, environmental destruction is becoming a serious problem because the regulation for metal production is not well effective in such areas.

Figure 2 shows the estimated UO (urban ore)-TMR compared with NO (natural ore)-TMR (Yamasue et al. 2009). As can be seen, utilization of urban ore is already effective for minimizing the total energy consumption for almost all metal elements, and thus utilization of UO is considered to lead to mitigate the climate change in the future. In addition, considerably not far in the future, some of the metals are suspected to fall into critical shortage, and as a result, it is considered that maintenance of the substance society could be threatened. Deterioration of metal production efficiency and increase in the metal consumption mean an increase of the energy consumption for maintaining civilized society, which easily impacts on the climate change, too. Thus, an improvement of rare metal production technology for suppressing energy consumption for the metal production will be a significant step for climate change mitigation as well.

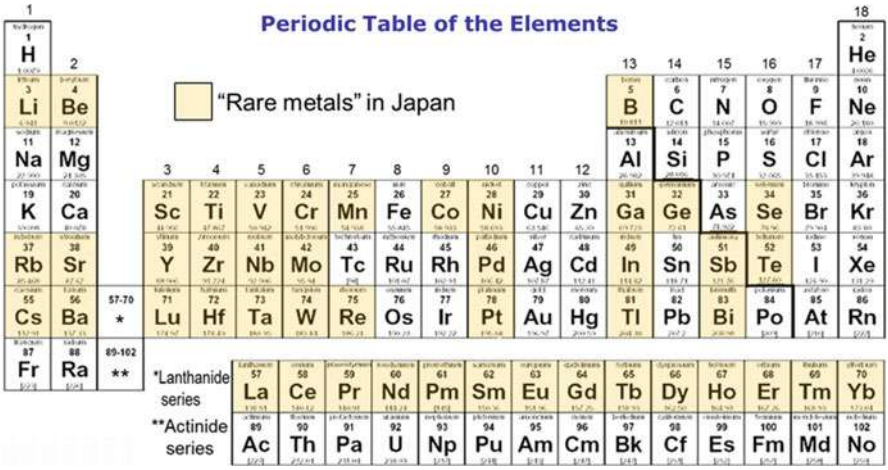

Fig. 1 Definition of the rare metals in Japan

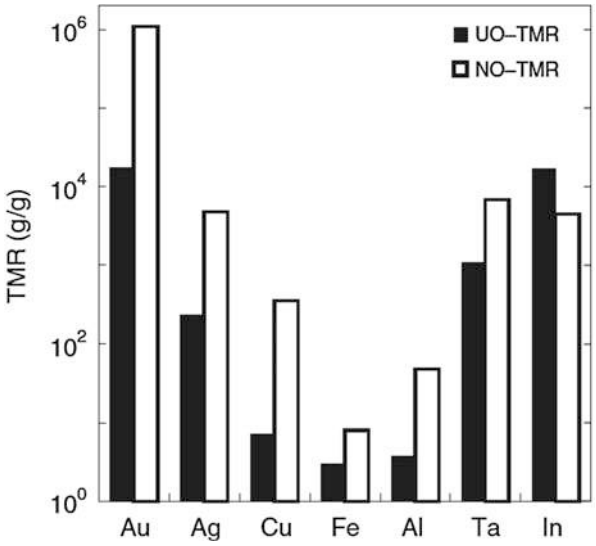

Fig. 2 The estimated UO-TMR compared with NO-TMR (From Ref. Yamasue et al. 2009)

On the other hand, almost all metal products remain somewhere on earth after usage. Some of them are soluble in water, but basically they exist in the solid state. According to the law of conservation of mass, most metals yielded ever from natural mines stay somewhere on earth, accumulated in the close area of human activities. Even in the narrow land of Japan, it is said that the total amount of accumulated metals in Japan is to surpass the annual metal consumption in the world. Thus, used products that are accumulated in the land have become to be called "urban mines." Most urban mines include products that have been routinely used without harmful substances and radioactive materials and are considered to be relatively safe

resources. Even when the metal quality of urban mines is not as high as that of natural mines where metals are concentrated by taking an enormous amount of time, for urban mine, it is possible to control of the distribution and concentration of the waste products for easy recycling. In the future, it will be possible to deliberately control the formation of urban mines, which will contribute not only to the sustainable development of civilized society but also to suppression of energy consumption due to the metal production, by extension, to contribute to climate change mitigation.

Although Japan is poor in natural resources, Japan has been supplying high-tech products to the world by importing the raw materials produced from natural mines overseas over the years. In recent years, however, due to the rise of resource nationalism, one experienced the soaring of metal prices and the imminence of supply itself. From such a background, a strategy is considered to attempt to collect resources, including rare metals from urban mines, and the strategic program has been carried out in Japan for the first time in the world. The purpose is not for recycling to reduce diffusion and waste of harmful substances but for thorough resource recovery. In this chapter, the recent efforts of the strategy in Japan will be shown, and a discussion will be presented on the development of urban mines that realize sustainable civilized society and the relaxation of climate change.

Recent Development of Urban Mines in Japan

From "Quantity Recycling" to "Quality Recycling"

Japan relies for most of the natural metal resources to support its manufacturing industry on imports from abroad, and in recent years Japan encountered a situation that stable supply of the resources, especially "rare metals," has been imminent by sudden export restriction and steep rises in metal prices. Since the characteristic of each rare metal is different from each element, it is difficult to be replaced by other rare metals, unlike energy resources. Therefore, even when weight-wise the usage of rare metals is negligible in the products, the shortage of the supply can lead to the stop of the production.

True depletion of metal resources is considerably ahead of the future, and a sufficient amount of metals should exist somewhere on earth; however, the stable supply is not a guaranteed issue. In addition, production efficiency of natural metal resources in the process will gradually decrease toward the depletion, which will require enormous energy and cost. This will become a significant impact on the manufacturing industry and the world economy.

By keeping the current situation that the society strongly depends on the natural metal resources, the world will become unsustainable at some point. On the other hand, the metals from natural mines, always, exist somewhere on earth. Most of them are already buried as wastes; some are used in the social infrastructure. Fossil energy disappears once it is used. Organic resources such as resin and paper are not possible to use repeatedly for a long period of time. However, the metals can be recycled forever in theory. Even if they lose product value, they still have industrial

value in the element itself; the smelting process can completely restore the original raw material.

The amount of recyclable metal is dependent on the degree of living standards and population in the area. Used products that are accumulated in a certain area (city) are called "urban mine" in contrast to the natural mine. In urban mine, resources can be acquired by recycling technology, not mine technology for a natural mine. Currently still good natural mines exist, and developing urban mines is not economical since recycling technologies are still costly. However, as the extraction of natural mines progresses to reduce the amount of reserves, the amount of reserves for urban mines increases. As described above, with the decline of natural mine production efficiency, one day, development of urban mines would become economically realistic. The pseudo-phenomenon actually occurred in Japan around 2010 due to import restrictions from soaring overseas metal prices. Therefore, in Japan, the development of urban mines was seriously considered in order to adapt the critical situation.

In Japan, recycling has been actively carried out since 1990. At the time, recycling was encouraged due to the shortage of waste disposal sites, and the aim of recycling was to reduce the amount of wastes, the so-called quantitative recycling. Target materials are abundant materials such as resin, glass, iron, and aluminum, and a major goal is to reduce the volume of wastes, not to recover the resource to reuse.

Until now, mass metals such as iron, aluminum, and precious metals have been recycled. But this time, "rare metal," which is not used in large quantities and not expensive as precious metals, attracted attention the most. Rare metals are also called "vitamins for industry" in Japan. Even if the usage is negligible, without it, it is no longer possible to manufacture a number of high-tech products. That temporal collapse of the balance of supply and demand, the situation that would be anticipated in the future, would be completely upsetting Japan.

Currently, there are few metal mines running in Japan, and raw materials have been imported and consumed by 120 million of Japanese people over the decades, and the several decades worth of materials has been accumulated in the national territory. This situation cannot still be called "urban mines" until the resource can be retrieved within a certain economy. While natural mines are formed by concentrating resources over incredibly long time, urban mines are not naturally formed by gathering a large amount of waste products. In other words, "urban mines" are not something to look for but to be intentionally developed (urban mining). Actually, urban mine development technology that realizes the reduction of the entropy of metal spread in land should be efficient and economical. When the urban mine development for retrieving rare metals was started in Japan, landfilled and reused wastes were not targeted, but the products owned by each person, "hoarding goods." The hoarded goods refer to digital home appliances that were not in use, sleeping in a desk drawer without being discarded.

In the early stage of urban mine development in Japan, where recycling infrastructure associated with the legislation in the 1990s is well established, it is thought that the rare metal can be easily recovered once the hoarded goods from the public are collected. The recovery operations of rare metal from small household appliances

in the designated area were conducted in 2008 in Japan. However, in reality, it was not possible to recycle the rare metals utilizing the existing recycling facilities.

Currently, among metals contained in the waste products, only noble metals (gold, silver, platinum, palladium, etc.) and some of base metals (iron, aluminum, copper, etc.) are recycled. Rare metals except for platinum and palladium are rarely recycled from waste products once available in the market. To realize the recovery system of rare metals from waste products, at least two problems must be overcome. First, used products widely spread to the consumers need to be stably collected when they are discarded. This requires the construction of rules and social systems. Second, it is required to develop the technology that realizes a high purity metal extraction from the collected waste products, high enough to be directly used by rare metal smelting and raw material manufacturers.

Although rare metal density is relatively high in small appliance wastes, the system for collecting these product wastes systematically did not exist until recently. Therefore, Small Appliances Recycling Act was made effective in Japan in 2013. It made it possible to collect small appliance wastes widely across the administrative area, being one breakthrough for the first problem. No obligation, however, exists on rare metal recovery. Without overcoming the latter technical problem, recycling of metals will only stay on recovering precious metals and part of the base metal even for small appliances wastes. Unlike recycling a conventional iron and aluminum used in construction materials, various rare metal concentrations in the waste products are about several hundreds to several thousands ppm. Thus, there exists a technical leap for recycling rare metals from small appliances in traditional recycling infrastructure, like trying surgery by using the pickaxe. At this time, "quality recycling" was started to be more paid attention to than "quantitative recycling," and the need for technological transformation had been widely recognized around 2010 in Japan.

Technical Challenges of Quality Recycling: Liberation

Physical Sorting Techniques and the Composition of the Waste Products

Because the amount of rare metals in waste products is very low compared to construction materials such as iron and aluminum, economical recovery of rare metals is difficult, and it is not practical to use hydrometallurgy processes with chemicals. Pyrometallurgy processes with high temperature, which are effective methods for recovering low concentrated copper and precious metals, are not ideal either because most of rare metals thermally dissolve and disperse into glass slug. Thus, it is of importance to separate copper and precious metals from the waste products by physical sorting before using smelting processes for rare metals. Development of low-cost physical sorting technology will be a key for realizing low concentrating rare metal recycling systems. Each waste product is thought to be consisting of various metal particles (hybrid particles) including rare metal particles. High purity sorting of rare metal strongly relies on the concentration and dispersion of the rare metal particles in the products.

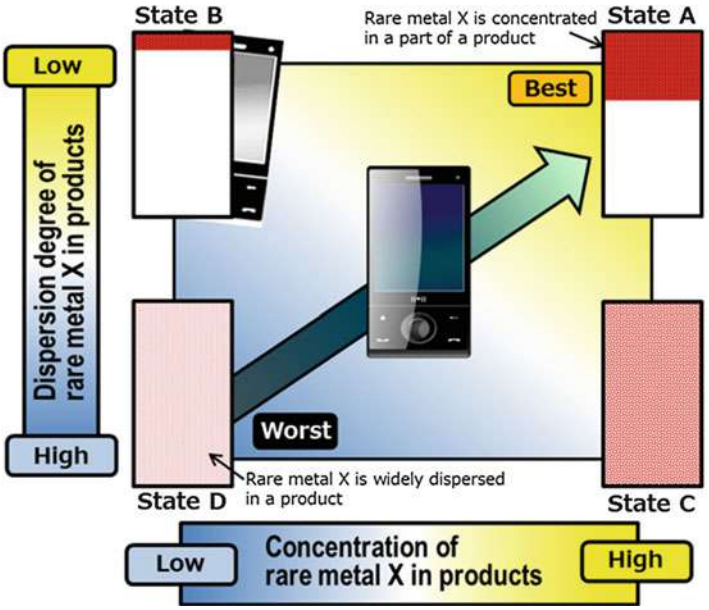

Fig. 3 Schematic image showing the existence status of rare metal in the waste product

Figure 3 is a schematic image showing the existence status of rare metal in the waste product. As can be seen, rare metal X is one of more than ten rare metals used in a smartphone and is considered to be concentrated by physical sorting. It is a great possibility of recovery if the concentration of the rare metal X is high enough after sorting. On the other hand, the possibility also depends on the dispersion of the rare metal X in the product. Here, dispersion is defined as the domain size (or distribution) of the rare metal X in the product. If the domain size is larger or the rare metal is concentrated in a particular area in the product, the dispersion of the rare metal X is considered to be small. Rectangular boxes in Fig. 3 show the rare metal X distribution in the product (smartphone). Status A is the best for physical sorting processes. The rare metal X exists in high concentration, locally in the product. In this case, it is quite easy to separate the particles with highly concentrated rare metal X from the rest of the particles by crushing or dismantling processes. This process is called "liberation – single separation." This is a very important operation in the physical sorting process and will be discussed later. Status A is not only easy for single separation but also for the rest of sorting operation due to the fact that the concentration of the rare metal X is high in the particles. The next best status for physical sorting is Status B at the upper left in Fig. 3. Even though the total amount of the rare metal X is low, it is expected to have liberation as good as Status A. Only this will cause difficulty at the latter operations in the process due to small amount of the rare metal X. Status C, even though the concentration of the rare metal X is high, is more difficult for liberation due to high distribution of X in the product. Status D is the worst scenario for physical sorting processes. In the case of a smartphone, they

typically have maldistribution of elements in the product, and thus it is not possible to apply physical sorting for single separation – liberation. Rather, they require very fine crushing processes to extract rare metal X. The required particle size after crushing totally depends upon the dispersion of the rare metal X. Usually, ordinal sorting processes can be applied down to several micron particle size, and it is not possible to apply physical sorting if liberation cannot be achieved still in this particle size.

Even when the liberation is possible for such small particles, it requires large amounts of energy for fine grinding. In addition, as discussed later, it also requires separation processes in the wet condition for less than 0.5 mm particles, while the millimeter size of particles can be applied to dry separation processes. The wet processes require another electric power for pumping water, water treatment process unit, which adds more energy consumption and cost. The product obtained by wet process is still not as good as that by dry sorting processes in the millimeter range. There is a trade-off between the purity and the recovery of X. Thus, the combination of fine grinding and wet separation processes is the last to be chosen in the physical sorting processes. These processes, however, are cost-effective compared to chemical processes and are effective for collecting the rate metals that are considered to be difficult to recycle. In the case of electrode and fluorescent materials that are used as fine powder, no crushing process is required and can be applied to wet sorting process in the ordinary recycling facility.

Importance of Liberation

Physical sorting processes for collecting metals from waste products require the decomposition of "hybrid" components into small "individual element" pieces in the first step. Large products may be decomposed by hand, and then, the pieces are sent to crushing processes. In many industrial processes, the purpose of crushing is to obtain uniform fine particles from complex particles, and the processes improve physical properties of the particles such as mobility, processability, and reactivity (Owada 2007). On the other hand, the goal of the physical sorting is to complete liberation. The ideal status is that a single element is a single particle. The element that is the target material for recycling can be atom, alloy metal or parts, etc. In the case of the particle including more than two elements, it is called "locked." It would be no problem when the locked material includes highly concentrated target material, and crushing processes would be effective for such locked constituents. If it is not the case, it is not possible to improve the purity of the element by utilizing physical sorting only. In the course of physical sorting processes, the crushing process is considered to be a pre-sorting process to realize the status of liberation, single separation of the target particle.

Figure 4 shows the 2D matrix model of liberation process, proposed by A. M. Gaudin (1939). It is a classical model, yet not enough for modeling the actual situation, but it helps in the understanding of the concept of liberation. Figure 4a shows the status before the crushing process, including target material in the matrix. "a" in the matrix is the size of locked and assuming that the product is cut into pieces

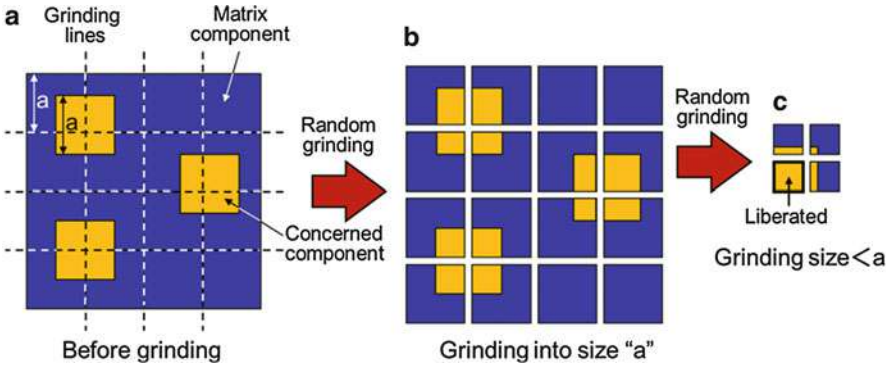

Fig. 4 2D matrix model of liberation process

uniformly with the size of "a," as shown in Fig. 4b, not influenced by the interface between the target material and the matrix. Some particles can be the status of liberation, but in the most of the pieces, the target material is still the status of locked. Another crushing process, the size less than "a," may lead to liberation status for the target material. In the actual process, such random crushing does not likely occur and the status of liberation can be easily obtained. Only the efficiency can be different for each crushing method; thus, wise choice of the method is crucial in order to realize high-quality liberation.

Figure 5 shows the schematic image of the relationship between progress of liberation and nonuniformity of crushed pieces. Let us consider Status A in Fig. 3 and apply crushing process in order to liberate the rare metal X. As crushing time proceeds, the particles become finer, and, eventually, particles of rare metal X are liberated. If this happens in a short period of time, which is the best scenario, the Status A shown in Fig. 5 will be realized, which leads to best pretreatment for physical sorting process. On the other hand, if longer crushing process time is required for liberating rare metal X, finer particles tend to be obtained, being Status B in Fig. 5 that is relatively difficult for physical sorting. Typically, Status B includes a wide range of particle size distribution, and it is almost impossible to collect particles under several microns by physical sorting process. Therefore, even when the nonuniformity of individual particle is realized, toward the right-hand side in Fig. 5, the status of well-mixed finer particles makes it difficult to separate the target particle. Also the same is applied to Status C in Fig. 5 where all particles are locked. To summarize, the process of liberation refers to achieving nonuniformity of individual particle by sacrificing the nonuniformity of the target material in the crushed product. The ideal situation is that nonuniformity of both individual particles and the target material is realized. Solid and broken lines in Fig. 5 show when the selective, optimized crushing process and random crushing process, respectively, are selected, which shows the idea of actual crushing process. Selective crushing is a very important technique to realize liberation at the coarse particle size. In order to realize efficient selective crushing, it is important to proceed to the breakup at the boundary

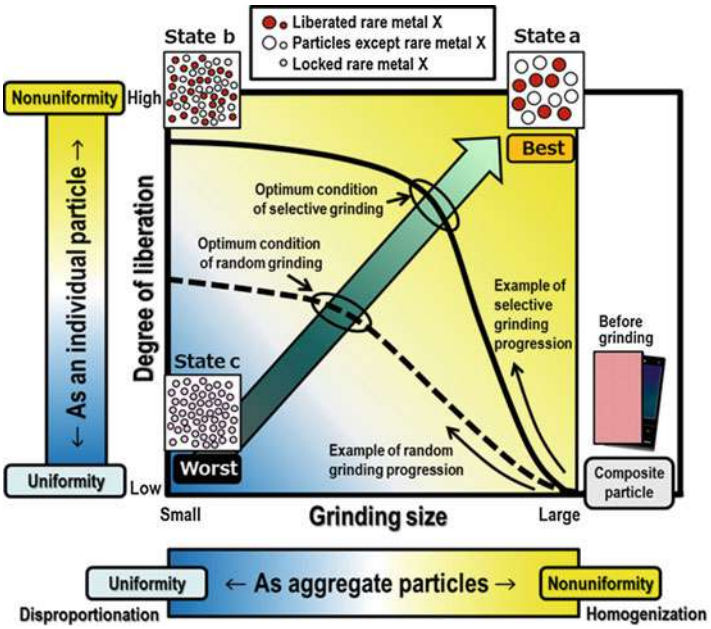

Fig. 5 Schematic image of the relationship between progress of liberation and nonuniformity of crushed pieces

of the rare metal X domain and the matrix. Since the waste products' properties are different, even considering culler phone, each one has different structure; strength, depending upon the model; manufacturer; and year of product; there is no all-fitted selective crushing machine. Currently, the selective crushing property of particular products is investigated by utilizing an existing crushing machine. Study of theoretical and systematic approaches is expected for realizing ideal selective crushing process.

Grinding Method Aiming at the Promotion of Liberation

Mechanical Crushing

Mechanical crushing is one of most realistic choices for early introduction to actual recycling plants. Mechanical crushing tends to break up products uniformly, and it is not easy to break up only at the interface as shown in Fig. 6a. It may, on the other hand, be possible to expect selective crushing as shown in Fig. 6b or c if there is a difference between mechanical properties of the target and the matrix. Figure 6b can be realized by combining thermal treatment and crushing processes, which were actually applied to the process for separating bone steel from concrete wastes (Mitsubishi Material Co, Ltd 2003; Matsumura 2003). Figure 6c can be realized by combining stirring and surface friction destruction processes.

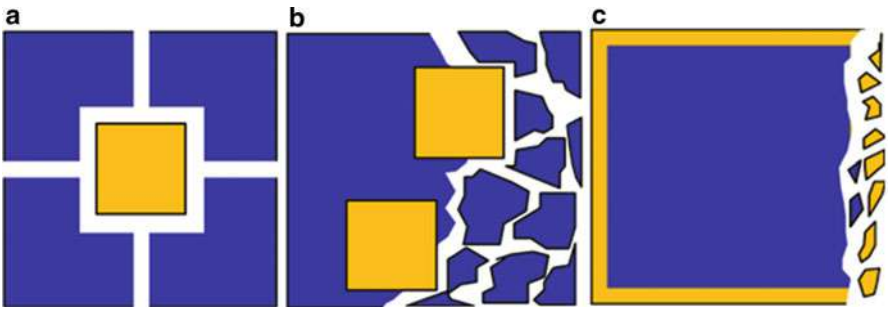

Fig. 6 Example of selective crushing for liberation

Not many cases are reported for metal recycling using mechanical crushing, but there is one good example, printed circuit boards. Actually, for the recycling of metal (copper) from the printed circuit board, the swing-type hammer mill process machine was applied, and it was found that the copper could be recycled as sphere particles due to its ductility (Furuyanaka et al. 1999). The selectivity of metal and nonmetal parts in the printed circuit board can be further improved by controlling the operating condition of the machine.

Other new processes are also under development (Koyanaka et al. 2006; Furuyanaka 2006; Koyanaka et al. 2006). One of them is the so-called active crushing method. It controls multiple operating conditions of impact crushing simultaneously during the actual operation. Single separation of target material, control of particle size, and ejection of crushed materials are optimized timely and continuously during the crushing operation.

Figure 7a shows the schematic image of the active crushing system (Furuyanaka 2006; Koyanaka et al. 2006). The system is based on the fast swing-type hammer mill, and the inverters for controlling hammer and feeder, electric air valve, and servo amplifier are connected to a PC, in which a certain operating pattern is programmed for automatic operation. In addition, the shape of the lining plate is also specially designed. Figure 7b and c shows examples of operating patterns for the speed of impact and the period of opening screen, which were actually applied to crushing circuit boards for TV after crushed using the cutter mill. As can be seen, the speed of hammer increases to 60 m/s with (b) 14 s and (c) 3 s, respectively. Using the pattern (c), one could obtain the metal separation efficiency of 50.6 %, with average particle sizes of 421 μm and 188 μm for metal and nonmetal, respectively. It was also shown that 59.6 % efficiency could be obtained by further optimization (Fig. 7b). As can be seen, accurate operation of mechanical crushing can provide realistic liberation of target materials. Not much verification so far is reported, but it is expected to increase the application of such techniques on recycling for portable devices.

Electrical Crushing

In order to realize the liberation of target materials without excess crushing, it is ideal to have selective separation at the boundary of target materials and the matrix.

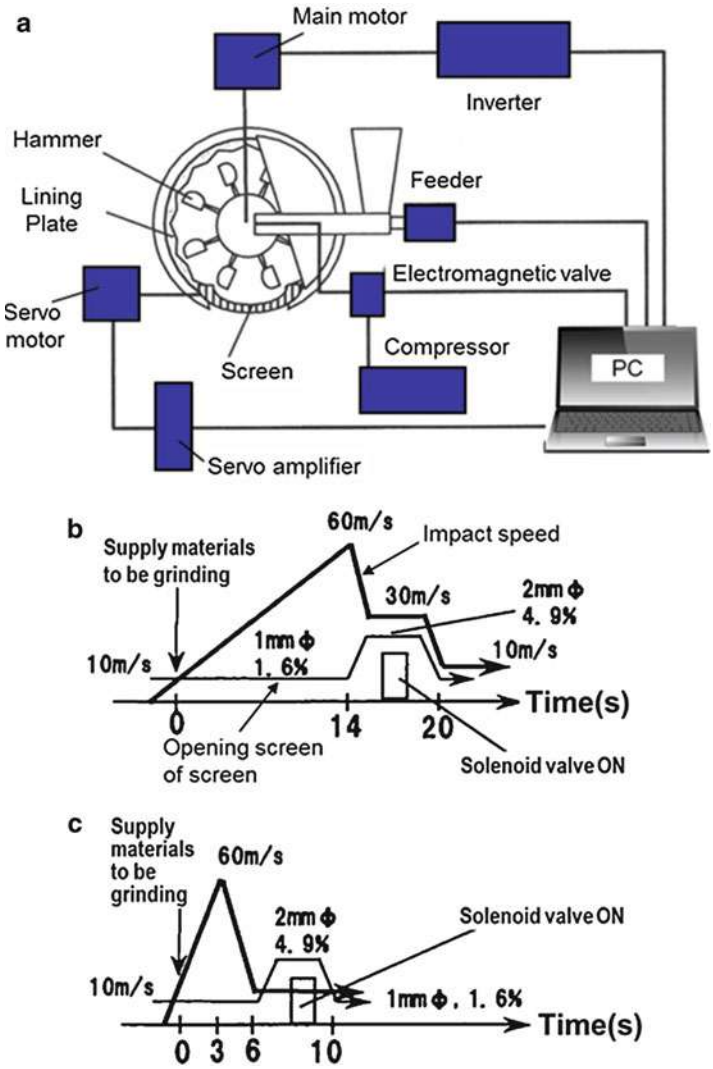

Fig. 7 (**a**) Schematic image of the active crushing system and (**b**, **c**) examples of operating patterns

Ordinal mechanical crushing methods, on the other hand, tend to result in uniform breakage, and it is difficult to crush designated area only. Therefore, electrical crushing is being considered, which allows crushing selectively along the boundary of the target material and the matrix. Mainly, there are two electrical crushing methods: electrical disintegration (ED) and electrohydraulic disintegration (EHD) methods. The ED method utilizes high voltage and large current in the liquid where particles (consisting of target material and matrix) are dispersed in a container. The particles are close to or touched at one electrode, and the other electrode is placed at

the other side of the container. The high-voltage pulse of several 10 kV in several 10 μs is applied, so the large current only flows at the boundary in the particles that leads to crush the particles along the boundary (Fujita et al. 2002). Many studies are reported especially for rocks, coals, and concretes and, in recent years, for liberation from used products on recycling purposes. For example, the method was applied to liquid crystal panels used for cellular phones and laptop computers, and it was confirmed that the panel was separated into two glass substrates, and indium (ITO) could be collected after different treatments (Shibayama et al. 2002).

The EHD method, on the other hand, utilized a shock wave generated by the large current flow in the liquid (Fujita et al. 2002). Explosives can be utilized instead of using the current flow. In either case, the shock wave generates tensile stress at the boundary and promotes selective crushes along the boundary. In the case of the cellular phone, it was reported that the shock wave propagated along the boundary between metal and resin and confirmed that metal parts were removed from the matrix (Kejun et al. 2001). As explained above, the electric crushing for liberation of used products is under development, and in the near future, it has a potential to be an innovative recycling method; however, it may also be difficult to introduce in the existing facilities due to the use of large current or explosives.

Alternative Technologies for Hand Dismantling and Picking: Easy Sensing

The most certain way to break up a complex product into pieces is dismantling. Dismantling is usually done by hand, while crushing is done by machines, and industrial robots may take human's place for dismantling processes in near future. From the technical point of view, dismantling is defined as liberating operation for individual product, while crushing as liberating operation for massed products. Thus, crushing is much more efficient and also cost-effective compared to dismantling. Nevertheless, hand dismantling is still the major method for recycling because it is an easier process for liberation. Actually, even in Japan (where the labor cost is considered to be higher), hand dismantling is applied for recycling motors, which are relatively large pieces, from used appliances. Since there is no almighty method for liberation, hand dismantling is still applied in many cases, even in some that are not cost-effective. Another advantage of hand dismantling is that breaking up and separation of pieces proceed in the same time. Although this method is very useful for applying for the variety of products, there is a limitation of this method from economical point of view, especially in Japan. Thus, the development of automated dismantling machines has been carried out, and some processes are successfully automated, for example, sorting process utilizing advanced sensing technology. This technology is very useful for getting rid of impurities from the uniform particle, but it cannot be applied to widely scattered pieces from dismantled products.

Under circumstances, the authors have been developing a cost-effective sorting machine utilizing "easy sensing" technology, alternative technologies for hand dismantling and picking. Instead of using expensive, high-performance sensors, this machine utilized a combination of cost-effective sensors, which were close to human sensibility, and highly controlled operation procedure based on the nature of target products.

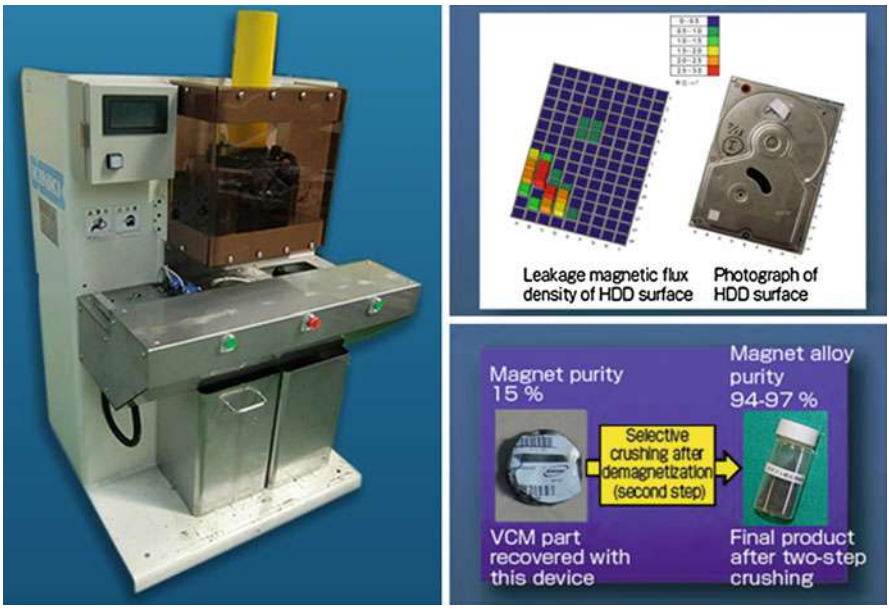

Fig. 8 Automatic collection of Nd magnet from HDD by HDD cutting separator (*HDD* hard disk drive)

For example, the authors have proposed a two-step crushing separation method for collecting neodymium magnets including rare-earth metal from hard disk drives (HDDs), "HDD cutting separator (HDD-CS)" as shown in Fig. 8. When HDD is normally crushed, the very strong neodymium magnets can be attached inside the crushing machine and cause many problems such as blockade at the screen. Even though they are luckily extracted out of the machine, they are agglomerated with metal pieces and not possible to be liberated. Thus, demagnetization process is typically applied in such case. Neodymium magnets have relatively low Curie temperature and can be demagnetized at around 350 °C. However, it is not cost-effective to use thermal energy only for extracting the magnet, 2 wt% of HDD, meaning that it requires 50 times more thermal energy for demagnetization. The HDD-CS solves such a problem by utilizing four magnetic sensors and location sensors that identify the leakage magnetic flux density and the position of magnets in the HDD without destruction. Then, the magnet is punched out with a nonmagnetic cutter. The accuracy of sensing is kept improving by optimizing the machine using the database of the leakage magnetic flux density for each HDD. This, small and cost-effective, machine realizes an automatic separation process of 400,000–1,000,000 HDD per year and can concentrate the magnet component ten times. After demagnetization, impact crushing, and screening processes, 94–97 % of magnetic alloy particles are successfully collected (Oki et al. 2011).

Another "easy sensing" technology, called "Arena Sorter," a sensor-based sorting technology, is also developed as an alternative hand selecting sensing technology. It

utilizes laser 3D measurement unit and weight detector that obtain the parameters (size, weight, and so on) of waste products, and they are recorded on the database. The system is operated using discrimination algorithm that utilizes neural network and the database (Koyanaka and Kobayashi 2011). For example of recycling cellular phones, the system successfully realized 90 % accuracy of automatic separation for tantalum capacitors from the cellular phones (Koyanaka et al. 2006).

Technical Challenges of Quality Recycling: High-Quality Separation

Challenges for the Optimization of Physical Sorting Processes

Even when ideal liberation is realized, particles still remain in a mixed status, and thus separation is required. For example, let us consider liberated metal particles including 100 ppm of target metal. This separation means that we need to pick up a target particle from a bucket filled with 10,000 particles. In the case of particles with centimeter order, separation by hand can be applied with high accuracy; however, it is not economical at the end.

As described above, one of the practical systems is sensor-based sorting system that utilizes materials' information obtained from the sensor. This can be cost-effective for such separation and is also called individual separation. Pressured air can be applied to the particle separation in the range of several mm–300 mm (Furuyanaka 2010). In addition, a variety of sensing technologies, such as color, images, transmission X-ray, and fluorescence X-ray, can be applied, and they are effective for the separation of specific particles (Owada et al. 2010). In the case of mixed particles consisting of many kinds of materials, on the other hand, accurate sensing cannot be expected. As the particle size decreases, it becomes more difficult to separate the particles. In this case, it may be more efficient to handle the particles as an aggregate. This is called "bulk separation" or "mass separation," which usually utilizes the difference in the properties of particles, such as density, magnetism, and wettability. In addition, the process can be categorized as dry separation and wet separation (usually in water). A dry separation process allows for high throughput and easy collection after separation, and a dry process unit is easy to install and cost-effective. On the other hand, a wet separation process utilizing bulk properties is expected to improve the separation efficiency compared to a dry separation process; however, it also has disadvantages that it consumes more energy for water circulation, dehydration, and drying processes. In addition, in many cases a surfactant is utilized in a wet separation process, which enlarges load for effluent treatment. After all, these two process types have an optimum range of particle sizes for separation as shown in Fig. 9. We conveniently define low-limit particle sizes shown in Fig. 9, and under certain reliability, low-limit particle sizes for dry and wet separation using bulk properties are 1 mm and 50 μm, respectively. As described above, if the liberation is achieved at the stage of coarse particles, dry separation can be applicable, and it realizes economical and highly efficient separation.

Once the crushing process is applied, it always generates fine particles less than 1 mm. Some rare metals in certain products have a tendency to be concentrated in the

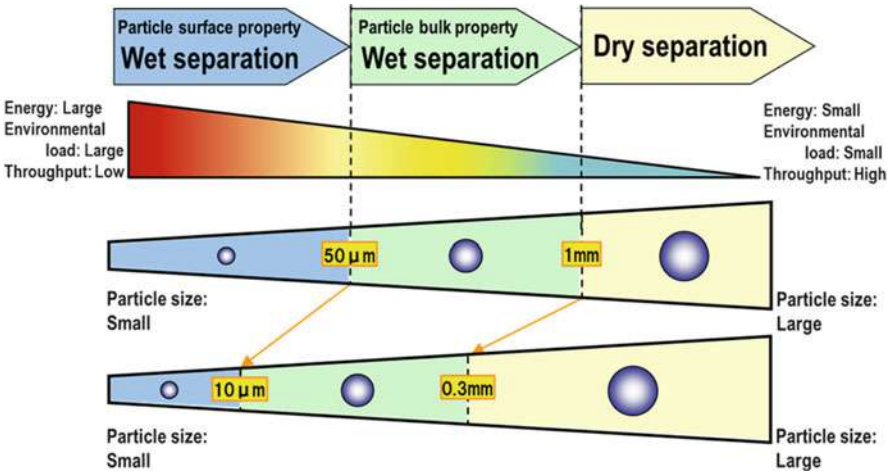

Fig. 9 Category of separation technology and concept of low limit of applicable particle size

particles, and thus, such fine particles will also need to be separated and collected (Oki 2008a; Oki et al. 2008). So far, the particles below 50 μm required wet separation processes utilizing surface property, such as flotation process. A recent study, on the contrary, showed the possibility of a dry process that realizes gravity concentration up to 10 μm particles using strong centrifugal force (Oki 2009).

On the contrary, one cannot achieve complete metal recycling no matter how individual elemental technology for recycling was developed. A great variety of products are manufactured and abolished in every year. Thus, construction of a flexible sorting process is necessary to cope with a change of such variations or the chronological changes. However, at the moment, the techniques to build these processes are not yet established, and one has to keep working on the development of these techniques to realize the most suitable sorting process and to derive the most suitable sorting condition.

Figure 10 shows the model of the simplest separation process, combining a grinder and a sorter. The targets fed to the sorting process have a variety of constituents such as various kinds of printed circuit boards and electric parts. The grinder itself also has a variety of models operable in the different treatment conditions. In addition, there are so many options for separation of crushed particles. Thus, although the model shown in Fig. 10 has only seven items, it gives ten million ways of separation processes, supposing that each item provides ten conditions. If 20 conditions were given for each item, 1.28 billion ways will exist. Since the efficiency of the liberation is determined as multiplication of grinding efficiency and separation efficiency, both processes need to be well optimized. Even if the simple model shown in Fig. 10 has one grinding and one separation process, the combination of possible patterns will be more than 100 million. In the actual case, a couple of grinding processes and three to ten of separation processes will be applied, which is an astronomical figure. Only a small portion of

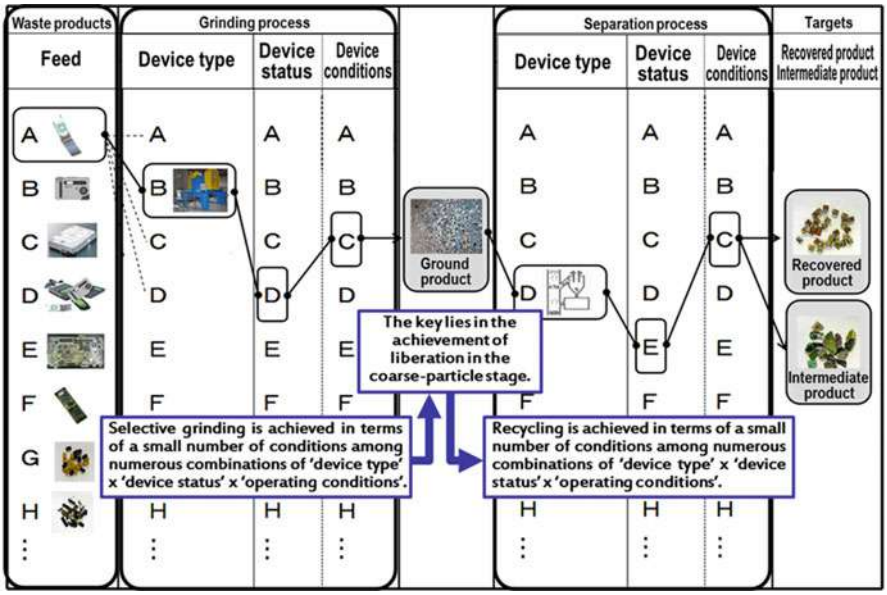

Fig. 10 The model of the simplest separation process

these patterns can actually be ideal physical separations for urban mine resources, and what makes it more difficult is that the cycle of product release is short and the amount and kind of rare metal are different from each product. Thus, one optimum separation pattern will no longer be effective in a short period. Because of this, it is very difficult to optimize the separation pattern, and in reality, they are operated under inefficient conditions.

Although the improvement of liberation processes by selecting optimum grinding and separation processes is important, it is very difficult to recognize the importance of the processes. Figure 11 shows the schematic image of a physical separation process that extracts and purifies rare metal X from waste product. For example, let us think about cellular phones as a feed. As described in Fig. 3, rare metal X can be located anywhere at the variety of status points in the cellular phone, and this affects the difficulty of liberation using a crushing process. In the crushing process, as shown in Fig. 5, the type of grinding machine and its operating conditions determine the size of particles and the degree of liberation. Even if the ideal liberation is realized such as Status A (or Status B) in Fig. 11, the results can be different depending upon the efficiency of the latter separation process. However, efficient separation after Status D does not often achieve higher purity of rare metal X than that of Status B with inefficient separation. Here, the information that can be obtained from typical recycle plants through the series of processes is threefold: (1) purity of rare metal X in the feed, (2) particle size after grinding, and (3) purity and yield of rare metal X after separation. Actually, important parameters that determine the quality of the entire process, such as the dispersion of rare metal X

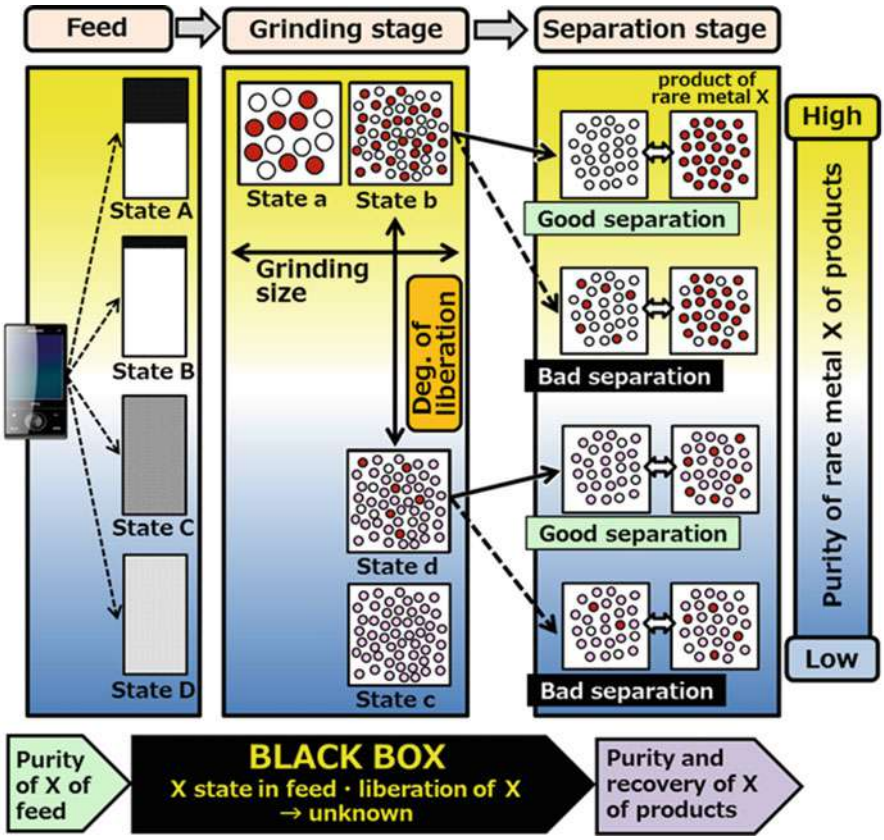

Fig. 11 The relationship between the selection of separation method and the degree of liberation

in the waste product and handy analysis method for the degree of liberation, do not exist. Important parameters in the processes from product feed to collection of separated particle are in the black box, and it is not possible to find out the source of problems such as poor purity of rare metal X after recycling. It could be due to the quality of liberation or separation. In this current situation, the concept of liberation and importance of selective grinding are not well recognized, and in not a few cases, only latter separation process is discussed without considering the degree of liberation.

In addition, component analysis of separated products does not provide sufficient feedback to the process for improvement, and this makes it difficult to optimize the process of physical separation. Development of simple and easy liberation measuring equipment, and the optimization of the selective grinding and sorting systems which depends on the liberation data, are indispensable issues for success of the rare metal recycling.

Selection of Sorting Technologies and Challenges

During the crushing process, particles with various sizes are generated. The ideal particle size range for better sorting results differs depending upon each sorting technology. Typically, the particles are separated into two or three particle size groups by a screening process, and an optimum sorting process is applied. The particles in the range below several hundred microns are usually not collected; however, collection of such particle range is becoming important especially for recycling precious metals and rare metals, as well as the sorting technology for such particle range.

In order to realize highly efficient, low-cost, and low-environmental impact sorting technologies, it is necessary to broaden the applicable particle range of each sorting technology, possibly of the technology in the right-hand side of the image shown in Fig. 8. For the example of improvement for the columnar pneumatic sorter, one of dry sorters, separation of 0.1 mm copper and aluminum particles is realized using model particles (Oki et al. 2007). A wet process can be utilized for finer particle separation where a dry process is no longer efficient. On the other hand, wet gravity concentration, based on particle bulk properties, still has the problem that the separation accuracy decreases as the particle size decreases due to low inertia. Typical particle size range for accurate separation is about 50 μm for conventional wet gravity concentrators such as shaking tables and spiral gravity concentrators. For the particle size below that, wet separation processes such as flotation using the surface properties of the particles can be effective. For the example of removal of ink from waste paper, flotation works very effectively. On the contrary, this process is not ideal for waste products with surface contamination that lower the separation efficiency significantly. Currently, application of wet separation techniques utilizing bulk property of particles is expected even for the particles below 50 μm.

Another gravity concentration technology utilizing strong centrifugal fields has been developed since the 1980s and has shown the possibility of gravity concentration up to 10 μ particles. Figure 12 shows a modified image of applicable particle sizes for each separation technology based on the literature by F. F. Aplan (2003). Among them, detailed information for conventional sorting technologies that can be used for mineral processing and metal recycling is available in the literature (Wills 2006). In this chapter, the authors focus on the gravity concentration technology that realizes wet separation of fine particles utilizing bulk properties. As the particle size decreases to below 50 μm, it becomes difficult to separate particles using wet gravity concentration. One of the reasons is that the mobility of particles in the water decreases and separation takes a lot of time. Another reason can be that it is difficult to separate the particles using the specific gravity difference as the inertia of the particles decreases. Gravity concentration using strong centrifugal fields, on the other hand, improves not only the mobility of particles but also the efficiency of separation.

Figure 13 shows the category of wet gravity concentration devices and the acceleration of gravity or centrifugal field affecting the separation (OKi 2008b).

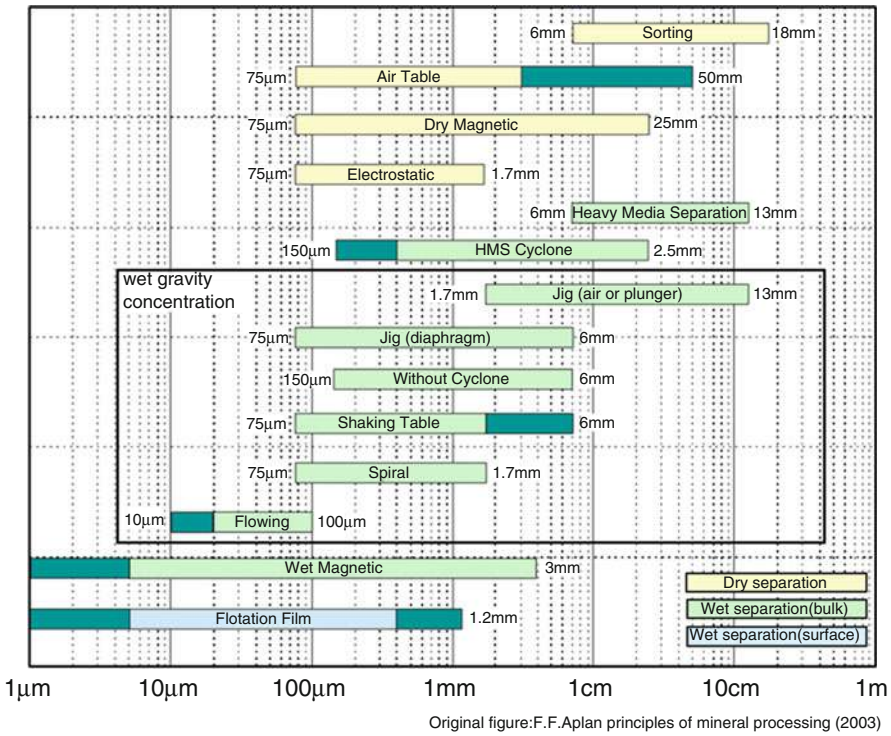

Fig. 12 Applicable particle sizes for each separation technology

Here, it shows the acceleration of rather small, lab-scale devices. Wet gravity concentration devices can be categorized into three types:

1. Water flow separation, method to separate utilizing particle sedimentation rate and velocity of the water stream
2. Film flow separation, method to separate utilizing the resistance between particles and water film on the slope and the friction between particles and the slope
3. Pulsatile flow separation, method to separate utilizing the upward and downward motion of water to differentiate the time reaching the bottom

Among these methods, separation by gravity settling, especially shaking table and jig, has been widely used for a long time as typical wet separation method. Hydro-cyclone using rotational flow and spiral separation devices are conventional installations for fine particles utilizing wet gravity concentration. In addition, the compulsive rotational wet gravity concentration method realized 10 μ particle separation utilizing strong centrifugal forces given by a mechanical rotating force. For the device shown in Fig. 13, maximum acceleration is in the range of 30–300 G (1 G = 9.80665 m s^{-2}). Although it is not possible to define the low-limit particle

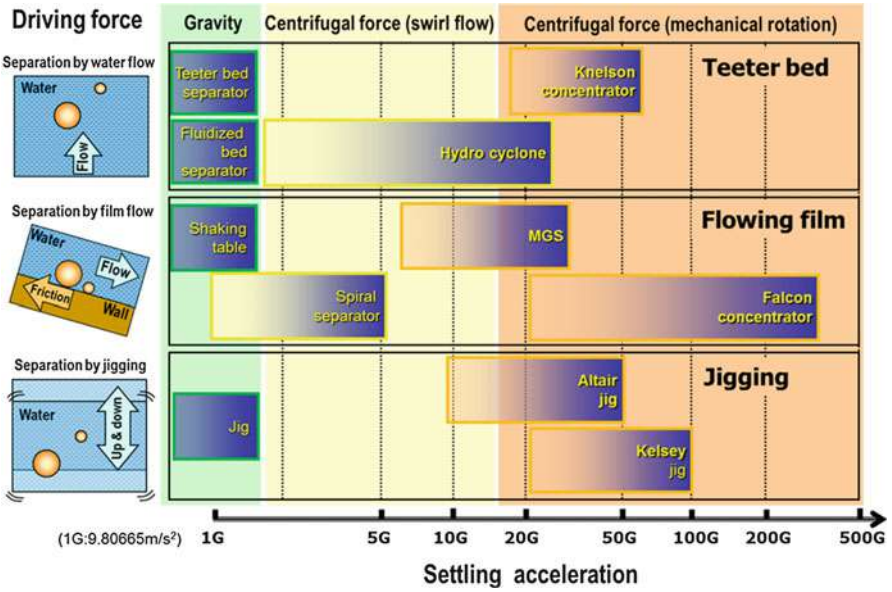

Fig. 13 Category of wet gravity concentration devices and settling acceleration

size or separation accuracy by the acceleration due to the difference in the particle motion or the method of particle collection, it is clear that the velocity and inertia of particles are increased by the acceleration. So far, compulsive rotational devices were utilized mainly overseas; however, the mechanism of particle separation and operability is still not clarified, and only few cases were applied to rare metal recycling. Since the wet process is promising, more application is expected in the future.

New Sorting Technology for Urban Mine Development: Smart Operation

A physical sorting process is usually combined from three to ten separation stages, and the combination of separation stages yields astronomical figures. Thus, most cases are abandoned before finding out the true performance of each device. To solve this situation, the authors have examined a system that promptly derives the optimum condition using a database and computer simulation. Without relying on experienced workers, the "smart operation" system realized automated operation at optimum condition. The system has been applied to recycling of printed circuit boards, and the author succeeded in the development of a sorting process that could collect tantalum capacitors at high purity for the first time in the world and achieved practical use upon introduction to a Japanese recycling plant in 2012.

Since tantalum is one of the most expensive rare metals and most of it is not recycled, the Japanese Government chose tantalum as one of five important metals (tungsten, tantalum, cobalt, neodymium, and dysprosium) that are preferentially recycled in 2012. Tantalum is mostly used in a tantalum capacitor on printed circuit

boards. At first, the recycling process of the printed circuit board for tantalum is developed based on the conventional liberation method (see Fig. 5). Considering the tantalum atom as the species of liberation, the authors aimed at the improvement of the liberation by fine grinding of the printed circuit board. After fine grinding, the authors conducted separation process based on the physical property of tantalum oxide, resulting in the concentration of tantalum to several times. Tantalum was, however, collected with a precious metal and other heavy metals due to low weight ratio of tantalum in printed circuit boards, around 1,000 ppm. As described before, rare metals such as tantalum need to be separated from copper or precious metals before pyrometallurgical treatment, and the recycling of tantalum could not be accomplished by the method mentioned above.

At first, it was considered that it was almost impossible to collect a certain electric element from a printed circuit board where various electronic elements were mixed. A phenomenon, however, was found that an electronic element was exfoliated from a printed circuit board as the original form by using a certain crushing device. Thus, we made an attempt to find out the most optimum separation pattern, considering the tantalum capacitor as the species of liberation and each electronic element has peculiar sorting properties. The authors classified over 400,000 electric elements in 320 categories according to the size and the function and built the database for their physical and sorting properties. Then, three kinds of separation methods, viz., size, specific gravity, and magnetic properties, are considered, and by numerical computation, the authors predicted the sorting result of approximately 2,055 trillion ways of patterns that include repetition use and performed narrowing of the optimum that a tantalum capacitor could concentrate afterward. As a result, the authors found the sorting process that realizes over 80 % of recovery of tantalum capacitors and purity of tantalum capacitors, from the mixture of exfoliated electric elements (Fig. 14, Oki et al. 2010).

Although the optimum sorting process pattern was clarified, there was no device that could realize the process pattern. Thus, the development of such device "inclined and low-intensity magnetic-shape separator" was conducted as the next step. This small device, rather used as an auxiliary unit, was a hybrid device that collected aluminum electrolytic capacitors at the inclined conveyor and collects quartz resonators at the low-magnetic field sorter. The device could collect iron and aluminum separately, and the rest that includes tantalum capacitor is sent to a special pneumatic sorter. This "double-tube pneumatic separator" is the main device of the sorting process and can control the airflow rates in the columns precisely using single blower. In the first column, elements heavier than the tantalum capacitor are collected by gravity, and in the second column, only tantalum capacitor is collected by gravity. The flow rate of the first column is slightly faster than that of the second one based on the numeric calculation. In order to realize highly accurate gravity concentration, this device introduces new operating parameters for both software and hardware. Especially, it is possible to operate automatically from the calibration of the device to the collection of elements by selecting the target elements (not only tantalum capacitor but also other elements) on the display, by operation control using electric element database (Oki et al. 2010).

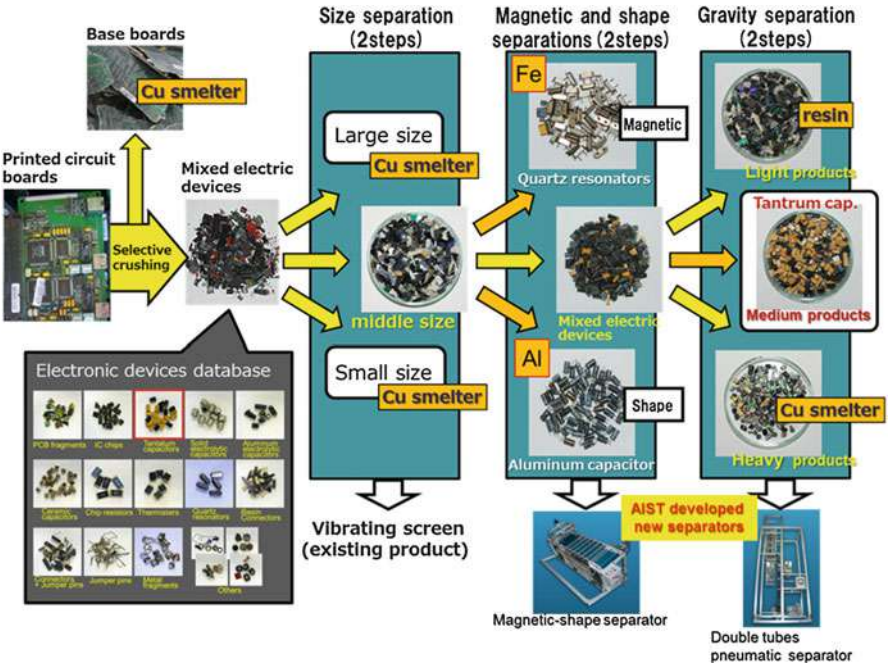

Fig. 14 Tantalum capacitor collecting process optimized by the simulation based on the database

It used to be assumed that the maximum separation efficiency of the tantalum capacitor was around 10–30 %; however, after such device development described above, the separation efficiency of 97 % was achieved by the trial run with a recycling plant where the device was installed (Oki et al. 2010, 2011). In this way, by using product information appropriately, it is possible to derive the most suitable sorting condition quickly and to recalculate the most suitable sorting condition by substitution of the information in the case of altering product specification, without going through again from the beginning. Use of the easy sensing technology and the smart operation technology just began, and it is expected that the development of recycling technology for other resources will progress further by the innovation of such physical sorting technology.

"Strategic Urban Mining" that Japan Aims for

Missing Link of Resource Circulation and Resource Circulation Interface Function

In recent years, the development of sensor-based sorting technology for recycling has been active around Europe, and in most of the cases, the mineral processing technology that was applied to the natural mine is converted into the physical

separation in the recycling. The mineral processing technology at the natural mine does not only utilize magnets for iron and gravity concentration for heavy metal but also make the most of the property of "minerals" based on the knowledge of geology and mineralogy, and minute sorting was conducted.

In addition, natural mines are usually developed for several decades, and there is enough time to optimize the mineral processing technology for a specific mineral. As a result, it is possible to obtain a variety of metals including rare metals economically.

On the other hand, when the technology is applied to urban mines, only the separating technology based on the element characteristic can be utilized due to less information of the waste products. As a result, except for precious metals, metals used for structural materials such as iron, aluminum, and copper became targets of the recycling.

In recent years in Japan, urban mines are expected to develop for supplying rare metals enough to manufacturing products; however, the technology still requires improvement from the conventional "quantity recycling" technology. The collection of rare metals was difficult in the old urban mine concept, but it can be said that a technical breakthrough will be achieved by compiling the characteristics of the waste products into a database and utilizing it for the separation process, as shown in the example of the tantalum capacitor.

On the other hand, however, the urban mining without considering infrastructure and system surrounding it does not realize efficient resource recovery as much as a natural mine can supply, even when new technology is introduced into a part of the resource circulation loop. Even if the recycling is promoted by both production and consumption sides, the resources do not circulate without considering an interface between both sides. In order to realize sustained circulation use of the strategic metals, it is important to construct a series of systems from the supply of reproduced raw materials to a product design, not only to develop resource recycling technology such as physical sorting. The authors thought that the introduction of innovative sorting technology and the eco-design functioned as a mediation technology, and the technology was named "resource circulation interface" (Fig. 15).

As discussed above, even if advancement of the physical sorting technology is accomplished, it will be difficult to apply it to all product forms with that alone due to the variety of the product designs released up to now. Thus, an easy recycling design (eco-design) can be considered to compensate for the technology gap. The effective and minimum easy recycling design can be achieved by the suggestion to the products as well as the design guidance of the parts and products that realized easy to sort without spoiling products' original function and charm. In this way, the improvement of the physical sorting technology is a key for the development of the urban mine including the interfacial function of global resource circulation of materials.

Aiming for Establishing Strategic Urban Mines

In order to succeed with efficient and deliberate urban mining, it is of importance to build a society system that introduces product eco-design and physical sorting

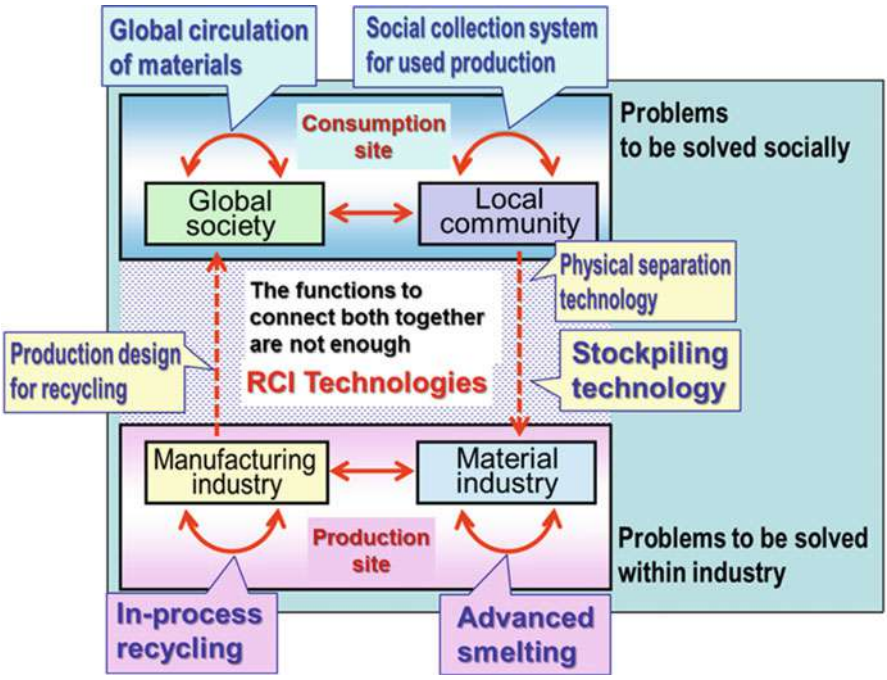

Fig. 15 Missing link and interfacial function of resource circulation

technology utilizing artifact databases. For this purpose, the authors have conducted a project called "Strategic Metal Resource Circulation Technology (Urban Mining)" between 2012 and 2014, aiming for the total development of urban mining in Japan. In this project, the authors specified important metals as "strategic metals" that are necessary to continue industrial activity and potentially have supply risk and evaluated the potential of urban mining and efficient collecting technologies. Venous industry (recycling industry), as shown in the upper part of Fig. 15, mainly focuses on the short-midterm technological subjects aiming for the development of urban mines that are scattered and disorderedly accumulated. Arterial industry (manufacturing industry) of the lower part of Fig. 16, on the other hand, focuses on the mid-long-term technological subjects for realizing a practical urban mining plan utilizing eco-design from manufacturer aspects.

As described above, by considering the demand and supply risk of metal resources, as well as the system that realizes deliberately and efficiently collecting strategic metals, the authors named their initiative "Strategic Urban Mine" in contrast to conventional disordered urban mines.

In addition, in November 2013, a new research base "Strategic Urban Mining Research Base (SURE)" was established in the National Institute of Advanced Industrial Science and Technology (AIST) for continuous research activity based

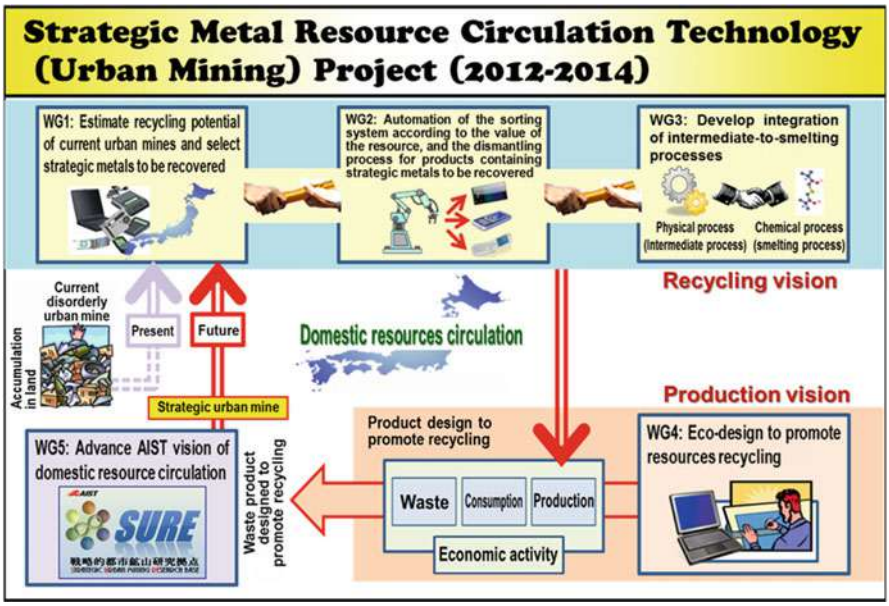

Fig. 16 Summary of Strategic Metal Resource Circulation Technology (Urban Mining) Project

on the project's concept. SURE holds 37 researchers from AIST (Fig. 17). And SURE maintains a laboratory for evaluation of sorting technology (SURE LATEST) at the AIST Tsukuba West site, aiming at the improvement of physical sorting technology. The laboratory has large space room and four separate rooms that hold about 60 physical sorting devices for grinding, crushing, and separation processes. Twenty of them were originally developed at the AIST (Oki 2012, 2013a, b, c, 2014a, b, c). Such open laboratory, the core of physical sorting technology, is the first attempt in Japan and expected to contribute accelerating development of urban mining development.

In order to introduce the strategic urban mine into the society, the support from industry side is necessary. For this purpose, the SURE consortium was organized in October 2014, together with companies related to metal resource circulation, aiming at an early realization of strategic urban mines by extracting needs from industry and society. Currently, the members of the consortium are 45 companies and 20 industry groups and public organizations and institutes.

Members of the SURE consortium discuss common subjects in the industry group or individual company's subjects such as eco-design and utilization technologies of recycled materials, in order to promote the strategic urban mining concept from the manufacturers' point of view. In addition, they can utilize the facility in SURE LATEST aiming at the extraction of potential problems at recycling plants for

Fig. 17 Structure of Strategic Urban Mining Research Base

better improvement of the technology. The SURE consortium is expected to propose a variety of new ideas related to urban mine development.

Future Prospects of Strategic Urban Mines

Obtaining enormous amount of metal resources from urban mines for supporting the civilization of human races will contribute not only to support sustainable development of civilization society to the future but also to mitigate climate change. While several incidents had happened in Japan, which accelerated the development of urban mining, up to now, there are still many issues that need to be solved from both technical and society system points of view. In this chapter, the authors showed the technical subjects for realizing total circulating usage of metal resources including rare metals and an attempt currently tackled in Japan.

Japan has already selected five important metals that need to be recycled and conducted related research on the nation level. It is, however, not possible to realize practical resource circulation with high international competitiveness if the technologies are developed individually.

Furthermore, even when one recycling technology has been established, the period of validity is not very long due to fast product cycle. The concentration of rare metal in the product also changes year by year, as well as characteristics of separation and crushing. In addition, the more a particular rare metal becomes important, the less material will be used in the product by promoting the use of alternative materials. It takes a lot of time to determine an ideal sorting pattern for a product from the enormous combination of crushing-sorting technologies, and when the process is ready, it is not a few cases that the target rare metal is no longer used anymore. Because of this, in the recycling process in many cases, a hand dismantling and picking process is used under inefficient conditions, and thus, the technology development does not always catch up with it.

In order to continue a steady development of rare metal recycling, it is necessary to conduct well-planned technology development based on the prediction of the future. From this point of view, there are two important forecasts: One is that which rare metals will be more important in the next 5 years and 10 years, in other words, which rare metals will be necessary to be recycled from urban mines. The other one is that we have to choose products from which rare metals are recycled. Currently in Japan, for the first one, five kinds of rare metals are selected as strategic rare metals; however, it is difficult to predict their true demand and price trend. At least, for the second one, those rare metals are already used in the products, and one can easily select appropriate products.

In order to proceed strategic urban mine development, the authors organized the Strategic Urban Mining Research Base (SURE) in the National Institute of Advanced Industrial Science and Technology (AIST). In this research base, the metals considered to be important in the next generation, not only rare metals, are designated to be “strategic metals,” and they are evaluated for their recycling potential. In addition, the database of physical properties for waste products is being constructed, and based on the database, automatic sorting technology for products including “strategic metal” and pre-smelting treatment technology are under development for preparing raw materials by recycling. These efforts will contribute to economical collection of strategic metal from the current “disordered urban mine” accumulated in the land.

Urban mines are one of the promising resources for Japan as a poor natural metal resource country. Fortunately, Japan is one of the major rare metal consumers and also is capable of smelting rare metal by its own. Japan’s urban mine will be more practical with the world top class recycling technology. In addition to these technological developments, it is necessary to reform the society system in order to realize productive and economical urban mine which overcomes the natural mines. The number of researchers and scientists will also be expected to increase for speeding up the development of technological aspect. Coping with sustainable civilization, utilization of renewable energy, and climate change mitigation is one of big challenges. All of them are interconnected, and from developing urban mine point of view, the activity of SURE including collaboration with private companies, and cultivation of human resources, is expected to contribute the climate change mitigation in the future.

DOI 10.1007/978-3-319-14409-2_54

Abstract

The University of Mississippi offered a seminar course entitled Climate Change – Causes, Impacts and Solutions twice in the last 4 years. The immediate goal of this course is to raise the public awareness of the climate change issue. The second objective is to consolidate a knowledge base for the various outreach, education, and research activities on mitigating the climate change. Junior, senior, and graduate students of science and engineering majors were encouraged to take this course. About 25 speakers from Mississippi, Alabama, and Louisiana gave lectures that covered their expertise in a wide spectrum of areas that include causes, impacts, and solutions of climate change. The slides used in these lectures are posted on the course web site for public dissemination: http://home.olemiss.edu/~cmchengs/Global%20Warming/. Students chose a specific research topic for approval in the early stage of the class. They submitted their research papers and made presentations at the end of the semester. Their overall performance is based on their classroom enthusiasm, final report, and presentation. When the course was offered for the first time, they also made recommendations to the Chancellor's Ole Miss Green Initiative of the University of Mississippi on the reduction of carbon emissions in the community. This chapter discusses the motivation, content, and outcomes of this course in detail.

Introduction

Climate change is arguably the most serious environmental issue. As discussed in the previous chapters of this handbook, from the greenhouse gas emissions to the affected areas of climate change, it is an environmental problem unprecedentedly large in quantity and space. The causes of climate change are complex. Its impacts on weather, ecology, and economy are potentially severe. Technologies for mitigating climate change are costly, and the infrastructure of green technology has just started to emerge. The decline in the supply of high-quality crude oil has further increased the urgency to identify alternative energy resources and develop energy conversion technologies that are both environmentally sound and economically acceptable. Although the concept of sustainability is not new, it has become a household phrase as people become increasingly aware of the severity and scope of future climate change. Climate change has thus become the central issue of sustainability literacy. At the same time, there has been a shortage of workforce

in the organizations that require some, if not much, knowledge about climate change.

Scientists and engineers play a pivotal role in developing green technologies leading to climate change mitigation. Therefore, there is an urgent need to equip the graduates with adequate knowledge about climate change so that they can function effectively in their careers. Under such demand, a campaign on climate change mitigation was planned in fall 2007. Personally, it was another twist in my life. I came to the USA in 1973 as a graduate student in applied mathematics, but the "energy crisis" in 1974 changed my plan. I switched back to chemical engineering in 1975 and started my research in coal hydropyrolysis. I have been maintaining activities in areas of hydrocarbon fuel conversions and pollution control since then. Coal was called "black gold" and "king coal" in the 1970s. Coal remains a major and indispensible energy source, particularly for developing countries such as China and India. However, coal suffered a severe image problem in the last decade because of the concern of its greenhouse gas emissions. As a fossil fuel researcher, offering solutions to the climate change concern becomes not only an obligation but also a serious challenge.

About 30 faculty members of the University of Mississippi (UM) and scholars in the region enthusiastically joined the "climate change study group" in fall 2007. The activities of this group include offering courses, editing a handbook, collaborating on clean energy production and conservation research, sponsoring workshops, and developing outreach and public awareness activities. The climate change class is discussed herein, and this handbook has outgrown from this exercise.

The engineering school at the University of Mississippi has a relatively small faculty and student population. Faculty has a fairly tight teaching arrangement. Fortunately, the administrators shared the same views and enthusiasm about the course.

Students also have tight curricula with 128 credit hours requirement for engineering majors that have been imposed by the Institute of Higher Learning of the State of Mississippi. Most students of the engineering school have to take two elected courses in science and engineering before they graduate. Sixteen students enrolled the climate change class before the course application was approved by the administrator. Some of them were from Chemistry Department and School of Pharmacy. They were seniors and graduate students. This size is about the average for the engineering classes at the university. The course was offered for the first time in spring 2008 and subsequently in spring 2009.

Course Scope, Format, and Title

Students signed up for the class with curiosities, more or less, in different aspects: the course content, the instruction format, as well as the instructors' change in teaching style. The reports about global warming and climate change they heard in the news media just about every day had profoundly promoted their curiosity and interests in the issue. They were notably happy to see an introductory course on climate change. Students in sciences and engineering were used to analytical courses in rigid setting

that include formal lectures covering relatively narrow scope of subjects with well-developed techniques for the analyses. At the outset of the preparation for this course, it was decided to deliver the materials in seminar style for several reasons. Naturally, the broadness of the course subject requires multiple lecturers from many different fields. The question-and-answer session at the end of each lecture allows students to express their thoughts and imaginations. Different lecture topics for different sessions inspire their thoughts about the relations among these subjects. Students are indeed eager to learn a serious subject through in much relaxed atmosphere. Most of the students had taken my engineering mathematics and chemical engineering thermodynamics courses (the second semester course in thermodynamics) prior to my offer of the climate change class. They were pleasantly surprised to know that a course of quite different delivery and learning styles was offered.

The Intergovernmental Panel on Climate Change (IPCC) and Al Gore were awarded the Nobel Peace Prize when the course request was approved by the university. The gigantic three-volume IPCC's Fourth Assessment Report (AR4) provides a comprehensive assessment of many aspects of climate change analytically written and edited by a selected group of 559 scholars. At the outset of the course planning, it was decided to cover the same three areas as those covered by AR4, and the course was entitled Climate Change: Causes, Impacts and Solutions. The detailed structure of the course is discussed later in this chapter.

Speakers of the lectures were invited mainly from the UM as well as the universities in the region to cover the topics in the fields of causes, impacts, and solutions of climate change. Most of them accepted the invitations without hesitation since the invited lectures were their expertise. There were 25 formal lectures when the course was offered for the second time in 2009. About 60 % of these lectures focused on mitigation technologies. Each lecture lasts about 60 min followed by a 15-min question-and-answer session. Two sessions at the end of the semester were reserved for student presentations. Formal lecturers were asked to assign homework, which they will be asked to grade in the following week.

Textbooks and References

Vanek and Albright's *Energy Systems Engineering: Evaluation and Implementation* was chosen as the textbook (Vanek and Albright 2008). The authors introduce the system concept in the analysis of energy conversion technologies at its outset. It is an interesting and beneficial approach, although the "system" concept has been introduced in several engineering courses such as process control, dynamics, reaction engineering, engineering economy, etc.; this textbook applies the concept to several different aspects of the energy systems including material and energy balances, economics analysis, carbon cycle, etc. They are uniquely demonstrated in energy systems in one place. The authors introduce the science and engineering fundamentals, technological costs, and impact on natural environment of each of the selected energy systems. Major working equations associated with the technology are identified; the functions of these equations are consciously illustrated by short

representative examples. These equations effectively link the current issues of energy systems and climate change with materials introduced in other courses, such as economics, heat transfer, thermodynamics, etc. They also provide the readers with an overview of the context within which these systems are being implemented and updated today and into the future. Their presentation centers around the utilizations of alternative energy resources and their roles in climate change mitigation. An extensive online ancillary package for instructors provides an instructor's manual, solution files, course syllabus, MATLAB scripts, and teaching PowerPoint files. Vanek and Albright indeed made it a friendly book to both the students and the instructors. The book was published in late 2008, i.e., after the price surge of oil; therefore, the economic analysis is based on fairly reasonable data. Moreover, this textbook contains representative homework exercises that serve the pedagogical needs and broad in nature. The cost of this book is moderate. These features render it suitable for a one-semester, introductory textbook for engineering students who would like to know the alternative energy options. Specifically, it covers energy supply and demands, issues surrounding CO_2 emissions, factors affecting and models of energy systems, economic tools for energy systems, climate change and climate modeling, fossil fuel resources, stationary combustion systems, carbon sequestration, nuclear energy systems, solar resource, solar photovoltaic technologies, solar thermal applications, wind energy systems, transportation energy technologies, systems prospective on transportation energy, and a conclusion chapter on creating the twenty-first-century energy system. The book, however, lacks coverage on a number of important areas including biomass conversion systems, energy efficiency for buildings, geothermal energy, and advanced combustion systems including oxy-fuel combustion and chemical looping systems. The seminar class did not cover all the topics in this handbook; however, several scholars in the regions were invited to cover most of these topics.

IPCC's AR4 (Intergovernmental Panel on Climate Change 2007a, b, c) was introduced to the class early mainly because it provides the most comprehensive and up-to-date scientific, technical, and socioeconomic information about climate change. It is available online at no cost; the paper copies are available from Cambridge University Press at moderate costs. The students were asked to read the "Summary for Policy Makers and Technical Summary" for each volume (with a total size less than 300 pages) in the first 3 weeks of the course so that they can have a general understanding of the subject. Some of the slides for the introductory sessions were extracted from the online version of these reports. While AR4 presents the most detailed advanced analysis presented by the IPCC and others, it does not contain textbook-level explanations about most of the scientific and technological terminologies. The major portions of the AR4 (other than the "Summary for Policy Makers and Technical Summary") serve as an indispensable reference to the complex subject, which deserve frequent visits during their study.

The ambitious book written by Tester et al. (2005) was adopted as a reference. This decadelong effort of five MIT professors is the first single source of the sustainable energy utilizations when it was published in 2005. It assesses technologies of converting fossil fuels (oil, gas, and coal), nuclear energy, and renewable

energies (solar, biomass, wind, hydro-, and geothermal) and discusses energy storage, transmission, end use, and efficiency/conservation issues. These technologies are assessed in a political, social, economic, and environmental context with life cycle assessment and systems integration methods. This textbook has been used in a graduate course on sustainable energy many times at MIT. The book was recommended as an advanced reference.

Dessler and Parson (2010) provide an integrated treatment of the science, technology, economics, policy, and politics of climate change. Aimed at the educated nonspecialist, and at courses in environmental policy or climate change, the book clearly lays out the scientific foundations of climate change, the issues in current policy debates, and the interactions between science and politics that make the climate change debate so contentious and confusing. This new edition is brought completely up to date to reflect the rapid movement of events related to climate change. In addition, all sections have been improved; in particular, a more thorough primer on the basic science of climate change is included. The book also now integrates the discussion of contrarian claims with the discussion of current scientific knowledge, extends the discussion of cost and benefit estimates, and provides an improved glossary.

Web sites of major international and US organizations were introduced to the students:

- Intergovernmental Panel on Climate Change, http://www.ipcc.ch/
- United Nations Framework Convention on Climate Change, http://unfccc.int/2860.php
- United Nations Environment Programme, http://maps.grida.no/theme/climatechange
- World Meteorological Organization, http://www.wmo.int/pages/themes/climate/index_en.php#
- International Energy Agency, http://www.ieagreen.org.uk/
- United States Global Change Research Program, http://www.globalchange.gov/
- United States Climate Change Science Program, http://www.climatescience.gov/default.php
- United States Climate Change Technology Program, http://www.climatetechnology.gov/

Table 1 2009 lectures

Session	Speakers	Title of lecture
1	Wei-Yin Chen	Overview of the causes of climate change – causes
2	Wei-Yin Chen	Overview of the impacts of climate change – impacts
3	Neil Manson	Reasoning economically about potential environmental catastrophes
4	Nathan Hammer	Atmospheric physics and chemistry
5	Charles Wax	Climate change – evidences and contrarian viewpoints
6	David Case	Climate change and US laws
7	David Case	International protocols and climate change
8	Yan Ding	Assessment of impact of sea level rise on coastal and estuarine infrastructure using numerical simulation model: CCHE2D-coast
9	Cris Surbeck	Effects of climate change on water resources
10	David Reed	Global climate change – impacts on biodiversity
11	Deb Gochfeld, Kristie Willett	Ecological and health impacts of climate change
12	Scott Gold	Surface chemistry and nanotechnologies: an approach for green energy
13	Jeff Roux	Energy conservation – use of foil radiant barriers to reduce residential/commercial energy usage in summer/winter for cooling/heating
14	Clint Williford	Biological conversion of biomass
15	Walter Cleland	Chemistry of CO_2
16	Waheed Uddin	Mobile and aerial sources of CO_2 and abatement strategies
17	Elizabeth Ervin	Nuclear energy: statistics
18	John Seiner	Fuel efficiency in transportation systems
19	Nathan Hammer	Photocatalytic reduction of CO_2 and water splitting
20	Robert Holt	Carbon sequestration
21	Wei-Yin Chen	Overview of the impacts of climate change – solutions
22	Robert Dahlin	Integrated gasification combined cycle (IGCC)
23	Tom Gale	Combustion on the horizon – oxy-fuel combustion and chemical looping
24	Amala Dass	Fuel cells
25	Steve Davis	Computational chemistry

Lectures Presented by Faculty and Scholars

Table 1 lists the lectures and speakers of the course in spring 2009. Among the 25 lectures, sessions 1, 3, 4, 5, 6, and 7 cover subjects in the "causes" category of climate change, sessions 2, 8, 9, 10, and 11 the "impacts," and the remaining 14 sessions the "solutions." Two sessions at the end of the semester are reserved

for students' project presentations. The contents of these 25 lectures are summarized below. More information about these lectures can be found in the slides used in these lectures, which have been uploaded for public dissemination: http://home.olemiss.edu/~cmchengs/Global%20Warming/.

Introduction to Climate Change: Causes, by Wei-Yin Chen

This is the first of three overview lectures given in this class that bore the same title of the course, one each on the causes, impacts, and solutions of climate change. The first two lectures covered the first two topics using one set of slides. The first introductory lecture on the causes covered the following topics:

- The rationale of offering a climate change class
- Impacts of increasing energy demand and lack of energy infrastructure on climate change challenges
- United Nation's efforts on climate change mitigation
- UNFCCC and Kyoto Protocol
- Total CO_2 emissions by country and CO_2 emission per capita
- Developed and developing nations' different views on CO_2 emission limits
- Paleoclimate archives and the scientific observations of greenhouse effects caused by human activities
- Greenhouse gases and their geographic and sectoral sources
- Radiative forcing of different greenhouse gases and their implication of human activities
- Nature climate change (i.e., the Milankovitch cycles) and its causes
- Thermohaline circulation and ice age
- Anthropogenic causes of climate change
- Natural carbon emission, carbon sinks, and carbon cycle and their relation with temperature rise and mitigation technologies

Finally, IPCC's comparison of economic development, population growth, and energy usage was used to illustrate the societal causes of global warming. The recent increase in CO_2 emissions was fueled more by economic growth than growing populations. It is not the poor masses, but the new and old rich that fuel global warming. And while energy and emission intensities have steadily decreased since the oil crisis in the 1970s, carbon intensity (carbon emission to energy consumption) has not. One conclusion could be drawn is that fixing prices for greenhouse gas emissions can help achieve emissions reduction, just like rising oil prices helped reduce energy and emissions intensity in the last decades.

Some of these slides were extracted from the IPCC's AR4 reports. Reading materials were assigned. Students were asked to start searching a term research topic.

Introduction to Climate Change: Impacts, by Wei-Yin Chen

The second lecture was on the impacts of climate change. History has shown that civilizations rise and fall to the pulse beats of climate. Erik Thorvaldsson's (known as Erik the Red) discovery of Greenland in 982 A.D. and the subsequent collapse of the Norse settlement less than 500 years later due to severe weather was one example. Flooding is generally believed to have caused the collapse of the Harappan civilization of India, 2500–1600 B.C. The outset of the lecture discussed how the analysis of climate predictability had actually promoted the evolution of modern chaos theory in the 1960s and 1970s.

Water's specific volume increases when the temperature rises. Sea level rise causes the most direct impact of temperature rises. Ice cap melting contributes a lesser degree of impact on sea level rise. Temperature rise also causes decline in biodiversity and natural disasters including droughts, heat waves, flooding, and cyclones. Sea level rise can contribute to disease spread and loss of traditional lifestyle. The natural disasters, in turn, can generate loss of traditional lifestyle, losses of water and food resources, biodiversity losses, economic losses, famines, casualties, and disease spread.

The abovementioned impacts were then discussed in more detail. IPCC's statistics and projections of these impacts are presented. The projected impacts on water resources, ecosystems, food productivity, coasts, and human health were presented as a function of warming from 1990 to 2100. As of 2007, there are concerns in all of these five areas. The projected sea level rise and its effects on land area, population, and GDP showed that Asia will have the most severe consequences. Records show an increasing trend of natural disasters, especially flooding and cyclones. The natural fluctuation of climate, El Nino and La Nina, was introduced. El Nino and La Nina originate in the Pacific Ocean but affect climate globally. The increase in El Nino frequency as the climate changes since 1970 has only recently been appreciated. The potential impact of sea level rise on the Nile Delta is presented. Its impacts on freshwater resources (ground- and surface water) of small islands and low-lying coastal area were explained. Freshwater, in turn, has profound influences on agriculture, ecosystems, and human health. Food production is affected by water, temperature, CO_2 level and ultraviolet radiation, and pest and diseases. Developing countries are expected to be affected more than the developed countries. Effects on tea and coffee productions in Kenya and Uganda were illustrated. Finally, the projected biodiversity loss between 2000 and 2050 and spread of several diseases, including malaria, were presented.

Reasoning Economically About Potential Environmental Catastrophes, by Neil Mason

At the outset of his lecture, Neil Mason, a philosophy professor, explained why environmental scientists should care about economics. It is known that economic evaluation mediates science and policy. The results of science never get translated

into action without some form of economic evaluation, either by private industry or by governmental regulators. Less obvious about the importance of economics is its role in moving forward a debate such as climate change. Skepticism about or outright denial of the results of scientific investigation can seem baffling, if not downright evil. Oftentimes, however, what is *really* going on is that skeptics or deniers (e.g., "intelligent design" proponents) wish to avoid the perceived evaluative implications (ethical, philosophical, religious, or economic) of the results of scientific investigation. Sometimes, the best way to move the debate forward is not to reiterate the science, but to address directly the evaluative presuppositions of the skeptics or deniers (e.g., "Why even think evolution is incompatible with belief in God?").

The major portion of the lecture covered the two competing approaches in making environmental policy decisions: the cost-benefit analysis (CBA) that has been the ascendancy in the USA (Sunstein 2005) and the precautionary principle (PP) that has been commonly adopted by the European Union and many of its member nations, as well as by the United Nations (Manson 2002; Sunstein 2005). The basic idea of CBA (Sunstein 2005) is to identify all potential costs and all potential benefits of a given course of action, assign to each cost and benefit both a probability of occurrence and a dollar value (positive or negative) of occurrence, crunch the numbers, and see whether the result is overall positive or negative. Using CBA, courses of action can be compared to see which course of action has the highest overall positive rating (or least bad negative rating). Then, policymakers should approve the course of action that maximizes net benefits or at least give some presumption in favor of that course of action (Sunstein 2005). Posner's CBA calculations (Posner 2003) regarding the building of the Brookhaven particle accelerator are illustrative (Sunstein 2005). With CBA, in order for a potential cost to factor into the decision, there is some estimate both of its dollar value and of its probability of occurrence that must be available; otherwise, that potential cost is a nonfactor.

The PP is considerably more vague than CBA, with a host of competing formulations (Manson 2002), but the basic idea is "better safe than sorry." Given that the results of our industrial/technological innovations cannot be foreseen, regulators are justified in restraining such innovations unless and until enough evidence comes in that the activity in question will *not* produce harmful results. The approach is "risk averse."

Standard objections to these approaches and responses are presented. Many examples are given. It is one of the lectures of this class that promotes critical thing about the basis in policymaking. As a homework exercise, the instructor asked the students to write an essay on what approach they would choose in determining the policies toward climate change.

Atmospheric Physics and Chemistry, by Nathan Hammer

Chemistry professor Nathan Hammer presented a lecture on atmospheric physics and chemistry. At its outset, the dynamical evolution of the Earth's atmospheric gas

since the primordial solar nebula 4.6 billion years ago was presented: from a composition similar to the emissions of today's volcanoes (rich in CO_2, H_2O, and H_2) to oxidizing gas that is rich in N_2 and O_2. O_2 has been stable in the atmosphere for 400 million years, as a result of photosynthesis and decay of organics on Earth. Trace gases are introduced. Among them, CO_2, CH_4, and N_2O are considered greenhouse gases due to their capabilities of absorbing vibration bands of the reflected sunlight from Earth's surface. Dr. Hammer presented the infrared absorption bands of these compounds and that result in trapping a fraction of reflected energy in the atmosphere. These trace greenhouse gases increase over time as the result of increasing use of fossil fuel combustion and activities of chemical industries. Human behaviors have caused increases in trace gas emissions that lead to the formation of photochemical smog from automobile tail gas and ozone depletion from chlorofluorocarbons (CFCs).

Geostrophic flow is driven by uneven distribution of pressure and temperature of Earth and the rotation of Earth (i.e., the Coriolis Effect); it, in turn, transports energy pole wards and reduces equator-to-pole temperature contrast. Prolonged temperature rise in this atmospheric circulation across the Pacific Ocean is called El Nino, or Southern Oscillation; similarly, prolonged temperature decrease is called La Nina. El Nino and La Nina usually happen 2–7 years with 9-month to 2-year durations. They cause global weather effects including droughts, hurricanes, moisture, and temperature patterns. Their causes, including global warming, are under active investigation.

The four layers of atmosphere were introduced: troposphere, stratosphere, mesosphere, and thermosphere. The chemical characteristics of their gas components and the temperature and pressure variations in these layers were discussed. In the troposphere, the main concerns are acidic gases, photochemical smog, and greenhouse gases. In the stratosphere, O_2 photochemically dissociates; the main issues are ozone depletion by nitrogen oxide (NO) and CFCs. The mesosphere is characterized by photochemical reactions of small diatomic molecules and reactions of atoms and ions. The thermosphere is characterized by ultraviolet radiation and ionic reactions. Dr. Hammer then discussed the mechanisms of the following chemical reactions or processes:

- Formation of photochemical smog starts with photochemical decomposition of NO_2 followed by ozone formation and a series of reaction involving volatile hydrocarbons.
- Ozone destruction by NO.
- Ozone destruction by hydroxyl radicals.
- Ozone destruction by CFCs.
- Aerosol formation dynamics.
- Ionic reactions.

The students were asked to write an essay about their understandings of the climate change as homework. The textbook by Wayne (1985), Seinfeld and Pandis (1998), and Jacob (1999) was recommended for additional information.

Global Climate Change: Scale and Complexities, by Charles Wax

The State climatologist and Mississippi State University Geosciences professor Charles Wax gave this lecture. At its outset, it covered the nature of climate change including the causes of Milankovitch cycles, sunspot activity, and emission of volcanic debris, which results in glaciations every 100,000 years and interglacials every 10,000 years. The correlations between the observed historical data between these nature phenomena were then discussed. The temperature decline after the medieval maximum, or the "little ice age," that took place between 1400 and 1900 AD, was at least partially due to the maunder minimum, or the prolonged sunspot minimum. It was suggested that the observed El Nino may be correlated with the Atlantic multidecadal oscillation documented in history. Coupled with changes in instrumental measurements and data interpretation methods, he mentioned the possibility that what have been observed may be part of a long story of ups and downs.

Climate Change and US Laws, by David Case

Law professor David Case gave two time-sensitive lectures, one on climate change and US laws and the other on climate change and international protocols. These lectures were given only weeks after President Obama was inaugurated. The proposals for climate change legislation at that time were discussed in detail: to include cap and trade, carbon tax, and Clean Air Act Amendment for regulating greenhouse gas emissions by EPA. The lecture covered the details of the process and subsequent developments, including Dr. Case's expectations on Obama administration's policy, of the 2007 *Massachusetts v. U.S. Environmental Protection Agency (EPA)*, 549 U.S. 497 (http://www.supremecourt.gov/opinions/06pdf/05-1120.pdf, 2007). *Massachusetts v. EPA* is a US Supreme Court case decided 5-4 in which 12 states and several cities of the USA brought suit against the EPA to force the agency to regulate carbon dioxide and other greenhouse gases as pollutants. Finally, the lecture covered the status of the National Environmental Policy Act (NEPA), Endangered Species Act (ESA), and common law litigation, such as *Connecticut v. American Electric Power* (S.D. N.Y. 2005) and *California v. General Motors* (N.D. Cal. 2007).

Climate Change and International Protocols, by David Case

Dr. Case's second lecture on *international protocols* focuses on the contributions of the multinational scientific body Intergovernmental Panel on Climate Change (IPCC). It covered IPCC's publications of the periodic Assessment Reports (AR), establishment of United Nations Framework Convention on Climate Change (UNFCCC), the functions of the Conference of Parties (COP), the journey of Kyoto Protocol, negotiations on post-Kyoto commitments, and skepticism about post-Kyoto regime. In addition to the *Massachusetts v. EPA* link mentioned above,

Dr. Case assigned three other reading assignments extracted from the book by Gerrard (2007).

Assessment of Impact of Sea Level Rise on Costal and Estuarine Infrastructure Using Numerical Simulation Model, by Yang Ding

Prof. Yan Ding of the National Center for Computational Hydroscience and Engineering gave a lecture on the impacts of sea level rise on costal and estuarine infrastructure using numerical simulation model. The lecture started with an overview on costal hazards due to hurricane, storm, and tides, current instrumental records for climate change, impacts of sea level rise, coastal zone structure, and coastal flood hazard zones. Most of this lecture was devoted to detailed numerical analysis of coastal and estuarine hydrodynamic and morphodynamic processes. Special cases were presented with comparison with recorded data. A list of references (including the slides on the web) was given, and the following homework assignments were assigned:

1. Find tidal datums in the Bench Mark Sheets of Gulfport Harbor, MS on the web site of NOAA Observational Data Interactive Navigation at http://tidesandcurrents.noaa.gov/gmap3/. Draw a figure to display the MSL, NGVD, and NAVD. Then, retrieve tidal datums in the Bench Mark Sheets of the USCG New Canal Station, Lake Pontchartrain, LA. Find the differences of the tidal datums between the two locations. Explain why they are different.
2. What are the impacts of sea level rise on coasts and coastal communities?
3. What are coastal zones? How are coastal flood hazard zones defined by Federal Emergency Management Agency?
4. What is the CCHE2D-Coast model? What are the model's capabilities to simulate coastal processes related to assessment of impacts of sea level rise?

Effects of Climate Changes on Water Resources, by Cristiane Queiroz Surbeck

Civil engineering professor Cristiane Queiroz Surbeck gave a lecture about the effects of climate changes on water resources. At its outset, the lecture covered the global ocean conveyor belt (thermohaline circulation), the effects of climate change on the circulation and therefore the distribution of Earth's water resource and quality and the hydrologic cycle. Then, the effects of climate change on water resources in the different regions of the North America were discussed. Through this case study, a few concepts and methods were discussed: the method for the estimation of hydrologic water budget through rainfall analysis, intensity-duration-frequency curves, and return period. A numerical example was given, and a specific water budget problem was given as homework.

Impacts of Global Climate Change on Biodiversity, by David Reed

Biology professor David Reed gave a lecture on the impacts of global climate change on biodiversity. At its outset, the definition, importance, and measure of biodiversity were covered. Origination and extinction through time have been observed in fossil record. The huge end-Permian mass extinction about 30,000 year ago marked the beginning of the diversity decline. The present extinction rate is shown to be at least 50 times higher than that of the post-Permian period. Cases of human-caused extinction were discussed. These cases led to the systematic and focal presentation of this lecture on the functions and importance of ecosystem services to the environment on Earth. These environmental services include food production, raw materials, recreation and water supply, atmospheric gases, water recycling, erosion control, soil formation, nutrient cycling, and purification of wastes. Plants are not only the sources of food, they are valuable sources of genetic materials, natural pesticides, and medicines. Climate change has shifted the range of 1,700 species toward the poles at an average rate of 6.1 km per decade, spread of diseases to higher elevations and more northerly latitudes, and population declines of polar bears and penguins. Since species habitats are more fragmented than in the past and are smaller than in the past, the impact of future climate change is expected to cause a higher rate of extinctions. About 10–20 % of all species on Earth are expected to go extinct by 2050.

Ocean and Human Health Consequences, by Deborah Gochfeld and Kristie Willett

Prof. Deborah Gochfeld of the National Center for Natural Products Research and Prof. Kristie Willett of Pharmacology made two related presentations in a joint seminar on ecological impacts of climate change. Dr. Gochfeld discussed the ocean health and Dr. Willett the human health consequences. These two lectures extend David Reed's biodiversity lecture into a more detailed analysis.

Dr. Gochfeld first introduced the ocean stressors imposed by humans: overfishing, pollution/sedimentation/eutrophication, and habitat modification, which reduce the resilience of species, communities, and ecosystems to climate change efforts. It was explained how local economies near major coral reefs benefit from an abundance of fish and other marine creatures as a food source and how drugs are produced from corals. The major portion of the lecture was devoted to the discussions about how climate change affects the seawater temperature, ocean chemistry (especially the decrease of carbonate ion, CO_3^{2-}, with increasing atmospheric CO_2 concentration), sea level rise, ocean circulation, solar and UV irradiance, and pathogen distribution and virulence. The results of these immediate effects were discussed in detail. For instance, changes in natural ocean circulation induce extreme weather, terrestrial climate, and disappearance of shallow water and intertidal habitats. Extreme weather, in turn, causes increased coastal erosion, especially beaches, increased river volume, flooding, drought, runoff (freshwater, sediment,

pollutants, nutrients), destruction of salt marshes, seagrass beds, mangroves, and coral reefs. Moreover, harmful algal blooms result from runoff of sediment, and nutrients are enhanced by elevated temperatures and solar radiation. Decrease in carbonate ion reduces the abilities of corals and other calcifying organisms (clams, oysters, mussels, and other important fish species) to produce skeletons or shells. Seawater rise causes flooded coastlines, wetlands, estuaries, disappearance of shallow water and intertidal habitats, and loss of nursery grounds, nesting, and feeding habitats of many organisms.

Dr. Willett's lecture covered stress-related problems, increased infectious disease, extreme events, increased number of poor, and increased agricultural yields. World Health Organization's (WHO) climate change site at http://www.who.int/globalchange/en/index.html was introduced at its outset. The primary, secondary, and tertiary impacts of climate change on human health at the outset were discussed. Temperature rise causes ozone and photochemical smog concentrations that induce several respiratory diseases and alleges. Statistics also illustrate that temperature correlates the populations of mosquitoes, ticks, snails, and parasites in contaminated water, which, in turn, transmit dengue fever, malaria, Lyme disease, schistosomiasis, and cholera. Extreme weather leads to flooding and drought that cause food shortage and malnutrition. The correlations between the temperature rise and the health issues observed in different parts of the world between 1990 and 1999 (Intergovernmental Panel on Climate Change 2007b) were also discussed. In addition to the IPCC report, WHO report (World Health Organization 2003) and EPA's climate change site, http://www.epa.gov/climatechange/ were assigned as the reading materials.

Surface Chemistry and Nanotechnology: An Approach to Green Energy, by Scott Gold

Prof. Scott Gold of the Louisiana Tech University gave a lecture on the surface chemistry and nanotechnology: an approach to green energy. This lecture covered two major portions: the sciences and technologies of template wetting nanofabrication and their technological applications in fuel cells and electrochemical supercapacitors. At the outset, it introduced the template materials, methods of wetting porous materials, reactive ion etching, sputtering processes, and posttreatment reactions that convert nanotube precursor to desired materials. He then discussed the applications of nanostructures from template wetting that include:

- Ceramics such as sulfated zirconia (superacid) for proton exchange membrane for fuel cells and acid catalysis
- Nanotubes of metals such as platinum, palladium, and gold as catalysts in fuel cells, and Raman spectroscopy
- Piezoelectric microelectromechanical systems (MEMS)
- Conductive and semiconducting polymers as electrical supercapacitors, photovoltaics, LEDs, photodiodes, sensor, and hydrogen storage

The second half of Dr. Gold's lecture focuses on fuel cells. Different types of fuel cells were introduced: alkaline, proton exchange membrane, direct methanol and other liquid fuels, phosphoric acid, molten carbonate, solid oxide, and enzymatic biofuel. Their applications and operating conditions were discussed. Research in fuel cells has been growing rapidly due to its low emissions, high-energy efficiency, and higher energy density than batteries. Reaction efficiency, design (current collection, fuel transport to catalyst, proton transport to membrane, and waste removal), material issues, and cost remain as technological barriers and research areas. Dr. Gold then presented the works of his group on nanofabrication: gold and platinum nanotubes on grapheme oxide (GO) and semiconducting polymer such as poly (3-hexylthiophene) (P3HT) nanotubes. Nanotube preparation and their enhancement in electron transfer rate coefficients for biofuel cell and supercapacitors were discussed in detail.

Energy Conservation: Use of Foil Radiant Barriers to Reduce Residential/Commercial Energy Usage in Summer/Winter for Cooling/Heating, by Jeff Roux

Prof. Jeff Roux of mechanical engineering gave this lecture on building design for energy conservation. At the outset, he presented the important role of energy conservation in climate change mitigation. IPCC AR4 concluded that the buildings sector will have the highest economical potential for global mitigation as a function of carbon price in 2030. Major currently available commercial technologies and practices for this sector include efficient lighting and daylighting, more efficient electrical appliances, heating and cooling devices, improved cook stoves, improved insulation, passive and active solar design for heating and cooling, alternative refrigeration fluids, and recovery and recycle of fluorinated gases. Key mitigation technologies and practices projected to be commercialized before 2030 include integrated design of commercial buildings including technologies such as intelligent meters that provide feedback and control and solar photovoltaic integrated in buildings. The research at the University of Mississippi on improved insulation for residential dwellings was then discussed. The lecture presented the characteristics and properties of various fibrous materials (fiberglass, rock wool, cellulose, and polystyrene and polyurethane foams) and their principles of operation. The large surface area of fibers inhibits the air within the insulation from moving. Air has a low thermal conductivity and is an excellent insulator if it can be made to remain stationary. The lecture also presented experimentally measured data (including summer and winter) at an occupied north Mississippi residence, which were transformed to various profiles such as time histories of temperature, heat flux, and water vapor concentrations. A mathematical model that incorporated conduction and radiation heat transfer and moisture transport was developed to predict the changes in total heat flux. Model predictions showed good correlations with the experimentally measured heat flux.

Biological Conversion of Biofuels, by Clint Williford

Dr. Clint Williford, professor of chemical engineering, gave a lecture entitled biological conversion of biofuels. The lecture started with an introduction on the historical correlations among oil price, supply, and demand. It then covered the greenhouse gas emissions from different sectors and fuel sources. Looking ahead, biomass conversion to fuels has been considered one of the seven wedges to maintain a constant CO_2 emission level between 2005 and 2055. This reduction corresponds to one billion tons of CO_2 per year, or an increase of bioethanol usage by 50 times. Nevertheless, the investment on biomass conversion grew rapidly in the last decade due to higher energy cost, concern for energy security, climate change, political supports, and technological maturity. The major portion of this lecture was on the current biofuel technologies: biodiesel, grain corn ethanol, cellulosic ethanol (cell EtOH), and biobutanol. In addition to the details of their conversion technologies, he explained the heat content of the products, pollutant emissions (unburned hydrocarbons, CO, particulate matter, and NO_x), fossil fuel replacement ratio, economics, and other issues during their usages. He then discussed his research on alternative biomass pretreatments for improved lignocellulosic ethanol production. Celluloses are abundant and widely spread. Conversion of cellulose to ethanol can relieve food demand from corn and cane; it is virtually eternal. Moreover, its positive impacts on CO_2 emission and nonrenewable replacement are both high (over 90 %) and have been spurring biofuel mandate. The technological difficulties of the conversion and its cost remain bottlenecks in its development. The separation of cellulose from lignin, however, requires innovations in the areas of the selections of enzymes, pretreatment process, and improved lignin utilizations. Dr. Williford also discussed the controversies of biofuels including the impact of deforestation, nitrous oxide emission from fertilizer, food price, and food export.

Chemistry of CO_2, by Walter Cleland

Professor of chemistry Walter E. Cleland gave a lecture on the chemistry of CO_2. This lecture was selected to promote critical thinking for developing innovative technologies for CO_2 capture and utilization. It started with an introduction of the various stable oxides of carbon, physical properties of CO_2, phase diagram, and Walsh diagram. Industrial processes involving CO_2 production and utilizations were then presented. CO_2 utilizations based on the physical properties of CO_2 include refrigeration fluid, cleaning solvent, solvent as a reaction media and extraction, and food and agrochemical applications such as beverage additives and fumigant. CO_2 utilizations based on the chemical properties of CO_2 include the production of urea, salicylic acid, inorganic carbonates and pigments, propylene carbonate, naturalization of caustic waste water, and CO_2 capture by various liquid and solid sorbents.

The majority of this lecture covered more detailed discussions of the CO_2 reactions for its production and utilizations. Productions of CO_2 mainly come from combustion and gasification of fossil fuels and their derivatives in stationary and

mobile sources. Fermentation, lime-kiln operations sodium phosphate manufacture, and natural gas wells also produce fairly sizable quantities of CO_2. CO_2 in these gas streams can be captured by amines (Girbotol process) and sodium or potassium carbonate process. CO_2, along with $KMnO_4$ (permanganate process) or $K_2Cr_2O_7$ (dichromate process), has been used to chemically reduce H_2S in gaseous streams to elemental sulfur.

The lecture then covered the reactions that involve CO_2 either as a reactant or as a product in the following categories: CO_2 reaction with H_2O; reaction with O_2, CO, and O_2; CO_2 with H_2 (reversed water-shift reaction); CO_2 with NH_3 (urea formation); CO_2 reactions with organics that have been used in carbon capture; coordination chemistry of CO_2 and metals; reaction of M-CO_2; reactions in biological systems; use of CO_2 as a C1 feedstock; carboxylation; polymerization; CO_2 reductions; and photochemical reduction of CO_2. The reactions of CO_2 with organics are of three major types: organic reaction with RO^- to form $ROCOO^-$, with RNH_2 to form $RNHCOO^-$ or RNHCONHR, and with RMgX or RLi to form $RCOO^-$. CO_2 is a poor ligand, but it does form a number of complexes and bonding modes with metals, which are important for activation of CO_2 in catalytic reduction reactions. For instance, M-CO_2 reacts proton or electrophile, such as R^+, and converts to M-CO or M-C(O)OR, respectively. CO_2 reacts with hydride, M-H, and forms M-O_2CH. Organophosphines, PR_3, react with M-CO_2 and O = PR_3. Isocyanide, M(CNR)-(CO_2), decomposes and forms RNCO and M-CO. Reactions of CO_2 in biological systems include animal metabolism, photosynthesis, enzyme-catalyzed carbonic acid decomposition, carboxylation of ribose, and catalytic reduction of CO_2 to CO. Using CO_2 as a C1 feedstock leads to the formation of carboxylates, lactones (RCOOR′), carbonates (RR′NCOOR″, ROC(O)OR′), ureas (RR′NCONRR′), and isocyanates (RNCO). Moreover, as a C1 feedstock, CO_2 reduces to formats ($HCOO^-$), oxalates ($^-O_2C\text{-}CO_2{}^-$), formaldehyde (H_2CO), CO, methanol, and methane. Carboxylation results in the formation of COO^- group on carbon, nitrogen, or oxygen atom in an organic compound such as direct carboxylation in ionic liquid from imidazolium carbonate. With metal-salen catalyst, polycarbonates form from epoxides and CO_2. Through metal and enzymatic catalytic mechanisms, CO_2 has been hydrogenated to formic acid and methanol. Finally, the fundamentals of photoelectrochemical reduction of CO_2 to formic acid and methanol were briefly discussed. A recent review by Beckman (2004) would be a valuable reading beyond this class.

Mobile and Area Source of Greenhouse Gas (GHG) and Abatement Strategies, by Waheed Uddin

Civil engineering professor Waheed Uddin gave a lecture on mobile and area source of greenhouse gas (GHG) and abatement strategies. This lecture introduced five topics:

- Quantifying traffic and built environment impacts on mobility and traffic congestion

- Evaluation of traffic and built environment impacts on GHG emissions and global warming
- Assessment of traffic and built environment impacts on air quality and public health
- Application of remote sensing and geospatial technologies and air pollution models for traffic visualization
- Environmental assessment and evaluation of abatement strategies

The transportation sector accounts for 28 % of total GHG emissions in the USA and 33 % of the nation's energy-related CO_2 emissions (EIA 2007). The USA in turn is responsible for 22 % of CO_2 emissions worldwide and for close to a quarter of worldwide GHG emissions (Energy Information Agency (EIA) 2007). Report has shown that GNP has been linearly proportional to the density of paved road, and GHG emissions have increased with increasing use of fossil fuels for the economic growth. Although average mileage per gallon of gasoline has increased 40.60 % from 1970 to 2000, average total fuel consumption per vehicle has decreased only 13.25 % from 1970 to 2000. Percent increase in vehicle mile traveled showed a strong correlation with increase in GDP. In addition to passenger cars, long haul tracks, light-duty trucks, aviation, marines, locomotives, motorcycles, and space missions are major portions of carbon emissions from mobile sources. Public transportation is one of the most significant means to reduce household carbon footprint. Moreover, traffic congestion and gridlock have steadily grown, and commuters spend 46 h annually stuck in traffic and waste five billion gallons of gas annually.

The lecture then covered carbon emission from buildings, whose carbon footprint can be extracted from high-resolution satellite imagery more cost effectively than traditional aerial photography. Large urban built-up areas (heat islands) demand more energy causing more carbon emissions and consequently more air quality degradation. As temperature rises, so does the likelihood that smog will exceed national standards of air quality; more power generation will produce more carbon emissions. As a result, sustainable transportation development must consider the following factors: land use, urbanization and social integration, built-up area effects on environment (air, water), built environment impacts on physical inactivity, traffic fatalities and injuries, traffic-related emissions and air pollution, traffic-related pavement noise impacts, construction process and material resources, energy demand, and diminishing natural resources.

To improve the spatial management and urban transport, it will be necessary to structure urban development with adequate transport policies and systems, manage efficiently the urban/rural/regional interfaces, and develop and implement enhanced GIS-based transport infrastructure asset management systems. Using the policy recommended by California's Climate Action Team (2007), Dr. Uddin stated the importance of "smart land use and intelligent transportation system (ITS)" to make the second-largest contribution toward meeting the state's ambitious GHG reduction goals. These policies include conservation and compact urban growth – by all government levels and by public, efficiency in vehicles by

vehicle manufacturer and consumers, efficiency in traffic flow by transport agency, better commercial truck fleet management by transporters, public mass transit, high-occupancy vehicle lanes, carpooling, flexible work hours, nonmotorized transport by government levels and by public, equity in road user charges for pollution and vehicle-mile traveled (VMT), and development in clean fuel and energy sources.

Nuclear Energy: Statistics, by Elizabeth Ervin

Civil engineering professor Elizabeth Ervin gave a lecture on nuclear energy with emphasis on statistical data. It was postulated at the outset that there are three motivations for developing nuclear energy today: it produces no controlled pollutants such as sulfur dioxides, nitrogen oxides, particulates, and GHG; it creates jobs and capital; and its image has changed in peoples' mind – 73 % of people approved its development in 2006. As a result, 36 new plants were under construction in 14 countries, and 223 had been proposed in 2006. A major human error at Chernobyl caused 56 deaths. However, the US civilian nuclear reactor program had resulted in zero fatality, compared to 33,134 coal miner and coal transporter deaths from 1938 to 1995 and 54,000 aviation deaths. Moreover, coal-fired power plant releases 100 times more radiations than equivalent nuclear reactor. At the presentation in 2008, there were 439 nuclear reactors operating in 31 countries; they provided 15.2 % of the world's electricity production in 2006 (34 % of EU and 20 % of USA). There were 104 commercial nuclear power reactor plants in the 64 sites and in 31 states in the USA. For seven states in 2006, nuclear energy made up the largest percentage of their electricity generated. Major unit operations of a nuclear power plant were introduced. Nuclear power generates economically competitive electricity, 1.82 cents per kWh, as compared to coal at 2.13 cents per kWh and natural gas 3.69 cents per kWh. Their power plants require much smaller spaces than those for biomass conversion plants, coal-fired power plants, and solar power plants. Disposal methods of nuclear fuel waste and low-level radioactive waste (LLRW) that consist of items that have come in contact with radioactive materials such as personal protective clothes have been developed. Fund, with an average of about 3.76 metric tons of dried used fuel per million dollars in the USA, has been committed to the management of nuclear waste. As of 2004, more than 690 containers have been loaded at 30 nuclear sites. This number is expected to grow to about 712 by 2015. Water discharged from a nuclear power plant contains no harmful pollutants and even meets regulatory standards for temperature. Prof. Ervin gave some facts about fission energy that are not commonly known. Nuclear energy has been widely adopted in medical procedures and cosmic. Many fruits and vegetables possess natural radioactivities. Uranium is a relatively abundant element (about as abundant as tin) that occurs naturally in Earth's crust. To resolve the shortage in nuclear workforce, the US Nuclear Regulatory Commission has created a curriculum education grant program as a multidisciplinary technical elective.

Fuel Efficiency in Transportation Systems, by Jack Seiner

The late Prof. Jack M. Seiner of mechanical engineering and National Center for Physical Acoustics gave a lecture entitled fuel efficiency in transportation systems. The lecture covered six topics: the motivation for transportation efficiency, carbon emissions by light-duty vehicles, alternative engine concepts, alternate fuels, alternate power sources, and roles of aerodynamic efficiency. The brief opening segment of his talk reiterated the major causes of climate change and the importance of improved energy conservation and enhanced fuel efficiency in transportation systems in climate change mitigation.

The discussion of carbon emissions by light-duty vehicles (the second part of the lecture) covered the concept of passenger miles per gallon (PMPG) for various transportation vehicles, estimation of auto sector CO_2 emissions, and global CO_2 emissions by economic sectors. It then reviewed the thermodynamics and thermal efficiencies of the two conventional piston-based engine cycles: the gasoline engine cycles and diesel engine cycles. These fundamentals led to major conclusions about the features and recent emphasis on diesel engines: diesel fuel has higher heat content than gasoline, and diesel engine has a 30–35 % higher thermal efficiency than conventional engine. For instance, a diesel engine in a light-duty vehicle such as a 2,000 lb Volkswagen Jetta gets 50 miles per gallon on the highway.

The discussion of alternate engines (the third part of the lecture) covered automotive gas turbines, rotary Wankel engine, Di Pietro rotary air engine, and other types of compressed-air cars. The history, design features, advantages, and technical issues of these technologies were discussed. The comparison of these engines considered the factors including pollutant emissions, efficiency, engine weight, fuel type, maintenance effort, life expectancy, number of parts, warm-up period, fuel flexibility, noise, and throttle lag.

In the discussion of alternate fuels (the fourth part of the lecture), the characteristics of gasoline with various alternate energy sources were compared: diesel, liquefied natural gas (LNG), compressed natural gas (CNG), ethanol and blended ethanol, liquid hydrogen, hydrogen at 150 bar, lithium, nickel metal hydride, lead acid battery, and compressed air. The number of vehicles that use these alternate fuels is increasing. Hydrogen and diesel have energy density higher than that of gasoline. Hydrogen does not have emission problems, but its storage in an efficient, safe, and cost-effective system has emerged as a major research area. Energies required for compression of H_2 to a gaseous state at high pressure and for liquefying H_2 are cost concerns. Energy loss in delivery in pipeline is another factor. Independently, means to store hydrogen by other materials have been investigated. Most of these works focus on hydrides, i.e., chemically bond hydrogen in a solid metal or carbon materials. In addition to hydrogen-packing density, performance indices include reversibility of hydrogen uptake and release, weight of hydride, kinetics of uptake and release, and the temperature and pressure dependence of H_2-hydride equilibrium. H_2 generation from hydrolysis of complex hydrides was discussed. Due to the complexity of these requirements, the US Department of Energy has announced a set of specific technical targets for hydrogen storage. The second half

of the discussion of alternate fuels was placed on biofuels. The historic development of "flexible fuel vehicles" was discussed first. He then discussed the feedstock, conversion technologies, emissions, policies, and challenges of various biofuels, with the emphases on the bioethanol and biodiesel. The serious challenges in the production of bioethanol include energy consumptions in the conversion of grain to ethanol (hydrolysis, distillation, drying, and emission control), water consumption, fertilizer use, and decrease in food supply. Biodiesel has a higher thermal efficiency than gasoline; the various sources of biodiesels, emissions prospective, and costs were then covered.

The alternate power sources for vehicles include hydrogen fuel cells, battery, and hybrids. This portion of the lecture covered the basic principles, comparison of various hydrogen storage systems, hybrid features and their prospective and their efficiencies in each of the energy conversion steps.

The last segment of this lecture covers the aerodynamic efficiency. It included the discussions of the factors influencing airplane ticket price per the nautical mile and nautical mile per gallon of gas. Recent development of blended wing body (BWB) for airplane design has shown advantages in weight of aircraft, fuel efficiency, and, therefore, the direct operating cost. The propulsion/airframe integration, aerostructure integration aerodynamics, and controls remain as major design challenges.

Photochemical Reduction of CO_2 and Water Splitting, by Nathan I. Hammer

Chemistry professor Nathan Hammer, a spectroscopist, gave a lecture on photochemical reduction of CO_2 and splitting of water. Solar energy is not only renewable, but also abundant. Indeed, more energy from sunlight strikes the Earth in 1 h (4.3×10^{20} J) than all the energy consumed on the planet in a year (4.1×10^{20} J). There is a high incentive to efficiently convert and store solar energy to reduce our reliance on fossil fuel. Photo- and electrochemical conversion of CO_2 and H_2O have been identified as one of the top five research areas in catalysis that require urgent attentions by the DOE's Basic Energy Science (Bell et al. 2007). Photocatalytic conversion of CO_2 to formic acid, formaldehyde, methanol, Co, and methane on catalyst surface has been demonstrated, and it is one of these potentially attractive approaches that brings CO_2 to a higher energy state by using solar energy. While CO_2 and H_2O react with photochemically excited electrons, water splitting takes place at electron holes. Water splitting can also be achieved by photolysis of water alone where O_2 forms on the photoanode and H_2 forms on cathode. The lecture covered the importance of these technologies, their fundamental reaction mechanisms, the role of band gap, and the characteristics and selection of catalysts in these photochemical reactions. It also includes several prominent works that demonstrate photochemical fixation of CO_2 on organic compounds, including the catalysts, reaction mechanisms, products, and secondary reactions.

Carbon Sequestration, by Robert Holt

Geology and geological engineering professor Robert Holt gave a lecture about his experiences in geologic carbon sequestration. He first explained the six known geologic sequestration options:

- Depleted oil and gas reservoirs
- Use of CO_2 in enhanced oil recovery
- Deep unused saline water-saturated reservoir rocks
- Deep unmineable coal seams
- Use of CO_2 in enhanced coal bed methane recovery
- Other suggested options including basalts, oil shales, and cavities

There are four CO_2 trapping mechanisms: structure and stratigraphic trapping, residual saturation trapping in large pores, solubility trapping by in situ water, and mineral trapping through chemical reactions. Mineral trapping is the most attractive process since it could immobilize CO_2 for a long time. However, it is comparatively slow because it depends on dissolution of silicate minerals. Security of trapped CO_2 (immobility) increases with time since the solubility and mineral trapping are slow.

The annual CO_2 consumption by the global chemical industries is only about 115 million metric tons, or less than 1 % of its production. At the same time, both natural and industrial analogues have provided evidences that geologic sequestration could be successful before other massive CO_2 utilization and storage technologies are developed. Distribution of natural analogues in the world, such as oil and gas reservoirs and CO_2 accumulation sites, is presented. Similarly, the distribution of industrial analogues in the world including natural gas storage, liquid waste disposal, and CO_2 injection for enhanced oil and gas recovery were presented. The lecture covered the CO_2 injection technology for enhanced recovery of hydrocarbons, the worldwide geologic storage potential, potential release pathways after injection, storage cost estimates, and monitoring technologies. Deep saline formation and sequestration in oil and gas fields have the highest capacities.

The last segment of his lecture covered the development of monitoring technologies at the University of Mississippi. The technology is based on a conceptual model for CO_2 transport in a saturated zone that involves buoyancy-driven CO_2 fingering with pulsation through coarse layers. It is visualized that pools of CO_2 are trapped beneath aquifer-confining layers; fingering and breakthrough of the trapped CO_2 occur when CO_2 pressure exceeds the non-wetting phase entry pressure. For phreatic aquifers, CO_2 moves into the unsaturated zone and pooling above the capillary fringe. Holt's research team has set up bench-scale apparatus and has been conducting field tests to answer the following basic scientific questions:

1. What controls CO_2 partitioning and dissolution into the aqueous phase?
2. What chemical reactions will occur and what are their rates?
3. What are the sizes of zones of detectable CO_2 and by-products?
4. What type of monitoring design will be required to insure detection?

Introduction to Climate Change: Solutions, by Wei-Yin Chen

This lecture was intended to give an overview on the solutions to climate change. It was originally arranged as session #12, the opening session on climate change mitigation, but scheduling issues left us few options except for this arrangement. The lecture included four major segments: energy conservation and efficiency, alternative energy sources, advanced combustion and gasification for efficient carbon utilization and enabling carbon capture and sequestration, and other advanced technologies.

The first segment on energy conservation and efficiency started with the IPCC's comparison (Intergovernmental Panel on Climate Change 2007c) of sectoral economical potential for global mitigation as a function of carbon price in 2030. The residential and commercial buildings sector leads the six other sectors in sectoral economical potential for global mitigation, which reflects the important role of energy conservation. Both building design and personal behaviors, such as the replacement of standard incandescent bulbs by compact fluorescent light bulb and shutting off lights and personal computers after work, could make notable contributions to carbon reduction. Energy supply sector ranks second in sectoral economical potential for global mitigation. Thus, the impact factors of various emerging technologies for power generation were discussed. According to IPCC's AR4, nuclear power, natural gas combined cycle, wind power, integrated coal gasification combined cycle (IGCC), pulverized coal combustion with oxygen (oxy-combustion) and carbon capture and sequestration (CCS), and pulverized coal combustion CCS are leading technologies that have the highest impact factors.

The segment on alternative energy sources covered the technical principles of nuclear energy, biofuels, wind and tide, geothermal energy, and solar energy. The rationale, scientific principles, and technologies are discussed. For the biofuel production and power generation, it covered biodiesel from vegetable oil and fat, ethanol from sugar cane and corn, ethanol from lignocellulosics, and thermal conversion of biomass.

The segment on advanced combustion and gasification for efficient carbon utilization and enabling carbon capture and sequestration covered the need for carbon capture and sequestration, the present sequestration technologies, and the post- and precombustion carbon capture technologies. Topics also included in the sequent discussion are basic design principles of oxy-fuel combustion, IGCC, chemical looping combustion, and integrated oxygen transport membrane for combustion.

The segment on other advanced technologies covered the fundamental principles of photocatalytic reduction of CO_2, electrochemical splitting of H_2O, and geoengineering approaches. The four geoengineering approaches include the use of stratospheric aerosols, cloud albedo enhancement, ocean iron fertilization, and sunshade geoengineering.

Integrated Gasification Combined Cycle (IGCC), by Robert Dahlin

Dr. Robert Dahlin, director of the Power Systems and Environmental Research of the Southern Research Institute, gave a lecture on IGCC. The lecture started with the presentation of the rationales behind the widespread use of coal in the USA: coal's abundance, wide availability, and more than 250 years' reserve (comparing to limited natural gas supply). IGCC flow sheets were used to discuss its major unit operations and the process features. These features include:

- Higher thermal efficiency than pulverized coal combustion
- Lower emissions
- Higher feedstock flexibility (coal, oil, natural gas, biomass, petroleum coke, and waste)
- Higher product versatility (chemicals, liquid fuels, power, and gas fuel)
- More economic means for CO_2 capture than pulverized-coal combustion (due to the higher CO_2 concentration from a gasifier)

Coal gasification was first used for streetlight in 1792. The USA had 1,200 gas plants in 1920s, but the discovery of natural gas led to demise of these plants. Increased energy demand, high natural gas prices, and stringent environmental regulations focused interests on IGCC. There are 117 operating plants and 385 gasifiers worldwide.

The lecture then covered the scientific reasons of the IGCC advantages over pulverized coal combustion mentioned above. IGCC removes the pollutants from synthesis gas before they are burned. High pressure and low gas volume provide favorable economics of pollutant removal; these operating characteristics also allow flexibility in pollutant concentration in feedstock. IGCC also produces less waste and consumes less water. IGCC uses two power cycles in series: gas turbine where power is generated from burning the syngas and steam turbine where power is generated from steam expansion. Syngas can also be used to produce chemicals and liquid fuels. Hydrogen can be used as a transportation fuel and fuel cell for generating electricity. These unit operations reveal not only the versatility of the IGCC process, but also a higher IGCC efficiency higher than that of pulverized coal combustion.

Some features of the 513 MW IGCC demonstration plant in Kemper County, Mississippi, were then discussed. Lignite will be its primary fuel and natural gas its backup. It has an air-blown rather than an O_2-blown gasifier. This modification eliminates the need of an air separation unit and reduces the capital and operating costs and cost of electricity. Moreover, it significantly reduces the emissions of SO_2, NO_2, CO, volatile organic compounds, and particulates. It is anticipated that about 50 % of the CO_2 will be captured.

The last segment of his lecture covered some of the research activities of Southern Company's IGCC Power Systems Development Facility (PSDF) at Wilsonville,

Alabama. These activities include the particulate removal by hot-gas filtration, high-temperature high-pressure particulate sampling system, development of drag correlations for the feeding system, tar cracking, gas clean up, and CO_2 capture. CO_2 capture for the high-pressure syngas in an IGCC plant will be less costly than a conventional pulverized coal combustion process. Southern Research is testing a wide spectrum of solvents and additives for capturing CO_2; representative data were presented.

Oxy-firing and Chemical Looping, by Thomas K. Gale

Dr. Thomas Gale, Power Systems Research Manager of the Southern Research Institute, presented his efforts on oxy-firing and chemical looping. Both are emerging carbon-capture-enabling technologies. The objective of Southern Research's oxygen-fired CO_2 recycle combustion project is to investigate, develop, optimize, and model O_2-fired utility boilers by:

- Retrofitting the existing Southern Company/Southern Research's 1 MW pilot-scale test facility
- Utilizing an advanced oxy-fired coal burner
- Measuring the operating and output responses to adjustable parameters
- Comparing these responses with CFD modeling results

The project has multiple participants. Coal is burnt by O_2 and recycled CO_2 in an oxy-fired boiler so that the flue gas contains mainly CO_2, not N_2 as the conventional pulverized coal combustion process. About 75 % of the CO_2 is recycled to avoid excessive flame temperature and maintain flow and heat transfer requirements. Thus, advanced burner for oxy-firing will be carefully signed to allow flame shape and heat release to be controlled and to provide a stable attached flame without natural gas assist. Since N_2 is not in the flue gas, the flue gas from an oxy-fired boiler has a 25 % volume of that from a conventional air-fired boiler, purification and compression are much less expensive for carbon sequestration. Air separation prior to combustion, however, creates sizable (about 25 %) energy penalty and notable electricity cost. Additional energy penalty comes from purification of CO_2 and compression and sequestration. These concepts were introduced in this lecture. Moreover, Southern Research's unique efforts were discussed that include Maxon oxy-fired burner, oxygen skid and piping system, distributed control system, gas flow control system, recycle system, safety system, conversion of facilities, axial temperature distribution and NO emissions from tests of two coals, computational fluid dynamics modeling conducted by Reaction Engineering International, and plans for the future tests. Parameter study for the future will be devoted to coal type, amounts of O_2 in primary flow, burner quarl tip, staging through the recycle-gas tip on the sides of the burner, and staging through the over-fired ports, and percentage of recycle. Flue gas composition, carbon burnout, inleakage, temperature profile, heat transfer, stability

of the test, acid-gas buildup, and apparent corrosion will be monitored during the tests.

In the second segment of the lecture, the basic concepts of the emerging chemical looping technology and Southern Research's research activities were introduced. An oxygen carrier, usually an oxidized metal, shuttles between two vessels in a cyclic chemical looping process. The oxide oxidizes (or gasifies) the fuel, such as coal and natural gas, in one reactor, while the reduced oxygen carrier is oxidized by air in a second reactor. Since the oxidant for burning fuel does not have N_2, the CO_2 concentration is high in the flue gas. Separation of CO_2 from the fuel oxidation reactor of chemical looping process is much less expensive than separating CO_2 from the flue gas of a pulverized coal combustor. Chemical looping is versatile, as it can be applied to both combustion and gasification.

Finally, Dr. Gale predicts the overall future of coal-fired power generation in the face of CO_2 emission regulation. Existing plants will have three choices as a result of immediate regulations: adding CO_2 scrubbers, retrofitting the boiler by installing oxy-firing with flue-gas recycle, or closing the plant. New plants may include oxy-fired furnace without much if any recycle and advanced thermodynamic cycles to offset the energy penalty or other advanced power systems such as oxy-fired IGCC. In the long term, chemical looping and IGCC look promising.

Fuel Cells, by Amala Dass

The lecture of chemistry professor Amala Dass included five arguments: fuel cell basics, fuel cell stacks and bipolar plates, types of fuel cells, proton exchange membrane fuel cells, and current status. A schematic is used to illustrate the major components and their functions in a hydrogen fuel cell (proton exchange membrane or PEM cell) at the outset. Slow reaction rate and hydrogen availability remain as challenges.

To gain high power output, multiple fuel cells are arranged in series, and bipolar plates are developed. PEM fuel cell uses relatively low temperature and can start quickly. It has been adopted in cars and buses. Five other major types of fuel cells have been developed: phosphoric acid, direct methanol (DMFC), alkaline (AFC), molten carbonate (MCFC), and solid oxide (SOFC). Hydrogen is the fuel for all of these fuel cells. The operating temperature ranges, electrolytes, catalysts, and operating characteristics of these fuel cells were discussed. Schematics were presented to illustrate the chemical structure and characteristics of the most popular PEM, Nafion. The strong C-F bond resists chemical attacks. Nafion's unique ionic properties are a result of incorporating perfluorovinyl ether groups terminated with sulfonate groups onto a tetrafluoroethylene (i.e., Teflon) backbone. The polymer is hydrophobic; the sulfonate side chains, SO_3^-, however, are hydrophilic. This leads to the desirable hydrophilic/hydrophobic micro-phase separated morphology. Advancement in nanotechnology has significantly enhanced efficiency of carbon-supported platinum catalysts.

Hydrogen is the common fuel for several types of the fuel cells mentioned above. The issues facing the infrastructure of hydrogen economy include H_2 production, delivery, storage, safety, and end-use materials. For fuel cell, the emerging technology faces challenges in the development of PEM stock, ancillary devices, fuel processors, fuel storage, fuel supply, and electric components. The industry for H_2-powered fuel cell (H_2FC) vehicles will have to overcome several critical technological barriers that include the hydrogen cost, H_2 storage capacity at reduced cost, and fuel cell cost with higher durability. It also has to overcome the economic and institutional barriers that include safety, codes and standard development, H_2 delivery infrastructure, domestic manufacturing and supply base, and public awareness and acceptance.

Computational Chemistry, by Steven Davis

Professor Steven Davis of the chemistry department gave an overview of computational chemistry techniques and their applications to reaction energetics and dynamics. The Hartree-Fock method was discussed along with its failure to include an accurate description of dynamic electron correlation. Characterization of chemical structures along potential energy surfaces was presented using the harmonic oscillator approximation to calculate vibrational frequencies to determine minima (stable structures) and maxima (transition states). Accurate potential energy surfaces were presented as determined using both single and multiconfigurational wave functions. Examples of highly strained structures with potential for solar energy storage were presented and their thermal isomerizations discussed. One such example, tricyclo[3.1.0.$0^{2,6}$]hexane (Davis et al. 2003), illustrated the necessity of using a multiconfigurational wave function plus Moller-Plesset perturbation theory to achieve accurate energies and correct electronic descriptions of transition states.

The use of trans double bonds in small hydrocarbon rings as a way to store potential energy was discussed and the advantages of using computational chemistry to determine relevant reaction pathways and energetics presented. The activation barriers were shown to be somewhat tunable by the substitution of heteroatoms for carbon atoms in the ring moiety (Davis et al. 2009). Multireferenced second-order Moller-Plesset perturbation theory (MRMP2) and coupled-cluster singles, doubles, non-iterative triplets [CCSD(T)] accuracies were compared for systems in which a single determinant was valid to provide a basis for accepting the MRMP2 energies for wave functions with strong multiconfigurational character.

A brief overview of how to choose the correct theoretical model to accurately determine chemical properties using computational chemistry was discussed. It was hoped that the students would gain an appreciation for the powerful tool computational chemistry has become as a companion to the experimentalist.

Table 2 Student presentations in 2008 and 2009

	Student	Research title
1	Damon Webster	Nuclear energy
2	Crystal Warren	Implementation of solar panels on commercial properties and the cost-based incentives
3	Joey Parkerson	Atmospheric carbon dioxide capture technologies
4	Michael McClure	Solar energy
5	Eddie Smith	Home energy efficiency
6	Archer Davis	Ice cores
7	Josh Sage	Hydroelectric energy
8	Leanna Smith	Green roofs
9	Brett Vescovo	US vs. global policy changes
10	Grady Cutrer	Green community
11	Sarah Mixon	Algae-based biofuels
12	Alison Kinnaman	Microremediation
13	Eric Williams	Biomass utilization
14	Shaolong Wan	Oxy-coal combustion
15	Benson Gathitu	Integrated gasification combined cycle
16	Guang Shi	Chemical looping combustion
17	Michael Brandes	Renewable wind energy
18	Whitney Hauslein	Ocean power
19	Katherine Osborne	Heat island infrastructure effects on climate change
20	Jonathan Jones	The hydrogen economy, hydrogen fuel cells, and implementation in Oxford, Mississippi
21	Ifejesu Eni-olorunda	The hydrogen economy – harnessing wind energy
22	Elizabeth Spence	How to go green
23	Ray Nalty	Weather control

Activities of the Students

Students were asked to choose a research topic at the beginning of the semester. They were asked to give a short oral report about their research status, questions, and difficulties in the middle of the semester. They were asked to give a term paper and an oral presentation at the end of the semester. A list of the students' presentations is given in Table 2. The topics range from offering tips in everyday life to modern technologies. Their presentations and papers were evaluated by a panel formed by a

group of faculties. Two outstanding works selected for the two awards were "Implementation of Solar Panels on Commercial Properties and the Cost-Based Incentives" by Crystal Warren and "Atmospheric Carbon Dioxide Capture Technologies" by Joey Keith Parkerson. They were given the title Ole Miss Idols of Climate Change Mitigation. In addition, each one of them received a $250 cash award. Their slides have been uploaded to the course Web site at http://home.olemiss.edu/~cmchengs/Global%20Warming/ along with the formal lectures.

Joey introduced the technology of capturing atmospheric CO_2 by using NaOH in a process that includes two chemical looping cycles: one involves NaOH/Na_2CO_3 and the other $Ca(OH)_2$/$CaCO_3$/CaO. In the sodium loop, NaOH is converted to Na_2CO_3 in an air/CO_2 contactor, and Na_2CO_3 is converted back to NaOH by $Ca(OH)_2$ in a causticizer. In addition to the causticizer, the calcium loop includes calciner and a slacker. $CaCO_3$ decomposes to CaO in the calciner, and CaO is hydrolyzed to $Ca(OH)_2$ in the slacker. Joey presented the capture technology as well as the cost evaluation, about $240 per ton of carbon. He argued that it would be competitive if compared to the cost for capturing carbon emitted from vehicles since no mobile device has to be carried.

Crystal proposed the widespread use of solar panels for commercial properties, legislative incentives for such installation, and mandatory installation by law. She presented the principles of solar panels, the rationales, cost estimate, and recommendations. Success stories of Wal-Mart, FedEx, and Google were discussed. She interviewed local business owners, including her mother and Wal-Mart, during her course of research. German government pays solar panel users 20 cents per kWh received from grid and receives 50 cents per kWh for energy sent back to grid. Crystal, on the other hand, proposed that federal, state, and local government each pays one third of the installation cost. She also proposed fixed energy prices for 15 years at 25 cents per kWh purchased from the grid and 50 cents per kWh for energy sent back to grid.

The Chancellor of the University of Mississippi launched the campus Green Initiative in the spring of 2008 when the course was offered for the first time. The students were excited about the initiatives; they felt that they can share their enthusiasms by transforming what they learned in the semester into actions. The Green Initiative, however, was in its infancy, and the administrators in charge had just started to organize a committee, which will eventually layout the tasks. The students decided to examine the current policies and facilities of the University and explore if there were rooms for improvement. They spent a few evenings together and deliberated their thoughts. The product of their discussions is a list of recommendations, which can be found at: http://home.olemiss.edu/~cmchengs/Global%20Warming/. An oral presentation was also made to the University administrators. The newly inaugurated provost, the retiring provost, and the university architect were among the participants for the presentation and its subsequent discussions. The two parts of the recommendations, policy and facility, were presented by the two students who were selected to be the idols of the climate change mitigation only a

couple of days earlier. In the last years, knowledge about climate change, sustainable energy, and environment has indeed been gradually incorporated into the curriculum. Research collaborations and outreach activities in these areas have increased. The University and City of Oxford, Mississippi, have established a public transportation. This course has notably induced public awareness.

Future Directions

Climate change affects the life of every living species on Earth. Only contributions from all concerned citizens could generate a monumental impact. Thus, climate change literacy must reach grassroot level that has several unprecedentedly large-scale characteristics. Disseminating climate change knowledge secures the immediate need of a strong workforce in the battle against climate change, which is gravely lacking. It raises public awareness and promotes actions of world citizens. More importantly, it is expected to catalyze innovations. In his State of the Union address of 2011 (Obama 2011), President Obama stated the philosophy of his science and technology: "This is our generation's Sputnik moment." The Russian Sputnik space satellite program in 1958 has stimulated the space race that, in turn, promoted innovations in many areas of science and technology. President Obama also characterized the nature of the new race in the same address: "We'll invest in biomedical research, information technology, and especially clean energy technology - an investment that will strengthen our security, protect our planet, and create countless new jobs for our people."

The clean energy activities are expected to grow rapidly in the near future. Mitigating GHG concentrations is closely related to the growths in energy demand, economy, and population. The adaption, impacts, and mitigation of GHG require knowledge in many different (if not all) fields and actions related to different sectors (if not all) of the civilization. Most notably, as this *Handbook* is organized, collaborations of political, legislative, educational, scientific, technological, and news media sectors will be necessary. For completeness, climate change literacy must cover all of these areas.

Science and technology will be in the core of these efforts. In the next few decades, there will be a wide range of research and development investments on the establishment of an alternative energy infrastructure, especially in the areas of biomass conversion, solar panel and concentrator, nuclear energy, wind turbine, hydropower, fuel cell, and geothermal energy. Fossil fuels, particularly coal, are abundant and widespread, and fossil fuel-based power generation is expected to remain a major driving force of the economy in the near future. CO_2 production, however, is much higher than its current utilization. Therefore, carbon capture and sequestration and large-scale utilization of CO_2 will be of great interests. Moreover, much attention will also be placed on technologies that enable carbon capture including chemical looping combustion, oxy-fuel combustion, and integrated

oxygen-transport membrane. Integrated coal gasification combined cycle (IGCC) is versatile and efficient. A hydrogen economy will depend on the development of technologies in several industrial sectors. Energy conservation and energy efficiency will be two major approaches to optimize the limited sources for power generation, transportation, buildings, and industrial sectors.

High-risk and high-impact innovations are not only required for clean energy research, but also desirable for science, technology, engineering, and mathematics (STEM) educations with emphasis on climate change literacy. Government investments on these topics are expected to increase worldwide. Efforts of the National Science Foundation (2011) and NASA (2011) are just two major sources for literacy funding in the USA. Synergistic collaborative alliances are welcome for generating projects with unique objectives and broad impacts. Creative use of information technologies, such as global seminars, could facilitate communication network. At the time of writing this chapter, the author has jointly offered a video, online global seminar class on sustainability with a colleague at the National Pingtung University of Science and Technology in Taiwan. The objectives of this course are to introduce modern issues to graduate students around the globe and to induce healthy and constructive debates representing the students in different regions of the world and different sectors of the society. In addition to the speed of the Internet, there is plenty of information available on the World Wide Web; therefore, Web-based teaching is expected to be more versatile and creative in the future.

Conclusions

Climate literacy can be offered with a group of faculties from different fields in various fashions. The broad nature of the subject renders it possible to cover only selected topics for the organized lectures and other topics for students' research. This course has generated a set of useful slides public dissemination. However, the Web sites mentioned in section "Lectures Presented by Faculty and Scholars" are also available.

Alternatively, some of the organized lectures can be replaced by students' deliberations on subjects such as "Should we promote the production of bioethanol as an alternative fuel?" or "Should we promote the growth of genetically altered plants for increased photosynthesis?" These discussions can certainly promote critical thinking about important issues and absorbing knowledge in related fields.

Activities of climate change literacy are expected to increase in the next decade. There will be more formal and short courses, workshops, summer camps, and outreach projects in other formats. Sustainability will be a central theme of these activities. With the adoption of modern information technology, climate change literacy is likely to accelerate President Obama's prediction that "This is our generation's Sputnik moment" (Obama 2011).

urban life. Similarly, a variety of technological approaches are possible for addressing these problems in the context of global warming mitigation. This chapter examines policies for mobility reduction, as these can have a significant impact on climate change mitigation. It mainly restricts itself to the high-mobility countries of the OECD and uses four such countries (Australia, Japan, the UK, and the US) as case studies.

The approaches considered here include:

- Using modern Information Technology (IT) advances to promote travel substitution
- Car pooling, especially in urban areas
- Land use planning, particularly increased urban densities
- Encouraging the use of more environmentally friendly travel modes
- Raising the overall level (and perhaps also changing the structure) of motoring costs
- Reducing the convenience of car travel.

It is found that the use of IT, car pooling, and land use planning, whether voluntary or legislated, cannot be expected to produce much reduction in either car passenger-km or vehicle-km. Nor will reliance on voluntary approaches for car travel reduction by encouraging more use of environmentally friendly travel modes. Only the last two approaches can produce large and sustained reductions in travel greenhouse gas emissions, but heavy reliance on market forces such as very large increases in motoring costs is inequitable in OECD countries. The only equitable approach is to reduce the convenience of car travel, for example, by large travel speed reductions and by a reversal of the usual present ranking of travel modes: car, public transport, and active modes.

Introduction: Travel Reductions for Climate Mitigation

In the high-mobility countries of the Organisation for Economic Cooperation and Development (OECD), many governments are seeking to reduce personal mobility, particularly car travel, for a variety of reasons. Reductions can be justified in general by concerns about global climate change, oil depletion and supply security, traffic casualties, and even personal fitness (Moriarty and Kennedy 2004; Sallis et al. 2004). In urban areas, additional concerns are air pollution, traffic congestion, take-up of land by transport infrastructure, and quality of urban life.

A variety of technological approaches are possible for addressing the problems listed, including improving vehicular fuel efficiency and developing alternative fuels and power systems. This chapter examines policies for mobility reduction, as these can have a significant impact on climate change mitigation. Nevertheless, the other arguments given above for the desirability of travel reductions can help acceptance of such policies. Although this study is mainly restricted to examining travel in only four OECD countries (Australia, Japan, the UK, and the US), the conclusions should have more general application, at least to other high-mobility OECD countries.

The approaches considered here include:

- Using modern Information Technology (IT) advances to promote travel substitution
- Car pooling, especially in urban areas
- Land use planning, particularly increased urban densities
- Encouraging the use of more environmentally friendly travel modes
- Raising the overall level (and perhaps also changing the structure) of motoring costs
- Reducing the convenience of car travel.

What level of greenhouse gas (GHG) reduction in passenger transport might be needed to avoid serious anthropogenic climate change? It is here assumed that reductions in the transport sector, including surface passenger transport, will need to match those in the world economy overall. The 2013 Intergovernmental Panel on Climate Change (IPCC) Representative Concentration Pathway 2.6 (RCP2.6) has used models showing that CO_2 emissions from fossil fuels may have to be cut by the year 2050 to as little as 30.5 % of the year 2013 values, and fall to zero by 2070, if global temperature rises are to be limited to 2 °C (Stocker et al. 2013).

(The European Union regards a rise of 2 °C since the industrial revolution as representing a prudent limit for avoiding dangerous climatic change.) Others believe that CO_2 atmospheric concentration levels are already too high, and emissions thus need to be cut to zero before 2050 (Moriarty and Honnery 2011). In 2010, travel by all modes accounted for seven billion tonnes of CO_2-equivalent emissions, with about 72 % coming from road transport (Sims et al. 2014). For overall CO_2 reductions, transport cannot be ignored.

Assume that global energy-related CO_2 emissions have to follow the RCP2.6 limits and that by 2050 need to be cut to 2.9 billion tonnes of carbon (2.9 GtC) annual levels (Stocker et al. 2013). By 2050, passenger transport emission levels would also have to fall proportionally, if emission reductions are shared equally across sectors. But emission levels in the OECD countries are far higher than the world average. For example in 2013, the US emissions of CO_2 from fossil fuel combustion was 3.8 times the world average (BP 2014). If equal per capita emissions for the entire world's population are assumed by 2050, then (provided US share of world population remains at its present level) US surface passenger transport emissions would need to fall to around 8 % of their 2013 value. What this simple calculation shows is that reduction of a few percent in transport emissions will not suffice: a drastic reduction is needed.

Overall, this study finds that the use of IT, car pooling, and land use planning, whether voluntary or legislated, cannot be expected to produce much reduction in either car passenger-km or vehicle-km. Nor will reliance on voluntary approaches for car travel reduction by encouraging more use of environmentally friendly modes (EFMs) of travel. Only the last two approaches can produce large and sustained reductions in travel greenhouse gas emissions, but heavy reliance on market forces, such as very large increases in motoring costs, is inequitable, at least in highly motorized countries. The only equitable approach is to reduce the *convenience* of car travel, perhaps by large travel speed reductions and by a reversal of the usual present ranking of travel modes: car, public transport, and active modes.

Surface Transport Patterns in Four OECD Countries

Before attempting to discuss any specific policies for personal mobility reductions in any country, it is necessary to look at both the present transport situation and the path surface transport took in that country to reach the present position. Four OECD countries (Australia, Japan, UK, US), representing all four continents from which the OECD has members, were chosen as case studies. Together these countries span the range of transport-relevant parameters (for example, public transport share, gasoline costs, urban densities, car occupancy rates) found in OECD countries overall (The one exception is for non-motorized transport, so the experience of other OECD countries will be briefly considered for these modes.). These four countries also have good travel statistics available in English.

It is also important to look at possible *future* patterns of surface travel. Accordingly, both the forecasts of global and regional travel from the latest IPCC Report

(Sims et al. 2014) and official travel energy forecasts for the US have been included. In addition, the findings of researchers who have used the existence of travel time and money budgets to project travel in each of the various regions of the globe have been discussed. Levels of surface travel both much higher and much lower than at present have been predicted by various authorities.

Studying past, present, and projected future travel patterns are important for several reasons. Comparison of present travel in the four countries can reveal insights into where policy levers should be applied for climate mitigation. Understanding is needed, for instance, as to why surface travel per capita in Japan is so much lower than in the other countries studied. Discussion of projected travel by official organizations in, say, the year 2040 is also important. If travel reductions are going to occur anyhow because of over-riding changes in technology, the economy, or lifestyles, the remaining task would then be to merely guide these changes.

Present Transport Patterns

Vehicular Travel

Table 1 shows the composition of vehicular surface travel in passenger-km per capita in the four countries considered. It is evident from the table that in 1960, car travel was well-established as the dominant mode in the US, but was still negligible in Japan. Australia and the UK were in an intermediate position, with Australia closer to the US in car ownership and use. Both personal travel by motorcycles and light trucks have been included with car travel. Motorcycle travel is negligible today in each country (less than 1 %), except in Japan. Even in Japan, the share of motor cycle travel appears to have peaked in the 1980s and today is only a few percent of total passenger travel (Statistics Bureau Japan (SBJ) 2014).

Table 1 also shows that combined public transport patronage is today lower in the UK and the US than it was in 1960, but has grown slightly in Australia, and strongly in Japan, with most of the growth on rail. In fact, bus transport per capita peaked in Japan in the early 1970s at around 1,000 passenger-km/capita and has steadily fallen since. In contrast, train travel is resuming the strong growth that temporarily reversed in the mid-1990s.

Figure 1 demonstrates that per capita private car travel over the past 10–20 years appears to have leveled out in Australia, Japan, and the UK. Even in the US, car travel per capita has since 2004 flattened out as well, before the recent global financial crisis actually reduced per capita travel levels. In Great Britain, even *total* car, van and taxi travel, fell from 674 billion passenger-km (bp-k) in 2007 to 643 bp-k in 2012 (DfT 2013). It is evident that the very high levels attained in the US are unlikely to be reached by the other three countries – or by any other country, in or out of the OECD. And perhaps not even again in the US: the total number of vehicles registered per 1,000 population may have peaked in 2007 (Davis et al. 2013). Another feature of the graph is that the later the country began its push to mass car ownership, the lower the peak level of travel per capita.

Table 1 Per capita surface passenger-km of travel by mode and country, 1960 and 2011

Country	Year	Bus/tram[b]	Train	Car[c]	Total	Car %
Australia	1960	390	875	6,500	7,765	83.7
Australia	2011	870	670	13,620	15,155	89.9
Japan	1960	495	1,955	130	2,580	5.0
Japan	2011	705[d]	3,090	6,350[d]	10,145	62.6
UK[a]	1960	1,550	785	2,950	5,285	55.8
UK[a]	2011	685	1,110	10,530	12,325	85.4
US	1960	650	200	11,100	11,950	92.9
US	2011	1,510	195	20,310	22,015	92.3

[a]Averages are for Great Britain only, i.e., excluding Northern Ireland
[b]Includes a small amount of coastal sea transport
[c]Includes all private road vehicle travel

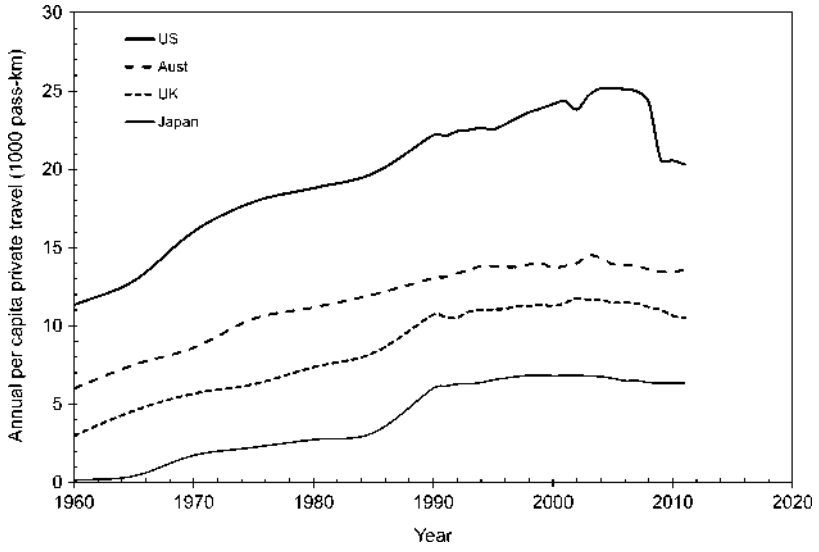

Fig. 1 Surface travel per capita versus year for Australia, Japan, the UK, and the US, 1960–2011 (Sources: As for Table 1)

In Australia, at least, males have been over-represented in car travel and under-represented in public transport travel compared with females. Further, females have been traditionally over-represented as car passengers, not drivers. This situation is changing, and today, the differences, although persisting, are small (Moriarty and Mees 2006). In all four countries, young female car driver licence-holding rates are approaching those for males. In a number of US states, there are now more female than male licence holders.

Non-Motorized Travel

So far, only vehicular surface travel has been considered. But non-motorized travel – walking and cycling – will, it is argued, be an important component of vehicular travel reductions for mitigating climate change. Non-motorized travel is better recorded for the journey to work trip, so most of the data presented here is for this trip type. For Melbourne, Australia, the available data span more than 50 years from 1951 to 2006, the date of the last national census. In Melbourne in 1951, about 11 % of work trips were by walking, with another 10 % on bicycle. By 2011, their share had fallen to 3.6 % and 1.3 %, respectively. Most of the drop in cycling had occurred by the late 1960s, although the fall in the share for walking was more uniform over time (Moriarty and Mees 2006). For Australia overall in 2011, the share of these modes was similar, with 4.5 % walking and 1.3 % cycling for the journey to work (BITRE 2013). As with motorized travel, females in the past had higher rates of non-motorized travel overall than males, but much greater rates of walking and lower rates of cycling for the work trip. Today their rate is similar to that for males.

For Great Britain overall, journey to work mode of travel data go back to 1890. In the 1890s decade, 59.4 % walked and 2.0 % cycled to work. Cycling peaked in the 1940s decade at 19.6 %, with a further 17.2 % walking (Pooley and Turnbull 2000). By 2008, the figures had fallen to 3 % for cycle and and 11 % on foot. In terms of travel distance, for all trip types cycling fell from 23 bp-k to about 4 bp-k between 1952 and 2007, although bicycle travel has been almost constant at between 4 and 5 bp-k for the past two decades (DfT 2012, 2013).

It is difficult to get data on the early use of non-motorized travel in Japan, but given the negligible vehicle ownership until the 1970s (ownership was only 5 per 1,000 population in 1960 (SBJ 2014)), the use of non-motorized modes was presumably high. In Tokyo, non-motorized trips were 25.8 % of the total in 1970 and still 21.7 % in 1990 for the journey to work (Newman and Kenworthy 1989, 1999).

In the US, these modes were even less used than in Australia, with 2.8 % walking for the work trip in the US overall in 2009 (BTS 2014). In 1983, the figure for walking was a little higher at 4.3 %. The highest level of walking to work was found in small cities and towns, with both large metropolitan areas and rural areas having somewhat lower levels (US Census Bureau 2012). Ausubel et al. (1998) presented a graph showing that daily walking per capita by Americans was around 4 km in 1880 and did not fall below 3 km until 1960, after which it fell rapidly to well below 1 km today.

These low values for non-motorized travel in the four countries today can be contrasted with several other OECD countries in Europe. Pucher and Dijkstra (2003) examined bicycle and walking trip-making in the urban areas in a number of OECD countries. Table 2 shows the results for selected countries for the year 1995.

The authors caution that the definition of a trip varies from country to country, but even so, the results are startling, and shows what is possible even today, given the right conditions. Climate seems to have a very little effect on the level of non-motorized trip-making. Sweden, part of which lies above the Arctic Circle, has far higher levels than several countries with more benign climates, such as

Table 2 Proportion of all urban trips by walking and cycling, various OECD countries, 1995

Country	All nonmotorized trips (%)	Walking (%)	Cycling (%)
US	7	6	1
Canada	12	10	2
England and Wales	16	12	4
France	28	24	4
Italy	28	24	4
Germany	34	22	12
Sweden	39	29	10
Denmark	41	21	20
Netherlands	46	18	28

Source: Pucher and Dijkstra (2003)

France and Italy. And as shown for 46 world cities by Newman and Kenworthy (1999) for 1990, the average for walking and cycling combined for the work trip was 5.1 % for six Australian cities, 4.6 % for 13 US cities, but 18.4 % for 11 European cities.

Predicted Future Transport Patterns

Vehicular Travel

Schafer and Victor (2000), following earlier work, argued that in all countries, both rich and poor, people have a fixed travel time budget per day. They therefore concluded that a shift from slower modes (public transport and non-motorized modes) to car travel is needed for people to travel further for a given daily time outlay. It is certainly the case that the observed decline in the share of these slower modes has been accompanied by a rise in car – and air – travel. They also postulated that in high-income countries, households spend a fixed share of their income on travel.

Personal travel levels themselves (including air travel, both domestic and international) were not anticipated to decline – indeed they saw large increases even in the high-mobility OECD countries. But to keep within their postulated daily travel time budget, they projected absolute declines in the level of car travel for present car-oriented countries, particularly the US, and large increases in high-speed travel (air and very fast train travel). Continued economic growth was seen as the method by which households could pay for this increased travel, while continuing to spend a constant share of household personal disposal income on travel. A variant of this approach has seen magnetically levitated (maglev) trains traveling at very high speeds in evacuated tunnels (to lower air friction) displacing car travel, presumably mainly for longer-distance trips (Ausubel et al. 1998; Moriarty and Honnery 2005).

Clearly, air travel within urban areas is not an option. But medium length trips are also unlikely to be made by high speed modes, even by high speed rail. Trips can only be at high speed if stops are very far apart, as there are definite limits to the rates

of acceleration and deceleration that humans can comfortably tolerate, which reduces average travel speed. Waiting at stops further reduces overall speeds. Although the surface travel reductions of Schafer and Victor do not translate into overall travel reductions (because of rising high speed travel) they do imply a reduction in future *surface* travel levels, including travel by car, in OECD countries.

But it is doubtful that people do in fact have constant travel time budgets, even when aggregated at the city-wide or even national level. And the empirical evidence also suggests that the share of disposable household income spent on travel has risen over time in the four countries studied here (Moriarty 2002b). Further, different sub-groups of the general population have very different average travel time outlays, as shown by the more than twofold travel time difference between female pensioners and full-time working males found in a 1986 Australian travel survey (Moriarty and Honnery 2005). Further, as U.K. researchers Lyons and Urry (2005) have stressed the increasing ability to use travel time for other activities, such as using a laptop on public transport trips, argues against individuals having fixed travel time budgets.

Other researchers, impressed by advances in the new IT, have also seen future reductions in surface travel. They have argued that not only surface travel, but all travel, urban and non-urban, surface and air travel, will decline because of substitution by IT. This view has been argued in some detail by MIT planner William Mitchell (2003). He used the term "demobilization" as a general term for the substitution of work, shopping, and other trips by networked computers. Others who have similarly envisaged a controlling role for IT as a means of travel substitution are Frances Cairncross (2001) and Joseph Pelton (2004).

As Tal (2008) has documented, the argument that IT will radically reduce travel has now been made for almost three decades. Actual results in the form of travel reductions that can be ascribed to teleworking or teleshopping so far have been disappointing (Moriarty and Kennedy 2000). There are two separate points that need to be examined when evaluating the "telework will reduce travel" argument:

- What is the present extent of teleworking and what is its likely growth in future?
- What impact does a given level of telework have on overall travel?

The numbers who telework for some or all of the time have not risen to anywhere near the levels forecast. Although Raiborn and Butler (2009) reported that in 2008, 11 % of the US workforce teleworked at least 1 day per month, up from 8 % in 2006, the percentage of "full-time equivalent" teleworkers will evidently be low. Even more important, teleworking households may not even reduce their travel overall. First, most households in OECD countries have more vehicle licence-holders than available personal vehicles. So even if a household car is not used for work travel on any given day, it may be used for other purposes by other household members – or by the teleworker for non-work trips.

Second, teleworking could affect the location decisions of households. If the commute trip by one or more household members is reduced through telework, the household may locate further away from the city center, where land prices are lower. At least for Australian cities, outer suburban (and non-urban) households travel

much further per capita than inner urban households (Moriarty 2002a). And for travel overall, including air travel, Smith (2008) has remarked that it is now so easy to plan travel by sitting at one's desk that IT could well have increased travel.

Similarly, teleshopping, or e-commerce, has also not fulfilled its early predictions; after more than a decade, e-commerce still only accounts for a 4 % share of all retail sales (US Census Bureau 2012), although for the category of computer hardware and software the share is much higher. With such a low overall share (and even at a much higher share, say 20 %), the effect on shopping trip frequency will probably be negligible, since a large variety of purchases are usually made on each shopping trip, even if only one shop (for example a super-market) is visited. It may also be true that much on-line shopping is additional to traditional shopping, and not a substitute.

None of these proposals for travel substitution is really new – all have low-tech precedents. A small proportion of the workforce has always worked from home. Mail order catalogues enabled remote shopping more than a century ago. Today, a telephone and a mailbox are still all that is needed for teleshopping. But whether a letter, telephone, or networked computer is used for ordering merchandise, it still needs to be physically delivered to the householder – with the exception of software. Any saving in private travel will thus be partly offset by a rise in freight vehicle travel. "Cyber universities" are less discussed today than they were a decade ago, but they are really just a new version of the old correspondence courses. In all, greater change probably came from the introduction of instantaneous communication with the telephone and the radio, than from the later introduction of modern IT.

Even if reductions in surface travel will not naturally occur by either the operation of travel time budgets or IT substituting for travel, there are other, more recent, arguments for future travel reductions. William Rees (2009) is a researcher who has a very pesimistic view on the likelihood of anything approaching "business-as–usual" in future cities. But his doubts are based on the need for very large reductions in both greenhouse gas emissions and oil consumption, and the limited ability of technical solutions like alternative fuels or efficiency gains to deliver in the limited time frame available.

All these views are in sharp contrast to the travel forecasts for OECD countries offered by various international and national authorities. The US Energy Information Administration (EIA) (2014), in its Annual Energy Outlook 2014, saw a gradual fall in US transport energy use, from 2012 to 2040, with transport energy in 2040 being 4.3 % below that in 2012 in the base case scenario. Nevertheless, vehicle-km by light vehicles was forecast to grow steadily from 2012 out to 2040 in the base case, even though it fell in the aftermath of the Global Financial Crisis.

The IPCC (Sims et al. 2014) warns that "Without policy interventions, a continuation of current travel demand trends could lead to a more than doubling of transport-related CO_2 emissions by 2050 and more than a tripling by 2100 in the highest scenario projections." The Organization of the Petroleum Exporting Countries (OPEC) (2013) gave an estimate of 897 million private transport vehicles in the world in 2010 and projected that this figure would rise to 1875 million in 2035. Although about two-thirds of all cars are presently in the OECD, the future annual growth in private vehicles in the OECD was forecast to be under 1 %. For China,

OPEC forecast car ownership to grow from 58 million in 2010 to a massive 442 million in 2035. This optimistic forecast assumes, of course, that neither oil availability nor concerns about global climate change impose limits.

Non-Motorized Travel

Most official future travel projections simply ignore non-motorized travel. If discussed at all, it is in the context of future travel in low-income countries. Schafer and Victor (2000) assumed that non-motorized forms of travel would be too slow for their time-constrained, high mobility future. Both the reports of the World Business Council for Sustainable Development (WBCSD) (2004) and the earlier IPCC reports devoted little space to non-motorized travel, with the WBCSD report assuming that it will gradually disappear as low-mobility societies move up the "ladder of mobility improvement," by which is meant that motorized travel will supplant it. Non-motorized travel was thus regarded as an inferior travel mode, and technical solutions (alternative fuels, vehicle efficiency improvements, etc.) were seen as the most important means of tackling climate change.

The very few available projections are thus usually only from advocates of these travel modes. Geurs and van Wee (2000) used backcasting to examine what changes were needed for a reduction in Dutch transport GHG emissions of 80–90 %. They concluded that compared to their "business as usual" scenario for 2030 transport, bicycle use, already high in the Netherlands (as shown in section "Non-Motorized Travel"), would need to double in terms of passenger-km in their major emissions reduction scenario. Given that car travel and motorbike/moped travel would need to be reduced by 50 % and 75 %, respectively, it is clear that cycling would become a major travel mode.

The present role of walking and cycling in the Netherlands demonstrates what is politically possible, even today. Income levels in the Netherlands are higher than most countries in the OECD, so that, unlike the situation in low-income countries, the popularity of these modes is not based on economic necessity. And at 51–54°N, the climate is less benign for walking/cycling that most other OECD countries. Nevertheless, its flat terrain and high population density are advantageous. In all OECD countries, however, there is increased concern about obesity and personal fitness (Pucher and Dijkstra 2003; Sallis et al. 2004). Non-motorized travel modes are well-placed to benefit from this concern.

Creating Environmentally Sustainable Behavior

Changing behavior as a means of achieving environmentally sustainable ends such as household travel and energy reductions is attractive because in principle it can be introduced rapidly. In fact, during gasoline shortages, changes in travel behavior can happen overnight, as motorists car pool, walk or use public transport to get to work. (However, after the emergency is over, very little permanent change in travel patterns has been observed.) These measures can also be very cheap to implement, compared with most other alternatives, and if voluntary, carry few political costs. The

important questions to ask of psychology are the following: How much change can be expected? Which approaches work best? Do voluntary approaches work better than more coercive approaches? Which demographic groups are most likely to change? In this section an attempt will be made to answer these questions, first for general environmental change and then for transport change.

General Principles for Change

Linda Steg (2008) has discussed three factors she considered important in promoting more environmentally sustainable behavior at the individual or household level: knowledge, motivation, and ability to make the necessary changes. Below, these three points are discussed in turn, then the significance of the findings for promoting pro-environment behavior (PEB) in general is discussed.

Knowledge is a necessary condition for adopting PEB. People have to be aware of the consequences of their consumption, such as their household domestic electricity use or private car use, on the physical environment. But consequences are not always easy to determine. For instance, the public's knowledge of the facts on climate change, and the reasons why nearly all climate scientists regard climate change as a serious problem, is generally poor, even among the educated populations of the OECD countries. The immense complexity of the climate change problem, with its multiple feedbacks operating at varying time scales, is one cause. Others include the significant natural variability of climate, making unambiguous attribution of cause difficult, and the stress on this uncertainty by industry groups with a strong interest in continued inaction on climate change.

Second, not only is knowledge important, but the public must be *motivated* to change their behavior in a more environmentally appropriate direction. When surveyed, most people in OECD countries profess to be concerned about the environment in general, but such concern does not always translate into action, as is shown by the continued rise in household energy consumption in many OECD countries, for example. Further, in the case of climate change mitigation, the link between individual reductions in GHG emissions and environmental benefit, particularly local, is tenuous. Other factors important for success or otherwise in achieving behavioral change include any extra costs and effort incurred, or any reduction in personal convenience. Policies will thus be more effective if they simply involve purchase of more energy-efficient equipment and do not restrict perceived freedom of choice (Steg 2008). Recycling involves no monetary costs and has been made convenient by the provision of recycling bins at households and businesses, and so has been widely adopted. Unfortunately, much household recycling may be only of marginal benefit in achieving ecological sustainability (Wikipedia 2014).

De Groot and Steg (2009) have further argued that ethical arguments (altruistic and biospheric considerations) for change in household practices are more effective than other approaches, such as those that stress cost savings. As they put it, it is better to get people to "act green" than to "act mean." Cost saving arguments can come undone when, for example, energy costs fall or household circumstances change. An

illustration of the former is the steep decline in sales of more energy-efficient hybrid electric vehicles in the US, following the fall of gasoline prices after mid-2008. Nevertheless, countries with higher costs for gasoline and domestic electricity and natural gas, in general use less energy.

Third, people must also be in a position to make the necessary changes. Money is often a barrier. Many households may not have the financial means to buy the new, more energy-efficient equipment, or to pay for retro-fitting their house to cut heating energy. They may find it easier to continue paying higher monthly or quarterly bills than to find the money for an energy efficiency improvement. It is not only physical or financial impossibility that matters; even cultural norms may make an action perceived as impossible.

Given these conditions needed for change, some suggestions for general strategies to promote environmental changes follow.

Promoting the purchase of more energy-efficient appliances (such as compact fluorescent globes in place of incandescent ones) can be a succesful strategy, especially if, as in this case, not only are the purchase costs low, but households suffer little inconvenience from the change. In the case of compact fluorescent globes, both costs and inconvenience were so minor that several governments have been able to mandate the phasing out of the less-efficient incandescent globes (Brown 2009). Changing the costs of energy, for example through a carbon tax, can also help reduce energy consumption, as can increasing the costs of travel. The road pricing schemes in London, and particularly Singapore, have had some success in reducing travel levels and marked success in changing travel patterns.

Researchers have found that higher income groups respond best to interventions for improving PEB. Studies in the US has shown that such groups are more likely to participate in "green energy" programs. For Australian capital cities, high income and high education households were also found to be more likely to have a strong environment commitment (Moriarty and Kennedy 2004). Torgler and García-Valiñas (2007) also reported that both better-educated and higher income individuals usually had stronger pro-environmental attitudes. They reasoned that "Wealthier citizens may have a higher demand for a clean environment and less environmental damages." On the other hand, in the US, sports utility vehicle ownership is much higher among the more affluent, and air travel in all countries is similarly concentrated among the well-off. Clearly, the issue of environmental support is a complicated one, where actions may not coincide with attitudes (Kennedy et al. 2009).

Thus the relationship between PEB and socioeconomic status is much more complex than revealed by surveys. Lower income households in OECD countries can be regarded as "involuntary environmentalists," because their per capita use of public transport is greater, while their use of domestic energy or water, is usually lower than that for higher income households. Similarly the higher levels of environmental concern usually (but not always) found for females (Torgler and García-Valiñas 2007) could have a similar basis. In any case, as shown in section "Present Transport Patterns," female use of more environmentally friendly transport modes is today not much better that that for males. These comments on involuntary environmentalism apply with even greater force to low income households of the

industrializing world. Nevertheless, higher income households, despite their greater resource use, are more likely to respond to campaigns for increased PEB (Gifford and Nilsson 2014).

Changing Travel Behavior

It is widely agreed that changing travel behavior is far harder than changing behavior for recycling or even general domestic energy conservation (e.g., Garling and Schuitema 2007; Dietz et al. 2009; Gifford and Nilsson 2014). In general, external constraints, whether real or perceived, on changing travel mode are usually severe in the car-oriented countries of the OECD. An important constraint is that alternatives to the car for any given trip usually involve longer travel times. It follows that bringing about voluntary change can be expected to be much more difficult than promoting other forms of pro-environmental behavior such as recycling. In addition, there are strong psychological benefits of car travel which other modes cannot match.

Clearly, transport GHG emission reductions would be easy if a carbon-neutral fuel was readily available at about the same price as existing petroleum-based transport fuels and could be used in existing vehicles. Proenvironment behavior would then be as easy as shifting to another brand of gasoline. But such a convenient solution to transport's GHG emissions will not be available for decades, if ever. Other approaches, such as travel demand management (TDM), are needed.

Dietz et al. (2009) have examined ways in which US households can voluntarily cut their carbon emissions. From behavioral research, they estimated that, nationally, the "reasonably achievable emissions reduction" potential in the household sector overall is 20 %. This reduction can be achieved in a decade, they argued, if "the most effective nonregulatory interventions are used." Although about 45 % of the estimated savings came from reductions in private vehicle fuel use, only about 11 % of this transport total came from travel reduction measures, namely from car pooling and trip chaining. Overall then, only 1 % (20 % $\times$ 0.45 $\times$ 0.11) of all household sector emissions could be reduced by voluntary TDMs. The authors assumed that only 15 % of households that were not currently car pooling or trip chaining would in fact voluntarily do so, if the most effective interventions were employed. In contrast, 90 % of households were anticipated to weatherize their houses.

Another US study (Greene and Schafer 2003) surveyed a large number of potential TDMs, both voluntary and legislated, to reduce vehicle-km of travel, including car pooling, congestion pricing, use of telecommuting, and land use planning. They estimated that combining all these approaches might reduce vehicular travel by around 10 %. Even this low figure – relative to what section "Introduction: Travel Reductions for Climate Mitigation" showed might be needed – they saw as representing an enormous challenge.

Garling et al. (2000) investigated the potential for voluntary reduction in car use by interviewing a number of randomly selected households in Goteborg, Sweden.

Respondents had reported beforehand they could eliminate at most 10 % of their car trips over the 8 days of the survey, but their actual reduction achieved over these 8 days was even less, because of unforeseen car trips. Stated intentions to reduce car travel were thus very different from actual behavioral changes. The authors concluded that a 10 % reduction, the same value as found for the US, was the most that could be expected from noncoercive measures.

Also in Goteborg, Hagman (2003) interviewed motorists about what they perceived as the advantages and disadvantages of car use. Interviewees were found to present the advantages in terms of their *personal* experience, for example, time savings. But only some disadvantages were based on personal experience; most were based on abstract arguments about adverse environmental effects. These arguments were derived from the media. Hagman thus concluded that "knowledge about advantages becomes absolute while knowledge about safety and environmental risks becomes relative and negotiable." He speculated that this difference could explain why presenting motorists with information on car travel's environmental costs has been unsuccessful in reducing driving.

It was reported above in section "General Principles for Change" that knowledge of the effects of consumption are considered important for promoting PEB in general. Tertoolen et al. (1998) used a field experiment in 1992 in the Netherlands to explore motorists' resistance to travel mode change. They found that providing information to car drivers on the monetary and environmental costs of car travel produced no measured reduction in driving, in line with other research. But Tertoolen and colleagues went further and claimed that information campaigns to reduce car use could have undesirable side effects. Their explanation was in terms of cognitive dissonance. If motorists cannot reconcile their general proenvironmental attitudes with information that their car use is damaging the environment, the dilemma can be resolved in two ways. The societally preferred way is of course to change behavior, but another way is by revising or even discarding their original proenvironmental attitudes. The authors show that the latter approach was common among their respondents. Motorists seem to react negatively to being branded as polluters, so that such an approach may not be at all effective in persuading them to use their cars less (Moriarty and Kennedy 2004).

Not all researchers would agree with De Groot and Steg (2009) that it is better to get people to "act green" rather than "act mean," at least for changing transport behavior. Wardman et al. (2007) used both revealed preference and stated preference surveys and modeling to find the most effective policies for reversing the steep decline in cycling noted in section "Non-Motorized Travel" in Great Britain. They argued that the best policy was a financial incentive for cycling to work. Payment of UK £2 daily to cyclists was found to double the level of cycling to work, whereas complete provision of segregated cycleways, an expensive undertaking, would only raise cycling by 55 %. Whether such modeled increases would actually occur is of course uncertain, but in any case, even a doubling of cycling commuter share would do little to reduce overall GHG emissions.

In an another recent study on factors affecting the success of programs to increase the use of cycling, Pucher et al. (2010) wrote:

> The current level of bicycling in a community also affects bicycling safety and the potential to further increase bicycling. Several studies have demonstrated the principle of "safety in numbers." Using both time-series and cross-sectional data, the studies find that bicycling safety is greater in countries and cities with higher levels of bicycling, and that bicycling injury rates fall as levels of bicycling increase. As the number of cyclists grows, they become more visible to motorists, which is a crucial factor in bicycling safety.

They added that as cycling use increases, "a higher percentage of motorists are likely to be bicyclists themselves, and thus more sensitive to the needs and rights of bicyclists."

They also showed the complexity of responses to policy initiatives to encourage cycling. Noncyclists in bicycle-oriented cities may respond much more positively to a given set of programs or infrastructure provision than noncyclists in cities with few cyclists. Context is very important. (Their findings are supported by the experience of cycling in Melbourne, discussed in section "Non-Motorized Travel," where it was shown that cycling to work collapsed in the 1950s – at precisely the time that car travel was growing rapidly.) Similar conclusions probably apply to policies to encourage walking – and even public transport.

Thus the overall empirical findings of behavior change psychologists and other researchers suggest that the prospects for voluntary travel reductions, at least, as a means of cutting energy use or GHG emissions, are not promising. Even using the most effective campaigns, only modest changes can be expected from voluntary transport change programs and even less from general media campaigns. These projected changes in travel behavior are small and reflect only the likely reductions in a "business as usual" transport future. As will be shown later, the *context* in which the changes are to take place matter a great deal. Even noncoercive measures could be effective if it becomes clear to the general populace that continuation of present practices is no longer an option. Unfortunately, in the context of adverse climate change, it was shown in section "General Principles for Change" that this is presently not the case.

Table 3 provides a list of TDMs under four categories, along with the percent savings considered possible by Greene and Schafer (2003) for individual measures. Both voluntary measures and what were seen as politically possible coercive interventions are included. In the next sub-section, a major voluntary trave change program in Australia is examined, and it is concluded that the findings of the psychologists are largely vindicated.

Voluntary Travel Reductions: An Australian Case Study

To evaluate the effectiveness of voluntary schemes, a case study from Australia is provided. In Australia, voluntary approaches to car travel reduction have mainly taken the form of TravelSmart interventions to encourage more use of environmentally friendly modes (EFMs) of travel – public transport, walking, and cycling. In contrast to other major Australian cities, where interventions have been small or nonexistent, the intervention in Perth, a city of about 1.7 million, was both far more

Table 3 Summary of travel demand reduction methods

General TDM category	Travel reduction method	Greene and Schafer (2003) vehicle-km savings estimates (%)
Physical change measures	Area-wide ridesharing	0.1–2.0
	Bicycle/pedestrian travel improvements	Less than 0.1
	Land-use planning to reduce trip distances e.g., mixed land use, "smart growth"	0.0–5.2
	Park-and-ride lots	0.1–0.5
	Public transport improvements e.g., improved intermodal interchanges	0.0–2.6
	High-occupancy vehicle (HOV) lanes	0.2–1.4
Legal policies	Prohibiting traffic in city centers	NA
	Decreasing speed limits	NA
	Compressed work week	0.0–0.6
	Parking control	NA
	Telecommuting	0.0–3.4
Economic policies	Parking pricing: work	0.5–4.0
	Parking pricing: nonwork	3.1–4.2
	Congestion pricing	0.2–5.7
	Tax on emissions per vehicle-km	0.2–0.6
	Decreasing costs for public transport	NA
Information and education measures	Individualized marketing	NA
	Public information e.g., advertizing campaigns for public transport	NA
	Giving feedback about consequences of behavior	NA
	Social modeling e.g., role model endorsement of public transport	NA

extensive and also earlier than in other cities, enabling an evaluation of the program.

The main idea was to target the less-committed motorists in a selected municipality, in recognition of the fact that while some of their trips have to be made by car, for many other trips presently made by car, EFMs are a real option, and the change could be made with only marginal loss of convenience. By providing information on these EFMs, the TravelSmart programs tried to shift some car trips to these modes. The information was tailored to the needs of the individual household, with local timetables for buses provided.

Such programs in Perth have now been in operation for more than a decade, and most of the city's total population have been targeted, so that reductions should appear at the city-wide level. As will be discussed later in section "Reducing Travel: Changing Urban Land Use Patterns" (see Table 5), levels of car passenger-km per capita, or car ownership, are today no lower than the

Table 4 Central Metropolitan Perth, Victoria Park, and South Perth journey to work, 1996 and 2001

	Central Metropolitan region		Victoria Park municipality		South Perth municipality	
Year	1996	2001	1996	2001	1996	2001
Population	117,700	121,950	26,720	27,690	36,450	37,520
Light vehicle travel (%)	78.2	75.5	76.1	75.9	83.7	81.9
Car occupancy rate	1.09	1.08	1.12	1.10	1.10	1.09
Public transport (%)	11.9	13.2	15.8	16.8	10.7	11.2
Walk/cycle (%)	8.1	9.5	5.9	5.6	3.9	4.8
All EFMs	20.0	22.7	21.7	22.4	14.6	16.0

average for Brisbane and Adelaide, cities closest in size and urban density. The initial municipality for comprehensive TravelSmart intervention was South Perth, which had blanket intervention in 2000. It is therefore useful to compare South Perth with the adjacent areas of Victoria Park and the Central Metropolitan region as controls, both at the 1996 Australian census, before the South Perth intervention, and 1 year later at the year 2001 census. As evidenced by the journey to work data in Table 4, no shift to a higher share of EFMs, or to a higher occupancy rate for the work trip was found as a result of the intervention 1 year earlier.

Any gains that were initially made thus do not appear to have persisted, although a 2006 evaluative report on all the Australian TravelSmart programs (Australian Greenhouse Office 2006) suggested that there is some "evidence that changes appear to be sustained for at least 5 years without maintenance or further intervention." And from the government TravelSmart website, it is evident that activities have ceased in recent years (TravelSmart Australia 2008). In fact, the website has not been updated since October 2008. But governments are willing to try these programs because it puts the responsibility on individuals to make the changes rather than on politicians facing re-election.

European experience with voluntary schemes has been similar. Garling and Schuitema (2007), after surveying the use of voluntary measures for TDM, summarized their findings thus:

> The conclusion is that non-coercive TDM measures alone are unlikely to be effective in reducing car use. Therefore, coercive TDM measures such as increasing cost for or prohibiting car use may be necessary but are difficult to implement because of public opposition and political infeasibility.

In summary, whatever the importance of voluntary approaches for promoting general conservation practices, they have not worked for private travel. The remainder of this chapter thus mainly looks at non-voluntary measures for reducing travel demand.

Reducing Travel: Changing Vehicle Occupancy Rates

Increasing the occupancy rate for cars appears to be an attractive greenhouse reduction method, for several reasons. First, it can be implemented with the existing vehicle fleet. Second, the costs are low compared with other approaches. Third, the potential is large: occupancy rates in OECD countries today are typically about 1.5 persons per car, or 30 % occupancy for a five-seater car. What is more, they were historically much higher, at around two persons per car in Australia and the US in the 1960s (Moriarty and Honnery 2008b).

Policies for increasing occupancy rates for personal vehicles can be voluntary or mandated. Neither approach has enjoyed much success. An important reason is that in all OECD countries, average household sizes have fallen in step with completed family size. In Japan, persons per private household have fallen from 3.28 in 1975 to 2.42 in 2010 (SBJ 2014). Fewer family members are then available to fill the car for weekend social trips. Figure 2 shows how US car occupancy rate (sports utility vehicles not included) has fallen in step with average US household size. The occupancy rates for cars appear to be tied very closely to the occupancy rates for houses.

In addition, cars per 1,000 population have risen in all four countries. As an example, in Melbourne, Australia, the car occupancy rate for the journey to work correlates almost perfectly ($R^2 = 0.99$) with persons per light vehicle available (Moriarty and Mees 2006). This suggests that occupancy rates for cars will be hard put to even maintain their present level if either car ownership continues to rise or household sizes continue their fall in OECD countries.

But even if a law was passed (and adhered to by motorists) requiring that average occupancy rates be doubled, it is doubtful that the net GHG reductions would be very significant. In order that roads do not choke up, a car-based passenger transport system requires trip origins and destinations, and so traffic, to be dispersed in both space and time. Only for commuting, with its low occupancy rates (less than 1.1 persons per car for Australian cities today), and travel concentrated in morning and evening peaks, would (say) a doubling of occupancy rates be feasible.

But whether GHG reductions would follow is uncertain: in California, Greene and Schafer (2003) reported that a car-pooling scheme did raise commuter car occupancy rates while in operation, but only at the expense of public transport patronage. Overall, they saw "area-wide ridesharing" as having the potential to reduce total US vehicle-km by 0.1–2.0 % and HOV lanes by 0.2–1.4 % (see Table 3).

Car pooling can also conflict with attempts by motorists to combine different trip purposes, another method of reducing car travel (i.e., vehicle-km traveled). To the extent that a car-pooling scheme was successful, it would radically change the *meaning* of private travel, replacing the perceived tyranny of public transport timetables with the new tyranny of dependency on the punctuality of others, often nonfamily members. Further, the circuitry of such chauffered trips will increase the total vehicle-km traveled, partly offsetting any GHG reductions. Since much of the easily arranged car pooling is already being done, it can be expected that major rises in car pooling would greatly increase this circuitry factor.

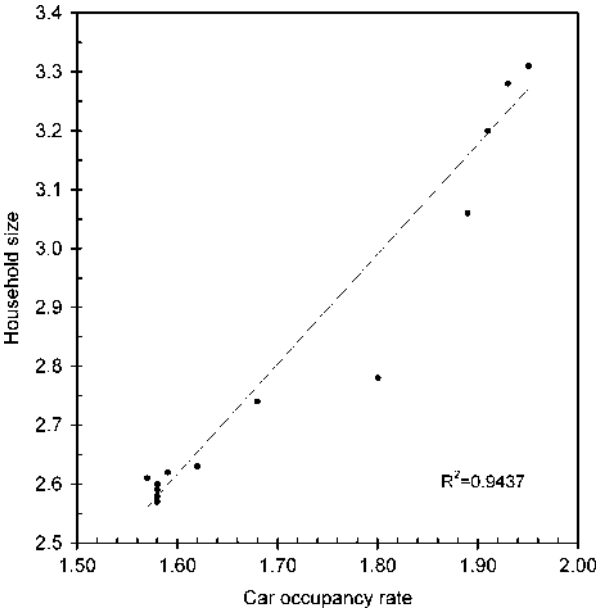

Fig. 2 Average household size versus car occupancy rate, US, 1960–2005 (Sources: US Census Bureau 2012; BTS 2014)

For public transport, the position is very different. As public transport loses patronage, the occupancy rates of public transport vehicles decrease. For the case of electric tramsin Melbourne, Australia, the occupancy rate fell from 24.6 in 1960, with overall patronage 783 million pass-km, to only 18.3 in 1980, 442 million pass-km (Newman and Kenworthy 1989). As patronage has grown strongly in recent years, occupancy is once again rising. Similar changes have been observed in Great Britain. Bus occupancy was 19 passengers per bus for 61.4 bp-k in 1974, fell to 8 passengers in 2000 at 46.2 bp-k, and has since risen to 10 passengers in 2007 at 50.8 bp-k (DfT 2013). Unlike car occupancy rates, public transport occupancies are independent of household size.

What this suggests is that public transport systems are often capable of much higher occupancy rates (but not often at peak hour, when many services are already at capacity loadings). Hence a shift to public transport from car can give a double boost to GHG reduction: one from the higher energy efficiency per seat-km that public transport enjoys over car travel, and second, from the higher occupancy rates possible from higher loadings (Moriarty and Honnery 2007, 2008b).

The reason for these occupancy rate changes is that when patronage falls, operators try to maintain service levels to prevent further passenger desertion. Conversely, as patronage rises, as is happening on many public transport systems in the OECD today, the rising patronage is initially accomodated on existing services, with additional services provided as required. In effect, if public transport patronage rises because of higher fuel prices, or rising congestion, seat occupancy increases naturally without any specific policy needed, either voluntary or nonvoluntary, for its increase.

In summary, public transport occupancy rates can be expected to rise, but the prospects for higher levels of car pooling are poor. Car pooling goes against several of the perceived advantages of the car, including privacy, direct travel between origin and destination, and no waiting (time of travel solely at the discretion of the driver). Instead, car pooling involves the need to negotiate with others, required levels of puntuality, choice of on-board music, and degree of driving caution. And even if car pooling could be politically mandated, the rise in occupacy rates would be partly illusory. In purely serve-passenger trips, the driver should not be counted as an occupant; public transport drivers are not counted. Increasing occupancy rates are not useful unless total transport GHG emissions are thereby reduced as well.

Reducing Travel: Changing Urban Land Use Patterns

Changing land use patterns is really only a mobility reduction option for urbanized areas, but in the OECD countries, 80 % or more of the total population live in urban areas. Many urban researchers have proposed such changes in existing cities as a means of both reducing vehicular travel overall, while increasing the share of public transport (e.g., Newman and Kenworthy 1999, 2006; Handy et al. 2006). The most discussed urban land use changes are policies to encourage (or mandate) increases in urban density. After allowing for differences in the definition of urban density for different cities – particularly if the cities are in different countries – urban densities can still vary by more than two orders of magnitude for different cities of the world (Newman and Kenworthy 1999). Figure 3 shows the exponential relationship for private travel versus urban density for 46 cities in Asia, Australia, Western Europe, and North America. Not only car travel, but all vehicular travel per capita, and transport energy consumption per capita, show similar curves.

While the density-private travel relationship is indeed strong, some caveats are in order. Australian and US cities, nearly all with densities of 1,000–2,000 persons/km^2, form a distinct group along the upper left-hand axis. For them, travel variations seem unrelated to density; all US cities had higher levels of car travel than any Australian city, even though the urban densities for the two countries fully overlapped. At the other extreme of the graph, in the bottom right-hand corner, lie six Asian cities, with very high urban densities and low levels of car travel. However, several also have much lower income levels than the other cities shown, and lower incomes will reduce both car ownership and travel.

The second problem relates to the definition of each city. The older cities of Europe often have boundaries that are much more restricted than those of Australian or North American cities, so that many of what would be called outer suburbs in the latter regions are excluded. Outer suburban residents typically travel much more than those living closer in and travel more by private transport (Moriarty 2002a). The result is lower recorded overall per capita urban travel levels in Europe's cities that would be the case if more extensive urban boundaries were used.

Travel per capita by residents in higher density areas of cities is usually lower than in areas of low density. A US example of this is found in the analysis by Fan and

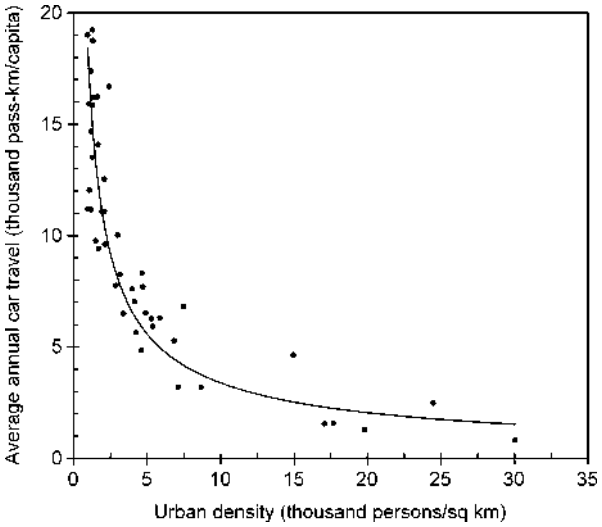

Fig. 3 Private vehicular travel per capita versus urban density, 46 world cities, 1990 (Source: Newman and Kenworthy 1999)

Khattak (2008) of the results of the 2006 Greater Triangle Region Travel Study in North Carolina. They concluded that travel overall in the region could be reduced by densification. But urban density tends to decrease with distance from the city center, and, as has just been shown, outer suburban residents travel more than inner city residents. An alternative explanation for their result might be that per capita travel rises with distance from the city center, as found for Melbourne, Australia (Moriarty 2002a).

The different areas of a city together form an interdependent urban system. If the inner city contains a surplus of workplaces over resident workers, as is true for many major cities, then workers from other areas must travel to fill these jobs. Similarly, the inner areas of major cities contain a variety of institutions and venues that are meant to serve the city as a whole, or even the entire region, many of them housed in or adjacent to the CBD. Examples include specialized shops and services, theatres, art galleries, and sports stadiums. Travel needs for inner area residents to these locations are minimized, but are of course higher for other urban residents.

Overall, of course, this arrangement of activities is efficient, minimizing total metropolitan-wide travel for (say) a major sporting event. Also helping reduce inner area car travel is the radial nature of many fixed rail urban networks, which results in denser and more frequent services there, and hence much greater public transport use per capita. Higher traffic congestion also discourages inner city residents from using cars for travel.

Looking at the four countries chosen, the urban densities of the three major Japanese cities – Tokyo, Osaka, and Nagoya – are far larger than those of the largest cities in Australia, the US, or even the UK. Indeed, the total annual number of motorized trips within a 50 km radius of central Tokyo was only slightly higher in 2009 than in 1995, and for street travel only (public and private), was lower in 2009

than in 1995. In a 50 km radius of central Osaka, vehicular trips also declined, with the total again lower in 2009 than in 1995 (SBJ 2014).

The very high job and population densities in these Japanese cities seem to have led to a saturation level for per capita vehicular travel at low levels compared with US or Australian cities. Further, only one-third of Tokyo trips, and about two-fifths of Osaka trips, are by private car. In Japan overall, the "car ownership intensity" (cars owned – which reflects car use – per unit of Prefectural Gross Income), correlates strongly ($R^2 = 0.8$) with the share of each prefecture living at high density (Moriarty 2007). A strong case can thus be made that very high urban densities, at least, lead to higher public transport patronage and far lower car travel levels.

Higher urban densities can potentially influence urban mobility levels (and mode choice) in two ways. First, for a given income level, a higher density city can support a higher density of shops and services of all kinds, simply because, for example, the total retail expenditure per km^2 will be higher. The distance to the nearest shopping center should therefore be lower in denser cities. The problem is that urban residents today don't necessarily use their nearest shopping center. A shopping survey from the 1990s in the city of Canberra, Australia's capital city with a population of around one-third of a million, illustrates this point (ABS 1998).

Canberra, unlike other major Australian cities, was consciously planned to have a defined hierarchy of shopping centers. In order of increasing size they are local centers, group centers, and town centers. In the survey, a local center was the nearest shopping center for 69 % of the city's population, a group center for 27 %, and for a town center, only 4 %. Yet only 19 % of households overall usually did their major food and grocery shopping at their nearest center. For the majority living nearest to a local center, nearly all of which have supermarkets, the figure fell to 5 %. (Nearest centers were, however, more popular for convenience items.) These findings can only be partly explained by the fact that the larger shopping centers were often closer to their workplaces, and sometimes presumably accessed from there.

These results can probably be extended to trip types of all kinds, as well as to other cities where, like Canberra, car travel is still perceived as both convenient and cheap. In support of this point, Moriarty and Beed (1988) compared the 1981 actual average trip length (airline) for the journey to work in Australia's major cities with the minimum average trip distance possible if all residences and workplaces were fixed, but workers could freely change workplaces. They found that such a change could halve work travel. Again, proximity to workplaces is not a sufficient condition for travel reduction.

By how much could urban density increases reduce vehicular travel and thus GHG emissions? Australia's five cities of one million-plus population provide a useful case study, particularly since the data are all collected using a common format. These cities – all state capitals – vary by over a factor of two in urban density from Brisbane to Sydney (see Table 5). Yet the two densest (Sydney and Melbourne) had a slightly higher level of vehicular passenger-km per capita than the three lower density cities (Brisbane, Perth, Adelaide). However, per capita public transport travel was much higher in these denser cities.

Table 5 Personal mobility, population, urban densities, five largest Australian cities, 2011

City	Population (millions)	Car (b-pk)	Public transport (b-pk)	Vehicular travel per capita (pass-km)	Density[a] (persons/ km^2)
Sydney	4.637	50.23	7.95	12,545	2,058
Melbourne	4.208	49.40	6.02	13,170	1,532
Brisbane	2.169	24.94	2.25	12,540	918
Perth	1.865	21.40	1.64	12,355	1,090
Adelaide	1.270	12.97	0.83	10,865	1,295

For low density cities, advances in traffic engineering techniques, together with the spread of traffic to off-peak times, may be able to accommodate some rise in urban density without making congestion much worse, which could explain the lack of response in Australian cities. For the US, Greene and Schafer (2003) reported that a doubling of local population and employment densities would only give a 5 % reduction in vehicle-km traveled (Table 3).

So, at best, even doubling the urban density of the smaller, lower density cities would achieve little in the way of travel reductions. It might be objected that for low-density Australian and US cities, all the above example shows that a mere doubling of urban density is not enough. But it is one thing to have the historically very high densities of many Asian cities – up to ten times Australian and US levels – but another to try to convert historically low density cities to very high density. It would also be enormously unpopular, and would in effect replace the political resistance to policies that directly reduce car travel (discussed below) with equally unpopular policies that might indirectly reduce travel.

Urban infrastructure has a lifetime of many decades – up to 70 years for houses, and even longer for transport right-of-ways. Even if the very large density changes were possible, it would take many decades to achieve. The world may not have that long for responding effectively to the challenge of global climate change.

A final argument against such large density increases concerns GHG emission reductions overall in the economy. Transport is an important, but not the only source of, emissions. All sections of the economy, not just the transport sector, will need to undergo drastic cuts in GHG emissions. An environmentally sustainable city might need somewhat lower density living to allow for households to supply much of their water needs from rainwater tanks, at least some food (mainly fruit and vegetables) from gardens, and part of their energy from rooftop photovoltaic cells and solar water heaters (Moriarty 2002a).

Neither the patterns found for Japan's largest three cities, nor those for the 13 US major cities analysed by Newman and Kenworthy (1999) fits this Australian pattern of vehicular travel per capita being independent of city size and density. In Japan, vehicular trips per capita in 2005 still showed a small *increase* with city size and population density (SBJ 2014), perhaps reflecting the continuing importance of public transport in these cities. This trend would fit in with the Australian experience,

where in 1947, when public transport dominated vehicular travel in Australian cities, vehicular travel per capita was *higher* in the higher density cities (which were also larger in size). In the US, there is a weak trend for cities with higher densities to have lower per capita vehicular travel – the opposite of Japan's experience, but more in line with the general world trend of per capita travel falling as urban density increases.

In summary, the very high historical urban densities achieved by the cities of Japan (and other Asian countries such as South Korea and China) do form an important constraint on the level of vehicular travel possible. At the low densities of many Australian and US cities, however, politically achievable density increases might not have much effect on total travel levels, although some shift to public transport should occur. But the short time frame the world has for climate change amelioration means that policy makers will have to work with cities largely as they presently exist. Further, as will be seen in section "Reducing Travel: Lowering the Convenience of Car Travel," for many cities the changes are unnecessary; the same result can be achieved by much more rapidly implemented changes to legislation.

Reducing Travel: Raising the Overall Level of Motoring Costs

Another possible approach is to increase significantly the costs of motoring, by adding further taxes on motoring fuels, and perhaps also increasing urban parking charges. Taxing motoring fuels has the advantage of reducing both urban and nonurban travel. Already, fuel taxes differ widely in the various OECD countries. Indicative gasoline and diesel prices for the year 2013 for various OECD countries, including those with the highest and lowest prices, are shown in Table 6. Since neither feedstock costs not refining costs vary much from country to country, most of the difference is due to different fuel taxes. Within the OECD countries, both gasoline and diesel prices vary by a factor of three. Combining this data with that for recent car travel from Fig. 1 suggests that the higher fuel prices found elsewhere in the OECD compared with the US is mainly responsible for the much higher levels of per capita travel in the US.

However, comparison of Japan and the UK shows the importance of factors other than fuel prices. Recent UK per capita car travel is 66 % higher than that in Japan, despite the higher gasoline prices in the UK. Less road space per vehicle in Japan, resulting in low travel speeds, is an important factor. Car travel in Australia is in turn higher than the UK, and petrol prices are lower. But when the higher urban densities of UK cities are also considered, and the lower national road space per vehicle, it seems that unacceptably high fuel price rises would be needed in Australia to ensure sufficient mobility reductions.

Nevertheless, by raising fuel taxes to a very high level, it would be possible to reduce car travel to any desired low level, both in urban and non-urban areas – assuming political feasibility – just as it was concluded that raising urban densities to very high levels would. It would also be very inequitable, particularly in Australia and the US, as suggested by the analysis above. In both these countries, households

Table 6 Indicative 2013 gasoline and diesel prices

Country	Gasoline (super) ($/l)	Diesel ($/l)
Australia	1.61	NA
Germany	2.11	1.60
Italy	2.34	1.85
Japan	1.66	1.30
Mexico	0.91	0.78
Norway	2.59	1.86
Turkey	2.68	2.40
UK	2.09	1.84
US	0.98	1.06

Source: IEA (2013)

having access to at least one car are fairly uniformly spread over all income groups, and only around 10 % of households are noncar owning. In Australia, at least, outer suburban households have, on average, a much lower income on a per capita basis compared with inner suburban households, but higher car ownership levels. They also have greater travel needs and have inferior public transport services (Moriarty 2002a). (In lower-income countries, on the other hand, where car ownership is often under 20 per 1,000 persons (OPEC 2013), raising fuel taxes would present much less of an equity problem.)

Surveys of motorists generally show that the respondents think that raising car travel costs will not be very effective in reducing travel (Steg 2008). But the actual responses to fuel cost rises tell a different story. (However, it may be that what the respondents really mean is that they do not *like* fuel costs rises and would prefer to see other measures adopted, such as cheaper, or more extensive, public transport provision.) Evidence for the efficacy of raised fuel prices comes from the effect of price rises on gasoline sales in the years before the global financial crisis. In Australia, per capita sales of fuel for light road vehicles peaked locally in 2004, and in 2012 were still below their 2004 level (ABS 2013). Similar effects seem to have occurred in a number of other OECD countries.

The fixed costs of car travel (including depreciation, registration, and insurance costs) presently dominate the annual costs of owning and running a car. For the US, Greene and Schafer (2003) found that for a 2001 model year car, gasoline costs were only 10.2 % of the total annual costs. However, this gives a misleading impression of their actual significance to motorists. Since fuel and parking costs are usually all that motorists perceive as the costs of car travel on a day-to-day basis, altering the *structure* of motoring costs could also reduce car travel.

At present, motorists can significantly reduce their unit costs by traveling more kilometers annually. Insurance and registration fees could be recovered by raising fuel taxes and could even be done so that the overall costs of motoring did not change for the average motorist. High annual travel motorists, however, would find themselves paying more per kilometer traveled, so that, once again, lower income outer suburban households might be disadvantaged.

Road pricing is an alternative market-based approach. Road space worldwide is still largely publicly provided, and freely available to all road users, regardless of the resulting congestion. Although toll roads, many of them privately owned, are centuries old, road pricing as a means of controlling traffic levels really began with the successful scheme in Singapore in 1975. The comprehensive and successful London scheme introduced in 2003 has led to renewed interest in road pricing in many other cities. Supporters can argue that since electronic road pricing is now technically feasible, rationing road space by electronic road pricing could be an important means for keeping urban congestion to tolerable limits. But road pricing, with its emphasis on road space scarcity, can only indirectly reduce vehicular travel and emissions. It can induce motorists to shift to public transport, but its main effect is probably to redirect traffic to other times and other untolled routes or destinations.

In summary, raising motoring costs can be an effective means of reducing car travel, but in OECD countries has adverse equity considerations. With less traffic on roads, average car speeds could (and probably would) be raised, resulting in a widening gulf between the high and low mobility sections of the population. Also, given that high-income households are more time-constrained than income-constrained, their car travel would rise, with an attendant rise in GHG emissions. In effect, the burden of reducing transport emissions would fall mainly on lower-income households. As discussed in section "General Principles for Change," they would become involuntary environmentalists. Major reductions in GHGs will not occur unless all sections of the population are engaged.

Nevertheless, it is likely that fuel cost rises – perhaps large ones – are unavoidable. Following record high costs for crude oil in the first half of 2008, prices slumped to under $40/barrel, but soon recovered and since 2011 annual prices have once again averaged over US$ 100/barrel (OPEC 2014). The age of cheap oil is over – unless the global economy collapses to such an extent that oil demand is greatly lowered. Higher motoring costs thus seem inevitable, and unlike measures such as reduced speed limits, will not be seen as the fault of governments of oil-importing countries.

Reducing Travel: Lowering the Convenience of Car Travel

Section "Reducing Travel: Changing Urban Land Use Patterns" has already discussed how high urban densities potentially allow trip distances to be shortened, although for low density cities, this potential is only very partially realized. But for very high densities of residents and workplaces, as in Japanese cities, another important effect occurs: because urban congestion is inevitably at high levels, the average speed of private car travel is much reduced, which tends to both lower car travel levels and raise the relative speed and economic viability of public transport, especially rail, with its own right-of-way. This is shown by Fig. 4, which plots for 1990, per capita car travel against the average car travel speed for the same sample of world cities as in Fig. 3, most of them (37) in OECD countries. The cities with low travel speeds and annual car travel are all in Asia. Although other factors are

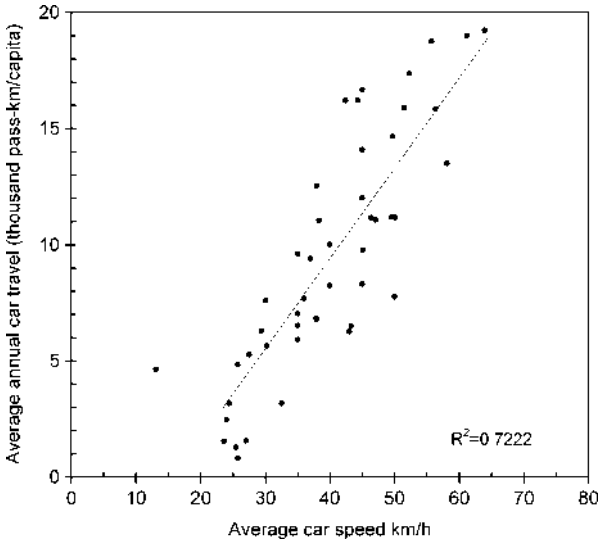

Fig. 4 Average per capita car travel versus average car speed for 46 world cities, 1990 (Source: Newman and Kenworthy 1999)

important, annual per capita car travel is clearly sensitive to average vehicle speed at least in cities.

As Table 1 showed, car travel is the overwhelming choice for surface travel not only for Australia and the US but also for the more densely populated UK. This perceived advantage of car travel over other modes arises from several causes. First, car travel, especially driving, produces psychological benefits such as mastery of the vehicle and the thrill of acceleration (Moriarty and Honnery 2005). Second, car travel allows much greater flexibility of travel: door-to-door travel at any time of the day or night, and so freedom from public transport timetables (even assuming public transport is an option). It also affords protection from the weather, greater perceived personal security, privacy from strangers, and the ability to transport much luggage. This last advantage is important for shopping and explains much of the popularity of drive-in shopping centers.

The third advantage concerns travel times. Because the extensive network of roads in most OECD cities is designed to provide vehicular access from origin to destination for almost every conceivable trip, distances by car are often shorter than by public transport (particularly fixed rail transport) for a given trip. Overall average trip travel times are also shorter by car because of higher average travel speeds; public transport has to make frequent stops to set down and pick up passengers. In general, car travel will always have an advantage over public transport modes on the first two factors discussed – it is inherent in the nature of private travel. But the third present advantage is not inherent in car travel: it results from the privileges granted to the car, such as speeding through residential areas, access to all areas of the city (usually including even the city center with its dense pedestrian traffic), and ability to park (even if a charge is made) at most locations (Moriarty and Honnery 2013).

As has been shown, in major Japanese cities where this third advantage is largely lacking, travel speeds by car are very low. The result is low vehicular travel levels overall, with rail replacing the car as the major travel mode. In Japan, such an effect has arisen "naturally"; its cities were largely formed before car travel was significant (Table 1). But given the political will, the privileges that have been given the car can be removed. Many cities in the OECD have taken tentative steps in this direction, with traffic-free central business districts, and priority for alternative travel modes, and "traffic calming" measures in residential districts.

But the city of Graz, Austria, with a population of 240,000 in the city proper, and 360,000 in the Greater Graz region, has gone furthest. In 1992, after a 2-year test period, the city imposed a 30/50 km/h speed limit on the entire road network. The 30 km/h limit was imposed on all side-roads and near centers such as schools and hospitals. These areas accounted for 80 % of the total city area. On all other roads, a 50 km/h limit was applied (European Local Transport Information Service 2008). The main purpose of the speed reductions was to improve road safety for all, but particularly pedestrians and cyclists, and to improve urban amenity. A modest reduction in the share of car travel has resulted and significant increase in cycling's share (Commission for Integrated Transport 2009).

The overall aim of policy would be to reverse the present transport priorities in OECD countries, so that non-motorized travel would be regarded as the default solution for urban trip-making, with public transport for back-up for necessary longer trips. Private vehicular travel would still be used in the transition to a low travel future, mainly in nonurban areas for longer trips difficult to service by public transport. The emphasis would be on "transport efficiency" (getting more access from each passenger-km) and less on mobility as an end in itself.

Future Directions

In this final section, the various arguments made in this chapter will be drawn together, in order to assess what policies for travel reductions would work in future in the various countries. Policies that work in cities will not always be effective in nonurban areas. Nor will policies that are successful in highly motorized countries necessarily be relevant in presently low-mobility countries. Further, the scope for vehicular travel reductions may be much smaller in congested cities like Tokyo, compared with many major cities in the US or Australia, with their far lower population and job densities.

First, an important concern when future mobility reduction policies are considered: Should the policies be voluntary, or mandated by governments? As discussed earlier, voluntary measures are easier to introduce and do not have the political costs to governments of more coercive measures. However, voluntary approaches to travel reduction have had little success. This conclusion should come as no surprise. After all, the decisive improvements in transport, from safety measures such as the installation of seat-belts and air bags, speed limits, and blood alcohol content limits, to technical environmental measures such as three-way catalytic converters, have all

been mandatory. So, of course, have been adherence to the highway code, proficiency tests and age limits for drivers, the requirement that vehicles have functioning brakes and turn indicator lights, tires with adequate tread, and so forth.

If measures are to be compulsory, what form should they take? They could involve very large changes to the monetary costs of motoring, as discussed in section "Reducing Travel: Raising the Overall Level of Motoring Costs." There, it was stressed that in highly motorized OECD countries it would prove inequitable, as reductions in motoring would mainly come from lower-income groups. Garling and Schuitema (2007) have also stressed that perceived fairness is important for public acceptability of TDM measures in general. In section "Reducing Travel: Lowering the Convenience of Car Travel," an alternative set of compulsory policies were explored. The main benefit of these approaches is that they target *all* travelers, because they change the relative travel speeds of the different modes. For many trips, EFMs would now become faster than car travel, particularly in areas closer to the city center. This loss of relative speed advantage for car travel could offset many of its inherent advantages, as already discussed.

An example from outside transport, from the authors' home city, Melbourne, illustrates these points well. Stream inflow volumes to Melbourne's water reservoirs have fallen over the past decade, while Melbourne's population has been growing rapidly (Melbourne Water 2014). Fortunately, when it became clear that reservoir levels were in sharp decline (together, they held less than 26 % of their design capacity in mid-2009), the problem was easily communicated to the public, and understood and accepted by all. So the state government was able to act fast and introduce policies to cut water use (although with recovery of reservoir levels since mid-2010, restrictions have been eased).

Of course, they were many exhortations for residents to do the "right thing" and conserve water. But ultimately the success of the program rested on the outright banning of certain categories of water use, such as car washing, for *all* residents – not by using market measures. Because the measures applied to all, their acceptance was much greater. One crucial reason why this policy could be successfully introduced can be seen by contrasting public perceptions of water shortages with that for global climate change. Unlike the disarray in opinions (at least by the public and the media) over the latter topic, which have still not abated, there were no media-promoted "Melbourne reservoir water level skeptics" to tell us that there really was plenty of water in the reservoirs or that alternatives to water would soon be available.

But what are the chances for success in introducing mandatory measures that could bring about very significant changes to travel behavior? World transport faces the twin problems of global climate change and depletion of conventional oil reserves. Climate change can be denied/avoided for a while longer – indeed, despite all the talk, international meetings, and the recently released IPCC report, this is the world's implicit response – but such a response is not an option for global oil depletion. The global annual available supply of *conventional* oil has likely peaked, and nonconventional supplies will be costly in both monetary and environmental terms and slow to develop. Oil use *per capita* peaked in 1978, and again in per capita terms has been constant from the early 1980s to the mid 2000s, but is now in slow

decline (BP 2014; UN 2014). If countries like China and India wish to increase their per capita use, it must fall in other countries if output is not raised. And given that most oil use is still in OECD countries, it is there that oil use must fall the most.

Climate scientists use the term external "external forcing" to refer to the way increased greenhouse gas concentrations are driving the planetary climate from thermal equilibrium. Given not only the strong attachment motorists presently have to their cars, but the lack of readily available and convenient alternatives to private travel, especially in the nonurban areas, it is likely that the "car culture" found in OECD countries will, in a similar manner, only change in a major way under "external forcing" of transport systems. Oil supply security issues and price rises will likely provide the initial external forcing in the future.

The Australian experience again provides a historical example of such external forcing. The only time when the fledgling car culture was seriously challenged was in 1929. Car ownership rose rapidly in the 1920s, but the Great Depression, followed by World War II and with it, gasoline rationing and the very low levels of car imports, stalled the rise of the car for two decades. Public transport patronage rose to record levels. Since then car travel has steadily increased its dominance of surface transport systems, both urban and nonurban. In recent years, however, driven by the crude oil price rises that began in the early 2000s (ABS 2013), Australia has seen not only sharp rises in public transport patronage but also a small reversal in market share (BITRE 2013). Similar gains have been recently reported for many other OECD countries, including the UK and Japan (DfT 2013; SBJ 2014).

Such rises in public transport patronage provide a benefit that can go far beyond that gained by substituting a given amount of passenger car travel by alternative (EFM) modes. In earlier papers (Moriarty and Honnery 2007, 2008a, b, 2013), the authors have advanced the idea that the dominant transport mode determines not only the modal share but also the total level of per capita vehicular travel and even the patterns of trip making. Australian historical experience suggests that the levels of vehicular travel are much lower when public transport dominates travel, as it did until the late 1940s. Consider the case of Melbourne. In 1947, public transport accounted for 80 % of vehicular travel and car travel 20 %. Yet within only 15 years, these percentages were reversed. Further, per capita travel levels today, with the car the dominant mode, are about four times those of 1947. What this demonstrates is that, under the right conditions, major transport changes can happen very fast.

Another important change was the shift in urban travel patterns. In 1947, vehicular travel in major Australian cities was strongly oriented toward the city center, since most workplaces, shopping expenditures and major centers for sports and entertainment were in the inner city area. Although many trips were local, such as visiting local shops and friends, most of these short trips were by nonmotorized means. Today, vehicular travel destinations are far more uniformly dispersed over the urban area (Moriarty and Honnery 2011). In each area of the city there is now a far better balance between workplaces and workers, shops and shoppers. Levels of personal travel *could* have been reduced, given this better balance. Instead, per capita levels rose several-fold in each of Australia's major cities. Most of this rise was for

discretionary trips such as shopping or social trips, rather than for nondiscretionary work or education trips. Overall, the suburbanization of many activities means that nonmotorized travel can now take over a large share of trips.

In urban areas of OECD countries, *localization* of activities will be increasingly needed. Residents will need to work, shop, recreate, and socialize more and more at the local level. This localization will in turn require both local areas to be more attractive, and residents to develop a "sense of place" and a sense of belonging. Urban planners will have to start thinking creatively about how to design areas for humans, rather than focusing mainly on traffic flow, the current preoccupation; urban planning is not reducible to traffic planning. The changes will also need to be implemented very quickly, as time is important if countries are to greatly cut not only transport's contribution to climate change but also oil consumption. As already mentioned, it is likely that impending oil shortages could act as a catalyst for necessary changes, forcing the public to realize that change is unavoidable and making their acceptance more likely.

Transport GHG reductions through personal travel reduction are different from other resource-using sectors in that synergistic effects come into play to a far greater extent than is possible elsewhere. Individuals can readily reduce their use of domestic energy or water use, even if their neighbours don't. Conversely, if the entire neighbourhood cuts its water use, it doesn't much help an individual household in the neighborhood reduce its own water use (except through peer pressure). But if, as advocated here, local shopping centers are used more intensively, the range of goods and services offered for sale will improve, most likely at the expense of the presently popular, drive-in centers. If public transport patronage rises greatly, service frequency will also rise and probably also service coverage. The latter could initially occur using buses, but in the longer term could be replaced by fixed-rail transport, if patronage justified it. For transport, government intervention will be crucial for success in changing to a new transport "logic."

How crises such as global climate change or oil depletion get interpreted is important for policy responses. However, while many people recognize as severe the challenges posed by oil depletion and global climate change, there are many others who don't see a problem, or if they do, think that one or more of a variety of tech fixes will solve these twin problems, without the need to resort to potentially unpopular measures such as mobility reductions. Policies promoting tech fixes are thus more likely to be tried first, and only when acknowledged to be inadequate, will the more fundamental changes advocated here be adopted.

This finally gives rise to another important question: whether incremental changes (such as the ongoing research and development of "green cars") will really help the move to an environmentally sustainable transport system. In section "Introduction: Travel Reductions for Climate Mitigation," it was shown how far reaching are the changes needed for OECD passenger transport. An analogy can help here: to get a couple of meters closer to the Moon, leaning a ladder against the back shed will suffice, but it is a dead-end approach for much closer approaches to the Moon. For that, a rocket must be built. However, other incremental approaches provide a very good fit to deeper change, including efforts to to make urban destinations more

accessible by active modes or to move people onto public transport. It is here that policy makers should focus their efforts in the interim period before more coercive policies must inevitably be introduced.

Acknowledgments Patrick Moriarty acknowledges the financial support of the Australasian Center for the Governance and Management of Urban Transport (GAMUT) for the research which underpins this book chapter. GAMUT is in turn funded by the Volvo Research and Education Foundations. He would also like to thank the Maintenance Technology Institute in the Department of Mechanical and Aerospace Engineering and the Department of Design, both at Monash University, for providing him with accomodation during the writing of this book chapter.

Nontechnical Aspects of Household Energy Reductions

Patrick Moriarty and Damon Honnery

Contents

Abstract

Domestic energy forms a significant part of total energy use in OECD countries, accounting for 22 % in the USA in 2011. Together with private travel, domestic energy reductions are one of the few ways that households can directly reduce their greenhouse gas emissions. Although domestic energy costs form a minor part of average household expenditure, the unit costs for domestic electricity and natural gas vary by a factor of 4 and 5, respectively, among OECD countries, and per capita use is strongly influenced by these costs. Other influences on domestic energy use are household income, household size, residence type (apartment/flat vs. detached house), and regional climate. Numerous campaigns have been carried out in various countries to reduce household energy use. A large literature

has analyzed both the results of these studies and the general psychology of pro-environmental behavior, yet the findings often seem to conflict with the national statistical data.

The authors argue that the rising frequency of extreme weather events (especially heat waves, storms, and floods), together with sea level rises, is likely to be a key factors in getting both the public and policy makers to treat global climate change as a matter of urgency. Costs of domestic energy are likely to rise in the future, possibly because of carbon taxes. But such taxes will need to be supplemented by other policies that not only encourage the use of more efficient energy-consuming appliances but also unambiguously support energy and emission reductions in all sectors.

Introduction

In 2011, world CO_2 emissions from energy and industry totalled 33.74 gigatonnes (Gt) (BP 2014). (A gigatonne = 10^{18} tonnes.) For the USA alone in 2011, total emissions were 5.5 Gt of CO_2, resulting from total energy use of 102.5 EJ (EJ = exajoule = 10^{18} J).

Of this total US energy, household energy use accounted for 22.6 EJ or 22.0 %, compared with 18.6 %, 31.4 %, and 28.0 % for the commercial, industry, and transportation sectors, respectively. The US Energy Information Administration (EIA) projects that domestic energy use in the USA will grow only slowly over the period 2012–2040, at an average of only 0.2 % per year (EIA 2014).

Along with private transport, cutting energy use at the household level is an important way for individuals to directly reduce their carbon footprint. (In this chapter, the terms "household energy use" and "domestic energy use" are used interchangeably.) Two possible approaches for reducing domestic energy consumption are, first, to encourage the purchase and use of domestic energy-using devices (see also chapter "► Energy Efficiency: Comparison of Different Systems and Technologies" in this handbook) and, second, by reducing the use of such devices. This could involve having fewer appliances (e.g., dispensing with second refrigerators in the household), running energy devices for fewer hours (e.g., turning off lights), or running at a lower setting (e.g., lowering thermostat settings in winter). This second approach to energy reductions is more important for household energy use than for either commercial buildings or industry, because for both of these sectors, energy costs are likely to be monitored more closely and policies for energy reduction, both technical and nontechnical, more readily implemented for purely economic reasons. Nevertheless, considerable scope still remains for both industry and commercial buildings to adopt these practices.

There is a further reason for a focus on domestic energy use. In many Organisation for Economic Co-operation and Development (OECD) countries in recent years, total primary energy use per capita, or even total primary energy use, has fallen (BP 2014). In the UK, for instance, total energy use has not risen for four decades, and total CO_2 emissions from fossil fuels peaked in 1970 and are now 26.5 % lower than the peak value. The problem is that recent decades have also seen the rise in imports to the OECD of energy- and CO_2-intensive manufactured products from Asia. As Davis and Caldeira (2010) show, such *embodied* CO_2 and energy can make a big difference to national emissions and energy statistics and render problematic the interpretation of energy time series data. Because domestic energy statistics only measure energy *used* by household equipment and not the embodied energy in the equipment, this problem is avoided.

This chapter is structured as follows. Section "Factors Affecting Domestic Energy Consumption" looks at patterns of domestic energy use in various selected OECD countries. Domestic energy prices, household income, household size, and climate were all found to be important for present domestic energy use. (In this chapter, the terms energy reductions and CO_2 reductions are used interchangeably, since, at the household level, energy reductions are – apart from rooftop solar devices and switching to gas from electricity for space and water heating – the only means available to reduce CO_2 emissions.) In section "Strategies for Household Energy Reductions," the numerous studies and field trials on reducing household energy use are reviewed. Researchers have looked at the effect of parameters such as income level, gender, age, and ethnicity on responsiveness to campaigns for energy reductions. The latest studies have concluded that significant energy reductions are

possible, but stressed that households face many barriers to reductions, including lack of relevant information. Building on the energy cost data in the previous section, the authors stress the importance of future carbon taxes for motivating energy reductions. In section "Future Directions," the possibility for conflicts between household energy savings and overall global climate change mitigation (or adaptation) is examined.

Factors Affecting Domestic Energy Consumption

Table 1 shows domestic energy consumption by end use for the USA for year 2011. Over half the energy use is for space heating and cooling (with the UK having a similar proportion (Steg 2008)), with almost one-fifth for water heating and refrigeration/freezers. Since 1993, the share for space heating has fallen, and the shares for both space cooling and appliances have risen (EIA 2013). Energy for space heating in the USA overall is expected to fall out to the year 2040, for space cooling to continue to increase (EIA 2014). Although space heating presently uses almost six times as much energy as space cooling in the USA overall, this ratio varies with regional climate. Households in colder climates spend a higher share of their total expenditure on fuel because of high winter fuel bills, which more than compensates for lower need for space cooling in the warmer months. In Australia, for example, in subtropical Brisbane (27° 30′ S), the figure is 2.1 %, compared with 3.5 % for temperate Hobart (43° S) (Australian Bureau of Statistics (ABS) 2012).

In OECD countries, nearly all of this domestic energy is supplied by reticulated electricity and natural gas. Table 2 shows the unit prices of these two domestic energy sources for 2012 for a number of OECD countries, including both the major economies and those with either very high or very low energy costs. The unit costs for domestic electricity and natural gas vary by a factor of 4 and 5, respectively, among OECD countries, with Mexico, one of the lowest-income OECD countries,

Table 1 Domestic energy use by function for the USA, 2011

having the lowest unit costs. The different costs have a large impact on domestic energy use. Comparing the USA and Japan, the much higher costs for domestic energy in Japan (2.3 times that of US electricity costs; see Table 2) coincide with a 3.5-fold reduction in domestic energy per capita (EIA 2014; Statistics Bureau Japan (SBJ) 2014). Only a small part of this difference can be explained by the 9.3 % higher gross national income (GNI)/capita reported for the USA (Table 2). Further, the slightly larger average household size in the USA compared with Japan (about 2.5 and 2.4 occupants, respectively) should, if anything, lower per capita domestic energy use. Similarly, the high-income, high-energy cost European countries (Denmark, Germany, and Sweden in Table 2) have much lower per capita domestic energy use than the USA. Further, the increase in domestic energy prices in the UK was seen as a partial explanation for the decrease in domestic energy use between 2005 and 2011 in England and Wales (Office for National Statistics (ONS) 2013).

The burden of domestic energy costs depends not only on unit prices but also on income level. As expected, the share of household expenditure spent on domestic energy declines for the higher-income quintiles (Table 3). However, higher-income

households also have more persons per household (ABS 2012; ONS 2013; EIA 2014; SBJ 2014), so it may be that the greater energy efficiency possible with larger households explains some or all of the decrease. The UK statistics also measure domestic energy costs for quintiles ranked on an "equivalised disposable income," which adjusts for the number of persons per household (with, e.g., two adults counting as one unit, but two adults plus two children counting for 1.4 units) (ONS 2014). This 2012 UK data shows that, after such adjustment for size, the poorest fifth of households spent 10.9 % of their disposable income on domestic fuel, compared with only 2.8 % for the wealthiest quintile – nearly a fourfold difference. For both quintiles, the share of disposable household income spent on domestic fuel had risen since 2002 (from 8.0 % for lowest and from 1.7 % for highest), even though average domestic energy use in the UK had fallen by 17 % over the decade. Nevertheless, in absolute terms, the highest-income quintile spent more on domestic energy (and produced more CO_2 emissions) than the lowest-income quintile, and the same was true for gross expenditure on domestic energy in Japan and Australia (see Table 3).

Energy use in households also varies with housing type. A 2008 UK study (Druckman and Jackson 2008) found that those living mainly in flats ("city living") had a much lower share of weekly expenditure on energy than "countryside" residents, mainly living in detached houses. An earlier study in Australia (Moriarty 2002) found that inner-city residents of Melbourne and Sydney, with a high share of residents living in flats, spent a lower share of disposable income on household fuel than outer suburban residents or nonurban residents, both groups mainly living in detached houses. Along the same lines, a Canadian study (Larivière and Lafrance 1999) measured the residential electricity consumption of Québec's 45 most populous cities and towns and found that the per capita energy rose as the share of single dwellings increased. This result would be expected if electric power was an important form of heating in a cold climate.

The size of the residence (in square meters (m^2)) is also an important factor, particularly for domestic heating and cooling. It helps explain some of the large difference between US and Japanese energy use. In the USA in 2011, average residence size was 154.5 m^2, compared with only 94.1 m^2 for Japan overall and as low as 63.9 m^2 for Tokyo prefecture (2008 values, the latest available) (EIA 2014; SBJ 2014). The high population density of Japan and the resulting high land prices explain much of this difference. Other important differences are in both ownership and average size of appliances. For example, in Japan in 2009, only 27 % of households of two persons or more owned dishwashers; in the USA in 2009, the corresponding figure was 64 %. Also, both the number of refrigerators per 1,000 households and their average capacity were larger in the USA (EIA 2013; SBJ 2014).

The *behavior* of the occupants has also been found to be crucial. A British study (Pilkington et al. 2011) examined space heating demands in "a terrace of six similar, passive solar dwellings with sunspaces." Space heating demand per occupant was found to vary by a factor of 14. This finding clearly indicates both that behavioral factors are important for domestic energy use and also that considerable potential

exists for energy reductions. Further evidence comes from a study of 3,400 German homes: Sunikka-Blank and Galvin (2012) again found that dwellings with the same energy performance rating (EPR) varied widely in space heating energy use. (The EPR, measured in kWh/m^2 per year, assesses the overall energy efficiency of a building, either using actual or modeled energy use data (Corrado and Mechri 2009).) But they also found that (energy inefficient) dwellings with high EPR ratings consumed much *less* energy than calculated, while the reverse was true for low EPR (energy efficient) dwellings. Similar results appeared to hold for several other EU countries. They concluded that the potential energy savings from changes to occupant behavior may be far greater than assumed. Section "Strategies for Household Energy Reductions" looks further at this potential.

Strategies for Household Energy Reductions

Domestic energy reductions rely on far fewer policy options than are available for reducing household private travel energy. In addition to legislation on vehicular fuel efficiency (see also chapter "► Reducing Personal Mobility for Climate Change Mitigation"), authorities can also influence the *levels* of private travel (in vehicle-km) by measures such as street closures in the inner city, speed limit reductions, priority for public transport and nonmotorized modes, limits on availability of parking spaces, road pricing as in London and Singapore, reduced arterial road construction in urban areas, provision of improved public transport, as well as increased charges for parking and taxes on transport fuels. Authorities can implement these measures because most of the road systems, and often the public transport systems, are publicly owned. A further limit on the capacity of regulations to drive change is the much longer lifetimes of housing stock relative to road vehicles.

Apart from increasing fuel costs, these policy levers are not available for reducing domestic energy use. As with road vehicle efficiency, governments can legislate the use of energy-efficient light globes and establish energy ratings for domestic appliances and minimum insulation standards for new buildings. But too much intervention in the domestic sphere would meet strong popular resistance. Because of this, authorities must rely far more on voluntary behavior change (and domestic energy cost increases) for reducing domestic energy use than in other areas of energy use.

Nevertheless, domestic energy conservation has at least one important advantage over travel energy conservation. It is very difficult for individual households to reduce car travel if other households do not, particularly for countries like the USA, where car travel accounts for over 90 % of all surface vehicular travel. Even if car travel is reduced as a result of a campaign, households will usually soon relapse back to former practices, since car travel is usually faster than other modes. On the other hand, individual households can make domestic energy reductions even if others do not. This section first reviews the extensive social psychology literature (see section "Social Psychology and Pro-environmental Behavior") on pro-environmental behavior (PEB), particularly the importance of information provision (see section

"The Role of Information Provision") before examining the role of carbon taxes (see section "The Role of Monetary Approaches and Carbon Taxes") and, finally, the context for energy conservation (see section "The Context for Domestic Energy Conservation").

Social Psychology and Pro-environmental Behavior

A vast literature is now available on the application of social psychology to energy conservation, and pro-environmental behavior in general, together with policy recommendations. According to Dietz (2014), "modest policies" aimed at raising the efficiency of US household energy consumption (presently 22 % of total energy) could reduce overall CO_2 emissions in the USA by 7 %. Surveys in OECD countries have consistently found that the public regard protecting the environment and saving energy as important (Steg 2008; Booth 2009). Obviously, it is not how people respond to surveys about PEB (i.e., their stated attitudes toward the environment and energy conservation) that is important but whether or not households do in fact reduce their energy use and whether any such reductions continue in the long term. For as Dietz (2014) has also stressed, few studies with a social psychology approach are able to study actual environmental behavior, as distinct from *stated* intentions. A 2010 survey of energy use in Hungarian households has shown how stated intentions and actual behavior can differ. The survey of over 1,000 people found that those who "consciously act in a pro-environmental way" did not necessarily use less residential energy than respondents who did not exhibit PEB (Tabi 2013).

Much of the social psychology literature on PEB has concentrated on individual attributes. Jagers et al. (2014) found that 21 % of the respondents in a Swedish survey met the requirements for "ecological citizenship." Their conclusions found support for a strong relationship between ecological citizenship and PEB: "Our results suggest that *individuals who think along the lines of ecological citizenship are more likely than others to behave in an environmentally friendly way in their daily lives*." Yet PEB was measured by response to items such as "try to save household electricity" rather than comparing actual household electricity use with other householders; hence, pro-environmental attitudes rather than actual pro-environmental behavior were being measured.

Gifford and Nilsson (2014) have recently reviewed the various "personal and social factors that influence pro-environmental concern and behavior." We discuss here some of their findings relevant to methods for reducing household energy use. In general, survey respondents with more knowledge about environmental problems indicated greater overall environmental concern. (The role of information is discussed in more detail in section "The Role of Information Provision.) Interestingly, older people generally reported higher pro-environmental behavior than younger people and women more than men. Not only did the authors report that environmentalists "tend to be middle- or upper-middle-class individuals" but, at the national level, "environmental concern has a clear positive relation with gross domestic product (GDP) per capita."

Yet, as we have seen in section "Factors Affecting Domestic Energy Consumption," the higher-income quintiles in OECD countries have higher domestic energy use per household, and, globally, the OECD and other high-income countries have much higher primary energy use and CO_2 emissions per capita than low-income countries (IEA 2013b). Residents of low-income households and countries could thus be regarded as "involuntary environmentalists" (see Moriarty and Honnery 2012): their low incomes constrain their energy use and carbon emissions. Further, survey results are usually only given as percentage reductions, ignoring the fact that low-income households already use much less energy than the average. But in the USA, a recent study (Bohr 2014) found that income effects on belief about the reality of climate change were mediated by political beliefs. Briefly, lower-income Republicans regarded climate change as a more serious issue than higher-income Republicans, but the reverse was found true for Democrats. Clearly, one needs to be careful in evaluating the transfer of social psychology findings to the national energy policy domain.

A related point is the choice of *incentives* for promoting PEB. One fairly consistent result in the published literature is the apparent superiority of nonmonetary over monetary rewards. Steg (2008) has argued that domestic energy conservation is best served by appealing to normative and environmental values, because they provide a more enduring basis for change than ones which maximize personal interests, such as cost savings. If, for example, cost reductions disappear, then so will the conservation behavior, if formed on that basis. Overall, this view can be summed up by arguing that "green" reasons for change are superior to "mean" reasons (de Groot and Steg 2009). Dietz (2014) simply stated that "self-interest is only one of several values that underpin environmental decision making."

Turaga et al. (2010) reached similar conclusions and stated that the empirical evidence suggested that PEB was more likely for people whose "core values" could be described as "social altruistic" and/or "biospheric". Of course, this still leaves the problem of how to promote PEB in householders whose behavior is more in line with *homo economicus*. These researchers also warned that government policies might crowd out motivations for altruistic behavior. They thus stress the need to create "carefully structured institutions." The question of monetary incentives in the real world is, however, not so simple and is discussed in greater detail in section "The Role of Monetary Approaches and Carbon Taxes".

Steg (2008), looking specifically at domestic energy conservation, reported three *barriers* to conservation. The first barrier was that many households do not have sufficient knowledge of means to effectively reduce their energy consumption, as discussed in section "The Role of Information Provision." The second was the low-priority households attach to reducing energy use. As discussed in section "Factors Affecting Domestic Energy Consumption," domestic energy is typically only of the order of 5 % of household expenditure, although a higher proportion for low-income households. The third barrier was the high costs for some energy-saving strategies, particularly if it involved the purchase of more energy-efficient appliances. She reported that two general strategies can be used to reduce household energy use. First, use psychological insights to change householders' "knowledge,

perceptions, motivation, cognitions, and norms related to energy use and conservation." Second, alter the *context* in which energy use decisions are made; this important topic is treated in detail in section "The Context for Domestic Energy Conservation."

"Social marketing" has become popular as a means of changing people's attitudes and behavior on environmental issues. As defined by Corner and Randall (2011), social marketing "is the systematic application of marketing concepts and techniques to achieve specific behavioural goals relevant to the social good." Their study is a critique of the application of social marketing techniques in the UK to engage the public more fully on climate change. The study showed that the approach may in some circumstances be effective, particularly for encouraging PEB that needs only minor lifestyle changes, such as recycling household waste. However, given the scope of overall CO_2 reductions needed by the UK and other high-emitting countries, social marketing for carbon reductions appeared to be less effective, and some of the approaches tried were even counterproductive. One particular problem was that attempting to tailor messages to individual groups may lead to compromises that negatively impact PEB in the longer term and in other domains. In other words, it is risky to consider the various environmental problems (and even non-environmental problems) in isolation.

A complication of this type arises from what social psychologists term "moral licensing." According to Merritt et al. (2011), moral licensing "occurs when past moral behavior makes people more likely to do potentially immoral things without worrying about feeling or appearing immoral." Tiefenbeck et al. (2013) carried out a field experiment in 154 households of a 200-apartment complex in Greater Boston in the USA. The study examined the effect of a household water conservation program on electricity consumption. "The results show that residents who received weekly feedback on their water consumption lowered their water use (6.0 % on average), but at the same time increased their electricity consumption by 5.6 % compared with control subjects." They concluded that such moral licensing "can more than offset the benefits of focused energy efficiency campaigns, at least in the short-term." In some ways, this effect is similar to the well-known concept of "energy rebound," where improving energy efficiency makes the operation of energy-using devices cheaper, thus leading either to some increased use of such devices or using the money saved for other (energy-using) goods and services.

The Role of Information Provision

It seems intuitive that households need accurate information on both energy costs and energy use of specific household equipment. Studies have shown that there is indeed an information gap. Attari et al. (2010) conducted a nationwide US survey on estimated energy savings from such actions as turning off lights or replacing existing lights by more efficient ones. They concluded that "For a sample of 15 activities, participants underestimated energy use and savings by a factor of 2.8 on average, with small overestimates for low-energy activities and large underestimates for high-

energy activities." Householders may simply think that the unit energy consumption of an appliance is simply related to its size (Steg 2008). Correcting this bias would seem essential for domestic energy decision-making.

At least one government agency (the Office for National Statistics in the UK) saw better information as partly responsible for the observed declines in UK household energy use in recent years. The list of possible explanatory factors for household natural gas and electricity reductions included technical efficiency measures such as better cavity wall insulation and "improved efficiency of gas boilers and condensing boilers to supply properties with both hot water and central heating," as well as continuous rises in the price of domestic gas and electricity after the mid-2000s (ONS 2013). But they also saw the provision of better information to households as important, specifically the "introduction of energy rating scales for properties and household appliances, allowing consumers to make informed decisions about their purchases" and "generally increasing public awareness of energy consumption and environmental issues." But as the following discussion documents, simply providing more information can have unexpected effects on energy use.

The rise of the new information technology (IT) has greatly enlarged the scope for providing data on domestic energy use to households. There is now a growing literature on intelligent or smart cities and smart houses. Cook (2012) has described possible future houses equipped with a vast number of sensors ("ambient intelligence") to automatically adjust temperature and lighting levels, for example. A barrier to the realization of such smart houses is the privacy issue. But even if the privacy issue could be overcome, there are doubts about the extent of energy savings possible with such information provision alone. An Irish study (McCoy and Lyons 2014) reported the results of a controlled trial of 2,500 electricity consumers. Householders were supplied with smart meters which gave them detailed information on usage. They found that electricity use fell as expected, but compared to the control group, these householders invested less on energy-saving equipment. The authors speculated that householders might realize that conservation measures can be an alternative to energy efficiency investments. In other words, energy conservation and energy efficiency measures may not always be complementary measures, as is often assumed.

Delmas et al. (2013) performed a meta-analysis on 156 published "information-based energy conservation experiments" conducted over the period 1975–2012. The studies focused on household electricity savings. The type of information provided in the various experiments included items such as tips on how to save energy and the provision of detailed data on own energy use or that of peers. From these experiments, they found average measured savings in electricity use of 7.4 %. However, the savings found depended greatly on the type of information provided. The authors concluded that "strategies providing individualized audits and consulting are comparatively more effective for conservation behavior than strategies that provide historical, peer comparison energy feedback." They also reported potential problems with information campaigns, in that feedback on costs and monetary incentives led to relative *increases* in household electricity use.

Another recent study from the USA (Gromet et al. 2013) provided further evidence that simply giving more information will not necessarily encourage PEB in householders. In one study, they compared responses of self-identified political liberals with self-identified political conservatives. They showed that conservatives were *less* likely to buy more expensive but also more energy-efficient light bulbs if they were labeled as being good for the environment than if they were not so labeled. Responses were reversed for liberals. The researchers believed that "the political polarization surrounding environmental issues" in the USA was the explanation for their unexpected findings. This finding may not therefore be applicable to other OECD countries: in the EU, several conservative governments support deep cuts to CO_2 emissions.

The Role of Monetary Approaches and Carbon Taxes

One government policy often mentioned as both an important and necessary part of any carbon reduction strategy in all sectors of the economy is carbon taxes (Van Vuuren et al. 2011a). The European Union (EU) already has an emissions trading scheme (ETS), although the prices in 2013 were at historically low levels. Given that every tonne of CO_2 emitted, regardless of location, has the same climate effect, a global carbon market would be preferable. At present, though, apart from the multinational regional EU market, existing carbon markets are either national or even subnational (Newell et al. 2014). But reliance on market-based incentives can be criticized because it can (and has) led to abuses, particularly the "reducing emissions from deforestation and forest degradation" (REDD) scheme of the UN Framework Convention on Climate Change (Moriarty and Honnery 2011).

Nevertheless, such carbon taxes are sometimes regarded as providing motivation for domestic energy use reductions. Certainly, the cross-country evidence presented in section "Factors Affecting Domestic Energy Consumption" on domestic energy costs suggests that monetary considerations are important for energy use. The IPCC estimated that after 2050, carbon taxes required to meet Representative Concentration Pathway 2.6 (RCP2.6) target would need to be as high as $250 per tonne CO_2 (Van Vuuren et al. 2011b). Here, we provide a rough estimate of the effect such a tax would have on lower end OECD domestic electricity prices. In recent years, electricity generation in OECD countries overall has led to emissions of 0.434 tonne CO_2/MWh (IEA 2013a). At $250 per tonne CO_2, this works out as $108.5/MWh. From Table 2, this value would roughly double domestic electricity prices in Mexico and the USA.

An important question is whether such carbon taxes would be regressive. Dissou and Siddiqu (2014) have argued that they need not be, if seen in the context of a comprehensive analysis. They argued that "Most studies have assessed the distributional impact of carbon taxes through their effects on commodity prices alone, while ignoring their impact on individual welfare brought about by changes in factor prices." They found a U-shaped curve for income inequality (as measured by the Gini coefficient) when plotted against the level of carbon tax. Although maximum

income equity was found at a tax of about $50, a zero tax had about the same equity effect as one of over $100 per tonne CO_2. Nevertheless, a tax rate of $250 per tonne CO_2 would substantially increase inequality.

However, a carbon tax is not the only way of reducing emissions by monetary means. Starkey (2012) examined the equity effects of "personal carbon trading" (PCT). In this UK proposal, every adult would receive for free an equal carbon quota, with the sum of these quotas amounting to perhaps 40 % of total allowable national emissions. The author compared this proposal with other emission reduction schemes, including a carbon tax, and showed that these other schemes can be designed to be as equitable as any PCT one. Another possible approach is to alter the *structure* of domestic energy costs, with lower fixed costs on energy bills and higher unit costs for energy use. This change could be revenue neutral overall, but, again, its equity implications would need to be evaluated for each country. Future price rises for fossil fuels are likely inevitable; policies will have to be designed to ensure that lower-income households, who already pay a higher share of household income for domestic energy, are not be further disadvantaged.

The level of carbon tax necessary will depend on the costs of either replacing fossil fuels by nonfossil alternatives (renewable and nuclear energy) or the costs of various carbon sequestration methods. The latter include biological sequestration in plants (especially forests) and in soils and also mechanical sequestration techniques such as capturing CO_2 from the flue stacks of fossil fuel electricity plants, followed by compression, transport, and geological burial (Van Vuuren et al. 2011b; Moriarty and Honnery 2011). For details, see also chapter "▶ Reducing Greenhouse Gas Emissions with CO_2 Capture and Geological Storage" in this handbook. A recent study (Marshall 2013) found an extremely broad range of both the unit costs of various carbon sequestration methods – from $10 to $2,000/tonne CO_2 sequestered – and global potential (in Gt CO_2).

Of course, imposing such high carbon taxes would be unwarranted if it could be shown that the costs of climate *adaptation* (again, measured in $ per tonne of CO_2 or equivalent) were much smaller. Some economists have argued that the global economic costs of a 2 °C temperature rise will be small, and an official US estimate was that the "social cost of carbon" (SCC) was $37 per tonne of CO_2 emitted. However, these and similar results derived from economic models have been heavily criticized (Revesz et al. 2014). In any case, integrated climate models show that climate costs will rise in a nonlinear fashion as temperature rises beyond the nominal 2 °C "safe limit." Ackerman and Stanton (2012) have thus argued that the SCC could easily be an order of magnitude higher or, given certain assumptions, even infinite.

The Context for Domestic Energy Conservation

What will induce households, as well as policy makers, to take climate mitigation seriously? At present, despite the high profile of the climate change problem over the past two to three decades in both the press and scholarly publications, there has been

no real progress in mitigation: in 2013, emissions from fossil fuels were 2.1 % higher than in 2012 (BP 2014). Possible reasons for such climate inaction could include pressure from fossil fuel-based industries and energy-exporting countries, skepticism about the reality of global warming, and belief in the efficacy of future technical fixes such as aerosol geoengineering to painlessly solve the problem (see also chapter "▶ Geoengineering for Climate Stabilization" in this handbook). Interestingly, the Asian OECD countries (Japan and South Korea) both report very high levels of belief in the reality of global warming (Wikipedia 2014) and have insignificant fossil fuel reserves (BP 2014).

The Intergovernmental Panel on Climate Change (IPCC) (Stocker et al. 2013), in its latest report (Fifth Assessment Report (AR5)), warned that the world will increasingly face greater extremes in climate, particularly in the form of heat waves and high-intensity precipitation. Over the past century, global mean temperature has risen less than 1.0 °C, yet in temperate climates, daily variation can be 20 °C or more. Such variation makes it difficult for laypersons to feel the urgency that climate scientists feel. But already, recent heat waves in Europe and elsewhere have led to tens of thousands of excess deaths (Moriarty and Honnery 2014). Climate scientists speak of *climate forcing* (or radiative forcing, in watts per square meter) from GHGs. Analogously, it can be expected that the spread of extreme weather events, both in intensity and frequency, will provide the forcing for both the public and their policy makers in all countries to take decisive action on climate mitigation, although intense arguments will continue regarding the sharing of emission reductions between countries.

On the other hand, there is a disconnection between national costs for climate mitigation and benefits accruing to the same nation (Moriarty and Honnery 2014). Climate mitigation is an example of a global public good; these tend to be undersupplied by market economies. In contrast, most of the health benefits from reducing local air pollution in a city will accrue to that city. The problem would have been less serious when the OECD countries both had the highest per capita emissions of CO_2 *and* accounted for most of the global emissions. In 1965, the OECD produced 68.3 % of fossil fuel CO_2; in 2012, even a much enlarged OECD accounted for only 40.3 % (BP 2014). The urgent need for countries like China and India, still with relatively low emissions per capita, but large total emissions, to reduce their emission levels, will complicate popular acceptance of deep emission reductions in the OECD.

Another factor that must impact ordinary citizens' perception of both the need for reducing fossil fuel use and acceptance of high domestic fossil fuel energy prices is national fossil fuel reserve estimates. One set of reserve estimates, those of BP (2014), is shown in Table 4. Countries like Denmark, Japan, South Korea, and Sweden have negligible amounts of fossil fuels. German reserves are almost all low-quality lignite, which produces high CO_2 emissions per unit of delivered energy – an embarrassment for a country striving for "green" credibility. Even the UK, once the world leader in coal production, and, until recently, an important natural gas (NG) and oil producer, finds itself today with only a few years' reserves of all three fuels at their current production rates.

Table 4 Fossil fuel reserve estimates at the end of 2012 for various OECD countries, in EJ

Country	Oil	NG	Coal	All fossil fuels
Australia	22.3	143.2	1584.0	1749.4
Canada	993.2	75.4	141.0	1209.5
Denmark	4.0	1.5	2.6[a]	8.1
Germany	1.5	2.3	569.4	573.2
Japan	0.3	0.0	9.7	10.0
Mexico	65.1	15.1	28.9	109.1
South Korea	0.0	0.2	1.8	2.0
Sweden	0.0	0.0	0.0	0.0
UK	17.7	7.5	6.4	31.7
USA	199.9	320.3	4825.9	5346.0
World	9531.3	7058.0	17665.0	34254.3

Source: BP 2014
[a]In Greenland

Most fossil fuels used in these countries are thus imported, and so these importing countries are increasingly dependent on the continued goodwill of both oil- and NG-exporting countries. Restrictions on both oil and gas exports have been used for political purposes. In the USA, in contrast, the public is being led to believe that shale gas (and even shale oil) will lead once again to oil and gas independence for the USA. The *context* in which appeals to the public to conserve energy are made in OECD Europe or Asia, compared with fossil fuel-rich North America or Australia, is thus very different.

Future Directions

One important consideration for both future climate change mitigation and adaptation is to ensure that actions taken at the local level (such as an urban area) do not conflict with actions needed at the global level. Similarly, local actions for climate mitigation or adaptation must not conflict with policies needed for ecological sustainability in general.

One proposal for climate change mitigation is to paint urban building roofs (and even roads) with reflecting paint, in order to increase their albedo – the share of insolation that is reflected directly back into space (Royal Society 2009). Unlike most other geoengineering proposals, such roof whitening should meet with little international opposition, since the actions involved are clearly on national territory. It would also represent a means for households to directly mitigate climate change without reducing domestic energy use. And unlike most climate mitigation measures, most of the temperature reduction benefits would accrue to the urban area concerned (see also chapter "▶ Geoengineering for Climate Stabilization" in this handbook).

However, a recent study (Jacobsen and ten Hoeve 2012) modeled both local and global climate effects. The study found that although local temperature reductions

would indeed occur, the global effect would be a modest temperature increase. Even if different climate models were to give different results, the study illustrates the importance of such potential conflicts. A further problem is that "cool roofs" will reduce winter as well as summer temperatures, both inside and outside buildings. In temperate climates, domestic heating energy needs will therefore rise. Another study of reflective pavements (Yang et al. 2013) also found a similar unintended consequence: "reflected radiation from high-albedo pavements can increase the temperature of nearby walls and buildings, increasing the cooling load of the surrounding built environment and increasing the heat discomfort of pedestrians."

In section "Factors Affecting Domestic Energy Consumption," it was found that residents of apartment blocks, and higher urban density living in general, reduced household energy consumption. Increasing the residential density of cities might therefore appear as a way to lower energy use and carbon emissions. Further, increased urban density has also been promoted as a means of reducing urban car travel and their associated emissions (Moriarty and Honnery 2013). However, several possible conflicts arise. First, higher-density living might interfere with the ability to use passive solar energy for temperature control and natural lighting (Steemers 2003). Second, it might reduce the potential for individual households to use PV (photovoltaic) roof panels or solar hot water systems or, in low rainfall regions, tanks for rainwater storage. One also needs to consider the effect of urban density on the urban heat island (UHI) effect. Of course, reduction in household energy use will reduce urban waste heat, which is one component of the UHI effect. But according to Kleerekoper et al. (2012), a more important cause is the "urban canyon" effect, which prevents escape of radiant heat, and impervious surfaces, which prevent evaporative cooling. Both are likely to be more important in densely built-up urban areas.

This chapter has shown that deep reductions in household energy and thus CO_2 emissions will require a variety of compatible policies. The national statistical data presented in sections "Factors Affecting Domestic Energy Consumption" and "Strategies for Household Energy Reductions" showed that household domestic energy use is lowest in countries with low fossil fuel reserves; these countries also usually have higher prices for domestic energy use. Public support for decisive action on climate change varies from country to country and even in one country from month to month. However, the rise in frequency of extreme weather events – heat waves, storms, and floods – together with rising sea levels, is likely to increase support for action in all countries.

The review of domestic energy conservation campaigns discussed in section "Social Psychology and Pro-environmental Behavior" found only limited permanent measured energy reductions. But it could be that this disappointing result occurs because respondents presently do not really feel that energy security and fossil fuel depletion and climate change are serious problems that will necessarily involve major lifestyle changes. In future, it is likely that, for both fossil fuel depletion and climate change reasons, the context in which domestic energy decisions are made will change. Past research on domestic energy conservation may then be of little relevance. But new research will also have to take a more comprehensive view of

energy savings than in the past, to ensure that neither conflicts between energy efficiency and energy conservation do not occur nor conflicts between energy savings in different sectors.

Abstract

A NASA-funded Innovations in Climate Education (NICE) Program has been launched in Alabama to improve high school and middle school education in climate change science. The overarching goal is to generate a better informed public that understands the consequences of climate change and can contribute to sound decision making on related issues. Inquiry-based NICE modules have been incorporated into the existing course of study for 9–12 grade biology, chemistry, and physics classes. New modules in three major content areas (earth and space science, environmental science, physical science) have been introduced to selected 6–8 grade science teachers in the summer of 2013 and 2014. The environmental science module allows students to explore the relationship between extreme climate events, water resources, and water pollution. In the earth science module, students investigate the effects of volcanic eruptions on Earth's atmospheric composition, global climate, and local landscape and water resources. The physical science module introduces students to the concept of urban climate and heating island effects. The NICE modules employ Roger Bybee's five E's of the learning cycle: engage, explore, explain, extend, and evaluate. Module learning activities include field data collection, laboratory measurements, and data visualization and interpretation. K-12 teachers are trained in the use of these modules for their classroom through unique partnership with Alabama Science in Motion (ASIM) and the Alabama Math Science Technology Initiative (AMSTI). Certified AMSTI teachers attend summer professional development workshops taught by ASIM and AMSTI specialists to learn to use NICE modules. Scientists are partnered with learning and teaching specialists and lead teachers to implement and test efficacy of instructional materials and models. This chapter serves as an example of how climate change education can be brought into K-12 schools.

Introduction

There is growing concern over the change that is occurring to Earth's climate and the impact it will have on the people, water resources, and ecosystems. Although the magnitude of climate change in the future is difficult to predict, there are likely to be effects on ecosystems and human systems such as agricultural, transportation, water supply, and health infrastructure – in ways people are only beginning to understand (International Panel on Climate Change 2007; National Academies 2008). These rapid changes make it less likely that human and natural systems will adapt. In order to deal with climate change impacts, greater efforts are needed toward educating the public about the science of climate change. The overarching goal is to improve the teaching and learning about global climate change through secondary education in a majority of high and middle schools in the state of Alabama, employing resources and data provided by NASA Innovations in Climate Education (NICE) Program.

In order to achieve this goal, new educational modules containing laboratory, field, and computer activities in targeted areas of global climate change education are developed. The main objective is to create modules that can be incorporated into the existing course of study for 6–12 grade science classes. Education modules used in high school classrooms were presented in the first edition of Handbook of Climate Change Mitigation (Lee et al. 2012). This paper presents the contents of new education modules developed for middle schools. High school and middle teachers are trained in the use of these modules for their classroom through partnership with Alabama Science in Motion (ASIM) and the Alabama Math Science Technology Initiative (AMSTI), respectively; both are administered by the Alabama State Department of Education. Specifically, the Alabama NICE program is designed to (1) improve understanding of climate change, enhance problem solving skills, generate greater interest in science, develop better informed persons capable of making decisions, and promote more interest in science, technology, engineering, and mathematics (STEM) careers among students; (2) enhance teachers' content knowledge of climate change and their ability to direct inquiry-based instruction and use of scientific data in the classroom; and (3) generate climate literacy, support for STEM education, climate conscious communities, and reduction in the carbon footprint among the diverse citizens of the state of Alabama.

Program Development and Implementation

Alabama Science in Motion Program

The NICE program is sustained through unique partnership with the Alabama Science in Motion (ASIM) and Alabama Math Science Technology Initiative (AMSTI) programs, which are funded by the Alabama State Department of Education. The program is free and allows all Alabama high and middle schools, no matter the size and location, to utilize the same high-tech, state-of-the-art laboratory and field equipment. In 1994 the governor of Alabama signed the Alabama Science in Motion program into legislation, and Alabama became the first state in the nation to institute a state-wide Science in Motion program. ASIM is administered by the Alabama Math Science Technology Initiative (AMSTI). In order for a school to be serviced by ASIM, they must be designated as an AMSTI school. This designation is given if all mathematics and science teachers and administrators come to 4 weeks of professional development training. At present over 40 % of the schools in the state are AMSTI schools. Of the current AMSTI schools, 80 % of the teachers attend a summer 2-week institute in biology, chemistry, or physics for years 1 and 2 of the program. The high school NICE modules are delivered in a separate four-day summer professional development workshop for teachers that have already received years 1 and 2 training. The NICE high school modules become the focal point for the professional development for all AMSTI teachers in grades 9–12 for ASIM year 3 and beyond training. The new NICE middle school modules were developed and delivered in the 2013 and 2014 professional development workshops for about

30 selected middle school teachers. The professional development workshops are delivered by ASIM and AMSTI specialists who are certified biology, chemistry, physics, and earth science teachers that serve their respective disciplines. This unique arrangement provides an equal opportunity for hands-on experimentation that many Alabama students would never experience. The program better prepares students for postsecondary education and recruitment into STEM disciplines.

Educational Modules

The NICE middle school education modules are developed by scientists in various content areas (e.g., earth and space science, environmental science, physical science) in conjunction with AMSTI specialists and lead teachers (Table 1). The modules employ Roger Bybee's (Bybee 1997) five E's of the learning cycle: engage, explore, explain, extend, and evaluate. The modules are aligned with the Alabama Course of Study, Alabama Graduation Examination, and National Learning Standards in Science, Geography, Technology, and Environmental Education (American Geographical Society 1994). Modules' learning activities include field data collection and laboratory measurements. Students employ remote sensing imagery and conduct

Table 1 Overview of NICE middle school educational modules

Science content areas	Main themes	Module activities
2.1. Earth and space science	Effects of volcanic activities on atmosphere and climate	2.1.1 Build a baking soda and vinegar volcano 2.1.2 Assess the reduction in light to Earth's surface using simple tools 2.1.3 Use graphic methods to explore impacts of volcanic eruption on climate
2.2 Hydrology–environmental science	Groundwater resource and climate change	2.2.1 Build an aquifer 2.2.2 Use the aquifer model to learn the basic vocabulary of groundwater and its hosting aquifers 2.2.3 Use the aquifer model to explore Earth's hydrologic cycle and impacts of climate change
2.3 Physical science	Urban heating island effects	2.3.1 Understand impacts of urbanization on local environment 2.3.2 Measure temperature and humidity to learn about pervious and impervious urban surfaces 2.3.3 Use remotely sensed images compare and contrast global cities 2.3.4 Watch a movie on renewable energy and analyze the pros and cons of adaptation and mitigation techniques for global climate change

hands-on laboratory experiments to investigate effects of global climate changes on physical environments and humans. NICE instructional materials include background content information (including an introductory Climate 101 Podcast), a detailed description of the specific exercise, pre-laboratory PowerPoint notes for teachers and students, pre- and post-laboratory test questions, and detailed procedures that utilizes the five E's of the learning cycle for each module. Climate 101 Podcast introduces teachers and students the basic key concepts and fundamental issues of global climate change. Students will leave the classroom with an understanding of the sources and impacts of climate change, the key national and international policies, and potential impact of climate change on human activity for many years to come. Currently, this climate change podcast is distributed as a DVD digital media file (including video and audio) via ASIM. The standards alignment (National Science Education Standards 1996) is articulated, and an equipment/materials list is generated, along with specific references. The modules enable students to gain hands-on experience in collecting and analyzing data, as well as to empower students and teachers to become more engaged in issues related to global climate change.

Earth and Space Science Module: Effects of Volcanic Activities on Atmosphere and Climate

Leading scientists: Ming-Kuo Lee

AMSTI specialist: Tyaunnaka Lucy, Jennifer Cox

Background. More than 50 volcanoes erupt each year worldwide and some of the catastrophic eruptions may change climate. For example, the 1991 eruption of Mt. Pinatubo in the Philippines blasted millions of tons of gases (e.g., sulfur dioxide) and solids (e.g., ash particles) into the atmosphere which circled the globe for weeks. These airborne-erupted materials (known as aerosols) may linger in the atmosphere for years before being flushed out by fluid motions (e.g., precipitation) in the atmosphere. These lingering aerosols can scatter the incoming solar radiation that reaches Earth's surface, resulting in lower temperature in the atmosphere. The sources of aerosols can be either natural (e.g., volcanic eruption) or anthropogenic (e.g., combustion of fossil fuels and biomass). A natural catastrophic volcanic eruption may cause a "measurable" change in Earth's climate on the timescale of several years (Russell et al. 1996). In addition to their effects on Earth's atmospheric composition and global climate, volcanic eruptions have effects in modifying the local landscape, weather, and water resources.

Learning goals and activities. Students learn (1) climate change can result from natural catastrophic events such as volcanic eruption and (2) understand the massive outpouring of gases and solids from volcanoes may increase the amount of aerosols in the atmosphere. In this activity students (1) build a baking soda and vinegar volcano, (2) assess the reduction in light to Earth's surface using simple tools, and (3) use simple graphing activities to illustrate climate impacts of volcanic eruption. This module is modified from a climate discovery educational module prepared by

the National Center for Atmospheric Research (NCAR) (http://eo.ucar.edu/educators/ClimateDiscovery/LIA_lesson8_9.28.05.pdf).

Engage. Students asked to read the following quote describing the conditions in Olongapo City, close to Mt. Pinatubo before and during its eruption in 1991.

> I was only 14 when it happened. But I remember that there was no sun for several days. The sky was either red or black. The ground was shaking all the time for days from the aftershocks. It was raining ashes and we had to wear a mask when we went outside. We also stayed inside the base for three days.

An image of the massive eruption of Mt. Pinatubo was provided (Fig. 1). Students brainstorm the changes in (1) the landscape near a volcano during and after an eruption and (2) in the atmosphere during and after an eruption. Students may be asked: What happens during a volcanic eruption and what materials are ejected from the volcano? What effects will the ejected materials have upon Earth's atmosphere? Students also make a list of potential changes for the landscape and water resources over time after a volcanic eruption. Teachers explain the eruption processes, materials ejected from volcanoes, and potential eruption impacts:

(a) The very hot magma (known as lava) leaves the magma chamber, forcing its way through the volcano and reaching Earth's surface. The lava flows down the sides of the volcano, cooling and solidifying over time, forming layers of ash and cinder along the cone. Some eruptions can be explosive, and ejected materials may include rock fragments (known as pyroclastic debris), ash (particles < 2 mm in diameter), and gas (H_2O, SO_2, and CO_2).

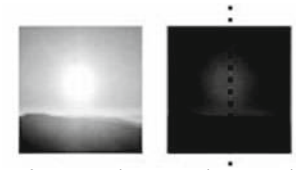
Fig. 1 An image of the massive eruption of Mt. Pinatubo on June 15, 1991 (From http://volcanoes.usgs.gov/hazards/gas/climate.php)

(b) The airborne-erupted materials (known as aerosols) may linger in the atmosphere for years before being flushed out by fluid motions like rain (e.g., precipitation) in the atmosphere. These lingering aerosols can scatter the incoming solar radiation that reaches Earth's surface, resulting in a lower temperature in the atmosphere. On the other hand, volcanic carbon dioxide, a known greenhouse gas, has the potential to promote global warming.
(c) Quick-moving lava (basaltic) with speeds up to 30 km/h can cover the land and create new rocks. The eruption of slow-moving lava (andesitic) forms a large mound (known as lava dome) above the vent. Explosive eruptions and accompanying earthquakes may trigger landslides. In cases where volcanoes are covered with snow and ice, water can mix with ash to form a mudflow called a lahar, which moves down the slope very quickly at speeds up to 50 km/h. The most common type of water contamination results from ash fall and causes a change in turbidity, acidity (pH), and toxic metals. Ash can clog streams and cause the turbidity (cloudiness of water caused by suspended solids) of water to rise and the pH of water to fall. Finer ash is able to carry more toxic metals and contaminate local water supply.

Explore

1. Students build a baking soda and vinegar volcano using the following steps:
   (a) First make the "cone" of volcano using model clay or dough. Make their own dough by mixing flour, cooking oil, and water. The dough should be smooth and firm. Mold the dough around the soda bottle into a volcano shape. Do not cover the hole or drop dough into it.
   (b) Mix vinegar (or warm water) with a pack of powdered drink mix.
   (c) Fill the bottle to about ¾ of its capacity with warm water.
   (d) Add 6–7 drops of detergent to the bottle contents. The detergent helps trap the bubbles produced by the reaction.
   (e) Add three tablespoons of baking soda to the liquid.
   (f) Slowly pour vinegar into the bottle until it starts to bubble and watch for the eruption (Fig. 2).
   (g) Recharge the volcano by adding more baking soda and vinegar.
2. Students assess the reduction of solar energy reaching Earth's surface following a volcanic eruption. Students use an infrared digital thermometer (i.e., an IR gun) to measure the temperature of a white surface exposed to direct sunlight. They then measure the temperature of a white surface in the shadow of Sun. Students compare and note the change in surface temperature. The white surface represents the surface of the Earth and sunlight obstruction represents the dust layer produced by a volcanic eruption that blocks incoming light.
3. Students explore the effects of a large eruption on the atmosphere and Earth's surface temperature. The illustrations of the Sun with different brightness (known as illumination) shown below reflect the amount of ashes and debris in the atmosphere. Students use a pocket light meter to measure how much illumination is spread over a given area in the illustration with maximum light (before

Fig. 2 AMSTI teachers built a baking soda and vinegar volcano



Before eruption During eruption

Measured illumination (in lux)		
Measured illumination (in fc)		

Fig. 3 Difference in the illustration with maximum light (before eruption) and minimum light (during eruption)

eruption) and minimum light (during eruption) (Fig. 3). The unit for illumination can be expressed either as lux (lumen per square meter) or foot-candle (fc, in lumen per square foot) (1 fc = 10.764 lx). Students draw two curves (amount of debris vs. time and temperature vs. time) in a diagram (Fig. 4) that demonstrates the impacts of volcanic eruption on atmosphere and Earth's surface temperature.

Explain. Students are asked to answer the following questions after the experiments:

(a) What type of gas is produced by mixing baking soda and vinegar? Will this gas be produced in real volcanoes? Is this gas considered a greenhouse gas?
(b) What are the temperatures of the white surface exposed to direct sunlight and those in the shadow of Sun? After a massive volcanic eruption, the airborne-erupted materials (known as aerosols) may linger in the atmosphere for years.

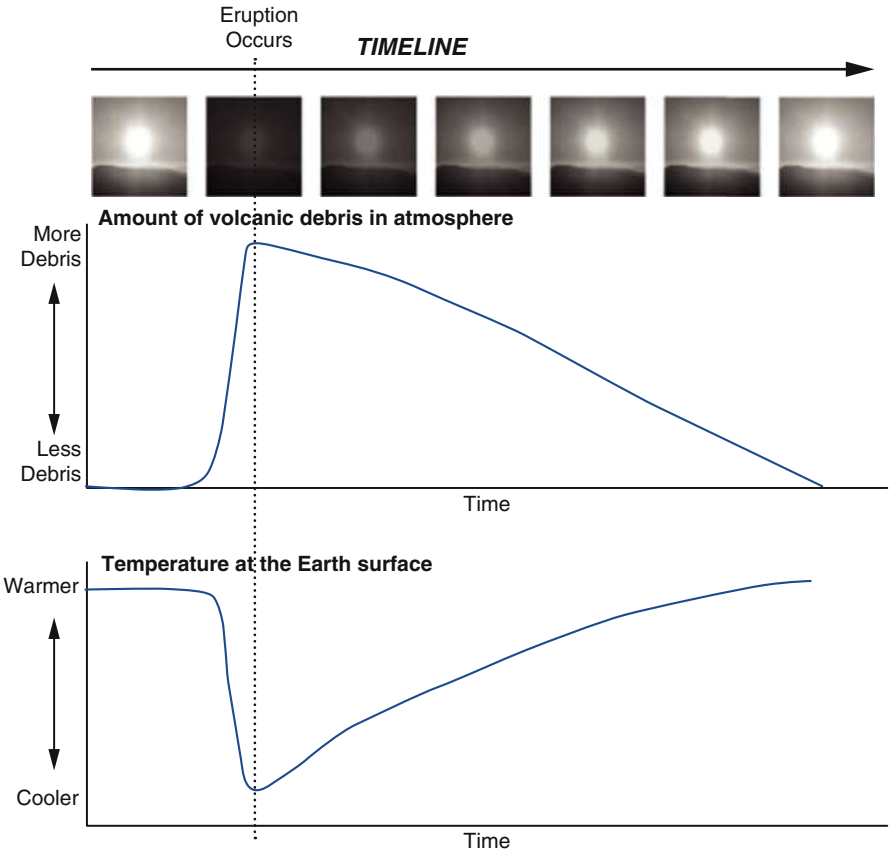


Fig. 4 The illustration of Sun before, during, and after a volcanic eruption

How do aerosols affect the incoming solar energy? How would Earth's surface temperature change (cooling or warming) in the years after a massive volcanic eruption?

(c) Use the illustrations of the Sun to answer the following questions:
- How does the relative amount of ash in the atmosphere change over time before, during, and after eruption?
- How will the amount of volcanic ash (and the change in ash through time) affect temperature on Earth's surface?
- Explain the correlation between the amount of ash and atmosphere temperature.

Extend. Students investigate what Earth's (geological) tectonic processes may cause volcanic eruption and where the active volcanoes are often located on Earth's surface. Students conduct research on selected supervolcanoes (e.g., Yellowstone) whose eruption in the past or modern time might dramatically affect Earth's atmosphere and climate.

Evaluation. Evaluations of student performance are based on (1) students' answers to pre-lab questions, (2) students' graphs (debris vs. time and temperature vs. time), (3) students' explanations on results, and (4) students' report on extension activities.

Equipment/materials needed. An infrared digital thermometer, an Extech light meter, man-made volcano ingredients (warm water, liquid dishwashing detergent, baking soda, vinegar, food coloring, or powdered drink mix).

Hydrology and Environmental Science Module: Groundwater Resource and Climate Change

Lead scientist: Ming-Kuo Lee

AMSTI specialists: Jennifer Cox, Tyaunnaka Lucy

Background. There is growing concern over the impacts of climate change on people and their water resources (Shat 2005; Foster 2006).Because of climate change, extremes in climate such as droughts and floods are likely to become more severe and more common (IPCC 2007, 2012; Karl et al. 2008). An increase in precipitation would lead to increases in surface runoff, sediment yields, nutrient loading, and release of human pollutants. An extended period of drought will lead to shortages of water and food supplies. Climate change can affect every component of our global freshwater budget, including precipitation, evaporation, groundwater, and surface stream flow and runoff (Chang and Jung 2010; Lee et al. 2013). Among various water resources, groundwater is the world's largest storage of clean freshwater. Groundwater is also the primary source of drinking water to nearly half of the world's population (Moench 2005) and the dominant source of water for irrigation and industrial activities. Future changes in climate and precipitation patterns will intensify pressure upon groundwater resources to meet the rapidly growing, global demand for freshwater.

Learning goals and activities. This module introduces students to the basic vocabulary used to describe groundwater and its hosting aquifers. Key terms (italicized) include *precipitation, surface runoff*, *water table*, *unsaturated zone, saturated zone, well casing,* and *well screen*. Students will build an aquifer to learn the fundamentals of Earth's hydrologic cycle, such as *recharge* and *discharge*, and the effects of rain, drought, and pumping on water table. After these activities students will better understand aquifers and the relationship between climate, water resources, and water pollution.

Engage. PowerPoint notes on basic groundwater and aquifer vocabulary, hydrologic cycles, and effects of climate change on water resources are presented to students by the teacher. Students then fill in the word boxes in the groundwater chart (Fig. 5), which show various components of the hydrologic cycle and a groundwater aquifer.

After learning the basic vocabulary and concepts, students build their own aquifer models (Fig. 6) using an aquifer kit provided by the NICE project team. Students follow the following steps: (1) Insert rubber stop into the drainage hole of the 1.5-gal

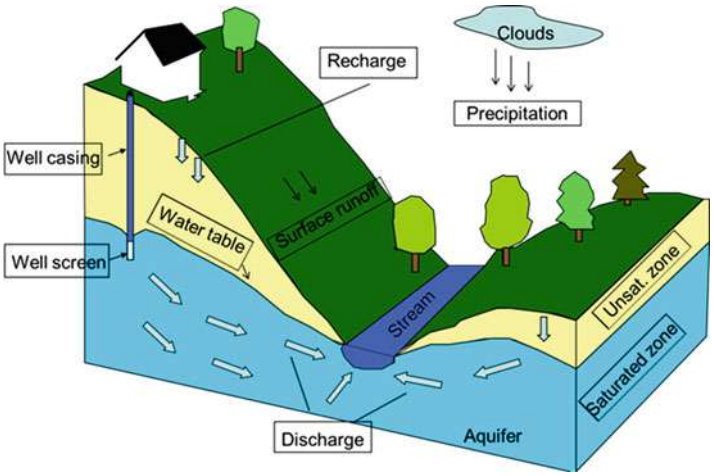

Fig. 5 A chart showing groundwater aquifer and hydrologic cycle

Fig. 6 ASMTI teachers built an aquifer tank model to demonstrate groundwater flow and contamination. Water can be added to simulate recharge or pumped out to simulate drought and overuse

tank; (2) slope a layer of gravel in the tank, with the lowest ground near the drainage hole; (3) insert a 1-in diameter well (a PVC pipe with holes drilled to serve as well screen) near the higher ground close to the side of the tank, with screen tapping the bottom gravel layer; (4) create a river by placing a clear plastic liner (with holes punched in the bottom) near the low ground; (5) lower a spray pump with plastic tubing to the screen interval in the PVC pipe; and (6) create a lake near high ground by patting down a thin layer of clay on a small circular depression.

Exploration

(a) Students simulate a precipitation event by slowly pouring water on ground surface using a cup with holes punched in the bottom. Some of the rain runs off on the surface into the river. Some of the rain moves down through the sediments and begins to fill up the aquifer (a process known as *recharge*). Students can see a river in the depression (discharge area) is fed directly by surface runoff and also by groundwater moving through the aquifer (a process known as *discharge*).
(b) Students mark the initial water table, saturated zone, and unsaturated zone (before the water table reaches the riverbed) using a water-soluble marker. They add more water and observe how the water table responds to rainfall. Students then use a spray pump (represents a municipal well) to withdraw groundwater from the aquifer. They observe how the water table declines in response to pumping. Groundwater cannot be withdrawn when the water table drops below the well screen interval.
(c) Students will slowly pour water into the lake underlain by clay, sand, and gravel. Students will compare the permeability of gravel, sand, and clay.
(d) Students simulate groundwater contamination by slowing pouring colored water (use food coloring or dye) on the ground near the water well, or students can spread colored powder (Kool-Aid) on the ground surface and then slowly pour water on the powder. Students observe how the contaminant reaches the groundwater and water well. Students will withdraw contaminated groundwater from the well using the pump.

Explain. Students are asked to answer the following questions after the experiments:

(a) Why some rainwater does not simply disappear on the surface while other rainwater quickly percolates through the ground? Are all the rock layers equally permeable?
(b) What happens to an aquifer when it rains? What happens to an aquifer when its groundwater is continuously withdrawn during a drought?
(c) Explain the concept of groundwater safety yield. What happens when the water table drops below the well screen?
(d) Explain why the safety and effectiveness of a water well depends upon its *siting*.
(e) Explain why a well needs to be properly sealed (known as well closure) when it is.
(f) List potential groundwater contaminants.

Extend. Students explore the concepts of the porosity of different geologic materials (i.e., clay, sand, and gravel) using the fluid saturation methods*. Students will find out which material is very porous (with pore spaces to store water) and permeable (allow fast water movement) and can make a productive aquifer for water supply. Contaminants must be removed from groundwater before it reaches

municipal water systems. Students will search and write a report on state-of-the-art groundwater remediation methods (i.e., remove contaminants by physical, chemical, and biological methods such as pump-and-treat, oxidation/reduction, and bioremediation). Information on specific groundwater cleanup technologies organized by type and contaminants can be found on the US Environmental Protection Agency (USEPA) website:

http://www.epa.gov/superfund/remedytech/remed.htm.

**Fluid saturation method can be used to measure the porosity. A clean and dried sample is weighted, saturated with a liquid of known density, and then reweighed. The weight change divided by the density of the fluid results is the pore volume. The volume of dried sample can be estimated using a beaker. Porosity is calculated as the ratio of fluid pore volume and volume of bulk sample.*

Example. The following procedure can be run to obtain pore and bulk volume of a sample and porosity using water with a density of 1 gm/cc. (1 cc = 1 mL):

1. *Weight of clean, dry sand:* $W_{dry} = 115$ *gms.*
2. *Bulk volume of clean, dry sand:* $V_b = 100$ cc (cc = cubic centimeters).
3. *Weight of sand saturated with liquid* $W_{\text{sat}} = 135$ gms ($\rho_w = 1$ gm/cc).
4. *Calculate the pore volume of fluid* $V_p = \frac{W_{\text{sat}} - W_{\text{dry}}}{\rho_w} = \frac{13\text{S} - 11\text{S}}{1} = 20$ cc.
5. *Porosity* $= \frac{V_p}{V_b} = \frac{20}{100} = 20\%$.

Evaluation. Evaluations of student performance are based on (1) students' aquifer model, (2) students' explanations of key terms and demonstration on aquifer model, and (3) students' report on extension activities.

Teachers use the following score sheet to evaluate students' work:

Aquifer Score Sheet

Students' Names: _____

Concept	Explain/ define	Demo/point out	Total
Groundwater recharge from precipitation	1	1. Recharge to groundwater	
Groundwater recharge from surface water	2	1. Existence of surface water 2. Recharge to groundwater	
Groundwater discharge to river	1	1. Water flow in river	
Water table	1	1. Point out the water table	
Saturated zone	1	1. Point out the saturated zone	
Unsaturated zone	1	1. Point out the unsaturated zone	
Permeability	1	1. Show permeability in 2 different materials	
Impact of a well has on groundwater	2	1. Water is withdrawn from well 2. Water level is lowered	
Groundwater contamination	1	1. Contamination is shown in groundwater	

(*continued*)

Concept	Explain/ define	Demo/point out	Total
Importance of well siting (location)	1	1. Location of wells to source of pollution	
Importance of well closure	1	1. Place cap on well	
Groundwater as part of hydrologic cycle	1	1. Connection among reservoirs	

Equipment/materials needed. 1.5-gal aquarium tank, gravels, sands, clays, one PVC pipe (1 in in diameter and 8 in long) with holes drilled to serve as the screen interval, PVC pipe cap, spray pump with plastic tubing, water-soluble marker, rain maker (plastic cup with holes in bottom), clear plastic liner (river), flashlight (to look down the well), food coloring, beakers, rubber stop, syringe (to drain water).

Physical Sciences Module: Urban Heating Island Effects

Lead Scientist: Chandana Mitra

AMSTI Specialist: Tyaunnaka Lucy

Background. Rapid urbanization has led to an increase in built-up area and impervious surfaces, increased greenhouse gas emissions, and more anthropogenic activities which are detrimental to the delicate yet complex environmental climate system of the Earth (IPCC 2007, 2012). Considered to be a cumulative effect of all these impacts is the urban heat island (UHI), defined as the difference of temperature between urban and surrounding rural areas. The urban heat island is a distinct "warm island" among the "cool sea" (Pérez and Peña 2010) which is graphically shown in Fig. 7. In countries like the USA, heat is the primary weather-related cause of death, and therefore, promotion of strategies for mitigating the UHI is a big concern for government agencies. There are two main UHI reduction strategies: first, to replace the black asphalt roofs with white-colored roofs and, second, to transform the concrete roofs to green roofs by planting grass and plants on them (Solecki et al. 2005). Overall the UHI can be mitigated by growing urban forests and parks and using more of renewable energy like solar and wind power instead of energy produced by fossil fuels. This would make the cities more sustainable and livable in future.

Learning goals and activities. This module introduces the basic knowledge about urbanization and what the impacts of rapid urbanization are on our environment. At the end of this activity, the students will understand how changing local environmental conditions like population increase, the materials you use on buildings, cars you drive, and the lifestyle you lead can affect city temperatures and create an urban heat bubble, also known as urban heat island. The students will be using infrared thermometers and hygrometers to measure the differences in temperature and moisture for different materials. They will also watch a movie that will give them an insight into the various renewable forms of energy which could be a solution to future climate change.

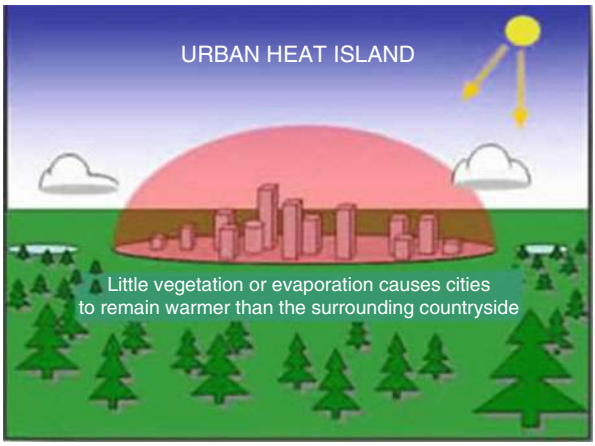

Fig. 7 Urban heat island source: http://www.nctcog.org/trans/sustdev/SDGreen/UrbHeatIsl.asp

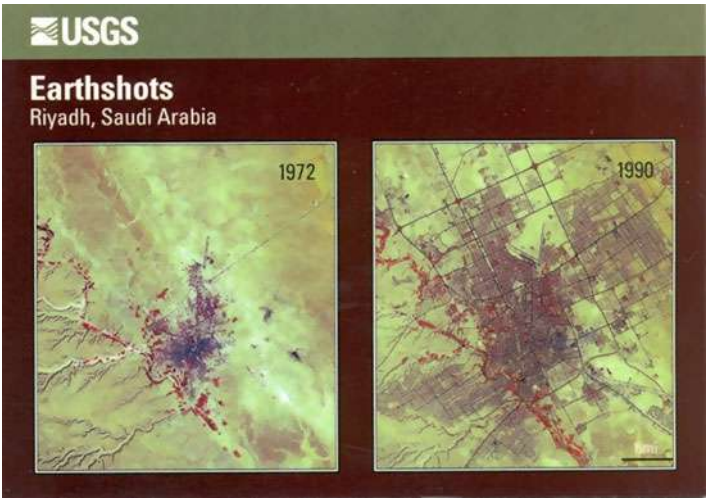

Fig. 8 Growth of Riyadh, Saudi Arabia (Source: USGS)

Engage. PowerPoint notes on urbanization, urbanization impact on climate change, permeable and impermeable surfaces, albedo, urban heat island, adaptation and mitigation techniques, and renewable energy will be provided.

To further engage the students, they will use tracing papers and the given Google and USGS images (http://earthshots.usgs.gov/earthshots/about#ad-image-0). With the help of the tracing papers, they will try to determine and see for themselves how cities are growing worldwide. A number of images downloaded from Earthshots–USGS will be provided, for example, Riyadh in Saudi Arabia (Fig. 8), Sydney in Australia (international), and Atlanta in the USA. This will give them an idea of the impact of uncontrollable city growth over short period of time and relate to the discussion earlier on impacts of population increase on environment.

The students will also be asked questions to engage them in a discussion involving their visit to Atlanta GA, did they see parks in Atlanta downtown, how much of Atlanta downtown is green, and what happens when a lot of people come and settle in a city. Besides these they will also be asked about the surface (green grass or concrete) they would like to walk on a hot afternoon, why people living in deserts wear white long robes, what happens when you burn coal, and whether they have heard about wind and Sun's energy usage. In this module Atlanta is the city of focus but the teacher can choose any big city which the students are familiar with. That will give the students a sense of involvement.

After learning the basic concepts and discussing the urbanization issues, students will use the instruments to measure temperature and humidity of various surfaces provided in the "urban heat island" kit by the NICE project team.

Exploration

(a) Option 1: Students will use infrared thermometers and hygrometers to measure the temperature of black and white surfaces and moisture level over a cemented concrete surface and a grass surface (Fig. 9). They will write their readings in the table provided below (can increase the rows if they feel like measuring more surfaces made of various materials). The students will calculate the differences and then discuss the reason why there is a difference in the temperatures. They will then relate the surface measurement differences to an urban environment. The teacher will help the students here by citing examples of heat absorption by black cars, white cars, desert people wearing long white robes, and black solar panels (example will be provided in the PowerPoint).

IR thermometer reading	Temperature (°C)	Temperature (°F)
White surface (roof if possible/white board) exposed to direct sunlight		
Dark black surface (roof if possible/black board) in direct sunlight		
Surface of black car		
Surface of white car		
Grass surface		
Concrete surface		
Hygrometer reading	Relative humidity (%)	
Concrete surface in direct sunlight		
Grass space in direct sunlight		
Concrete surface under shade of tree		
Green space under shade of tree		

Option 2: If the teacher wants, then he/she can make the students do a day-long study taking measurements every hour or every 2 h, documenting the temperature for different materials. They can prepare trend lines using graph papers (temperature and humidity variations vs. type of surface) to show how the

Fig. 9 AMSTI middle school teachers using IR thermometers to measure temperature of black cars and hygrometer to measure humidity of green grass

temperature varies depending on material in an urban environment. The teacher will help the students to relate the trend lines with urbanization and discuss the benefits of having white roof over black roofs and green space and urban parks over all impervious surfaces.

(b) The teacher will show in class the movie "Carbon Nation" (a movie on renewable energy) as a part of exploration. This movie is 84 min long which is one of the best climate change solution movies. The movie does not directly deal with the subject of climate change but focused mainly on using renewable energy which will help mitigate some of the effects of climate change and make our Earth a better place to live in.

Explain

(a) Why do you think dark roofs are hotter than white roofs? How does albedo help in reducing white roof temperatures?
(b) What are the problems of having dark roof?
(c) Do you think having green parks, green roofs, and green walls will help lessen the effect of UHI?
(d) The more concrete we have in our cities, the chances of having more urban flooding will increase – is this true? (The teacher will ask the students to relate this to the "Aquifer module" and make them relate urban flooding with impermeable surface and surface runoff.)
(e) Students will take notes while watching the movie "Carbon Nation" on the different types of renewable energy and what the benefits of each are. Is it possible to replace nonrenewable energy with renewable energy? Students will discuss the long-term and short-term benefits of using renewable energy.

Extend

(a) The students will use various methods (pictures and articles from magazines, journals, newspapers, Internet sources) to prepare charts and collages on the

things they learned during lab. They can work in groups. They will learn about each renewable energy, their limitations and examples from different parts of the world; try to find out if anywhere in their area solar power is harnessed; learn about electric cars and if they are better; and the gases that cause global warming and why they are increasing in the atmosphere.

(b) Students will investigate what would happen if there is an increase in heat in urban areas, discuss in class about ways in which population can be attracted away from cities to suburban areas, and conduct research on the growth of various cities in the USA and worldwide to see how cities are growing and at what rate.

(c) Another extension would be to talk to their neighbors and educate them on roof color and material and write a report on what feedback they received. The students can work in groups for this.

(d) Ask the students to find out if the city nearby or the city in which they live has a Climate Action Plan. They should search on the net cities which have implemented the maximum UHI mitigation techniques (Portland, Chicago, New York City, State of California).

Evaluation. Evaluations of student performance are based on (a) students' answers to questions based on PowerPoint notes, (b) their understanding of temperature and humidity differences and their effects on urban–rural climate patterns based on responses in class, (c) students' graphs (temperature and humidity variations vs. type of surface), (d) students' explanations of results and answer to the explain section, and (e) students' report on extension activities.

Equipment/materials needed. Overhead projector, an infrared digital thermometer, hygrometer, Google and USGS images showing growth of cities, tracing paper, reading material (urban heat island, city growth over time, adaptation and mitigation techniques to reduce urban heat island effect, renewable energy), two cardboard sheets (black and white) to represent different colored roofs.

Program Dissemination

Several methods of dissemination have been employed. Results of outreach activities and education materials were divulged through publications, conferences, and education symposium. Education modules used in high school classrooms and their evaluations were presented in the first edition of Handbook of Climate Change Mitigation (Lee et al. 2012). This paper presents the contents of new education modules developed for middle schools. Moreover, more than 10 papers have been presented at national conferences hosted by the American Geophysical Union, Geological Society of America, America View Fall technical meeting, and American Meteorological Society. Last, the College of Sciences and Mathematics hosted a climate change education symposium to educate faculty, graduate students, and undergraduate students on the interdisciplinary interface of sciences and mathematics. A forum "Frontiers in Global Climate Change" was held in the spring semester

of 2012. The leadership team served as the coordinating committee for the symposium. The keynote address was delivered in a fashion so that individuals not engaged in specifics of climate change research can become more informed. This forum enabled the leadership team to continue to meet and to refine background understanding regarding NICE education. In addition, it provided the leadership team with specific training in topics relevant to NICE. The symposium was advertised on-campus and to neighboring institutions in the region, which includes two historically Black colleges and universities: Alabama State and Tuskegee University. Media coverage was requested as well through Auburn University Office of Marketing and Communications.

Conclusions

Successful implementation of NICE education modules should enable significant advances in high school climate change science education. New resources including instruction materials for teachers and students have been developed in forms of laboratory handouts, database, laboratory kits, and multimedia products (podcast, movie, and PowerPoint files). The modules use new technology or innovative tools including computer software, web-based data search and visualization, and scientific data collections using sensors. The instruction materials are aligned with state and national academic standards, and teacher professional development program is implemented through partnership with ASIM and AMSTI programs. The overall teacher satisfaction from the teacher training was 4.88/5.00. The overall conclusion from the pre–post attitude assessment was the teachers came to the workshop interested in learning more about global climate change and were aware that it is an environmental concern that needs more public attention. While they also believe the government should be involved and NICE should be a national priority, they are not sure how at this point in time. After completing the module teacher training, the teachers reported a strong agreement that the content developed in the modules of this project for teaching global climate change concepts should be included in the Alabama secondary curriculum. At the culmination of the project, the team and AMSTI director will convene a final project meeting to disseminate the final evaluation results and plan for sustained delivery of NICE modules by AMSTI personnel.

A preliminary conclusion of this project is that high and middle schools can effectively partner with universities to offer students a meaningful and enriching science experience that increases their understanding of the concepts of Earth's system and climate change, and underscores the need to take action. Such a project can give these students access to expertise and equipment, thereby strengthening the connections between the universities, state education administrators, and the community. This project can serve as an example for improving K-12 school education in climate change science around the world to raise public awareness and perception.

Acknowledgments This project was supported by a grant from NASA NICE Program (NN09AL73G; Principal Investigator: Chris Rodger) and funding from the Alabama Science in Motion (ASIM) and Alabama Math Science Technology Initiative (AMSTI). We thank Mr. Matthew Williams (Office of Sustainability, Auburn University) for preparing a global climate change podcast as part of the instructional materials. We also thank America View, consortium of remote sensing scientists to expertise on satellite images.

Abstract

This chapter will describe some simple models that have been used to explain the basic principles of the Earth's climate to primary school students (aged 4–11), secondary school students (aged 11–16), post-16 students (16–19), and the general public (all ages) including those with disabilities. It will then describe a range of hands-on practical activities that demonstrate aspects of the climate system at the appropriate level. Assessment and impact of these activities on the learner's level of cognition are then presented showing that the hands-on approach is a most effective way of communicating such concepts irrespective of the age of the learner. Furthermore, the varied impacts of a "lecture demonstration," that is, a talk where points are illustrated by exemplar experiments that visually portray the science concept, are presented.

The many misconceptions that surround the understanding of the Earth's climate system and how teachers and other science communicators can deal with such issues in a classroom setting are discussed. The sourcing and use of the myriad datasets linked with the Earth's climate that are freely available for schools' projects are discussed with illustrations drawn from projects undertaken already.

Often the impact of such engagement activities on the provider themselves is ignored; here the tangible benefits to all providers involved are discussed with some case studies as illustrations.

Finally, the future prospect for the Earth's climate is nearly always portrayed as negative. In this chapter, the idea of stabilization wedges and ways that the worst-case scenarios for climate change can be averted is discussed. Using a variety of metrics, it is possible for a wide range of learners to appreciate the impact of any mitigation strategy, that is, literally "speaking in a language they can understand."

Introduction

The Need for Education in Climate Science

It is essential that teachers are armed with the correct (factual) information about the Earth's climate system, so that they can educate the next generation of students. It goes without saying that such education is essential so that these students can make informed decisions about their response to potential climate change. In the UK, climate chemistry is now included in many science courses that are taken by 16-year-old students, toward the end of compulsory education. Further work on climate change is part of advanced-level (A-level) chemistry and other courses that are taken by preuniversity students. Many of these courses have associated textbooks which do not go into sufficient depth to answer some of the questions that arise. More confusion results from incorrect information from a number of sources including the press, the Internet, and teachers that are not sufficiently knowledgeable about the topic (see section "Some Misconceptions Concerning Climate Change and Greenhouse Gases").

A fundamental problem is that a basic explanation of the Earth system and the need for naturally occurring greenhouse gases and their impact is often muddled.

The Research Councils UK (RCUK) (2002) was anxious that high-quality teacher training on the Earth's climate, and several other topics, was put in place by the creation of a daylong course to be hosted by the Science Learning Centres and run by experts in the field (Science Learning Centres 2004). The RCUK is split into seven sub-councils (arts and humanities, biosciences, engineering and physical science, economics and social science, medical, natural environment, and the science and technology facilities) and administers funding for research in the UK of around £2 billion a year in these areas. The Science Learning Centres were originally a network of nine regional centers and one national center, which provide continuing professional development for both primary and secondary teachers in the UK. These have recently contracted to five regional centers and the National Science Learning Centre in York. Therefore, in the UK, such a partnership was very potent in terms of its ability to bring expert researcher and teacher together. These courses are not compulsory for teachers to attend, and although feedback is very good, it will take a long time for the material to be disseminated from teacher to teacher. It is hoped

that one consequence of this chapter would be that it is of assistance to teachers and other educators looking to improve their understanding of climate science.

The Granny Model: Basic Concepts

Figure 1 introduces the Granny model; it consists of a heater and a very sensible Granny (grandmother). She wants to keep warm but knows that if she sits too far away from the heater, she will be cold and if she sits too close to the heater, she will be too warm. So she places her seat a sensible distance away from the heater so that she is neither too hot nor too cold, but just the right temperature (sometimes this is known as the Goldilocks hypothesis). The Granny represents the Earth and the heater is the Sun. It turns out that the Earth is just the right distance away from the Sun for the average surface temperature to be about 10 °C, based on simple heat flux arguments (see section "The Granny Model: The Underpinning Mathematics"), and this qualitative explanation works well at KS3 (Key Stage 3, 11–14-year-olds in the UK). There is a problem with this simple model, in terms of the Earth system, illustrated by Fig. 2. Clouds in the sky and ice at the Earth's surface act as mirrors and reflect back to space about 30 % of the energy arriving from the Sun. It turns out that about 6 % is reflected by ice at the surface and 24 % from the atmosphere (mostly by clouds), and this reflectivity (30 %) is known as the Earth's albedo, A (where $A = 0.3$). Other surfaces on the Earth are reflective but nowhere near as much as ice (see Table 1).

Figure 3 shows how this new feature can be incorporated into our Granny model. If it is imagined that Granny's pet dog has sat in front of the fire, it will block some of the heat from the heater reaching Granny. In the Earth system, the presence of clouds

Fig. 1 The Granny model, part 1. Mean temperature of the Earth is around 10 °C

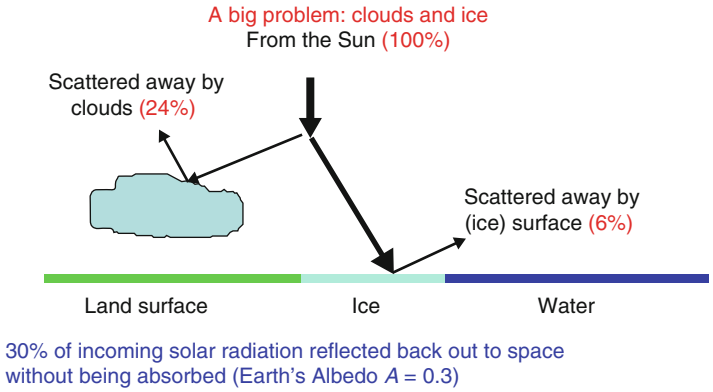

Fig. 2 A problem with the Granny model, part 1

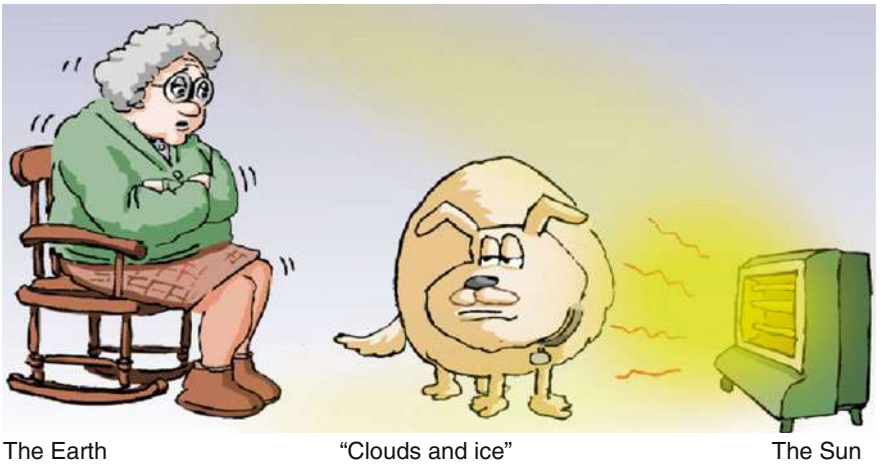

Fig. 3 The Granny model, part 2 (with clouds and ice). With clouds and ice mean temperature of the Earth ∼−18 °C

Table 1 Reflectivity of different types of surface with respect to incoming solar radiation

Surface type	Reflectivity (%)
Fresh snow	90–95
Dry sand	35–45
Grass-type vegetation	15–25
Needleleaf coniferous forest	10–20
Broadleaf deciduous forest	5–10

and ice would reduce the average surface temperature of the Earth to −18 °C, very cold indeed, making the Earth uninhabitable. The average surface temperature of the Earth is much hotter, so there must be a compensatory mechanism. What could the Granny do? She could move the pet out of the way (water is essential to the Earth, and one would not want to remove clouds and ice – even if they could be removed). She could move closer to the heater (although the Earth's orbit fluctuates, it cannot move close enough to the Sun to compensate; in any case, there are issues to do with evaporation of water and the formation of more cloud!). Finally, she could stay where she was and put on a blanket. The final option is what the Earth does; it puts on a blanket (greenhouse gases) to compensate for the loss of heat caused by clouds and ice.

For Fig. 4, the audience is asked to imagine that they are in space looking at the Earth and observing the heat being released from the surface of the Earth (in the infrared region). The figure clearly shows that not all of that heat escapes to space but that some is trapped by greenhouse gases in the atmosphere, such as carbon dioxide, ozone, and methane (CO_2, O_3, and CH_4), and that these act as a blanket around the Earth (or around the Granny).

Figure 5 now completes the Granny model where she has a blanket to offset the heat lost. The combination of these two effects (the Earth's albedo leading to cooling and the greenhouse gases leading to a warming) cancels out, ending up with an average surface temperature of about 16 °C. Hence, greenhouse gases are essential to

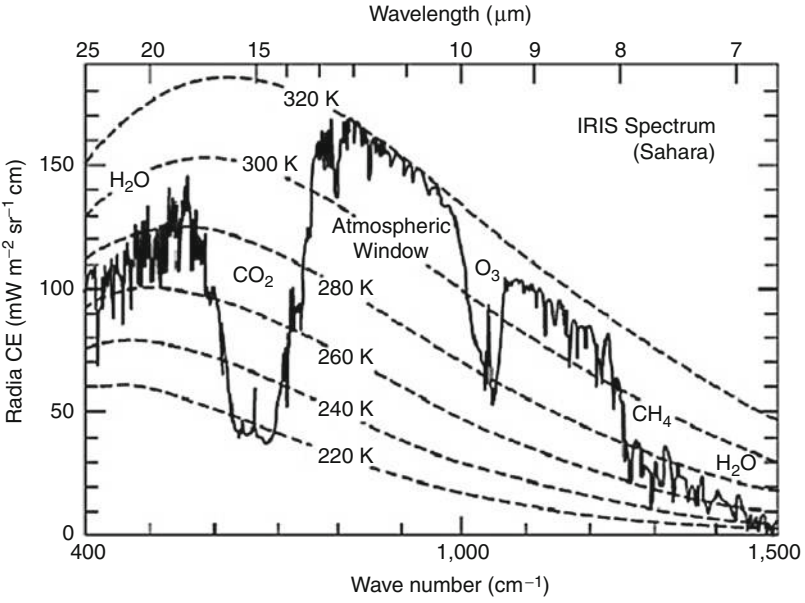

Fig. 4 Spectrum showing the outgoing infrared radiation from the Earth and the parts of the spectrum that are absorbed by greenhouse gases in the Earth's atmosphere

Fig. 5 Granny model, part 3 (clouds, ice, and greenhouse gases). With clouds and ice and greenhouse gases, the mean temperature of the Earth ~16 °C

the Earth system. A PowerPoint of this model is available for download from the Bristol ChemLabS outreach website at http://www.chemlabs.bristol.ac.uk/outreach/resources/Atmos.html.

The Granny Model: The Underpinning Mathematics

A First Attempt to Model the Climate

The simplest model of the climate is one where incoming solar energy and outgoing terrestrial energy emitted from the planet are equal, that is, an "energy in equals energy out" model or a balanced flux model. Throughout this section, it refers to energy; however, tacitly this means energy flux, that is, energy per second. It is known from measurements that the energy from the Sun reaching the top of the atmosphere, termed the solar constant S, is 1,370 W m^{-2}. If it is assumed that the radius of a perfectly spherical Earth is R_E, it can be seen that the Earth absorbs solar radiation over an area πR_E^2 (i.e., a flat disk of atmosphere) but emits energy from an area $4\pi R^2{}_E$ (i.e., from the entire surface), as illustrated in Fig. 6a, b. If an energy analysis is now carried out and it is assumed that energy in and energy out are the same, it is possible to arrive at the following:

$$\text{Energy in} = \text{Eneregy out} \tag{1}$$

$$\begin{aligned}&\text{Energy per unit area per unit time} \times \text{total area (disc)}\\ &= \text{Energy per unit area} \times \text{total surface area (sphere)}\end{aligned} \tag{2}$$

$$1370 \times \pi R_E^2 = \sigma T_E^4 \times 4\pi R_E^2 \tag{3}$$

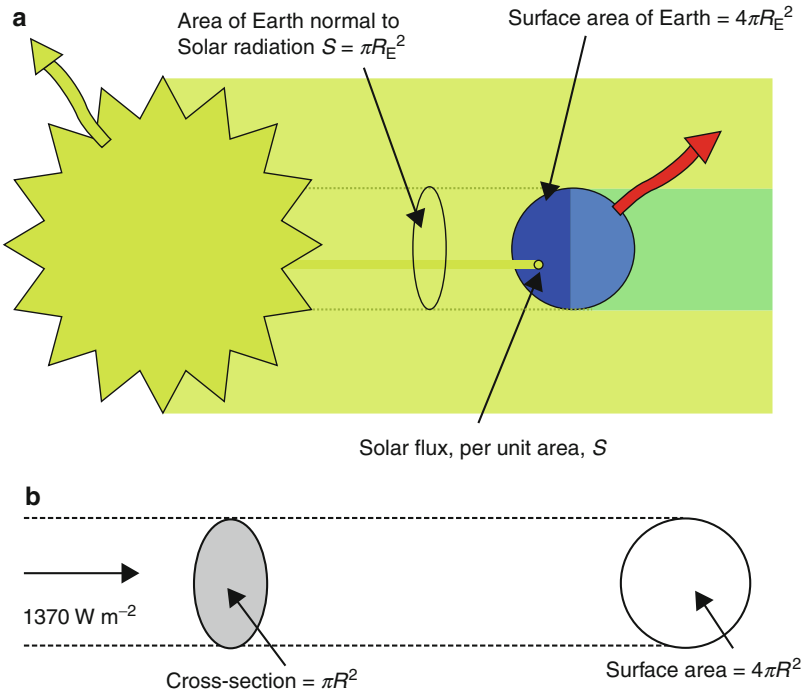

Fig. 6 (**a**) A schematic of a balanced flux model for the Earth. (**b**) A simplified version of the schematic of a balanced flux model for the Earth

Rearranging Eq. 3 yields an expression for the surface temperature of the Earth:

$$T_E^2 = \frac{1370}{4 \times 5.67 \times 10^{-8}} \tag{4}$$

$$T_E = 279 \text{ K} (6^\circ\text{C}) \tag{5}$$

First, it should be noted that the σT_E^4 comes from the Stefan-Boltzmann law. All bodies radiate energy as electromagnetic radiation. A blackbody absorbs all radiation falling on it and emits that radiation as a function of its surface temperature, where that flux of energy radiated is equal to σT^4; here σ is the Stefan-Boltzmann constant, 5.67×10^{-8} W m^{-2} K^{-4}, and T is the surface temperature of the body in Kelvin.

Second, a first glance at the result in Eq. 5 looks like a sensible figure for the average surface temperature of the Earth, maybe a little too cold. The problem with this very simple model is that some energy is reflected back out to space by clouds and ice without being absorbed. Approximately 24 % of the incoming energy is reflected by clouds, and another 6 % is reflected by the surface, for example, ice. This gives a total albedo (A) for the Earth of 30 % or 0.3. Therefore, the left-hand side of Eq. 4 must now be rewritten as $0.7 \times 1{,}370 \times \pi R_E^2$, and the calculation of T_E becomes

$$T_E^4 = \frac{1370 \times 0.7}{4 \times 5.67 \times 10^{-8}} \tag{6}$$

$$T_E = 255 \text{ K}(-18^\circ\text{C}) \tag{7}$$

This new value for the average surface temperature in Eq. 8 is obviously far too low and leads naturally to the question: "Why is the Earth so warm?" In order to answer this question, a slightly more complex model is needed.

A One-Layer Atmosphere Model

If it is assumed that the atmosphere is made up of a single layer of miscible gases, a more accurate model can be constructed that can be used by students using a spreadsheet. In this model, allowances are made for absorption by the atmosphere of the incoming visible light from the Sun and absorption of the outgoing infrared light emitted from the Earth.

Figure 7 summarizes the elements of the model. F_S is the solar constant divided by 4; hence, the incoming energy from the Sun is $F_S(1 - A)$, where A is the albedo, that is, removing that portion reflected back to space. This incoming energy is in the UV and visible region. τVIS is the fraction of this incoming energy that is transmitted through the atmosphere, that is, if the atmosphere absorbs it, all τVIS is zero, if the atmosphere absorbs none of it, τVIS is equal to 1. Hence, the energy reaching the surface of the planet is $F_S(1 - A) \times \tau$VIS. The Earth will act as a blackbody and will emit the energy denoted as F_g, from the surface of the Earth. This terrestrial radiation is centered in the infrared region of the spectrum. τIR is the fraction of infrared energy transmitted through the atmosphere, being zero if the atmosphere absorbs all of it and unity if the atmosphere absorbs none of it. Certain gases in the atmosphere do indeed absorb the infrared energy (greenhouse gases), and so outgoing energy is $F_g \times \tau$IR.

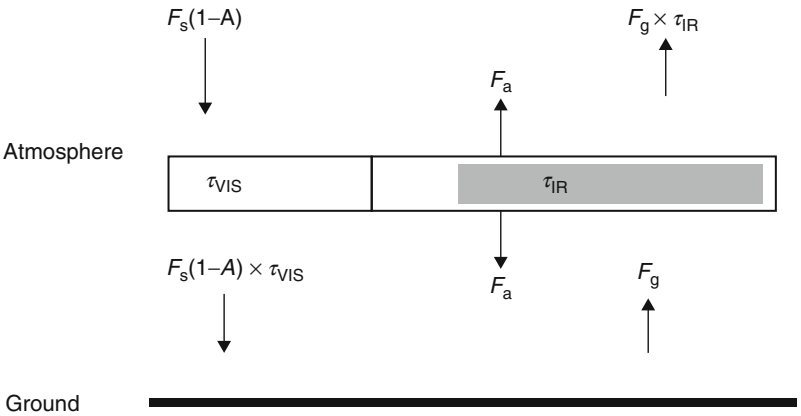

Fig. 7 Schematic of a one-layer atmosphere

Assuming that the energy from the atmosphere is denoted as F_a and that the energy in and out at the surface of the Earth and the top of the atmosphere are both balanced, then:

At the surface of the Earth,

$$F_S(1-A)\tau\text{VIS} + F_a = F_g \tag{8}$$

And at the top of the atmosphere,

$$F_g\tau\text{IR} + F_a = F_S(1-A) \tag{9}$$

Combining Eqs. 8 and 9,

$$F_g = \frac{F_S(1-A)(1+\tau\text{VIS})}{(1+\tau\text{IR})} \tag{10}$$

Finally, noting the Stefan-Boltzmann law once again, F_g can be expressed as

$$F_g = \sigma T_E^4 = \frac{F_S(1-A)(1+\tau\text{VIS})}{(1+\tau\text{IR})} \tag{11}$$

Equation 11 can be rearranged to make T_E the subject:

$$T_E = \left[\frac{F_S(1-A)(1+\tau\text{VIS})}{\sigma(1+\tau\text{IR})}\right]^{0.25} \tag{12}$$

Assuming that $F_S = 342.5$ W m^{-2} (solar constant divided by 4) and that τVIS $= 0.8$ and τIR $= 0.1$, then $T_E = 288.5$ K (15.5 °C). It is Eq. 12 that can be put into a package such as Microsoft Excel so that students may see the effects of changes in global temperature when parameters are changed.

A One-Layer Atmosphere Model Simulation

Further example output is shown in Table 2. In experiment 1, it is assumed that the atmosphere does not absorb any of the incoming or outgoing energy fluxes and the albedo is 0.3, giving a temperature of 254 K. If there are no clouds or ice ($A = 0.0$), the Earth then warms up in experiment 2–278 K, showing the importance of albedo. From experiment 2–3, the atmosphere now absorbs all the outgoing infrared radiation, and the Earth warms to 330 K. If clouds and ice are now introduced in experiment 4, the temperature drops to 302 K. These four factors, F_S, A, τVIS, and τIR, play a vital role in determining the surface temperature of the Earth, and students can investigate this for themselves. These models have been very popular with teachers and their students at secondary school in the UK and are beginning to be used in other countries.

Table 2 Output from the one-layer atmosphere model

Experiment				
Variables	1	2	3	4
FS/W m^{-2}	342.5	342.5	342.5	342.5
A	0.3	0.0	0.0	0.3
τVIS	1.0	1.0	1.0	1.0
τIR	1.0	1.0	0.0	0.0
T_E/K	254	278	330	302
T_E/°C	−19	5	57	29

Typical questions that could be asked that would require the students to use this model are:

1. Which of the variables has the greatest effect on average global temperature?

This is a somewhat open-ended question; one would first assume that the solar constant is the most important. However, if A approaches 1, that is, the Earth's surface becomes very reflective, covered in ice like the snowball Earth (see section "A One-Layer Atmosphere Model: Taking the Investigation Much Further"), then the temperature plummets.

2. What would happen to the surface temperature if the ice caps melted?

This question is asking the student to reduce A by approximately 6 %. It is quite surprising how much the temperature rises with modest reductions to the Earth's albedo.

3. If the average distance from the Earth to the Sun was increased by 1 % of the current value, what would the temperature be assuming albedo is 0.3, τIR = 0.3, and τVIS = 0.6?

This question opens up the importance of the solar constant and how small fluctuations in the Sun's energy (e.g., solar flares or sunspots) can affect surface temperature. Indeed, students can explore what would happen to the Earth's surface temperature if the Earth moved closer to the Sun or further away from it. As a simple approximation, one can assume that the Sun's energy is evenly spread over the surface of a sphere. Therefore, for simplicity it can be stated that the solar constant scales with $1/R^2$, so the solar constant $S = 1{,}370/R^2$, where $R = 1$ is defined as the distance from the Sun to the Earth at present. Therefore, if the distance from the Sun to the Earth is halved (just a bit further than Mercury is from the Sun), the solar constant increases by a factor of 4, and if the distance from the Sun to the Earth is quintupled (increased by a factor of 5 bringing the Earth slightly closer to the Sun than Jupiter), then S is reduced by a factor of 25 (see section "A One-Layer Atmosphere Model: Taking the Investigation Much Further").

Of course, far more challenging questions could be asked, for example:

1. The sand in the Sahara desert can be made into a glass mirror. If a perfectly reflecting mirror is put at the Earth's surface in the Sahara desert, it could reflect back incoming solar radiation and cool the planet.
2. How big would the mirror have to be in order to cool the planet by 1 °C?
3. What fraction of the Sahara desert would that be?

A One-Layer Atmosphere Model: Taking the Investigation Much Further

The one-layer atmosphere model opens us the possibility to investigate a myriad of interesting and more complex systems, and some of these are given here and tie in very well with current topics being presented at school level.

Surface Temperatures on Other Planets

The one-layer atmosphere model can be used to estimate the surface temperature on other planets. For simplicity, in the first instance, it can be assumed that the planet's atmosphere does not interact with energy entering or leaving the planet (τVIS and τIR are equal to 1) and that the planet's albedo is zero (nonreflecting). Using the approximation developed in question 3 from the previous section, $S(R) = 1{,}370/R^2$, it is then possible to work out the temperatures. Data for the relative distances are collected in Table 3, and from this an estimate of the surface temperature of each planet is then given and compared with actual measurements. It should be noted that these actual measurements are averages and should not be taken as the exact number.

Table 3 Estimates of the surface temperature of other planets in the solar system using the one-layer atmosphere model

Planet	D, Distance to Sun/millions of miles	D/D_{Earth}	S W m^{-2}	T K	T °C	T actual[a] °C
Mercury	36	0.4	8,562	441	168	167
Venus	67	0.7	2,796	333	60	457
Earth	93	1.0	1,370	278	5	10
Mars	142	1.5	609	228	−45	−46
Jupiter	484	5.2	51	122	−151	−153
Saturn	891	9.6	15	90	−183	−184
Uranus	1,790	19.2	4	65	−208	−197
Neptune	2,800	30.1	1.5	51	−222	−223

[a]Actual temperatures are taken fromhttp://wiki.answers.com/Q/What_is_the_surface_temperature_on_the_planets and http://theanswermachine.tripod.com/id2.html. Accessed 31 Aug 2010). Note that $S = 1{,}370/(D/D_{\text{Earth}})^2$ and $T = \{S/(4\sigma)\}^{0.25}$ (in Kelvin)

However, the first point is that the agreement is stunning apart from one planet, Venus. The surface temperature of Venus is much hotter than predicted. Why is this? It turns out that a runaway greenhouse effect has taken place and not even decreasing τIR to zero can reproduce the very hot temperature experienced (further modifications are required). The atmosphere of Venus is around 96 % CO_2, and the subsequent trapping of infrared radiation has caused the planet to experience much higher surface temperatures than predicted simply by its distance from the Sun.

Snowball Earth

Through geological evidence, it has been proposed that some 650 million years ago, the Earth was nearly completely covered in ice (see Hoffman et al. 1998). Such a snowball Earth is believed to have preceded the Cambrian explosion of life on Earth. Evidence for this comes from the fact that there are glacial deposits near the equator, and magnetic measurements also support this. In order for there to be glacial deposits in the tropics, there needs to be ice. Using the one-layer model, it is possible to investigate what would happen to surface temperature as the albedo (or amount of ice) increases. Taking τVIS and τIR to be equal to 1 for simplicity, it is then possible to calculate the effect on temperature as A is increased, that is, $A = 0$, $T = 278$ K, $A = 0.5$, $T = 234$ K, $A = 0.75$, $T = 197$ K, $A = 0.9$, and $T = 156$ K. It soon emerges that the model diverges from linearity and as A approaches zero the temperature plummets. To raise the temperature again, it is believed that greenhouse gases (CO_2 and CH_4) eventually rose to a level where the temperature started to rise again and ice melted causing a feedback on warming.

Global Dimming

It is a well-known phenomenon that one of the reasons that the Earth's surface temperature has not increased over the last 50 years as dramatically as originally predicted, even though greenhouse gas levels have increased significantly, is because of a process known as global dimming. In the process of burning fossil fuels, particulate matter is also released as well as water. It has been shown that the energy from the Sun reaching the Earth's surface has decreased since the 1950s by around 5 % (see Wild et al. 2005) and is believed to be caused by the addition of particles that increase the albedo of the Earth. The one-layer model can be used to investigate this impact by increasing the albedo (similar to snowball Earth in fact) of the Earth, where increasing A from 0.3 to 0.31, for example, cools the surface temperature by 1 °C, in keeping with the global dimming hypothesis. Indeed, the role of aerosols and volcanic eruptions (which inject sulfur-rich species into the atmosphere and lead to more cloud cover) can all be investigated using this model, all leading to a cooling.

Stratospheric Ozone Depletion and Climate Change

A topic that is often confused is the relationship between stratospheric ozone and climate. Ozone (O_3) is formed in the stratosphere, a region of the atmosphere between about 10 and 50 km in altitude. Its location arises because of the balance between the need for high-energy photons of light (UVC radiation) found in greater abundance the higher in altitude one goes and high pressures which decrease dramatically with increasing altitude. The reactions governing the formation of ozone are those derived by Chapman in the 1930s and are known as the Chapman mechanism and are summarized in reactions (Eqs. 13, 14, 15, and 16).

$$O_2 + h\nu \rightarrow O + O \sim 200 \text{ nm} \tag{13}$$

$$O + O_2 + M \rightarrow O_3 + M \tag{14}$$

$$O_3 + h\nu \rightarrow O + O_2 \sim 250 \text{ nm} \tag{15}$$

$$O + O_3 \rightarrow O_2 + O_2 \tag{16}$$

O_2 absorbs a photon of vacuum UV light (around 200 nm) and dissociates to form two O atoms in reaction (Eq. 13). The O atoms can add to O_2 in the atmosphere to form O_3, ozone, but need to have a relatively high pressure, denoted by M, so that the newly formed molecule can be stabilized. Since Eq. 13 is most efficient at the top of the atmosphere and Eq. 14 is most efficient at the bottom of the atmosphere, it is not surprising that somewhere in the middle the amount of ozone made is at a maximum, hence the location of the stratosphere. Ozone itself absorbs high-energy vacuum UV (around 250 nm), shown in reaction (Eq. 15). There are two important consequences of the ozone layer in the stratosphere. First, between O_2 and O_3, they filter out all the UVC radiation (200–280 nm) from the atmosphere which would cause life on the surface of the Earth to be severely compromised if it were not removed. Second, reaction (Eq. 15) gives out a lot of heat; hence, the stratosphere is a warm layer relative to the top of the troposphere (the layer of the atmosphere from 0 to 10 km approximately). This warm layer moderates the weather in the layer below and has other beneficial dynamical effects. The τVIS term relates directly to the absorption of the Sun's energy by O_3 and O_2. The one-layer model shows what would happen to the surface temperature if there was no ozone layer (e.g., $A = 0$, $\tau\text{VIS} = 1$, and $\tau\text{IR} = 1$) returning a value for $T = 278$ K, with an ozone layer ($A = 0$, $\tau\text{VIS} = 0.8$, and $\tau\text{IR} = 1$) $T = 271$ K, that is, a cooling of about 7 K or 7 °C.

Taking this further, it was discovered by Nobel Prize winner Paul Crutzen and others in the 1970s that the natural catalytic cycles reduce the amount of ozone in the stratosphere. These cycles arise from H_2O, CH_4, and N_2O being present in the atmosphere through natural cycles. If there was more ozone, that is, no natural removal processes, then $\tau\text{VIS} = 0.7$ may be a more reasonable number ($T = 267$ K), and the drop in surface temperature would be an additional 4 °C. Some may suggest that such a warming caused by gases released by biological processes occurring at the Earth's surface proposes a Gaia-type link, yet another interesting avenue for class discussion.

The destruction of stratospheric ozone will, of course, increase τVIS from 0.8 toward 1.0 and will lead to a warming of the surface. However, ozone is itself a greenhouse gas, and so by removing it, the amount of τIR transmitted would increase, that is, a cooling. So there is now an interesting balance to investigate, but this is not the end of the story. The species that have been responsible for polar stratospheric ozone depletion, the chlorofluorocarbons (CFCs) such as $CFCl_3$ and CF_2Cl_2, are also greenhouse gases (reducing τIR). So ozone is removed, which both cools and warms the planet, and in addition, the CFCs also warm the planet. These CFCs are in fact very potent greenhouse gases and absorb IR in the region known as the atmospheric window (see Fig. 4), a region of the spectrum where IR largely escapes to space.

Milankovitch Cycles and Ice Ages

Over the last 450,000 years, the Earth's climate has undergone four ice ages (glacial periods) where temperatures have been about 10 °C colder than they are today. During the ice age, large parts of the Earth were covered in ice. At the end of every ice age, there is a sudden rise in temperature (scientists are still trying to understand exactly why), and the Earth goes into a period known as an interglacial. This cycle of glacial and interglacial occurs on a timescale of about 100,000 years. Figure 8 shows this variation in temperature and comes from ice core data taken from Antarctica. What causes ice ages?

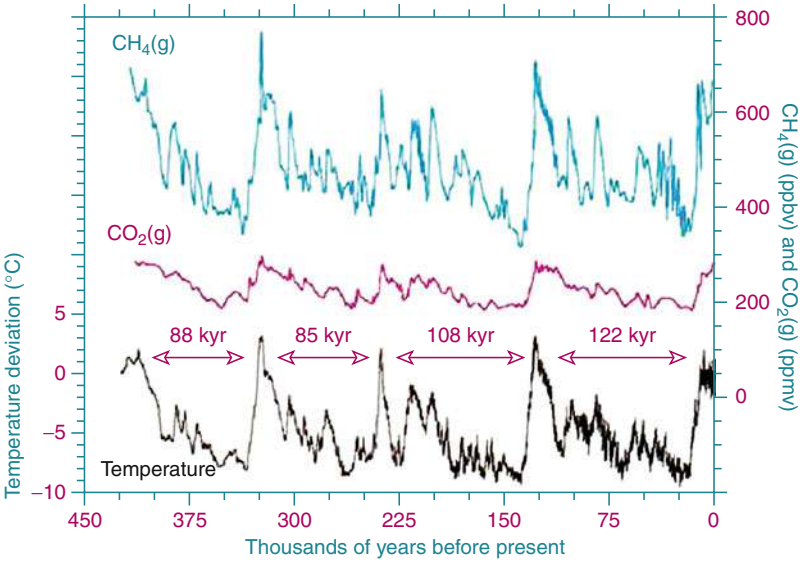

Fig. 8 Data taken from the Vostok ice core showing the changes in surface temperature and levels of CO_2 and CH_4 over the last 450,000 years

Milankovitch Cycles

Climate shifts correspond to three cycles related to Earth's orbit around the Sun that affect the intensity of solar heating (heat from the Sun). The discovery of these cycles is attributed to Milutin Milankovitch. These shifts are caused by gravitational attraction between the planets (mainly Jupiter) and Earth.

Eccentricity of Earth's orbit (see Fig. 9a) varies from nearly circular to elliptical. At low-eccentricity orbits, the average Earth-Sun distance is less, but when the Earth is in a more elliptical phase, the Earth-Sun distance is greater, and the heat from the Sun per unit area is less and leads to the onset of an ice age. This can be modeled by reducing S as the Earth-Sun distance increases. The timescale of this is about 100,000 years.

Axial tilt or obliquity of the Earth's axis of rotation (see Fig. 9b) changes from about 22° (currently 23.5°) to 24.5° and has a timescale of about 41,000 years. As the tilt increases, it changes the heat that reaches various parts of the Earth's surface.

Precession (wobble) changes the quantity of incident radiation (heating) arriving at each latitude during a season and has a timescale of about 22,000 years. These orbital cycles explain qualitatively why the Earth experiences ice ages (glacials) and interglacials. In Fig. 8, it can also be seen that two important greenhouse gases in the atmosphere, CO_2 and CH_4, also rise and fall with temperature. The reason for their fall as the Earth enters an ice age is because the surface of the Earth is being covered in more ice and this reduces the flux of CH_4 to the atmosphere from natural systems such as wetlands and animals and CO_2 from respiration. Using the one-layer model and increasing A (more ice) and increasing τIR (decreasing levels of greenhouse gases) from a base case will lead to a cooling, in agreement with observations. Therefore, past climates can also be investigated and explained by this model.

Present-Day Climate

There are many diagrams on the Internet and elsewhere that show how the surface temperature of the Earth has changed over the last 200 years. One thing is clear: Figure 8 shows that over the last 450,000 years, the level of CO_2 varied between about 170 and 280 ppm; today the level is around 400 ppm. Also during this period, CH_4 varied between about 350 and 700 ppb and is now around 1,750 ppb. Such a rise over the last 200 years has been conclusively shown to be due to the burning of fossil fuels. Evidence for this is interpreted from the carbon isotope ratio present in the sample. The one-layer model would suggest that such a rise in greenhouse gas levels should lead to a rise of about 1–3 °C in temperature. Part of the reason why the rise has not been on the high side is due to global dimming, mentioned earlier (see section "Stratospheric Ozone Depletion and Climate Change"). The point is that there should be no debate about warming due to increased levels of greenhouse gases; the debate should be how large the increase will be and how quickly it takes place. Data from present-day studies will be discussed in section "Impact and Assessment."

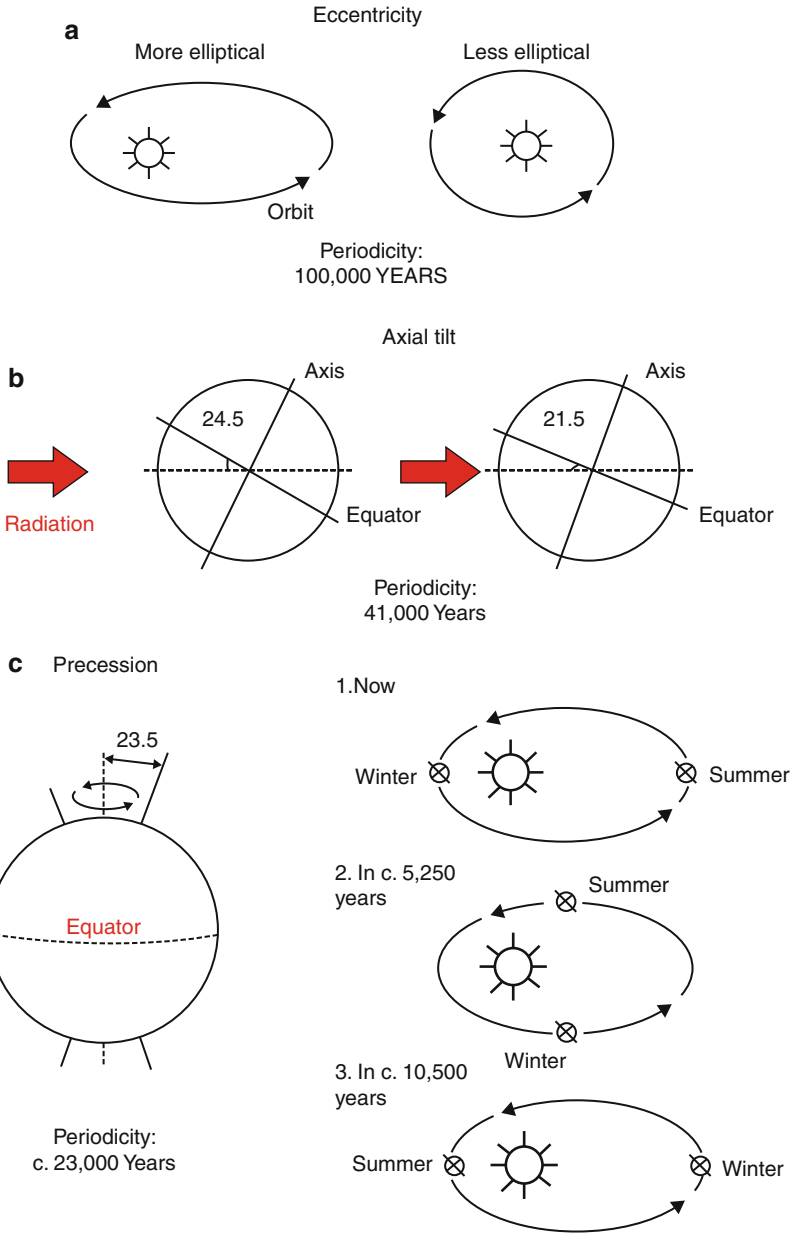

Fig. 9 (**a**) Eccentricity of the Earth's orbit around the Sun has a period of ca. 100,000 years. (**b**) Axial tilt of the Earth relative to the Sun has a period of ca. 41,000 years. (**c**) Precession of the Earth has a period of ca. 23,000 years

A Simple Mathematical Model That Can Be Used to Predict the Atmospheric Level of Greenhouse Chemicals Given Their Lifetime and Emission Rate

The following mathematical model should allow more able students and their teachers to make some more advanced predictions on the levels of greenhouse chemicals as a function of time given their emission rate and lifetime. Many scenarios can be explored to determine emission levels required to achieve a variety of equilibrium concentrations.

There is myriad of "greenhouse gases" in the Earth's atmosphere, i.e., many species can absorb infrared radiation over the wavelengths being emitted by the Earth. The most well known are CO_2, CH_4, and N_2O, but chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), and in particular the hydrofluorocarbons (HFCs) also play a role. A fundamental concept in atmospheric science that is required is the *budget* of a compound. Put simply we consider the sources of the compound and the loss processes ("sinks") for the compound. If the *sources* and *sinks of a compound* balance, it will lead to a constant concentration being observed in the atmosphere. If sources are greater than sinks, then the concentration of that compound in the atmosphere will increase with time and vice versa. However, can we be more quantitative? If the budget is balanced, what will the constant concentration be and what controls this parameter? It turns out (see appendix for derivation) that the concentration of a compound A at time t, $[A]_t$, is

$$[A]_t = E/R\left(1 - \exp(-Rt)\right) \tag{17}$$

where E is the source or emission rate and R is the loss rate (units s^{-1}). We can use the concept of lifetime τ, which is simply the reciprocal of R (1/R), to rewrite Eq. 17:

$$[A]_t = \tau E(1 - \exp(-t/\tau)) \tag{18}$$

When sufficient time has elapsed, i.e., when an equilibrium has been established, a constant concentration of A, $[A]_{constant}$, is reached and is equal to E/R or τE. If the emission rate E increases, a new $[A]_{constant}$ is established which is bigger than before; if the emission rate decreases, the new $[A]_{constant}$ is now smaller. If R, the loss rate, increases, $[A]_{constant}$ decreases. If the loss rate decreases, $[A]_{constant}$ increases. Hence, the concentration of any compound, whether it is carbon dioxide, ozone, methane, nitrogen oxides, chlorofluorocarbons, etc., in the atmosphere is determined simply by E and R or E and τ. The overall impact will be a sum of the individual compound impacts.

Using the main greenhouse gas carbon dioxide (CO_2) as an example, we can imagine that there are natural processes, not involving human (anthropogenic) activity, releasing carbon dioxide (CO_2) into the atmosphere (respiration, aerobic decomposition of organic materials, natural forest fires, volcanic activity) and that

that CO_2 is taken up by plants via photosynthesis and in the oceans first as dissolution and then into the lengthier precipitation processes to form carbonate rock. This natural system leads to an equilibrium, and at that point the level of CO_2 is equal to a baseline concentration, $[CO_2]_{baseline}$. If there is now a constant emission of CO_2 arising from human activity (E_{human}), it will lead eventually to a new, higher-level $[CO_2]_{perturbed}$ which is larger than the baseline. This new-level $[CO_2]_{perturbed}$ is equal to

$$[CO_2]_{perturbed} = [CO_2]_{baseline} + E\tau \tag{19}$$

Current data, based on measurements in ice cores of trapped air deposited with preindustrial levels (before 1800) of CO_2, show that $[CO_2]_{baseline}$ ~280 ppm and that human activity is releasing about 8 ppm per year of CO_2 into the atmosphere (6.5 ppm due to fossil fuel combustion and cement production, etc., and 1.5 ppm through deforestation) and that about half of this stays in the atmosphere (the rest taken up by natural sinks within the lowest part of the troposphere by surface contact processes such as photosynthesis), so the annual emission of CO_2, E_{human}, is about 4 ppm per year. If we assume a lifetime of CO_2 in the whole of the atmosphere of ~100 years, the new CO_2 level will be

$$[CO_2]_{perturbed} = [CO_2]_{baseline} + E_{human}\tau = 280 + 4 * 100 = 680 \text{ ppm}$$

It should be noted that the natural sinks for carbon dioxide are within the boundary layer within the troposphere. If carbon dioxide were to be contained into the bottom 1–2 km of the troposphere, the lifetime of the CO_2 would be in the order of 4 years. Apart from a small reduction in carbon dioxide due to being dissolved out in rainfall at higher altitudes within the troposphere, there are no sinks for carbon dioxide above the boundary layer (approximately lowest 2 km). The carbon dioxide at high levels needs to be circulated through the boundary layer to be removed. This explains the difference in lifetime.

How long will it take to achieve the new equilibrium level?

$$[CO_2]_t = [CO_2]_{baseline} + \tau E_{human}\,(1 - \exp(-t/\tau)) \tag{20}$$

We can plot Eq. 20 as a function of time (Fig. 10) which shows that the time taken is between 200 and 300 years. However, the emission rate, E, of CO_2 is predicted to increase over the next 50 years if no action is taken, and hence the level of 680 ppm would be reached more quickly as a result. It should be noted that CO_2 is the dominant greenhouse gas (not including H_2O) at the time of writing; although gases such as methane (21 times more potent) and nitrous oxide (290 times more potent) are much better at absorbing infrared radiation than CO_2 on a molecule per molecule basis, their rise in concentration is 2.5×10^{-4} that of CO_2, and so their contribution is small but not insignificant to infrared radiation trapping.

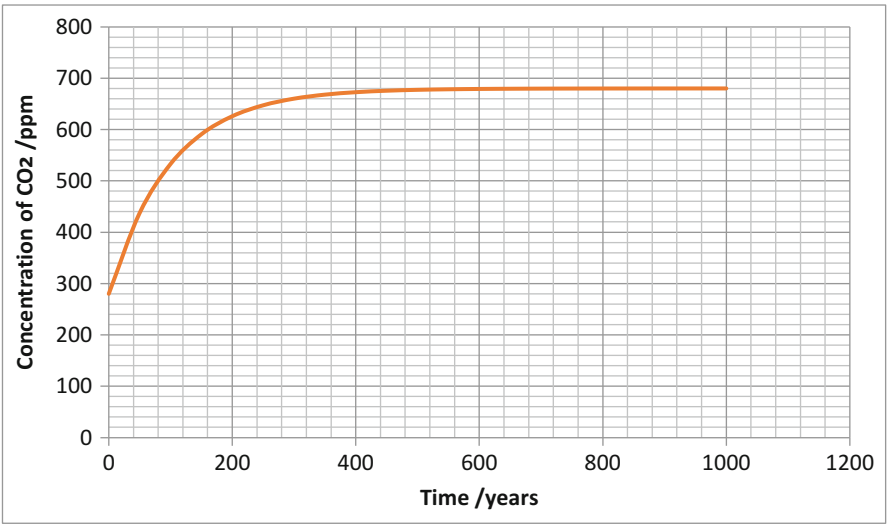

Fig. 10 Graph of concentration of carbon dioxide (ppm) against time (years)

What would emissions have to change by to reduce $[CO_2]_{perturbed}$ to 500 ppm?

$$[CO_2]_{perturbed} = 500 \text{ ppm} = [CO_2]_{baseline} + E_{human}\tau = 280 + E * 100$$
$$220 = 100E_{human}$$
$$2.2 = E_{human}$$

This amounts to a 45 % reduction in current emission rates.

Simple Mathematical Climate Model to Investigate the Role of the Oceans in *Slowing* Climate Change

The question of the impact of the oceans in taking up excess carbon dioxide from the atmosphere and the timescales involved is often queried. This simple model will allow exploration of these ideas.

$$\text{Mass of ocean} = 1.3 \times 10^{21}\text{kg}$$
$$\text{Heat capacity of water} \sim 4 \text{ Jg}^{-1}\text{K}^{-1}$$
$$\text{Heat capacity of the ocean} = 5.2 \times 10^{24}\text{JK}^{-1}$$

The heat capacity of the ocean is approximately 1,000 times that of the atmosphere, and so it can absorb excess thermal energy from the atmosphere.

If we imagine that since the year 1800 the increase in greenhouse gases has caused a rise in heating of ~1 Wm^{-2} (so-called radiative forcing) (http://www.ipcc.ch/), the total energy flux increase ΔE_f is

$$\Delta E_f = 1[Wm^{-2}] \times 4\pi R_E^2 (\text{surface area of the Earth where } R_E \text{ is the radius})$$
$$\Delta E_f = 4\pi\left(6.3781 \times 10^6\right)^2 W$$
$$\Delta E_f \sim 5 \times 10^{14} W$$

The time taken for this energy flux to cause a rise in temperature of 1 K in the atmosphere can now be calculated since energy (J) over power (watts) is time (seconds):

$$\text{Time}_{\text{atmosphere}} = 5 \times 10^{21}/5 \times 10^{14} = 1 \times 10^7 s \sim 116 \ \textit{days}$$

However, the time taken for this energy flux to cause a rise in temperature of 1 K in the ocean is

$$\text{Time}_{\text{ocean}} = 5.2 \times 10^{24}/5 \times 10^{14} = 1.04 \times 10^{10} s \sim 330 \ \text{years}$$

Hence, the timescales for climate change are driven by the ocean's thermal mass. It should be noted that this does not mean that temperature will not rise, but does mean that the timescale will be longer.

Climateprediction.net: Taking Part in Climate Simulations

Climateprediction.net is self-billed as "the world's largest climate forecasting experiment for the twenty-first century." It does this by recruiting help from people around the world who can offer time on their computers when their computers are switched on but are not being used to their full capacity. This is an example of citizen science that school students may wish to engage with.

The full climate model has many parameters that can be adjusted; to explore all of these parameters, an extremely large number of simulations must be performed. Even with the computer resources available to the climateprediction.net team, such an ensemble of simulations would take a very long time. The idea behind climateprediction.net is that anyone can download a version of the model that will explore one of these particular parameters from a group of preset scenarios. The model will take about 3 months to run in the background while one works, without compromising the speed of the computer.

Calculations are performed in three parts. The first part runs calculations using data from the years 1850 to 1900, checking the resulting predictions against temperature records: this is known as the calibration run. The second part runs a simulation from 1901 to 2000. The third stage then runs a simulation of the future climate (2000–2100) with one parameter changed, for example, the sensitivity of climate to uncertainties in the sulfur cycle. Once the calculations are complete, the data is automatically uploaded to the UK's Meteorological (Met) Office the next time the computer is online. The interface software which is provided free of charge with the simulation gives the computer user a graph of the changes to the climate, as they are calculated. Temperature variations by season with latitude, longitude, and

altitude are just some of the variables that can be visualized. Such features can enable a cross-curricular school project linking geography and the physical sciences. The climateprediction.net web site also offers information and resources specifically for schools (http://www.climateprediction.net/education/).

By August 2010, the project has run 74,842,477 model years and has 43,691 active hosts running the different simulations. In 2014, alone volunteers donated nearly 7,500 years of computing time completing half a million successful simulations. A set of current experiments may be found at the project web site as will details of how to get involved.

How does the simple model compare with more sophisticated models such as the Hadley Centre climate model used by the UK's Met Office? In fact, the two models are very similar, except that the Hadley Centre model does not consider the atmosphere as one layer but splits it into a number of boxes based on altitude, latitude, and longitude. For each box, the model directly calculates the amount of incoming UV/visible radiation transmitted and scattered within that box and the amount of outgoing infrared radiation transmitted by that box, based on the concentrations of key greenhouse gases and the surface area of cloud and ice. The most sophisticated versions of the Hadley Centre model also consider the heat flux into and out of the ocean and the uptake of CO_2 by vegetation. If the principles of the one-layer model are understood, comprehending the more complicated climate models is possible.

Writing Articles for School Students and Their Teachers

There are many publications, specialists, or otherwise that report new science to the general public, for example, *New Scientist*. There are also many publications that are aimed specifically at school students and their teachers. In Europe, examples include *Science in School* (http://www.scienceinschool.org/ last accessed February 21, 2015), *Physics Education* run by the Institute of Physics (http://iopscience.iop.org/0031-9120/ last accessed February 21, 2015), and *Chemistry Review* (http://www.york.ac.uk/chemistry/schools/chemrev/ last accessed February 21, 2015). In Brazil, the Ciência para Todos/ Science for All blogsite (http://www.ccell11.com/ last accessed February 21, 2015) aims to do this in Portuguese, Spanish, and English. Ideally, one would want cutting-edge research reported in a way that can be understood by the school community and indeed the general public. To do this effectively, articles should take into consideration the language and terminology that students are familiar with (Tuah et al. 2009); ideally then, the articles should be written by an expert in the field with the help of a practicing school teacher (Harrison et al. 2006; Shallcross and Harrison 2009). In 2005, at the School of Chemistry at the University of Bristol, the first ever full-time School Teacher Fellow (Shallcross and Harrison 2007a, b) position was established. Here an experienced secondary school science teacher was permanently seconded to work with the School of Chemistry, and one of the many things that took place was a rapid increase in the production of articles for a school audience. In concert with the School Teacher Fellow, researchers in the department have been encouraged to write such articles, and a number of

articles on aspects of climate change have also been written (Shallcross and Harrison 2007c, 2008a, b; Shallcross et al. 2009a, b). Elements of these articles focusing on practical and hands-on tools for education in climate science are given in the next section.

Practical and Hands-on Activities

A Climate Change Lecture Demonstration: A Pollutant's Tale

One method of effectively engaging with large numbers of the public on aspects of atmospheric chemistry and climate change is through a lecture demonstration. A lecture demonstration is different to a "chemistry magic show" because the experimental demonstrations chosen are used to illustrate the chemistry being discussed and are not just there for the "wow" factor. The "wow factor" is there in that some of the demonstrations are spectacular, but their use in telling the climate story is their primary value. The secondary aims are tied up with the promotion of chemistry and the "edutainment" value of the talk. One such portfolio of talks was created by the authors entitled "A Pollutant's Tale" together with its version aimed at primary school students "Gases in the Air." These have been performed in excess of 1,400 times in an 8-year period to a total audience of over 225,000 in twenty countries from China to New Zealand to South Africa to the USA and Europe (2006–2014). The several versions of the talk aimed at secondary school students and the wider public all contain the same experiments but the depth to which the explanations are given are age/prior knowledge appropriate. Some of the demonstrations used double-up to reinforce areas of knowledge required by the school curriculum. The talk is best given by two people but can be given by a suitably dexterous and informed individual. It needs 30 min setting up time and 20 min clear-up and can last from 50 to 80 min depending on the audience. The basic lecture demonstration is also now being given by other groups.

The lecture demonstration begins with a comparison of the Earth's atmosphere with the atmospheres of other planets in our solar system (Table 4). The gas giants being predominantly composed of hydrogen and helium give the excuse to set fire to balloons of these gases to reinforce knowledge of the chemistry of these gases and to start the lecture off with a bang. The chemistry of the gases in the Earth's atmosphere is next with experiments looking at liquid nitrogen and the production of oxygen via

Table 4 Three most abundant gases in each planetary atmosphere

Neptune	H_2 (80 %)	He (19 %)	CH_4 (1–2 %)
Uranus	H_2 (82 %)	He (15 %)	CH_4 (2.3 %)
Saturn	H_2 (96 %)	He (3 %)	CH_4 (0.45 %)
Jupiter	H_2 (93 %)	He (7 %)	CH_4 (0.3 %)
Mars	CO_2 (95 %)	N_2 (2.7 %)	Ar (1.6 %)
Venus	CO_2 (96 %)	N_2 (3.5 %)	SO_2 (0.015 %)
Earth	N_2 (78 %)	O_2 (21 %)	Ar (0.93 %)

the elephant's toothpaste experiment (catalytic decomposition of hydrogen peroxide using potassium iodide). From here the audience is introduced to volatile organic compounds (VOCs), a term for which most audiences have no knowledge. The audience is invited to analyze several examples of VOCs, that is, samples of plant origin VOCs such as lime, coconut, vanillin, and lavender are given to the audience to smell, by dipping thick blotting paper strips into a solution of these fragrances. These "smell sticks" are color-coded with food dye so that several samples may be given out at the same time. Synthetic versions of historically animal-derived fragrances of "whale vomit" (ambergris) and civet (originally extracted from the anal gland of the civet cat and still smelling like it) are also used. The question is raised "Where do all these smells go?" This question leads onto the subject of combustion, incomplete combustion being demonstrated by the production and ignition of acetylene and complete combustion of methanol vapor in the "whoosh bottle experiment" (see section "Methanol Whoosh Bottle"). The true demise of the VOCs via free radical mechanisms is then given to appropriately experienced audiences. From here the talk goes onto other pollutants starting with nitrogen dioxide (see section "Nitrogen Dioxide Preparation"). The audience is taken through some research data on the nitrogen dioxide concentration in a city across a day, and its connectivity with photochemical smog is developed with audiences whose background knowledge is suitable.

A major section of the talk then targets carbon dioxide with inspection of Bristol CO_2 levels over a year's data capture and then to the "Keeling CO_2 curve" from Mauna Loa. A moment is taken to look at why Hawaii and also to get the audience to consider that studying science could get them to some very pleasant places to work! Two very basic demonstrations with dry ice (solid CO_2) are performed, the inflation of rubber gloves showing that dry ice sublimes and also that carbon dioxide is soluble in water and will neutralize an alkaline solution becoming weakly acidic (see section "Solubility of CO_2 in Water/Precipitation of Calcium Carbonate"). Three to five minutes are then taken to explain climate using the Granny model (see sections "The Granny Model: Basic Concepts" and "The Granny Model: The Underpinning Mathematics"). A graph of temperature data for the past 150 years is shown which then leads onto the computer modeling of the climate. This is done showing both natural forcings and human contributions and finally the sum of the two. The use of computer modeling to first be able to match the past events before it can be used to make predictions is discussed. The predictions on temperature and rainfall for the area of the world that the lecture demonstration is being delivered are then highlighted. The question "What can be done about it?" is then posed. A graph showing the carbon emissions by year from 1955 to 2055 is put up. The wedge of carbon needed to be removed to avoid the "business as usual" situation is highlighted, and the Pacala and Socolow (2004) stabilization wedge idea is explained. The take-home message then becomes that no one has to wait around for someone to invent ways of removing carbon. In fact, there are already 11 technologies that currently exist. If the social and political willpower were present employing these technologies, it would not only remove the projected carbon load but even reduce it below the current levels. It is very important to leave younger students with a positive message rather than one of

"gloom and doom." The final demonstrations, to end on a bang, are a reminder of the chemistry of helium and hydrogen (a fossil fuel replacement). One version of the PowerPoint of "A Pollutant's Tale" may be downloaded from http://www.chemlabs.bristol.ac.uk/outreach/A-Pollutant-Tale.html, and Spanish and German translations are available from the same webpage.

Demonstrations and Experiments That Can Be Done in School to Augment Climate Change Education

There are a number of chemicals that are important to consider for climate change, either as contributors to climate (soot and carbon dioxide formation), as alternative fuels (methanol and hydrogen), or as alternative energy sources. In this section, several classroom demonstrations and experiments to introduce these materials and describe how they can be used to enliven climate change lessons or lectures are presented. *Safety note*: Local rules and regulations on health and safety should be applied before trying these out. Always practice the experiments before presenting them in front of students, and the environment that the experiments are to be performed in should be taken into account.

Soot/Particulate Carbon

Soot fits into the category of airborne particulate matter. Particles are considered hazardous when they are less than 5 μm in diameter, as they are not filtered out by the upper respiratory tract before entering the lungs.

Black carbon will enhance global warming, but not all particles in the atmosphere do. It all depends on their optical properties: if the particles are very reflective, like a mirror (e.g., sea-salt particles), they can reflect incoming solar radiation back to space and decrease the radiation that reaches the Earth, causing a reduction in surface temperature. If they are dark, such as soot, they will absorb incoming and even outgoing radiation and enhance warming.

Soot is a product of incomplete combustion of carbonaceous fuels, for example, in car motors, central heating, or power stations. There are a number of reactions that can produce soot. The simplest teacher demonstration is to burn small pieces of expanded polystyrene packaging, holding them with tongs over a heatproof mat. The yellow flame produced is very smoky, and the smoke contains black specks of carbon. However, this is not a suitable reaction for students to perform, as the polystyrene drips molten droplets of burning material; instead, the teacher should demonstrate this. Another teacher demonstration, that is a little more spectacular, is the combustion of glucose with an oxidizer. If 5 g of glucose powder is mixed with 5 g of potassium chlorate on a heatproof surface, it can be ignited by a few drops of concentrated sulfuric acid. The eruption of flame also produces a lot of gray smoke which can be discussed in terms of incomplete combustion (safety note: this experiment must not be made by students, as it is dangerous).

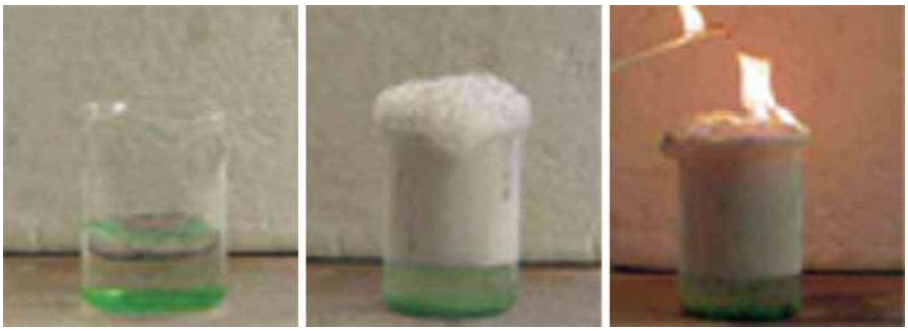

Fig. 11 Addition of calcium carbide to water (with some washing-up liquid added) and then ignition of the resulting foam

If a class experiment to produce soot is needed, the combustion of freshly prepared acetylene (ethyne, C_2H_2) gas is an entertaining reaction (see Fig. 11). Take a 250 ml glass beaker, place it on a heatproof mat, and half fill the beaker with water. Add a good squirt of washing-up liquid (to trap the acetylene gas produced as a foam) to the water and also a few pieces of calcium carbide (CaC_2). The reaction is immediate, liberating bubbles of acetylene. The teacher or student can then use a lit splint, taper, or match to ignite the foam. This burns dramatically with a yellow flame with smuts of carbon.

$$CaC_2 + 2H_2O \rightarrow Ca(OH)_2 + C_2H_2 \tag{21}$$

Solubility of CO_2 in Water/Precipitation of Calcium Carbonate

If dry ice is available, an interesting experiment can be performed to demonstrate the solubility of carbon dioxide in water. This can be used to introduce a discussion about the uptake of carbon dioxide (CO_2) by the oceans as a possible mechanism for removing carbon dioxide from the atmosphere. For this very visually impressive reaction (see Fig. 12), add a handful of dry ice (take care to avoid cold temperature burns) to a large (1 l) beaker of water that has been made alkaline (pH = ~12) with sodium hydroxide solution and to which a small volume of universal (pH) indicator has been added.

Apart from the impressive condensation of water vapor, forming a cloud above the beaker, the formation of carbonic acid (a weak acid) causes a series of color changes to the indicator from purple through to orange (see Fig. 12). For a more impressive cloud, use hot water, as there is more water vapor to condense. The condensation is caused by very cold carbon dioxide gas produced when the dry ice

Fig. 12 Tim Harrison and Dudley Shallcross with dry ice reacting in alkaline water

sublimes, using energy from the much hotter water. Some of the carbon dioxide dissolves in the water.

A small piece of dry ice placed in limewater (calcium hydroxide solution, $Ca(OH)_{2\,(aq)}$) can also be used to show the precipitation of carbon dioxide as calcium carbonate. The oceans of the world dissolve carbon dioxide gas and can precipitate calcium carbonate, which is used in shell construction by numerous creatures. The rate of dissolution is too slow to compensate for the increase in atmospheric carbon dioxide:

If no dry ice is available, then a 2 l drink bottle could be filled with carbon dioxide gas, and about 30 cm^3 of 2 mol dm^{-3} sodium hydroxide can be added. Place the cap on the bottle and shake. The bottle should start to collapse as the carbon dioxide gas reacts with the sodium hydroxide, thus reducing the pressure inside the bottle. The solution forms exothermically so that it gets warm. This shows that carbon dioxide gas is acidic. This has implications for the change in the ocean's pH as the high concentrations dissolve over time.

Methanol Whoosh Bottle

Methanol is a biofuel, an alternative to fossil or nuclear fuels, and this experiment can be used to demonstrate its combustion. In addition to being a renewable fuel, methanol has the advantage over fossil fuels of not releasing "stored" carbon dioxide into the atmosphere; instead, it recycles carbon dioxide that is in the environment anyway.

Fig. 13 Igniting the methanol "whoosh" bottle experiment

Methanol vapor (which is toxic) can be ignited inside an 18–20 l plastic water bottle of the type used in water dispensers. Note that after the experiment, the container will no longer be fit for its original purpose! Be warned some polymers used to make these containers may melt! Also the water bottle must be dry, as the tops of wet bottles tend to melt during the combustion!

Pour around 20 ml of methanol (methyl alcohol, CH_3OH) into a dry 20 l water bottle and shake to vaporize. The pressure of the vapor can be sensed by the hand held over the bottle's mouth if the room is warm. Pour out the surplus liquid methanol. Put the bottle behind a transparent safety screen on the floor and away from any overhead heat, flame, flash sensors, or curtains. Put a lighted taper or long match to the mouth of the water bottle, holding it at arm's length with fingers outstretched. A blue flame will erupt with a loud roar as the methanol vapor completely combusts (see Fig. 13). The experiment should not be repeated with the same container until it is dry again otherwise the methanol burns more slowly and the top of the container begins to melt! Using ethanol or methylated spirits is not recommended as more heat is generated and the container gets very hot. Some demonstrators use propan-2-ol as the fuel. Ethanol burns too hot to do this safely.

Another dramatic demonstration of combustion uses 5 g of glucose mixed with 5 g of potassium chlorate on a heatproof mat. A few drops of concentrated sulfuric acid initiate the reaction between the powders which produces flame and smoke, as also mentioned above. This is a variant on the more well-known "screaming jelly baby" demonstration where a soft jelly sweet is quickly inserted into a clean boiling

tube a quarter full of potassium chlorate which has been heated strongly until molten. In both cases, the potassium chlorate being an oxidizer can be thought of as releasing oxygen to allow the sugar to burn releasing energy as heat and light from the fuel/air mixture.

Hydrogen-Filled Balloons

This teacher demonstration could be used to introduce hydrogen as an alternative fuel to replace fossil fuels and especially to raise the question of whether the combustion product is a greenhouse gas.

One way to demonstrate that hydrogen is a fuel is to fill a balloon with hydrogen (from a cylinder) and tether it to a chair placed away from sensors and flammable materials (such as posters, blinds, or curtains) using a piece of thin string. Ignite the balloon using a lit taper or match, fastened to the end of a meter ruler or a long pole at arm's length. Students should remain several meters away, as during the resultant explosion bits of the rubber balloon tend to fly in all directions. Those with sensitive hearing should place their hands over their ears. The flame and heat energy liberated are spectacular (see Fig. 14) and should lead to discussion of hydrogen's suitability as a fuel.

Fig. 14 Igniting a hydrogen-filled balloon

The Reduction of Iron Oxide on a Match Head

The use of blast furnaces in the iron and steel industries contributes to the atmospheric concentration of carbon dioxide. The crucial reaction, which reduces iron oxide to pure iron by means of carbon monoxide, is

$$Fe_2O_{3(s)} + 3CO_{(g)} \rightarrow 2\ Fe_{(s)} + 3CO_2(g) \tag{22}$$

Students can mimic this reaction on the head of a match! Moisten an unlit match with water and roll into sodium carbonate (Na_2CO_3) powder, and then in iron oxide powder (Fe_2O_3), so that both stick to the match head. Use a second match to ignite the first and let it burn for a moment or two. Crunch the first match head onto a watch glass or Petri dish. Drag a magnet against the underside of the watch glass; the small particles of iron formed will be visible as they follow the magnet's pull. Try this with the starting materials to show that no magnetic materials were initially present. The match provides both the energy for the reaction and the carbon monoxide as a reducing agent. The sodium carbonate acts as a flux material.

Alcohol Burners

Unburned hydrocarbons enter the atmosphere and are oxidized by the hydroxyl radical (•OH) to form predominantly alcohols and carbonyls. Therefore, starting with an alcohol reduces the number of oxidation steps that must take place. Computer model simulations show that the concentration of •OH in the atmosphere is increased when hydrocarbons are swapped for alcohols and carbonyls. Increasing the concentration of •OH will increase the removal rate of greenhouse gases containing a C–H bond. It is also well known that the oxidation of alcohols leads to smaller production of secondary pollutants such as tropospheric ozone. Therefore, using alcohols has a positive effect on both air quality and the removal of greenhouse gases. Moreover, the smaller alcohols can be removed, to a small extent, by physical processes such as dry (taken up by a surface) and wet (rain, fogs, and aerosols) deposition, whereas their hydrocarbon counterparts cannot.

Alcohol burners are the small burners made of glass (see Fig. 15), complete with a wick, which traditionally come with children's chemistry sets and are readily available from school equipment companies. They can be used to determine the energy released in the combustion of shorter primary alcohols such as methanol, ethanol, propan-1-ol, butan-1-ol, and pentan-1-ol. The production of such fuels is a topic in its own right. Note it is too dangerous to use petrol or diesel in these burners.

Fuel Cells

Fuel cells produce electricity from a reaction between a fuel such as an alcohol or hydrogen at the anode and an oxidizing agent such as oxygen or chlorine at the

Fig. 15 Alcohol burner setup under a beaker to which a known volume of water is to be added

cathode. The fuel and the oxidizing agent react in the presence of an electrolyte. A fuel cell is different from a chemical battery because in fuel cells reactants can be replenished, whereas the chemicals being consumed in batteries are not, as they are sealed. A fuel cell will continue to work as long as its reactants are replaced.

There are several demonstration fuel cells available for purchase to show the principle to students. In an alcohol/air fuel cell (see Fig. 16), the cell consists of two parts: an adapted plastic beaker with a conductive pad connected to a terminal (the anode) and an insert containing the catalyst. A defined volume of a source of alcohol (such as antifreeze) or of an alcohol itself (such as propan-1-ol) is mixed with 55 ml of alkali (such as sodium hydroxide) and put into the plastic beaker. The insert (colored red in the image) is put into the beaker to complete the cell. Air can pass through the insert into the alkaline alcohol mixture.

The voltage produced by the fuel cell can easily be measured using a cheap multimeter/voltmeter.

Grätzel Cells

Grätzel cells, also called "nanocrystalline dye solar cells" or "organic solar cells," convert sunlight into electricity directly. Named after their inventor, Michael Grätzel, a Swiss engineer, the function of Grätzel cells is based on artificial photosynthesis using natural dyes found in cherries, blackberries, raspberries, and blackcurrants, among others. These purple-red dyes, known as anthocyanins, are very easy for school students to extract from fruits and leaves by simply boiling them up in a small volume of water and filtering.

Fig. 16 Fuel cell using gin to generate electricity

These cells are very promising because they are made of low-cost materials and do not need elaborate apparatuses to manufacture. Although their conversion efficiency is less than that of the best thin-film cells, their price/performance ratio (kWh m^{-2} $annum^{-1}$) is high enough to allow them to compete with fossil fuel electrical generation. Commercial applications, which were held up due to chemical stability problems, are now forecast in the European Union Photovoltaic Roadmap to be a potentially significant contributor to renewable electricity generation by 2020.

Grätzel cells separate the two functions provided by silicon in a traditional cell design: normally, the silicon both acts as the source of photoelectrons and provides the electric field to separate the charges and create a current. In the Grätzel cell, the bulk of the semiconductor is used solely for charge transport, while the photoelectrons are provided from a separate photosensitive dye (the anthocyanin). Charge separation occurs at the surfaces between the dye, semiconductor, and electrolyte.

The dye molecules are quite small (nanometer sized), so in order to capture a reasonable amount of the incoming light, the layer of dye molecules needs to be made fairly thick, much thicker than the molecules themselves. To address this problem, a nanomaterial is used as a scaffold to hold large numbers of the dye molecules in a 3D matrix, increasing the number of molecules for any given surface area of cell. In existing designs, this scaffolding is provided by the semiconductor material (titanium oxide), which serves double duty.

Production of Biofuels from Vegetable Oils

There are a number of ways of making biofuels from a range of vegetable oils, but the reaction is essentially the same. A biofuel is made by alkaline hydrolysis of the triglycerides in a vegetable oil and the following reesterification of the triglycerides to the methyl ester (a transesterification is done to obtain a less viscous fuel, which is termed biodiesel). In practice, both steps can take place in the same preparation, provided a mixture of methanol in alkali is used. This mixture contains the methoxide ion. During hydrolysis, a fatty acid is liberated from the triglyceride. Together with the methoxide ion, the methyl ester of the fatty acid is then formed. Glycerol (propan-1,2,3-triol) is a waste product of this last reaction. The disposal or use of the glycerol is one of the challenges for this growing industry.

One can either use a large tube or a reflux method involving Quickfit^{TM} laboratory glassware. If using a reflux for the reaction, the biofuel can be separated from the glycerol by solvent extraction. If the experiment is being performed by students in a well-equipped laboratory, the products formed from several different starting vegetable oils can be compared using GCMS (gas chromatography-mass spectrometry).

In the simpler preparation, 12–13 ml of a vegetable oil of choice is put into a boiling tube with 2 ml of potassium hydroxide in methanol (5 % w/w). The liquids are mixed without shaking to prevent trapping air and foaming. The mixture is left to stand in a water bath at 60 °C. The reaction rate can be followed by measuring the viscosity: one can time how long it takes for a small ball bearing to drop through a defined depth of the mixture in the tube every 5 min at regular intervals for up to 2 h. Furthermore, you can leave a sample for a whole day in these conditions to observe the extent of hydrolysis. *Note*, if previously used vegetable oil is utilized, please remember to strain out any food residues first!

Nitrogen Dioxide Preparation

Few students make or even see the gas nitrogen dioxide (NO_2) as it is poisonous, and science teachers are put off by the necessary risk assessment. Nitrogen dioxide can be made in small volumes very simply using a source of copper and concentrated nitric acid. In the UK, it is permissible to use copper coinage as a source of copper and as such adds to the interest of the demonstration. If coinage use is not possible, then a spatula of copper turnings – not bulk copper metal or copper powder – should be used. The copper is placed in a wide-necked conical flask or 400 ml beaker placed on a white tile against a white background to make the color change more easily seen.

After a short while, orange-brown fumes of nitrogen dioxide can be seen. The reaction increases speed after a few moments. Provided there are no drafts, the density of the gas may be seen by pouring out the gas from the reaction vessel. The acidity of the gas may be demonstrated using damp universal indicator paper or blue litmus. Some closer members of the audience may get to smell the chlorine-like odor,

and it may remind them of the smell that is sometimes detected near busy roads or outside of central heating boiler ducts. The reaction may be stopped by diluting the acid in the reaction vessel with water. The blue color of hydrated copper (II) can be seen.

The color of the gas is important, indicating that it absorbs light at around 400 nm. The NO_2 is easily broken down to NO and O atoms by this photolysis process. The O atom produced can add to O_2 as shown in reaction (Eq. 14) and gives rise to the production of ozone near the surface. Such production of ozone near the surface is bad for animal and plant health and is associated with photochemical smog. As the oxidizing properties of nitric acid are concentration dependent, this reaction has a number of other teaching uses.

Detection of Atmospheric Carbon Dioxide Levels Using IR Sensors

Carbon dioxide (CO_2) is the most commonly known greenhouse gas. One might well ask how levels of CO_2 are measured in air samples, particularly as their concentrations are so low. A lot of people will remember from their own school science lessons that carbon dioxide can be detected through the use of limewater (saturated calcium hydroxide solution) where the clear and colorless solution turns chalky, misty, and milky or forms a white precipitate depending on interpretation. All these descriptions refer to the formation of a suspension of calcium carbonate ($CaCO_3$). Few have any understanding of how the concentration of carbon dioxide in the atmosphere can be known. Few will have any understanding of infrared spectroscopy and its link with molecular bonding.

How Do Infrared (IR) Sensors Work?

Two types of carbon dioxide sensors have been used with school students and teachers (Harrison et al. 2006): one which allows gas to diffuse into the sensor and one which is pumped. They both work in similar ways.

Carbon dioxide molecules absorb energy at specific frequencies of infrared radiation and use the corresponding energies to stretch or bend the covalent bonds between the carbon and oxygen atoms accordingly. Low energies cause a bond-bending motion, and high energies cause bond stretching. The frequencies at which this occurs are within the infrared part of the electromagnetic spectrum (between 4,000 and 650 wavenumbers, corresponding to 2.5–15 μm). A wavenumber is the unit commonly used in spectroscopy to relate wavelength to energy. A wavenumber ($1/\lambda$) is the reciprocal of wavelength (λ) and is directly proportional to energy. This absorbance at this wavelength can be used to determine the CO_2 concentration in the air.

There are two main types of carbon dioxide sensors (Harrison et al. 2006). The more expensive research sensors pump air through the sensor, while the cheaper devices rely on diffusion. For either type of detector, air passes into the absorption cell. This is effectively a small darkened cylinder within the sensor. At one end of the

absorption cell, there is an infrared light source coupled to a fixed wavelength filter, which provides a narrow band source of infrared light, for CO_2 at around 2,350 cm^{-1} (wavenumbers, i.e., 4.3 μm). At the other end of the tube, there is an infrared detector or photon counter that measures the infrared light intensity. The more CO_2 molecules are in the air sample, the more infrared radiation is absorbed in the cell, and the less infrared radiation reaches the detector. For small absorptions, the Beer-Lambert law shows that

$$\text{Concentration} = \frac{(1 - (I/I_0))}{\sigma l} \tag{23}$$

where

l is the path length (length of the cell).

σ is the absorption cross section for CO_2 at the wavelength being used and is known to a high accuracy.

(I/I_0) is the ratio of infrared radiation arriving at the detector when the cell is empty (I_0) to when it has an air sample in it (I).

I_0 is not measured for each reading, but will be measured frequently to check that there are no appreciable fluctuations in the instrument infrared light intensity.

Students who have used such sensors (see Fig. 17a, b), on loan from the University of Bristol, have been surprised that the carbon dioxide reading inside an empty classroom is much greater than that outside, the latter being well above 0.037 % (370 ppm) as reported for the CO_2 atmospheric concentration in some textbooks. New school buildings in the UK appear to have windows that are not designed to be opened! Simple experiments in a lecture theater with ~200 students show that the CO_2 concentration will reach ~1,400 ppm after 50 min.

The CO_2 sensors that have been used with students are tuned to the CO_2 ν_3 asymmetric bond stretch at 2,349 wavenumbers (Harrison et al. 2006). An asymmetric stretch is where the carbon-oxygen double bonds (C=O) absorb energy and one of the two bonds lengthens, while the other one contracts. For CO_2, there can only be one asymmetric stretch. This particular bond stretch is important because carbon dioxide is the only molecule present in high quantities in the atmosphere to absorb at 2,439 wavenumbers. Therefore, only absorption by CO_2 can cause a change in infrared light intensity at this wavelength. It is common for an optical sensor to be tuned to a specific frequency where the molecule absorbs. Usually it is the most intense absorption that is chosen to be detected because there will be the greatest sensitivity. Using the method with other gases, this is not always possible as there may be others that also absorb in that region. In that case, a different absorption is chosen free from interferences.

Examples of simple investigations that can be made with such sensors without logging include measuring the levels inside a classroom before and after it is in use, measuring roadside levels of carbon dioxide and the differences that are there in moving away from the road (wind direction, season, time of day also play a part),

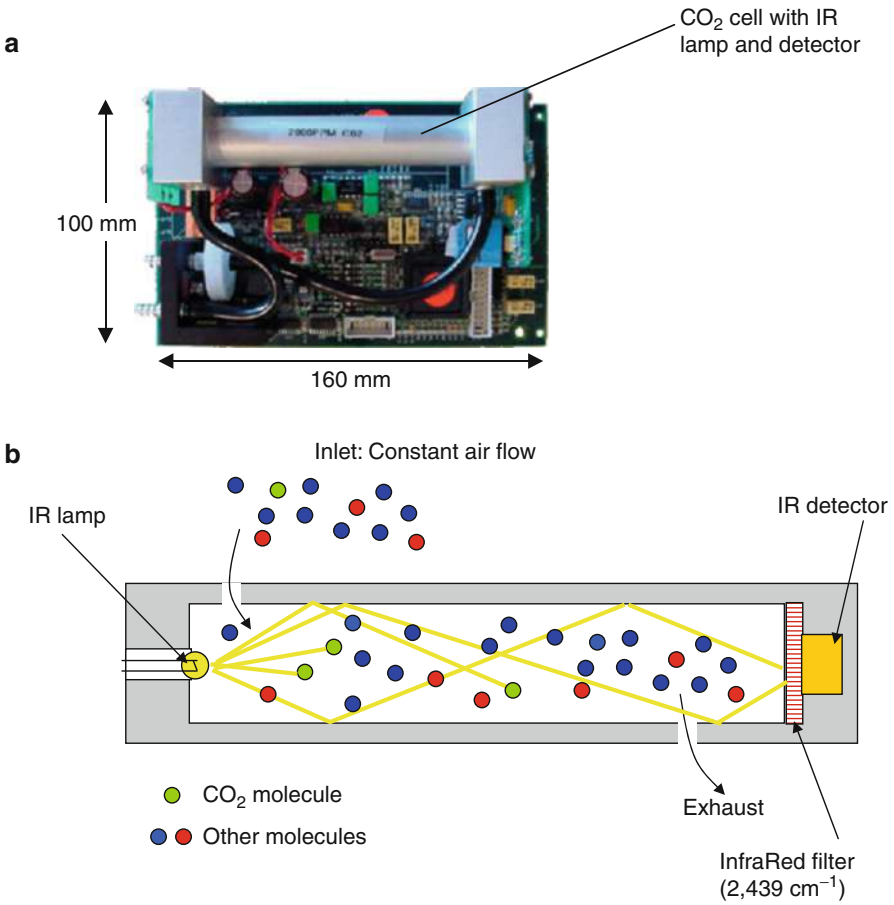

Fig. 17 (**a**) Internal circuitry of the CO_2 detector. (**b**) A schematic of the CO_2 cell within the sensor 2,439 cm^{-1} = 4.1 μm

and measuring levels above and below trees and other vegetation. With a logging device, simple investigations of the change in concentration in a classroom during the lesson, with and without windows and doors open, are easy to do. Roadside data measurements over a period of time provide a rich source of information not only about emissions from cars but also about the dynamics of the atmosphere. Fourier transform analysis (Harrison et al. 2006) of these data has revealed cycles of minutes (corresponding to traffic light signal cycles), 8 h (rush hour peaks), 12, and 24 h revealing the rising and falling of the Earth's boundary layer. Very-long-term measurements, of course, provide seasonal cycles that a student can investigate and reveal, even in urban measurements, a winter peak and summer trough caused by photosynthesis.

Impact and Assessment

"How does one know that what one does in terms of climate change outreach is doing any good?" is often a question asked of work with primary and secondary school students or indeed with the wider public. It is often a question asked of prospective funders either directly or by implication on grant applications when the use of evaluators is required. In this section, some feedback methods are discussed that may be useful for employment in outreach activities.

A major current issue in the field of science communication is evaluating the impact of activities designed to engage people with science and technology. Evaluation is widely seen as the primary tool to identify best practice and provide empirical evidence of the positive impact of such activities. However, there is no standard method for doing this or for comparing the results.

The majority of published evaluations involve the use of quantitative data generated through written questionnaires. Using such methods to evaluate the impact of short-duration activities is often inappropriate or impractical. Are there alternatives to the traditional questionnaire for obtaining feedback about the impact of some types of science communication activity? What are the effects, if any, of the activities on participants?

Generic Learning Outcomes

In a recent research exercise, Rivett (2009) investigated a number of physical science outreach events, including the use of lecture demonstrations at primary and secondary level on atmospheric chemistry and climate change. These activities were evaluated using a variety of unconventional techniques. The events were evaluated using *postcard writing, children's drawings, comments boards and walls, observation*, and *unsolicited and teacher feedback*. An *interactive voting* system and some *written questionnaires* developed and administered by third parties were also utilized. These largely focused on identifying the immediate to short-term impact of the activities. They generated largely qualitative data but included a quantitative component.

These data were analyzed using the *Generic Learning Outcome* [GLO] (Generic Learning and Archives Council 2008) framework, which is becoming a common evaluative tool across the Museum and Science Centre sector. GLOs are a way to look at different types and levels of impact using one tool. The model stems from a view of learning as a personal and individual experience, which is context dependent. Five categories are used to code participants' responses: *knowledge and understanding*; *skills*; *attitudes and values*; *enjoyment, inspiration, and creativity*; and *activity, behavior, and progression*.

The alternative evaluation techniques tested resulted in the production of a large amount of useful data and a greater range and depth of information on impact than might be expected. The qualitative nature of the tools is more appropriate for small

sample sizes (which might lack statistical significance). They were generally uncomplicated to use and simple to analyze using the GLO framework.

- *Write a postcard* feedback revealing the greatest range and depth of learning outcomes, comparable with an externally designed *written questionnaire*.
- *Observations* were a rich source of data, but did not necessarily capture the impact on all participants. *Teacher feedback* provided information about a range of learning outcomes, but not from the pupils' own perspective. *Children's drawings* gave some useful information about a limited range of learning outcomes.
- *Comments boards* provided a deeper insight into participants' experiences than initially expected, but generally only about a subset of learning outcomes. To generate meaningful data about impact, questions must be carefully worded to guide responses.
- *Unsolicited feedback* does not give reliable evidence of learning outcomes, but can be analyzed to provide limited information about impacts.
- *Interactive voting* provided the least information about impact in this study, because the questions asked generally did not focus on learning outcomes.
- The major category of learning outcome reported by participants is *enjoyment*, but evidence for *knowledge* gained, changes in *attitudes*, and *behavior* is also strong. It is the questions asked which hold the key to elucidating different learning outcomes.

Suggested Questions to Discern Different Learning Outcomes

The evaluation techniques differed in their level of convenience. Data collection tools such as the *postcard feedback* and *Post-it note comments* were cheapest and simplest to administer and could be analyzed rapidly using the GLO method.

The majority of these techniques can only evaluate the immediate impact of the activity. This is due to when they are administered, which could be instantly after the event or at the most up to 1 or 2 weeks afterward. Asking participants to complete these styles of evaluation, a significant amount of time afterward is impractical and becomes more a test of memory than anything else. Teacher feedback was shown to provide an indication of longer-term impact, although this may be rather subjective.

The GLO framework is a useful coding device which allows wider comparisons with other studies. It enables outcomes beyond immediate "reaction" level to be investigated in a meaningful way. The GLO approach reveals that impact is not a neat, linear process but occurs at many levels and over a multiplicity of timescales.

The learning outcomes themselves are extremely varied. There may be no or even a negative impact, a transient effect, or something deep and long lasting. The level of impact is impossible to predict and is not the same for all participants. Discovering the medium- to long-term impact of any of these activities is beyond the scope of the techniques tested.

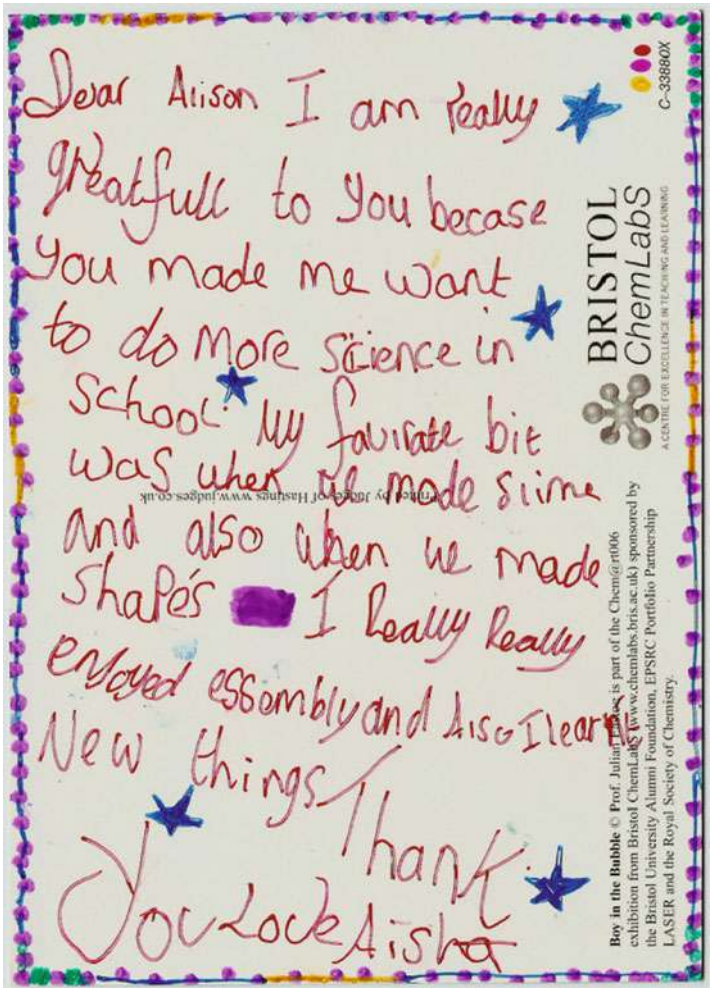

Fig. 18 A postcard from a primary school student, providing feedback on an activity

However, a learner's enthusiasm for a subject is usually retained much longer than memory of facts or content. There is evidence that memorable activities which provide positive experiences of science can affect future behavior. Given the right support, situational interest may become sustained and so increase motivation and satisfaction with a subject.

Science communication activities like those investigated are just one part of the many and varied experiences in people's lives. A single event cannot be expected to have a significant impact on the life choices of the majority of participants. What can make a difference is ensuring, through thorough and reliable evaluation, that there are a range of high-quality opportunities for people of all ages to experience different aspects of science, meet role models, and develop their interest and abilities.

Table 5 Suggested questions that can be used for evaluation of activities

What was your favorite part of the day	*Formative/process/ enjoyment*
Was there anything you did not like	*Formative/process/attitudes*
Please tell me anything you learned today	*Knowledge/skills*
How did today make you feel about science	*Attitude/enjoyment*
Did you find out how to do anything new or do anything better	*Skills/knowledge*
Do you think you will do any science activities following this event	*Behavior/attitudes*

The study identified a number of techniques which provide a range and depth of information about the learning outcomes experienced by respondents. They can easily be embedded into science communication activities and do not require time-consuming analysis.

The impact of the physics and chemistry activities studied was found to be very positive for the majority of participants and was similar to those found in other studies. A myriad of effects are seen at a variety of levels and over a range of timescales.

This postcard (Fig. 18) sums up how a simple evaluation method can pay dividends in terms of the level of information gathered and show true evidence of the potential impact of science communication activities. A list of suggested questions for a GLO analysis is provided in Table 5.

Some Misconceptions Concerning Climate Change and Greenhouse Gases

The following are the main misconceptions that workshops with students or with teachers have unearthed. It is important for all educators working in climate change to realize that ideas and models that are commonly used with peers are not general knowledge and the "obvious" needs to be spelled out. One such example with a group of experienced teachers was the term "aerosol," which was only considered to be a spray can!

All greenhouse gases are synthetic/man made.

No, several natural processes release gases which can absorb outgoing infrared radiation (i.e., they are greenhouse gases), for example, CO_2 is produced during respiration and natural combustion, N_2O is produced by denitrifying bacteria in soil, and CH_4 is generated by termites and cows.

Global warming means that the entire planet will warm up evenly everywhere.

No, warming will be quickest at the North Pole and slowest in the southern ocean.

All pollution in the atmosphere causes global warming.

No, for example, air pollution that leads to aerosol formation can cool the planet down (global dimming), e.g., SO_2 emissions.

All greenhouse gases are bad for the planet.

No, a natural background level is essential for the average surface temperature to be habitable (see sections "The Granny Model: Basic Concepts" and "The Granny Model: The Underpinning Mathematics").

If more carbon dioxide means a warmer temperature, surely faster photosynthesis at the higher temperatures will remove the excess CO_2.

Photosynthesis is controlled by enzymes, so at some temperature this process will stop. Also, at higher CO_2 levels, stomatal conductance drops (the plant does not have to work so hard to obtain CO_2), and there is evidence that its physiology changes significantly.

If burning waste materials produces CO_2, then why not simply not burn organic waste instead of letting it rot.

This is a contentious issue; during rotting, a myriad of gases are released into the atmosphere, and many will be greenhouse gases that will eventually be converted to CO_2 in the atmosphere. So there is a strong argument to burn the waste, harness the energy, and capture the CO_2 produced.

CO_2 is worse than methane.

Figure 4 shows us that CO_2 already absorbs a significant fraction of outgoing infrared radiation around 660 cm^{-1} (25.2 μm), and therefore to absorb more would require a bigger jump in concentration than that for CH_4. It turns out that CH_4 is 21 times more potent than CO_2 over long timescales.

Carbon dioxide is always heavier than air.

Below 100 km, gases are all well mixed in the Earth's atmosphere, and even though CO_2 is heavier than air, it is well mixed.

It is only burning fossil fuels that causes emissions of CO_2.

Respiration also produces CO_2 as do a number of key industrial processes such as iron and steel, aluminum, and cement production.

Datasets That Can Be Used in a Class Setting

There are many datasets that are freely available, such as the UK National Air Quality Archive (NETCEN) (1996), that are a fantastic resource for students and teachers who want to have more hands-on activities concerned with air quality and climate change. However, the main problem is finding out about these archives, being able to access them and, of course, being able to comprehend what these data are and how to use them. A very profitable way forward is to provide background material for teachers and to run master classes in how to use these data. Through these classes, it has been possible to refine the notes provided and extend the scope of the class. There are also datasets that are well documented such as the Advanced Global Atmospheric Gases Experiment (AGAGE) dataset.

One such use of a dataset was research into how fireworks affected air quality during the UK's Bonfire Night. Students from several year groups from three schools were instructed on how to handle data from the UK-AIR website (http://uk-air.defra.gov.uk), and their research was published (Harrison and Shallcross 2011).

AGAGE

AGAGE (1978) is a project that has run since 1978 (then called the Atmospheric Lifetime Experiment, ALE) and consisted originally of five surface stations that were spread across the Northern and Southern Hemisphere, away from major pollution sources. These sites were in Ireland, the USA, Barbados, American Samoa, and Australia (see Fig. 19) and use gas chromatography coupled with a variety of detectors to measure CFCs (chlorofluorocarbons), compounds that were responsible for depleting stratospheric ozone and their replacements the HCFCs and HFCs (hydrochlorofluorocarbons and hydrofluorocarbons). In addition to these gases, measurements of key species such as CO_2, CH_4, and N_2O are made. Extensive information is available, and clear notes on data are provided. Using data such as that from AGAGE can transform classroom teaching and cognition on the subject of climate.

Global Warming Potentials

It is useful to define a concept called the global warming potential or GWP. In the "Introduction" section, it was explained why greenhouse gases are so important to the Earth's climate system and that to be a greenhouse gas, it needs to absorb infrared radiation corresponding to the wavelengths shown in Fig. 4. The most important of these greenhouse gases is CO_2, and the GWP is defined relative to CO_2. The GWP is calculated using a computer model and allows greenhouse gases to be "ranked" in

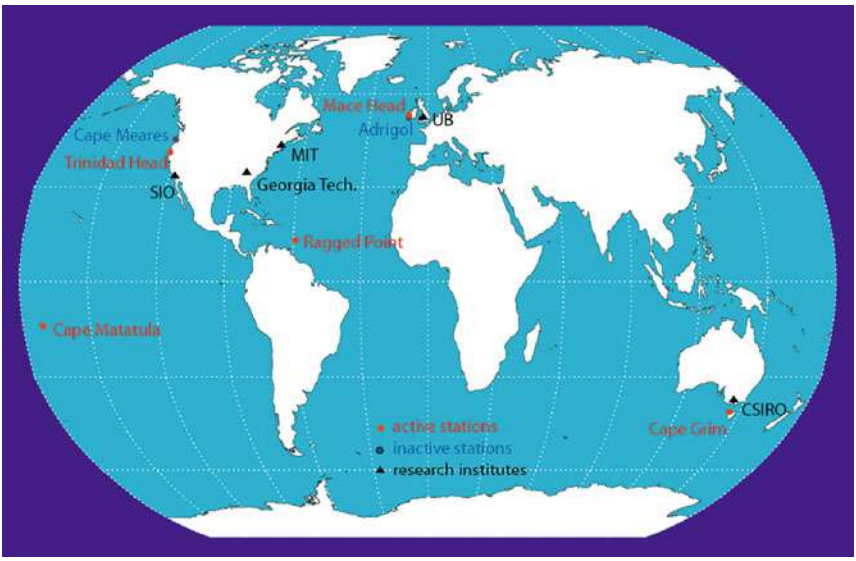

Fig. 19 Original surface sites for the AGAGE project

Table 6 Some global warming potentials for a range of trace gases over a 20-year and 100-year time horizon

Trace gas	Lifetime (years)	GWP time horizon 20 years	GWP time horizon 100 years
CO_2	~120	1	1
CH_4	10	63	21
N_2O	150	270	290
$CFCl_3$	60	4,500	3,500
CF_2HCl	15	4,100	1,500
CF_2Cl_2	130	7,100	7,300

terms of their potency. It is not too difficult to see that the two factors that determine a GWP are how strongly does the gas absorb infrared radiation emitted by the Earth (effectively the size of the absorption cross section of the gas) and how much of the gas (determined by its source strength and lifetime) is present. In a GWP computer model, one would typically release a unit mass of CO_2 and a unit mass of the gas whose GWP is to be determined. After 20 model years, the radiative forcing or heat trapped by CO_2 is calculated and scaled so that it equals 1. Using this scaling factor, the radiative forcing of the gas under inspection is also calculated. The model is run for 100 model years, and the radiative forcing is calculated again and scaled to CO_2. Some data from key greenhouse gases are collected in Table 6. The table reports the GWP on a 20-year and 100-year time horizon and, because of the definition, CO_2 in unity always. Interestingly, for all other gases, the GWP either increases from a 20-year time horizon to a 100-year one or decreases. Further inspection shows that those gases that have a shorter lifetime than CO_2, that is, CH_4, $CFCl_3$, and CF_2HCl, all decrease, while the remaining two, N_2O and CF_2Cl_2, whose lifetimes are longer than CO_2 increase. This change in GWP with time (hence the need to stipulate the time horizon) arises because if the gas is removed more quickly than CO_2, relative to the year 20, the ratio of X/CO_2 in the year 100 will have decreased, that is, far more of X will have been removed than CO_2. Hence, with time the effectiveness of the gas will decrease, that is why the GWP of CH_4 drops from 63 to 21, for example. In a similar vein, N_2O is longer lived than CO_2, and so with time the CO_2 will decay more rapidly, and the N_2O becomes even more effective with time. Regardless of lifetime, it is clear that species containing C–F and C–Cl bonds have very high GWPs. This was explained in section "Stratospheric Ozone Depletion and Climate Change," that is, that these gases absorb in the region known as the atmospheric window and have high absorption cross sections, coupled with their lifetime, leading to the high GWP. Compounds of particular concern are the PFCs (perfluorocarbons), fully fluorinated saturated hydrocarbons (e.g., CF_4 and C_2F_6). These molecules have incredibly long lifetimes (sometimes known as immortal molecules) and very large absorption cross sections and can therefore have a GWP of many thousands. It has been speculated that if man colonizes another planet such as Mars, PFCs would be needed in the terraforming process to flood the atmosphere with high GWP gases and raise the surface temperature.

Methods Used to Monitor Greenhouse Gases

It is instructive to know how the levels of greenhouse gases in the atmosphere are determined. First, the site of the monitoring station is important; it needs to be away from major pollution sources, so that changes to the background concentration can be determined. This criterion dictated where the AGAGE stations would be located (see Fig. 19), and it also then requires that the stations are in remote locations. Hence, the monitoring systems need to be robust, reliable, and low maintenance. For the majority of gases, gas chromatography (Fig. 20) with either an ECD (electron capture detector) or an FID (flame ionization detector) or a mass spectrometer is used. Since many of these gases are present in trace quantities, the air mass must first be pre-concentrated, and to achieve this, a cooled microtrap (−50 °C) containing some solid adsorbent is used to trap the gases of interest (ADS in the figure). Many liters of air can be trapped in this way, and once collected this slug of air can be driven off the trap in 1–2 s by ballistic heating. This slug of concentrated air is then separated into its components by passing it through a GC (gas chromatography) column. As the gases pass over a solid or liquid phase (an adsorbent), some bond to the surface more efficiently than others, and so separation takes place. For gases such as CFCs, HCFCs, and N_2O, which have electronegative elements such as F, O, and Cl, an ECD is a good detector. An ECD consists of a beta (electrons) emitter that provides a baseline current. As the molecule passes through the beam, it absorbs electrons and a dip in current is observed. This invention of Lovelock is incredibly sensitive. For other species, they can either be burned in a flame, where ions are produced and detected, or "weighed" using a mass spectrometer.

Outreach: Impact on Providers and Others

What Is the Impact on Postgraduates and Researchers Who Engage with Schools, Teachers, and the General Public?

There are several reasons why researchers such as postgraduates should get involved with outreach in topics such as climate change excluding the most important one, which is that taking part in well-organized and well-thought-through activities is great fun!

Communication Skills

Working with school students causes researchers to evaluate the language that they use to communicate their work. Researchers who only used to communicating their science to peers do not always realize that their language is very specific and has acceptance of mutually understood models. They forget that this language and use of models are not widely understood by others. Working with school students directly, or writing articles for them, brings this home. The advantage for the researcher is being able to communicate their work to wider audiences including to those less expert. There are many instances when it may be vital to be able to explain to someone what research you are doing, for example, a potential funder. To younger researchers, the opportunity to give presentations to groups of school students increases their confidence and makes the delivery of talks at seminars and conferences of their peers a less daunting task than it would otherwise be. For younger researchers, it also forces them to really understand the background to their material, as they will almost certainly be asked that obvious but not trivial question about their subject, by an enthusiastic teacher or student.

Role Models

School students still see stereotypes of scientists as being male, middle-aged with long white hair. Putting young researchers, perhaps with colored hair and studs through their noses, in front of school students makes a big difference. Bristol ChemLabS outreach often has requests for outreach teams to be composed of specific gender and racial types to act as role models in particular places. For example, in areas in certain countries of social deprivation with a high proportion of immigrant descendents, to have teachers that are from that group can have an amazing impact on the student's enthusiasm. In another instance, a totally female team was requested to work with primary aged girls who had become disillusioned with science and mathematics. The feedback from both implied that these targeted role models had the desired effect.

Supervisors

Many supervisors may be reluctant to let their postgraduates engage in outreach activities as this removes them from the research laboratory environment. Students report that they really value short periods spent away from their labs engaged in outreach. Students give as examples, coming back into the labs afresh, the ability to

look at their work with renewed enthusiasm as they treat outreach engagements as "periods of tranquility" in an otherwise chaotic work program. Indeed, some students have only managed to complete their PhDs because of this outlet. In other cases, the climate change science being presented to school students has suddenly clarified the point of a piece of PhD research and then has led to it moving on in a new direction.

Increased Employment Prospects

Students can access many more potential careers such as those directly involved in science communication and teaching. Working for an outreach team also gives them additional referees that can comment on their skills for these and other positions. Increasingly, employers value the soft skills, such as communication and team work skills, over technical expertise of graduate chemists. Outreach work can develop these.

Impact on Recipients

Well-focused activities with supporting resources can have a lasting (Harrison and Shallcross 2010; Tuah et al. 2009) impact on teachers and their students, in terms of cognition in this subject area. Through schools one can also interact with whole families, for example, parents. A combination of lecture demonstrations, model workshops, and hands-on practical sessions has been found to be a powerful portfolio for a wide range of learner types and ages. Such approaches have also worked well for those with disabilities, for example, visually impaired.

Is Climate Change All Gloom and Doom? Introducing Stabilization Wedges

When learning about climate change, the students can become despondent easily. They can feel that warming of the Earth and the resultant consequences are inevitable. Both to give some hope to the students and to demonstrate to them the potential of scientific research, ideas presented in a recent paper by two leading climate scientists (Pacala and Socolow 2004) can be introduced into lessons. Their paper discusses how CO_2 levels can be stabilized and other carbon-based greenhouse gas emissions into the atmosphere using technologies that already exist.

Stephen Pacala and Robert Socolow devised the concept of stabilization wedges as a way to reduce carbon emissions over the next 50 years. Figure 21 shows how carbon emissions have increased over the last 50 years and how they are predicted to change in the next 50 years largely based on changes in population. By 2055, it is predicted that there will be 14 gigatons (billion tons) of carbon (GtC) emitted per year if nothing is done now. This will lead to a level of CO_2 in the atmosphere that is around three times the CO_2 level before the industrial revolution started and is predicted to cause a rise in the Earth's average surface temperature of 1–5 °C.

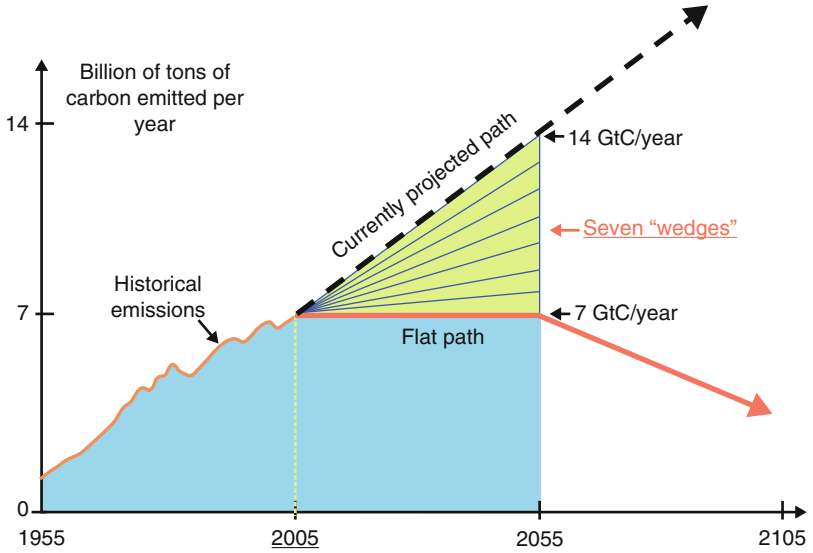

Fig. 21 Carbon emissions, past, present, and future, and the concept of stabilization wedges

Pacala and Socolow suggest that the objective is to maintain carbon emissions at their present levels of 7 GtC per year. As there is no one method to remove this carbon burden, they devised the idea of stabilization wedges. A wedge represents an activity that reduces emissions to the atmosphere that starts at zero today and increases linearly until it accounts for 1 GtC per year of reduced carbon emissions in 50 years. The cumulative total is therefore 25 GtC of reduced emissions over 50 years.

What Activities May Achieve This Effect?

Improved Fuel Economy

A typical car emits a ton of carbon into the air each year. There are one billion cars in use today, and the figure will grow to two billion. Two wedges could be saved if their fuel economy were improved from 30 miles per gallon (mpg) of fuel to 60 mpg.

Reduced Use of Cars

Assuming an increase by 2055 to two billion cars and assuming that no improvement in fuel economy was achieved, a wedge could be saved if the number of miles traveled was reduced from 10,000 miles per year to 5,000 miles per year. Both of these options could save more than one wedge if there is an overprediction regarding the increase in the number of cars in use by 2055. More use of telecommunication and mass transit will reduce the use of cars further.

More Efficient Buildings

Many savings can be made in terms of energy efficiency in buildings, for example, replacing all the world's incandescent light bulbs with compact fluorescent lights would provide a saving of one fourth of one wedge. However, to save one wedge of carbon requires a cut in carbon emissions from buildings of 25 % by 2055. This can be achieved using known and established approaches to energy efficiency. The largest savings are in space heating and cooling, water heating, lighting, and electric appliances.

Improved Power Plant Efficiency

Currently, coal-powered plants operate at about 32 % efficiency and are responsible for about 25 % of all carbon emissions. Improving plant efficiency to 60 % through use of better turbines, fuel cells, etc., would save half a wedge if the quantity of coal-based electricity is unchanged. Emissions from power plants can be reduced both by changing the fuel and by converting the fuel to electricity more efficiently at the power plant.

Decarbonization of Electricity and Fuels

For example, per unit of electricity, carbon emissions are half as large from natural gas power plants as from coal-based power plants. A wedge would be achieved by displacing 1,400 GW of baseload coal with baseload gas by 2055. However, a wedge would require an amount of natural gas equal to that used for all purposes today. A wedge worth of gas would require 50 LNG (liquefied natural gas) tanker deliveries every day or the equivalent of 50 Alaska gas pipelines. This scenario also assumes that no losses of CH_4 (which has a higher GWP than CO_2, see above) would occur during exploration and distribution.

Carbon Capture and Storage

One wedge of carbon can be saved by providing carbon capture and storage at 800 GW of baseload coal plants of 1,600 GW of natural gas plants. A wedge will require injecting a volume of CO_2 equal to the amount of oil extracted every year back into subsurface locations. There are currently less than ten CO_2 storage (pilot) projects that each injects one million tons of CO_2 per year. By 2055, 3,500 will be needed.

Decarbonization of Electricity and Fuels: Nuclear Fission

The rate of installation of nuclear power plants required to save one wedge of carbon from electricity is equal to the global rate of nuclear expansion from 1975 to 1990. Phasing out of nuclear electric power would create the need for another half wedge of emission cuts. There are of course continuing issues concerning removal and storage of nuclear waste, natural catastrophes (compare Fukushima), and the threat of terrorism.

Increased Use of Renewable, Nonfossil, Energy Sources, Including Wind, Electricity, Photovoltaic Electricity, and Biofuels

Installed wind capacity has been growing at about 30 % per year for more than 10 years. It is around 50 GW peak at present, and therefore a wedge of carbon would require 40 times the current deployment. The wind turbines would occupy about 30 million hectares (about 3 % of the area of the USA), some on land and some out to

sea. However, since the windmills would be widely spaced, it is possible to use the land for other purposes as well. A wind electricity wedge would require a combined land area the size of Germany.

The current global deployment of photovoltaics is about 3 GW peak, with a growth factor of about 30 % per year. Therefore, to save 1 GtC per year would require an increase in the deployment by a factor of 700 by 2055 giving 2,000 GW peak. This would be equivalent to an area of about 2 million hectares, assuming an output of 1,000 W peak per m^2 or 2–3 m^2 per person. A photovoltaic electricity wedge would require an array of photovoltaic panels with a combined area about 12 times that of metropolitan London.

Biofuels such as ethanol can replace fossil fuels, but a wedge of first-generation biofuels (e.g., ethanol from sugar cane or biodiesel from rapeseed or soy bean) could be achieved by the production of 34 million barrels per day of ethanol to replace gasoline by 2055. This assumes that the ethanol is from fossil-free carbon and is 50 times larger than the current production rate. This would require 250 million hectares of high-yield plantations equivalent to one sixth of the world's cropland. One wedge from biofuels (first generation) would require planting an area the size of India with biofuel crops. For details, see the respective chapter on biofuels in this handbook.

The pros and cons of implementing each of these technologies would make both interesting projects and the subjects for class debates whether in science or in social studies. The approaches – as well as the problems they are designed to reduce – will impinge more on the lives of the young rather than on their teachers or the authors of this chapter. All options are based on current technologies, and therefore some of these options may well provide more savings as technology improves. The consequences of these do generate comment particularly from younger audiences.

Deforestation

If the current rate of clear-cutting of primary tropical forest were reduced to zero, over the next 50 years that would save half a wedge. A further half wedge would be saved if reforestation of 250 million hectares of tropical land (currently 1,500 million hectares) or 400 million hectares of temperate forest (currently 700 million hectares) took place over the next 50 years. One wedge of saving would require new forests over an area the size of the continental USA.

Soil Management

Conversion of forest or natural grassland to cropland leads to aeration of the soil through annual tilling. This practice accelerates the decomposition of stored carbon and releases it back into the atmosphere. It is believed that 55 GtC has been lost from soils (two wedges worth) historically. Currently, 110 million hectares out of a total of 1,600 million hectares of cropland worldwide undergo conservation tilling. Conservation tilling will involve nondisruption to the soil, for example, drilling of seeds without plowing, soil erosion control, and planting of cover crops. It is feasible that a half to one wedge can be saved through conservation tilling of all croplands. Currently, conservation tillage is practiced on less than 10 % of global cropland.

Conclusions and Summary

The need to make the public more aware of climate change and the potential consequences of it, not only on planet Earth as a whole but also on the individual, is going to increase. Frequently aired radio and television programs, whether for an educated public or school-aged students, need to be made. Articles in popular magazines and not just science-specific journals need to be written for a range of audiences. If possible, access to scientists well versed in public communication at venues that do not intimidate such as bars and social centers, rather than university lecture theaters, for *café scientifique* experiences is going to be needed. Naturally, all these will be pointless if the level of communication is not appropriate to the audience.

In schools in the UK, there has been a major move to promote "science literacy" so that students can make educated decisions about information they receive on a great number of issues from nuclear power to alternative fuels and to evaluate adverts and newspaper articles. These students also look at "how science works," so they are also taught about how research is funded and now can have opinions as to whether research in some areas should be funded. These are of course not just future major consumers and tax payers but are also the voters of tomorrow. Whether this education trend will develop more widely or not, scientists need to communicate their findings as widely and in an accessible way as possible.

The models developed in this chapter and associated practical experiments have enhanced the cognition of teachers and students with respect to the Earth's climate system. It provides these learners with tools to carry out their own investigations and projects and does not require expensive equipment or facilities. The Earth's climate system can be distilled to something that can be understood by the vast majority of people, and it is a great shame that at present there is still considerable misunderstanding that persists. The notion of stabilization wedges is a very powerful one and provides learners with some light at the end of the tunnel. Using the models developed, it is possible to carry out simple calculations and arrive at the estimates provided in terms of land area required, for example. The ability to make such "back of the envelope" calculations not only is a very useful life skill but allows the learner to critically assess the viability of each option presented. There is clearly much still to do in terms of providing the tools to allow new learners to understand the underpinning science of this important topic. However, the material described in this chapter makes a start at least on this road.

Even More Contemporary Atmospheric Chemistry: Criegee Biradicals

Many school science curricula may expect examples of contemporary science. One recent case in atmospheric chemistry concerns the Criegee biradical. It involves elements of preuniversity chemistry such as free radicals, alkenes, and ozonolysis. In 1949, Criegee and Wenner first proposed that ozonolysis of alkenes such as ethene proceeds through carbonyl oxide intermediates, such as the $\bullet CH_2OO\bullet$ biradical.

First, an adduct is formed, and this cyclic structure decomposes rapidly to form a carbonyl and a Criegee intermediate (the details can be found elsewhere in this reference work). Such biradicals had not been detected until recently when a group of British and American researchers succeeded using the Advanced Light Source at the University of California (Berkeley, USA) and photoionization mass spectrometry (PIMS). The importance: free radicals regulate ozone levels in the stratosphere and oxidation rates throughout the lower atmosphere, and some of the accepted atmospheric chemistry is now being rethought through. An outline of the fundamental science for teachers has been published (Shallcross and Harrison 2013).

Future Directions

The Bristol ChemLabS outreach project, the range of activities being described here, is a sustainable program. While the activities such as lecture demonstrations; writing of articles suitable for teachers, school students, and members of the public; and teacher training will continue, their scope will expand. Already, requests for inclusion of climate change sessions for the Prince's Teaching Trust which supports newly qualified (chemistry) teachers and teacher training sessions in Perth, Australia, are being planned. The Royal Society of Chemistry has recently awarded a grant to the ChemLabS team to deliver lecture demonstration training to postgraduate chemists in other universities, several of whom it is hoped will adopt "A Pollutant's Tale" for their own delivery, as has been done in South Africa. Last, an interactive climate change book, suitable for navigation by members of the public of all ages and prior knowledge, is being considered. The climate change challenges are not going away in the short term, and so the outreach needs to educate will not either.

public. Climate engineering is being assessed as a set of tools to deliberately, and on a large scale, moderate or retard global warming. There are several concepts available, like injecting aerosol-forming SO_2 into the stratosphere or placing huge objects in orbit to partly shade Earth from incoming radiation or fertilizing the ocean with iron for increased algae growth and creation of carbon sinks. Such concepts are highly speculative, and irrespective of whether they would work, they bear huge risks, from adversely affecting the complex climate system on a regional or global scale to potentially triggering droughts, famine, or wars. More research is needed to better understand promising concepts and to work them out in depth, so that options are made available in case they should become necessary in the future, when climate change mitigation and adaptation measures do not suffice and fast action becomes imperative. Apart from the technological hurdles, which are anyhow mostly far beyond today's engineering capabilities, huge social, moral, and political issues would have to be overcome. The purpose of this chapter is to highlight a few common concepts of CDR, ERM, and SRM for climate engineering to mitigate climate change.

Introduction

Climate engineering (also dubbed geo-engineering, geoengineering) is defined as "the deliberate large-scale intervention in the Earth's climate system, in order to moderate global warming" (Shepherd 2009). Another, more positive term found in the literature is "climate remediation" or "climate intervention."

It can be considered a variant of macroengineering (the implementation of extremely large-scale design projects such as the Panama Canal) and similar in type to terraforming (planetary engineering, i.e., altering the environment of an extraterrestrial world). The expression is not to be confused with **geological engineering** (likewise termed geoengineering or geotechnical engineering, which is concerned with the design and construction of earthworks, including excavations, hydraulic fracturing (fracking), drilling, and underground infrastructure).

Climate engineering can be seen as the most desperate, bizarre climate change mitigation measure. Yet, due to slow progress with conventional and incremental measures, it has recaptured widespread attention among scientists, politicians, and the public. Climate engineering or "hacking the planet" (Kintisch 2010) is hyped as "quick fix" and "only solution" on the one hand and bedeviled and rejected as wacky idea, simply gambling, being impossible, and very dangerous on the other hand. Some see it as a metaphoric "Faustian bargain" or man's attempt to "play God." Finally, one needs to acknowledge that climate engineering concepts mostly "treat the symptoms rather than cure the illness" of climate change.

It is not so easy to find one's position toward climate engineering, and according to Heyward and Rayner (2013), some "scientists involved in geoengineering discourse convey mixed messages about the need for technocratic management of the

anthropocene at the same time as expressing strong commitments to the importance of public participation in decision making about geoengineering." The Intergovernmental Panel on Climate Change (IPCC) states that every option has to be considered, yet it expresses a critical attitude toward climate engineering due to the inherent, unknown risks and assesses it in its 2007 report as "largely speculative and unproven and with the risk of unknown side-effects." It was around the year 2008 (Ming et al. 2014) to 2009 that a critical discourse of geoengineering started to emerge, mainly in American magazines (Biello 2009; Kunzig 2008) and German newspapers (Anshelm and Hansson 2014). Kennedy et al. (2013) write that "No study of coping with climate change is complete without considering geoengineering."

Social science teaches that transformation dynamics evolve from hope-inspired alternative choices rather than fear-driven technical constraints (Stirling 2014). With a lot of disappointment from commitment and implementation of climate change mitigation measures over the last years, and continued GHG emissions, many scientists feel certain despair, giving an inclination toward options provided by climate engineering.

Climate engineering can be considered a complementary approach to conventional measures: Preserving the climate (quick fix) while CO_2 is gradually brought under control by natural and/or artificial processes. In this scenario, climate engineering would "buy time" for mankind and the globe.

The major issue, even with reversible actions of climate engineering, is that the climate system is very complex. Identifying unintended consequences is not a trivial – if at all possible – task. Such consequences could be most severe and irreversible, like droughts or wars. In this context, it is worthwhile to think about the theory of chaos, which is rooted in the pioneering work of MIT meteorologist and mathematician Edward N. Lorenz (1963). Moreover, a slight drifting of the continents or a minor shifting of ocean currents may bring ice to one land and desert sands to another; see Lorenz (1972).

Safe Limits

The concept of Earth as a self-regulatory system was developed in the late 1960s by J. E. Lovelock and became popular under the name "Gaia hypothesis" and "Daisyworld" model (it is a parable on the biological homeostasis of the global environment. "Daisyworld" contains white and black flowers. When temperatures rise, more white daisies grow, increasing reflection. Sinking temperatures are counteracted by a growth of black daisies: They absorb more sunlight. Hence the balance of white to black daisies controls the temperature and stabilizes it. The simplistic Daisyworld model intuitively describes the coupling between climate and the biosphere). Lovelock's concept is being discussed controversially (Weaver and Dyke 2012; Boston 2008). For sure nature can buffer anthropogenic impact to some extent, but not endlessly, and climate change is testimony for this finite buffering capacity.

In their seminal paper "A safe operating space for humanity" (compare *The Limits to Growth* work by the Club of Rome in 1972), Rockström et al. write that "Although Earth has undergone many periods of significant environmental change, the planet's environment has been unusually stable for the past 10,000 years. This period of stability — known to geologists as the Holocene — has seen human civilizations arise, develop and thrive" (Rockström et al. 2009). They define nine interlinked planetary boundaries, three of which have already been overstepped. For instance, the estimated safe threshold identified for atmospheric CO_2 is 350 ppm or a total increased warming of 1 W/m^2 (current warming is approx. 1.9 W/m^2 radiative forcing from 400 ppm of CO_2 (Butler and Montzka 2013), not considering the additional radiative forcing by other greenhouse gases such as CH_4).

Climate Engineering Approaches

Climate engineering is still in its infancy, at a theoretical stage, where ideas are being generated, discussed, and elaborated. The Secretariat of the Convention on Biological Diversity concluded that "There is no single geoengineering approach that currently meets all three basic criteria for effectiveness, safety and affordability. Different techniques are at different stages of development, mostly theoretical, and many are of doubtful effectiveness" (Secretariat of the Convention on Biological Diversity 2012).

Global climate engineering is untested and mostly untestable (MacMynowski et al. 2011). Its roots go back to 1965, when advisors to US President Lyndon B. Johnson suggested spreading reflective particles over 13 million km^2 of ocean in order to reflect an extra 1 % of sunlight away from Earth (Kintisch 2010). This was one of the first high-level acknowledgements of climate change. Interestingly, no suggestions to cut down CO_2 emissions were reported to have been made. The president did not follow these early geoengineering suggestions.

Even prior to that, in 1955, John von Neumann foresaw "forms of climatic warfare as yet unimagined" in *Fortune* magazine (von Neumann 1955). In 1974, the Russian researcher Mikhail Budyko suggested that cooling down the planet could be achieved by burning sulfur in the stratosphere, which would create a haze from the resulting aerosols (higher albedo) (Teller et al. 1997). This and other concepts will be touched upon below. Space-based geoengineering concepts build upon Tsiolkovsky's and Tsander's 1920s idea of utilizing mirrors for space propulsion (Kennedy et al. 2013). As these examples show, ideas to engineer the climate came up quite early.

Small-scale weather modification can already be achieved today, e.g., by cloud seeding to induce rainfall. The historical Project "Stormfury" (1962–1983) attempted to weaken tropical cyclones with silver iodide (Willoughby et al. 1985). For a brief review on "rainmaking attempts" and "weather warfare," which is outside the scope of this chapter, see Chossudovsky (2007) and *Climate Modification Schemes*, American Institute of Physics (AIP) (2011). Weather modification action has been limited by the international community, e.g., during war by the 1977 UN

Environmental Modification Convention. Another regulation in this respect is the London Convention (1972) and its 1996 Protocol, which are global agreements regulating dumping of wastes at sea. Article 6 prohibits exports of wastes for dumping in the marine environment, which includes, e.g., CO_2 in CCS (carbon capture and storage) schemes (Dixon et al. 2014).

Examples where man has modified local climate (impacts) include artificial snow in skiing resorts or irrigation for crop yield amelioration. Previous environmental interventions by man have sometimes brought about unwanted – and unexpected – effects, also in the near past, e.g., streamlining riverbeds leading to local floods or the creation of urban heat islands.

Joe Romm, founding editor of the blog Climate Progress, has linked "geoengineering to a dangerous course of chemotherapy and radiation to treat a condition curable through diet and exercise — or, in this case, emissions reduction" (McGrath 2014). Al Gore, former vice president of the USA, was quoted on climate engineering to be "utterly mad and delusional in the extreme." He said that searches for an instant solution were born out of desperation, were misguided, and could lead to an even bigger catastrophe (Goldenberg 2014). "The idea that we can put a different form of pollution into the atmosphere to cancel out the effects of global warming pollution is utterly insane" (Goldenberg 2014).

In fact, the idea of "engineering" the Earth's climate is a shocking one. There is yet little information available, and "technically feasible" concepts are totally vague on costs, effectiveness, reversibility, risks, and side effects.

However, serious scientists have started to investigate options for climate engineering more deeply, since swift remedial action might be needed once the Earth's climate system reaches a "tipping point" (positive feedback, thermal runaway, e.g., thawing of permafrost releases CH_4, which further increases temperatures). It seems necessary to study climate engineering, to be prepared. There is also the threat of unilateral action by another country (Dean 2011), should a local benefit from such action be expected. Tipping point rhetoric is challenged in Heyward and Rayner (2013).

Climate engineering ideas and concepts fall into two broad groups: **carbon dioxide removal (CDR)** and **solar radiation management (SRM)**. Several researchers discern **Earth radiation management (ERM)** from SRM, where ERM techniques focus on atmospheric convection enhancement (building of thermal bridges) and increasing outgoing IR heat radiation (i.e., long wavelength). The focus of SRM is on (short wavelength) incoming radiation. The term ERM was introduced by David L. Mitchell et al. (2011). He includes CRD and cirrus cloud reduction into SRM (Mitchell and Finnegan 2009). CRD techniques are remediation, whereas SRM are intervention.

CDR techniques are generally not considered that controversial, and they do not seem to introduce global risks, as they work on the local scale. Costs and technical feasibility have been limiting CDR deployment, e.g., reforestation or CCS. CRD attacks the root cause of climate change. However, the effects work slowly to bring down temperatures again.

SRM targets an increase in the amount of solar energy radiated back into space, effectively dimming the Sun. The necessary albedo enhancement is envisioned for

deserts, oceans, mountains, clouds, and also manmade objects like roofs or roads. Prominent concept examples include deployment of giant orbiting sunshields in space, emission of huge amounts of SO_2 (Crutzen 2006) and particles into the stratosphere to mimic the action of volcanoes, increase of the Earth's albedo by "painting" deserts white, spraying sea water into the atmosphere to produce and whiten clouds, redirecting ocean streams and changing their salinity (Could a massive dam 2010), or pumping seawater into pole regions and creating ice. Such techniques bear the risk of upsetting the Earth's natural rhythms. SRM approaches act quickly. However, they do not remove the root cause of climate change, mainly CO_2 levels in the atmosphere, so other aspects like ocean acidification are not tackled.

Raymond Pierrehumbert, professor in Geophysical Sciences at University of Chicago, said "The term 'solar radiation management' is positively Orwellian. It's a way to increase comfort levels with this crazy idea" (Rotman 2013).

According to Shepherd (2009), CDR methods should be regarded as preferable to SRM methods. SRM methods are expected to be cheaper, though.

The Royal Society wrote in a 2009 report (Shepherd 2009): "Solar Radiation Management methods could be used to augment conventional mitigation. However, the large-scale adoption of Solar Radiation Management methods would create an artificial, approximate, and potentially delicate balance between increased greenhouse gas concentrations and reduced solar radiation, which would have to be maintained, potentially for many centuries. It is doubtful that such a balance would really be sustainable for such long periods of time, particularly if emissions of greenhouse gases were allowed to continue or even increase."

Although technological hurdles exist, it is expected that devising working technologies (i.e., installations that cool the atmosphere) are easier than understanding their effects or how governance (Shepherd 2009) should be applied.

The focus of this chapter lies on SRM, which directly modify the Earth's radiation balance; compare Fig. 1. It also covers CDR, which influences the global carbon cycle (see Fig. 2), and ERM, as well as touching upon governance and other related aspects of climate engineering.

Radiation Balance

Energy on Earth mainly comes from the Sun. The solar constant is approx. 1,361 W/m^2, which translates into a power of 1.730×10^{17} W for the entire Earth. The average incoming solar radiation is approx. ¼ of the solar constant (342 W/m^2). The radiation balance of the Earth is shown in Fig. 1 in a simplified version.

Climate engineering aims at modifying this radiation balance to achieve a lower net heating effect. In climate science, **radiative forcing** or climate forcing is defined as the difference of insolation (sunlight) absorbed by the Earth and energy radiated back to space. Currently, it is 2.916 W/m^2, which corresponds to 479 $CO_{2\text{-eq}}$. 1.88 W/m^2 thereof is due to CO_2 and 0.51 W/m^2 due to CH_4 (Butler and Montzka 2013).

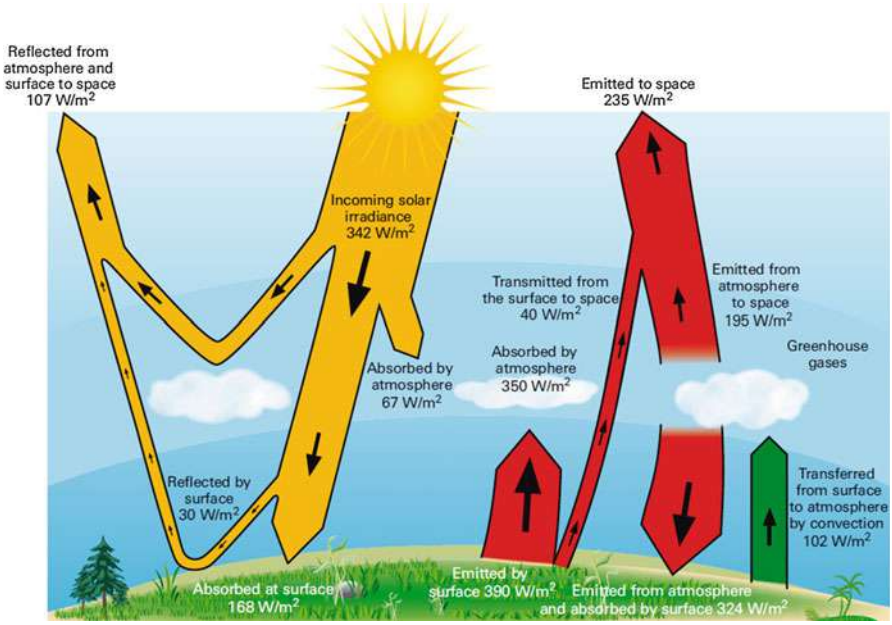

Fig. 1 Schematic showing the global average energy budget of the Earth's atmosphere. *Yellow* indicates solar radiation; *red* indicates heat radiation; and *green* indicates transfer of heat by evaporation/condensation of water vapor and other surface processes. The width of the *arrow* indicates the magnitude of the flux of radiation and the numbers indicate annual average values. At the top of the atmosphere, the net absorbed solar radiation is balanced by the heat emitted to space (Source: Shepherd 2009)

Global Carbon Cycle

Figure 2 shows the simplified global carbon cycle in Gt of carbon per year (1 Gt = 1 Pg = 10^{15} g). One can see that the ocean is the largest sink.

The various carbon sinks present opportunities for geoengineering. Subsets of special techniques are **biogeoengineering** and **Arctic geoengineering**. In biogeoengineering, plants or other living organisms are used or modified to beneficially influence the climate on Earth, e.g., by creating carbon sinks. An example is iron fertilization of the oceans. Iron is a growth-limiting factor, so fertilization would be expected to produce more algae, taking up CO_2, like land-based biomass.

"Global dimming" is an aspect that could be exploited for climate engineering. Monoterpenes from boreal forests (Rinnan et al. 2011; Aaltonen et al. 2011) were found to contribute to global dimming (cooling), apart from being a CO_2 sink, so tree planting would be a working biogeoengineering approach. **Global dimming**, generally, is caused by an increase in particulates such as sulfate aerosols in the atmosphere due to human action. The effect of anthropogenic global dimming has interfered with the **hydrological cycle** by reducing evaporation and so may have reduced rainfall in some areas. Global dimming also creates a cooling effect that may

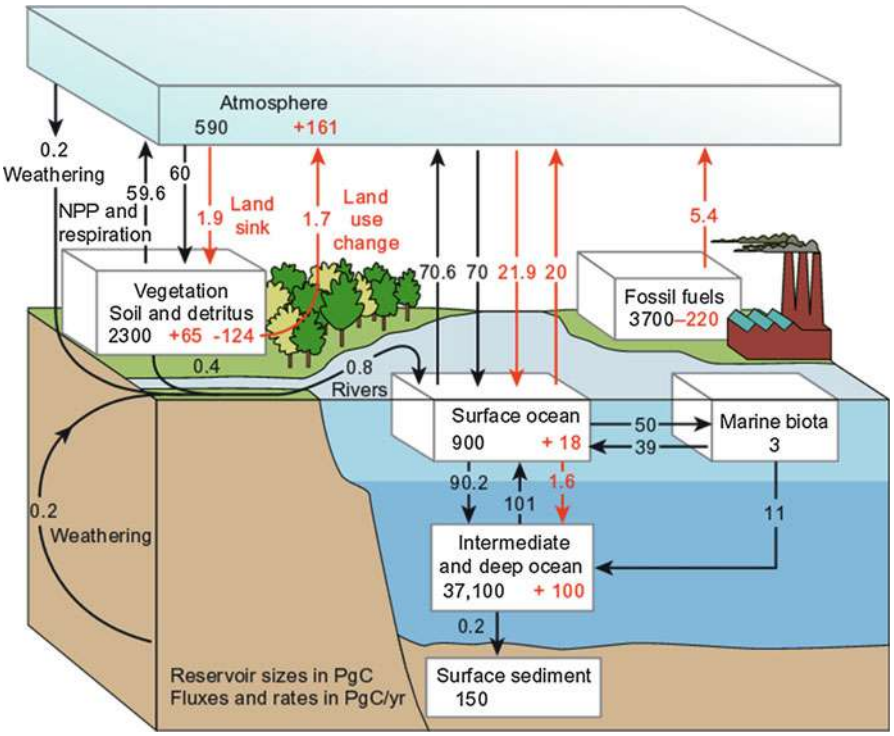

Fig. 2 Simplified representation of the global carbon cycle. The values inside the boxes are standing stocks (in Pg C); the *arrows* represent annual fluxes (Pg C/y). The *black arrows* and *numbers* show the preindustrial values of standing stocks and fluxes; the *red arrows* and *numbers* indicate the changes due to anthropogenic activity (Source: Cole 2013)

have partially counteracted the effect of greenhouse gases on global warming. With sulfur levels in fuels being further reduced, e.g., for ships, the global warming contribution of combustion emissions will increase in the future.

Arctic geoengineering focuses geographically on the Arctic, which plays a key role in maintaining current climate due to its albedo and stored methane. The Arctic ice is disappearing quickly, though, and concepts have been envisioned to support ice buildup.

Impacts of Climate Engineering

The targeted impact of climate engineering is to bring down global air and surface temperatures. Undesired side effects might also occur, though, particularly in SRM schemes. Several researchers have run computer models to investigate the effect of blocking part of the solar radiation. Shading the Sun would, according to the models,

reduce the global temperatures, but also lead to profound changes to precipitation patterns including disrupting the Indian Monsoon (Shepherd 2009). Anthropogenic SO_2 in the stratosphere at a level necessary to counteract the radiative forcing of human CO_2 and CH_4 could cut rainfall in the tropics by 30 % (Ferraro et al. 2014). Also, it would lead to acid rain. There is further concern that SO_2 in the troposphere can harm the ozone layer; see also section "Stratospheric Sulfate Aerosols."

Evidence that such action would in fact result in a net cooling was provided by the eruption of the volcano Mt. Pinatubo in the Philippines in June 1991. It resulted in a −0.5 °C variation in the Earth surface temperature, due to the effect of sulfate aerosol-induced albedo enhancement. However, already by the year 1995, the effect had vanished, and the temperature returned to the former value (Gomes and de Araújo 2011). Note: Another volcanic event with transient, global impact on the climate was the 1815 eruption of Mount Tambora in Indonesia, which led to a "year without summer" and famine due to reduced crop yields (Stilgoe et al. 2013a).

Sticking with this geoengineering example, potential side effects of SO_2 injected into the stratosphere by, e.g., balloons, artillery, or jet planes, are:

- CO_2 emissions from the missions
- Litter, e.g., from returning balloon shells
- Noise, e.g., from the artillery
- Depletion of ozone
- Regional droughts, e.g., in Africa and Asia from weaker monsoon activity
- Impact on cloud formation, particularly cirrus clouds, with unpredicted effects
- Acidic rain, leading to further ocean acidification, and other effects on the ecosystem
- Whitening of the sky due to aerosols, more diffuse radiation
- Less yield from solar energy collectors, impacting renewable energy production
- Temperature changes in the stratosphere, influencing atmospheric circulations in the troposphere with unknown effects

The Geoengineering Model Intercomparison Project (GeoMIP) around Ben Kravitz assesses the projected impacts of geoengineering by different climate models, focusing on SRM (http://climate.envsci.rutgers.edu/GeoMIP/publications.html). In 2013, 12 climate models simulating quadrupled atmospheric carbon dioxide levels and a corresponding reduction in solar radiation were compared (Kravitz 2013). In Fig. 3, an overview by the Convention on Biological Diversity (http://www.cbd.int/convention/) shows which intended and unintended effects might result from geoengineering.

It is expected that both SRM and SDR would affect biodiversity and ecosystems, which finally have a significant impact on human well-being. As stated above, quantification of intended and also identification of unintended consequences of SRM and to a lesser extent ERM and CDR techniques are difficult to achieve.

On the benefits, risks, and costs of stratospheric geoengineering, see e.g., Robock et al. (2009).

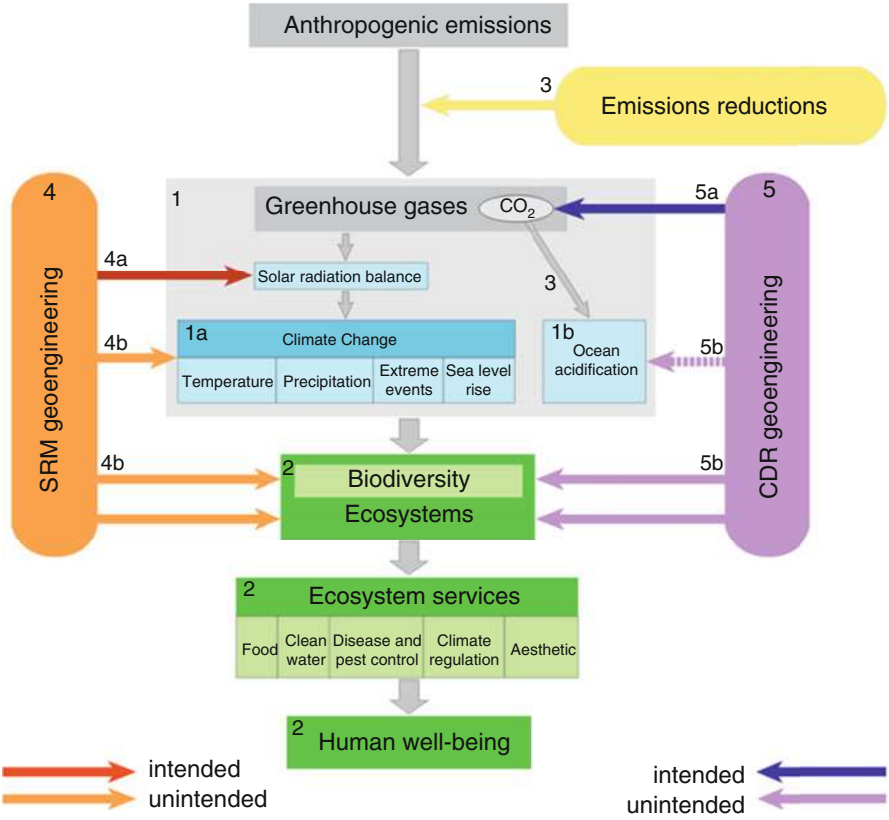

Fig. 3 Conceptual overview of how greenhouse gas emission reductions and the two main groups of geoengineering techniques may affect the climate system, ocean acidification, biodiversity, ecosystem services, and human well-being (Numbers refer to the chapters in the cited source, from which reproduction with permission was made (Secretariat of the Convention on Biological Diversity 2012))

Legal, Moral, and Social Issues

"Whose hand will be on the planetary thermostat?"(Robock 2014). Action by one nation would impact climate globally, but who is entitled to enact and control climate engineering? Would the target of climate engineering be to reduce future global warming, i.e., to maintain current temperatures; to limit global warming to, e.g., 2 K; or to bring back temperatures to preindustrial levels? Who would set the target? These questions cannot be answered at this point in time, as outlined in this section of this chapter.

Legal Issues

Signed by 150 government leaders at the 1992 Rio Earth Summit, the Convention on Biological Diversity is dedicated to promoting sustainable development. Conceived as a practical tool for translating the principles of Agenda 21 (a voluntarily implemented action plan of the United Nations with regard to sustainable development), it states "that no climate-related geo-engineering activities that may affect biodiversity take place, until there is an adequate scientific basis on which to justify such activities and appropriate consideration of the associated risks for the environment and biodiversity and associated social, economic and cultural impacts, with the exception of small-scale scientific research studies" (http://www.cbd.int/convention/). Thereby, private or public experimentation and adventurism are avoided, yet research is possible. R&D in climate engineering is justified so that man understands his options once a said environmental tipping point has been surpassed (contingency planning to have "something on the shelves" when needed). Research priorities in this respect are worked out in Shepherd (2009).

Moral and Social Issues

While anthropogenic greenhouse gas emissions are an unwanted side effect, climate engineering constitutes a large-scale, intentional effort to alter the climate.

Responsibilities and global political governance are not clear. It is conceivable that different governments have different targets for global temperatures. Some areas of the world show higher crop yield in an elevated temperature scenario, for instance. So actions by one country to alter the climate, motivated by expected local benefits, might result in war. Multilateral commitments and agreements over time periods of several 100 years would be necessary, as this is the time that, e.g., SO_2 from climate engineering would have to remain in the stratosphere in a delicate balance with anthropogenic CO_2 emissions it is offsetting, so there would also have to be imperative controls over CO_2 levels at the same time.

The governance of emerging science and innovation is discussed in Stilgoe et al. (2013b), citing canceling the geoengineering project "SPICE" (see below) as an example. For public perception of geoengineering, see Corner et al. (2013) and Sikka (2012). Governance principles concerning climate engineering were also elaborated in the 2010 Asilomar International Conference on Climate Intervention Technologies (http://climate.org/resources/climate-archives/conferences/asilomar/report.html).

Preliminary Climate Engineering Field Experiments

Climate engineering has a global scale, and documented field trials to date are very limited. Some concepts can hardly be tested at all.

Fig. 4 Whitening the mountain Chalon Sombrero in Peru in a geoengineering pilot project (Source: Collyns 2010)

One of the largest experiments, known as **LOHAFEX**, was an Indo-German fertilization experiment in 2009, in which six tonnes of iron as iron sulfate solution was spread over an area of 300 km^2 (Ebersbach et al. 2014) in the South Atlantic. It was expected to trigger an algal bloom, resulting in CO_2 update and some of the algae ending up in the ocean bed as carbon sink.

A much disputed, similar experiment was carried out in July 2012 by entrepreneur Russ George, who put approx. 100 t of iron sulfate into the Pacific Ocean several hundred miles west of the islands of **Haida Gwaii**/Canada. The intention was to increase the production rate of phytoplankton for salmon fishing (Sweeney 2014).

In 2005, a pilot project in Switzerland to **cover a glacier** with a reflective foil was carried out. On the Gurschen glacier, it was found that the blanket reduced the melding by 80 % (Pacella 2007). More trials on an area of more than 28,000 m^2 were done on the Vorab glacier (Pacella 2007).

Painting the Andes: In 2009, the World Bank has awarded a seed grant to 26 innovative climate adaptation projects, selected from 1,700 proposals (World Bank). Among them was one idea from Peruvian inventor Eduardo Gold to whiten the Chalon Sombrero peak in the Andes (Collyns 2010). This pilot project (see Fig. 4) has received positive media attention.

In the UK **SPICE** project (Stratospheric Particle Injection for Climate Engineering, 2015), a trial balloon flight was planned; see Fig. 5.

The idea was to send a balloon 1 km into the sky and to eject water droplets. These droplets should create clouds, increasing the albedo. The experiment had to be canceled due to opposition from environmental groups (Shukman 2014; Zhang et al. 2015).

Tree planting (reforestation, afforestation) (Zomer et al. 2008; Schirmer and Bull 2014; Trabucco et al. 2008) and peatland restoration (Bonn et al. 2014) activities are

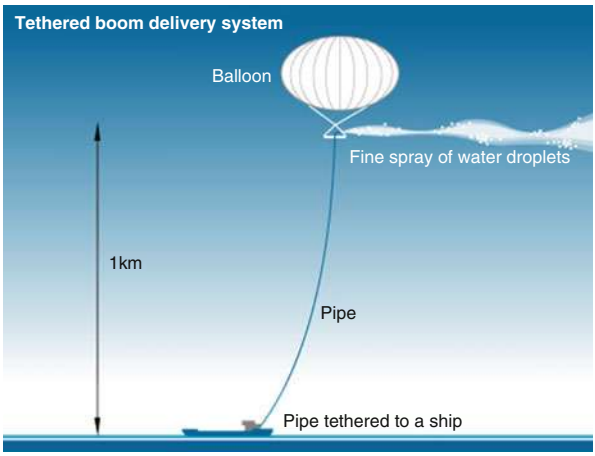

Fig. 5 Concept of the SPICE experiment (Source: Vidal 2011)

being considered in several parts of the world. According to the IPCC, reforestation refers to establishment of forest on land that had recent tree cover, whereas afforestation refers to land that has been without forest for longer time periods (IPCC 2015).

Cool roof experiments: In cities, the temperature is typically 1–3 °C higher than in the surrounding countryside, due to, e.g., heat-absorbing infrastructure such as dark asphalt parking lots and dark roofs (Oke 1997). By increasing the reflectivity, more radiation is sent back into space, and energy costs (air conditioning) can be reduced. Pilot projects are, e.g., the "White Roof Project" (http://www.whiteroofproject.org/) and New York's "NYC °CoolRoofs" (http://www.nyc.gov/html/coolroofs/html/home/home.shtml).

Keeping groundwater level and salinity low. In Australia, rising levels of salty groundwater pose a problem for farmers. By pumping that groundwater into shallow evaporation ponds, crops are protected, with a positive side benefit of increased albedo (Edmonds and Smith 2011); see Fig. 6 (note that "geoengineering" is a side effect here).

Edmonds and Smith (2011) also describe reflective covers on water bodies to prevent evaporation losses. According to Ming et al. (2014), 40–50 % of the water stored in small farm dams of "hot" countries may be lost due to evaporation. Such covers, as a side effect, increase the albedo and thereby contribute to climate change mitigation; compare Fig. 7.

Proposed Strategies for Climate Engineering

Potential approaches are surface based (e.g., albedo modification of land or ocean), troposphere based (e.g., cloud whitening), stratosphere based (e.g., injection of SO_2 or Al_2O_3), and space based (e.g., gigantic space-based mirrors, lenses, or sunshades). Below, several selected concepts are briefly introduced.

Fig. 6 Image of a 700 × 900 m^2 wheat field in Western Australia in which a 66 m diameter evaporation pond was created (Source: Edmonds and Smith 2011)

Fig. 7 Reflective evaporation covers on a mine reservoir at Parkes in Australia (Edmonds and Smith 2011)

Carbon Dioxide Removal (CDR)

As mentioned above, the first set of concepts can be summarized as CO_2 removal schemes (CDR) as visually summarized in Fig. 8.

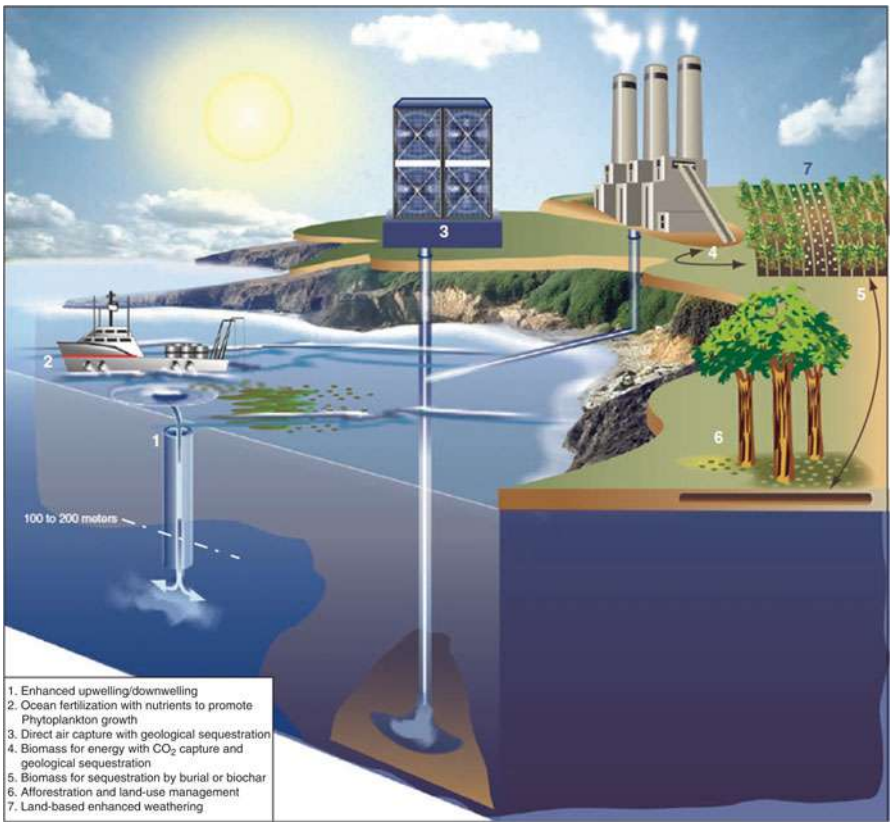

Fig. 8 Depiction of some popular CDR concepts. See text for details (Source: Climate 2010)

Carbon capture and storage (CSS) and carbon sequestration projects are out of the scope of this chapter; see elsewhere in this handbook and in the DOE/NETL CO_2 capture and storage roadmap (2010). Other CDR concepts include (Shepherd 2009):

- Use of biomass as carbon sink.
- Protection of and (re)creation of terrestrial carbon sinks such as grasslands.
- Enhanced weathering to remove CO_2 from the atmosphere.
- Direct capturing of CO_2 from the ambient air (concepts to wash CO_2 out of the atmosphere include "artificial trees" and scrubbing towers), known as industrial air scrubbing (IAS) or direct air capture (DAC) (de_Richter et al. 2013). Costs are expected to be prohibitively high (House et al. 2011).
- Enhancement of oceanic uptake of CO_2, for example, by fertilization of the oceans with naturally scarce nutrients such as iron or by changing ocean currents.
- Biochar (when biomass is pyrolyzed, char (biochar) remains. It can be mixed with soil to create terra preta, a carbon sink (Hyland and Sarmah 2014)).

There are numerous other concepts, such as removing (dark) vegetation from the mountain tops or changing the composition of ship and aircraft exhaust. The interested reader will find a collection of ideas in various internet sources such as Wikipedia. Out of the concepts presented from (Shepherd 2009) above, two are described briefly as an example.

Enhanced Weathering

In enhanced weathering, inorganic matter is used to take up CO_2, a process that occurs in nature, but slowly. For instance, if carbonates are formed, CO_2 is stored long term. This chemical approach to geoengineering involves land- or ocean-based techniques. Examples of land-based enhanced weathering techniques are in situ carbonation of silicates such as ultramafic rocks (ultrabasic rocks, which are igneous and metaigneous rocks with a very low silica content and a high magnesium and iron content). Ocean-based techniques involve alkalinity enhancement of the sea, e.g., by grinding, dispersing, and dissolving olivine, limestone, silicates, or calcium hydroxide against ocean acidification and for CO_2 sequestration. Enhanced weathering is considered as one of the most cost-effective options. CarbFix (2015) is a feasibility project of enhanced weathering in Iceland. For details on mineral carbonation/mineral sequestration, see, e.g., Herzog (2002) and Goldberg et al. (1998).

Bioenergy with Carbon Sequestration (BECS), Biochar, and Wood Burning

BECS is a hybrid approach in which bioenergy crops are grown and used as fuel, and the CO_2 emissions are captured and stored (see CCS elsewhere in this handbook). Biochar and BECS could together contribute a carbon sink of 14 GtC/year by 2100 (Edenhofer et al. 2012). The concept of burying wood in anoxic environments (e.g., deep in the soil) is that decomposition would be much slower, providing a long-term carbon sink; compare Fig. 9. According to Zeng (2008), the long-term carbon sequestration potential for wood burial is 10 ± 5 GtC per year, and currently about 65 GtC is available on the world's forest floors in the form of coarse woody debris suitable for burial. The cost for wood burial is estimated to be lower than the typical cost for power plant CCS. Approx. 100 tC are bound as coarse wood carbon from a typical mid-latitude forest area of 1 km^2 in 1 year (Zeng 2008). However, there is the potential for counterproductive emissions of methane from anaerobic decomposition of the buried wood.

It is estimated that, by storing carbon in deep sediments, deep ocean sequestration can capture up to 15 % of the current global CO_2 annual increase. It was hence suggested to dump crop residues in the deep ocean (Strand and Benford 2009).

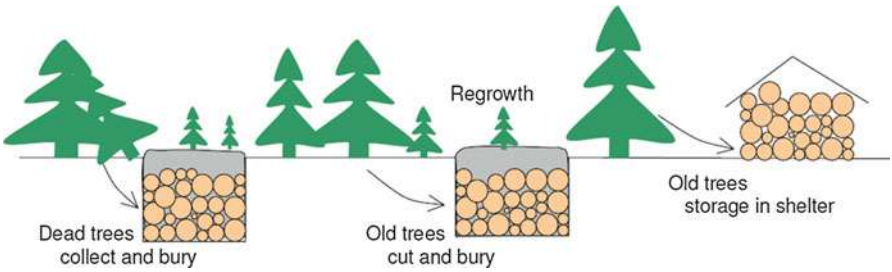

Fig. 9 Schematic diagram of forest wood burial and storage (Source: Zeng 2008)

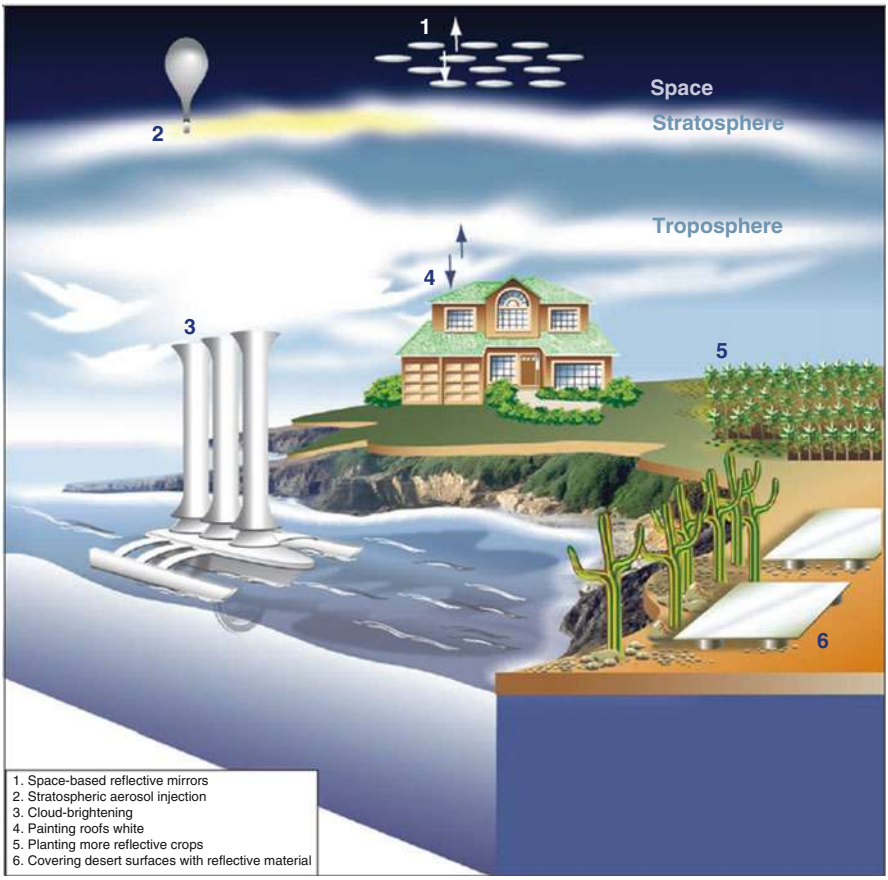

Fig. 10 Depiction of solar radiation management (Source: Climate 2010)

Solar Radiation Management (SRM)

The second set of techniques for climate engineering is the SRM category. SRM stands for "solar radiation management" or "sunlight reflection methods;" compare Fig. 10.

Four of such SRM concepts are explained below.

Cloud Reflectivity Modification

This approach considers altering the reflectivity of clouds in two ways: thinning of cirrus clouds and brightening (low) marine clouds. High, cold cirrus clouds let sunlight penetrate but capture infrared radiation. Hence, thinning or removing cirrus would have a net cooling effect on Earth. By contrast, low, warm clouds (stratocumulus, which cover approx. 1/3 of the ocean's surface) reflect sunlight efficiently. This "cloud whitening" or "marine cloud brightening" could be achieved with cloud condensation nuclei (CCN) such as fine seawater droplets. The effect is considered to be more pronounced on the sea than on the land, as clouds over the landmass have more (natural and anthropogenic) CCN available. Proposed schemes include seawater sprays produced by unmanned ship, ocean foams (Evans et al. 2010) from air bubble bursting, ultrasonic excitation (Barreras et al. 2002), and electrostatic atomization.

Stratospheric Sulfate Aerosols

SO_2 is known to cause global dimming, as it leads to aerosol formation, and the aerosols reflect sunlight. The mechanism is that SO_2 is oxidized to sulfuric acid, which is hygroscopic, has a low vapor pressure, and hence forms aerosols (Robock 2014). It was suggested to inject sulfur into the stratosphere as SO_2, sulfuric acid, or hydrogen sulfide by artillery, aircraft, and balloons (Rasch et al. 2008). According to estimates by the Council on Foreign Relations, "one kilogram of well placed sulfur in the stratosphere would roughly offset the warming effect of several hundred thousand kilograms of carbon dioxide" (Victor et al. 2009).

This approach was estimated to be over 100 times cheaper than producing the same temperature change by reducing CO_2 emissions (Keith et al. 2010). The SO_2 injection would have to be maintained, as tropospheric sulfur aerosols have a comparatively short atmospheric lifetime. Also, other particles have been considered, e.g., Al_2O_3.

Space Lenses, Space Mirrors, and "Dyson Dots"

Space-based concepts aim at transforming the solar constant into a controlled solar variable (Kennedy et al. 2013). They envision large space-based objects, which might be manufactured on the moon, mining local materials, or using material from asteroids. Concepts of giant lenses (Early 1989), dust rings (Bewick et al. 2013), and sunshades (Kosugi 2010) to block part of the Sun's incoming radiation using the effects of reflection, absorption, and diffraction were worked out. A convex lens with 1,000 km in diameter is considered sufficient, and in a Fresnel embodiment, it would only be a few millimeters thick (Early 1989). Shading the Sun by approx. 55,000 orbiting mirrors with 100 km^2 size, made from wire mesh, or by trillions of smaller mirrors (comparable to a DVD), was suggested (Ming et al. 2014); however, such

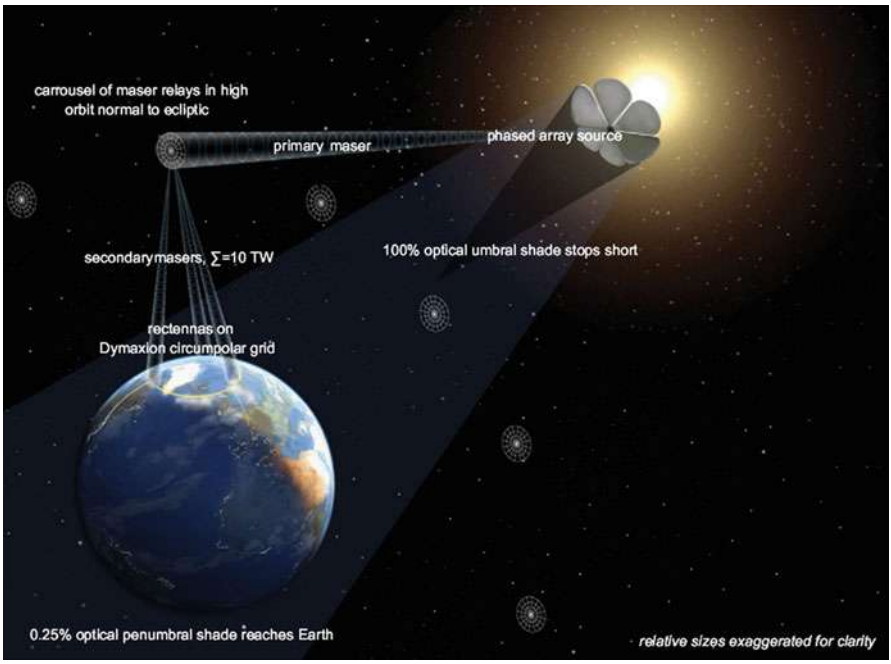

Fig. 11 Dyson dot concept with "self-funding" master energy delivery to the Earth (Reproduced with permission from Kennedy et al. 2013)

concepts are widely viewed as unrealistic. Current engineering capabilities are far from being able to realize such science-fiction-like concepts, not speaking about the costs, which are estimated at a century worth of global domestic product of all nations combined (Ming et al. 2014).

The "mirrors and smoke in space" concept was refined and coined "Dyson dots" (Kennedy et al. 2013). The concept is to place one or more large lightsail(s) in a radiation-levitated position sunward of the Lagrange point 1 (L1, SEL1). In this point, the gravitational forces on an object exerted by Earth and the Sun are equal. L1 is approx. 1.5 million km from Earth.

A 700,000 km^2 parasol in L1 would reduce insolation on Earth by at least 0.25 %. A photovoltaic power station on the sunny side of the parasol could "beam" energy to Earth via a maser (microwave laser) on the order of global demand, hence essentially funding the entire project. The "Dyson dot" concept is shown in Fig. 11.

The expression "Dyson dot" is based on the concept of a "Dyson sphere," a hypothetical megastructure imagined by Freeman Dyson in 1960, who speculated in a science article entitled "Search for Artificial Stellar Sources of Infrared Radiation" that advanced extraterrestrial civilizations could have housed in their star with a megastructure, maximizing energy capturing.

A 0.25 % reduction in the Sun's energy output was observed in the period of mid-sixteenth to mid-seventeenth century dubbed "sunspot cycle shutdown time,"

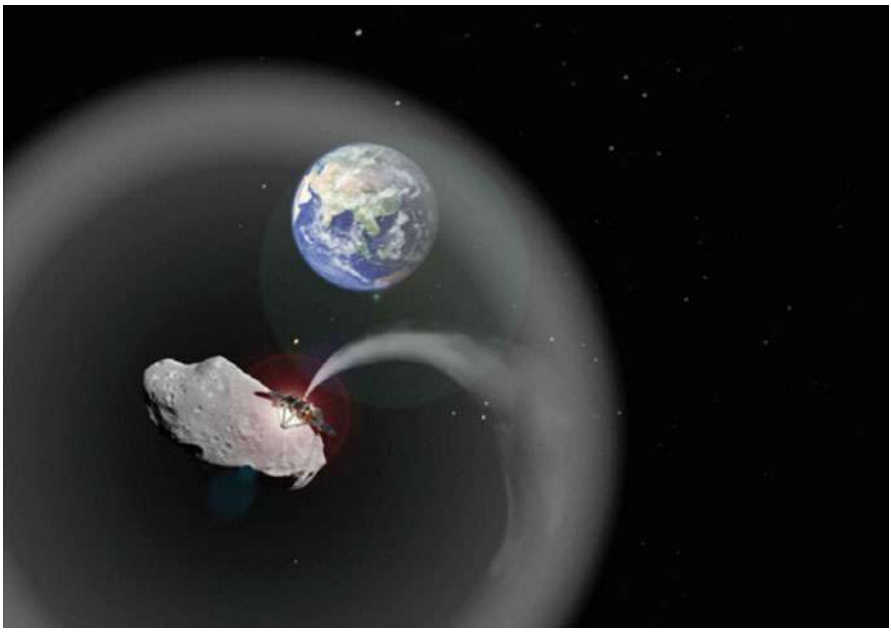

Fig. 12 Impression of an L1 positioned dust cloud for space-based geoengineering (Source: Bewick et al. 2012)

"Maunder Minimum," or "Little Ice Age," so this order of magnitude is what space geoengineers are aiming at.

Dust Clouds

Clouds of extraterrestrial dust placed in the vicinity of the L1 point are an alternative concept to thin-film reflectors, aiming at significantly reducing the manufacturing efforts. The material should be mined from captured asteroids, being moved by solar collectors or mass drivers (Bewick et al. 2012); see Fig. 12.

For details on such a dust concept, see, e.g., Bewick et al. (2012). Dust for sunlight blocking might also be mined on the moon.

Other Greenhouse Gas Remediation Ideas

There are many other geoengineering concepts than those introduced above, some of which are mentioned here:

CFC Destruction by Lasers

Chlorofluorocarbons (CFC) are persistent in the atmosphere, having huge GWP, yet they are accessible via their photochemistry (Stix 1993). Extremely powerful lasers might be used to break up tropospheric CFC.

Ocean Heat Transport

Ocean heat transport (downwelling of ocean currents) is outlined in Zhou and Flynn (2005). This concept aims at changing oceanic currents to shovel heat energy to deeper regions of the ocean. Also, solar-driven heat pumps might be used to this end.

Methane Remediation

Since methane is also a GHG of big concern, other geoengineering concepts target reducing CH_4 emission, e.g., by soil oxidation into CO_2 (Tate 2015).

ERM and Energy Production

Earth radiation management (ERM) aims at increasing the long wavelength radiation sent into space, which today is being trapped by GHG. ERM can be combined with energy production in so-called meteorological reactors (Ming et al. 2014). The term "meteorological reactor" stands for a climate engineering installation that fulfills two purposes: reduction of radiative forcing and energy production. Possible embodiments are:

- Solar updraft tower
- Solar downdraft energy tower
- Atmospheric vortex engine
- Heat pipes
- Radiative cooling, emissive energy harvesters (EEH)

Figure 13 shows an overview of such ERM schemes.

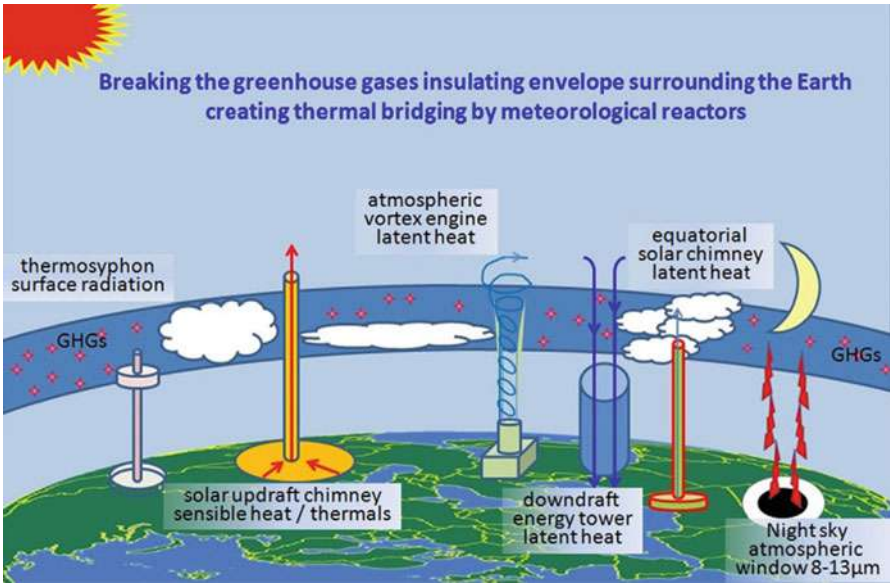

Fig. 13 Principal longwave radiation targets of meteorological reactors (Source: Ming et al. 2014)

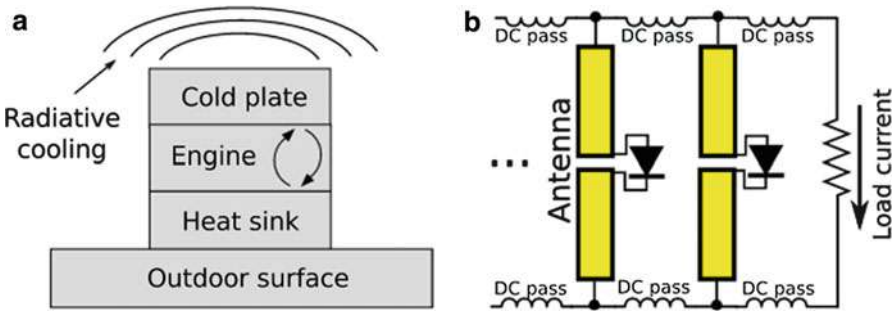

Fig. 14 Two possible EEH designs. (**a**) In a thermal EEH, a heat engine operates between the ambient temperature and a radiatively cooled plate. (**b**) In an infrared rectenna EEH, the whole panel is at ambient temperature, but the circuit's electrical noise is coupled to the cold radiation field via antennas (Source: Byrnes et al. 2014)

The "chimney effect" is used to create air motion, which can drive a generator. The hot air is moved into higher layers of the atmosphere, where it can radiate off heat energy. In Fig. 14, emissive energy harvesters (EEH) designs are depicted.

For details on "meteorological reactors" in ERM mode, see Ming et al. (2014) and http://www.solar-tower.org.uk/meteorological-reactors.php.

Climate Engineering in the Context of Climate Change Mitigation and Adaptation

Figure 15 is an illustration of the conceptual relationship between SRM and CDR with climate change adaptation and mitigation, in the context of the interdependent human and climatic systems.

The Kaya identity (O'Mahony 2013) mentioned in the caption of Fig. 15 is based on Japanese scientist Kaya and can mathematically be expressed as F = pop * (GDP/pop) * (E/GDP) * (F/E), with F being global anthropogenic CO_2 emissions, pop being global population growth, G the world GDP, and E the global energy consumption. Carbon emissions F can be estimated as the product of growth (pop), economic expansion (GDP/pop), energy intensity (E/GDP), and carbon efficiency (F/E).

Is It Geoengineering or Not?

The term geoengineering expresses, as stated initially, deliberate *large-scale* intervention in the Earth's climate system. CDR methods with a local to regional and/or low global impact are hence not real geoengineering approaches. The delineation is not exactly clear-cut. An attempt was made by the 2011 IPCC Expert Meeting on Geoengineering; see Fig. 16.

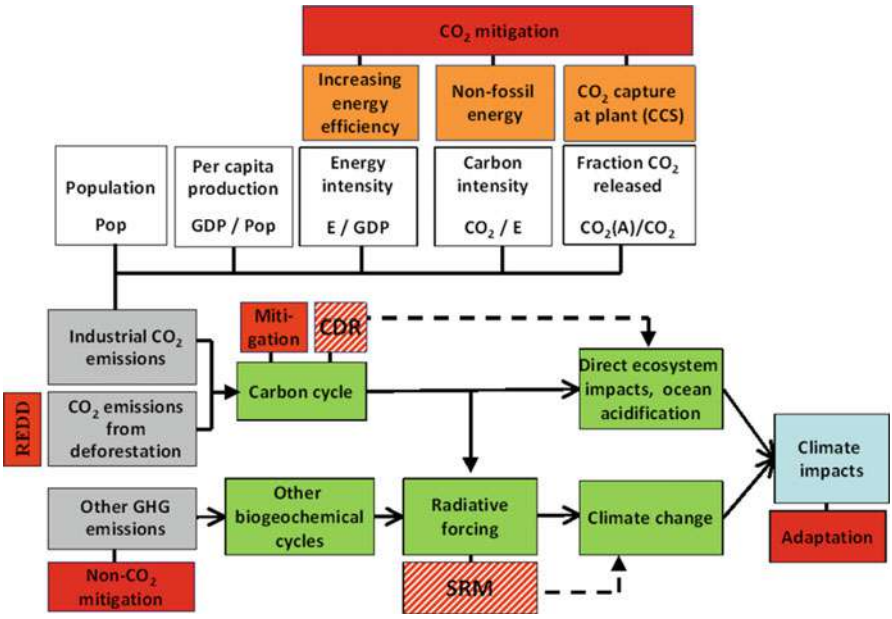

Fig. 15 Illustration of mitigation, adaptation, solar radiation management (*SRM*), and carbon dioxide removal (*CDR*) methods in relation to the interconnected human, socioeconomic, and climatic systems and with respect to mitigation and adaptation. The *top* part of the figure represents the Kaya identity. REDD stands for Reducing Emissions from Deforestation and Forest Degradation (Source: Edenhofer et al. 2012)

As Fig. 16 shows, ocean fertilization and ocean alkalinization are seen as geoengineering-type projects, as can be large afforestation/reforestation.

Discussion

Having presented some geoengineering concepts, a discussion about their targeted effectiveness and commercial viability has to be carried out. Geoengineering appraisals in their context frames were studied in Bellamy et al. (2012), where "climate emergency," "insufficient mitigation," and "climate change impacts" were cited most often. The appraisals were found to be mostly expert analytic, involving calculations/computer modeling, expert reviews and opinions, economic assessments, and MCA (multi-criteria analysis) (Bellamy et al. 2012). This study also investigated the frequency of different geoengineering proposals; see Fig. 17.

Stratospheric aerosols and space reflectors were investigated most often. There was a balance between solar- and carbon-based concepts.

A qualitative ranking of storage potentials and local vs. global impact is shown in Fig. 18.

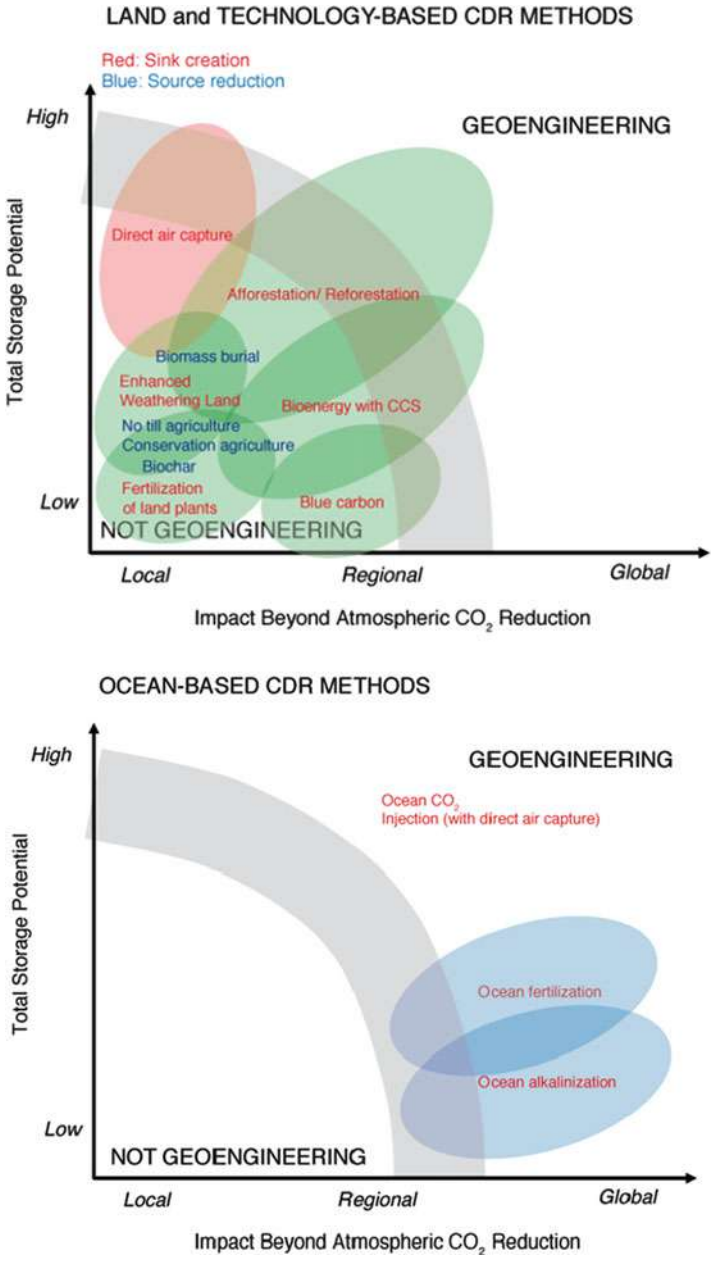

Fig. 16 Scale and impact are important determinants of whether a particular CDR method and specific application should be considered as geoengineering or not. Note that the specific positioning of the different methods is only illustrative and does not constitute a consensus view of the experts participating in the 2011 IPCC Expert Meeting on Geoengineering that produced this chart (Source: Edenhofer et al. 2012)

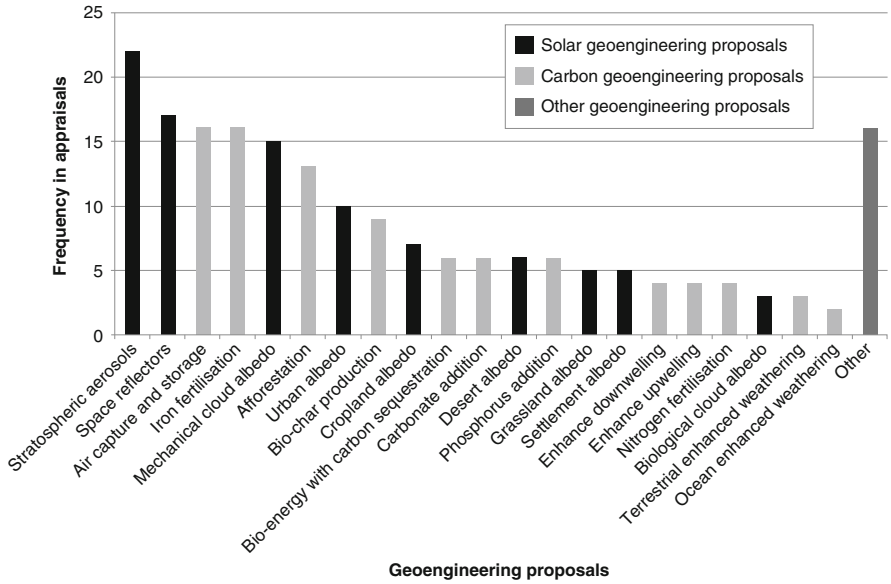

Fig. 17 Relative abundance of geoengineering concepts in the scientific literature. "Others" were cited no more than once (Source: Bellamy et al. 2012)

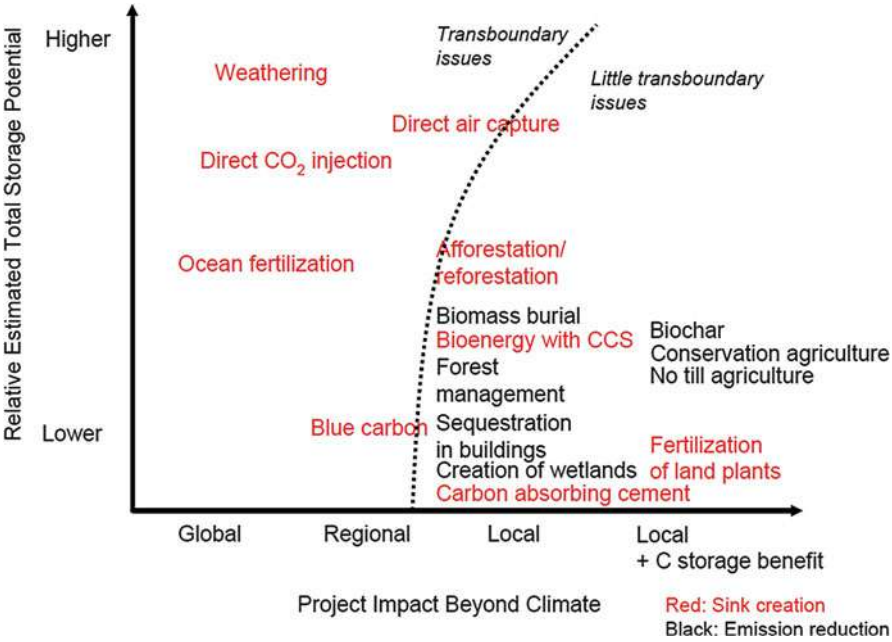

Fig. 18 The relative estimated total storage potential for emission reduction and sink creation projects at different scales (Source: Edenhofer et al. 2012)

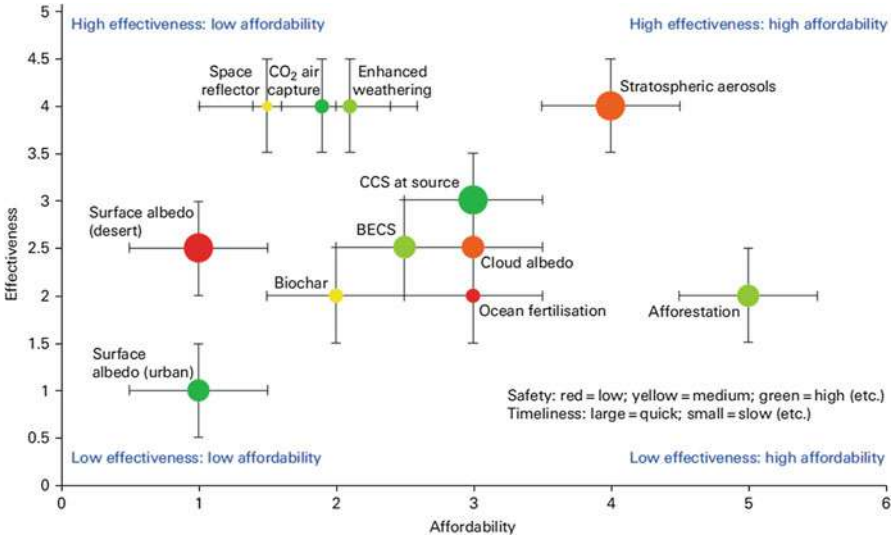

Fig. 19 Preliminary overall evaluation of the geoengineering technique (Shepherd 2009)

As Fig. 18 shows, concepts with a large estimated global potential are carbon sinks, with the ocean being particularly important. For these, transboundary issues arise.

Blue carbon is the carbon captured by the world's oceans and coastal ecosystems (Blue Carbon Initiative 2015).

An overall evaluation in terms of affordability and effectiveness, reproduced from Shepherd (2009), is shown in Fig. 19.

The color of the bullets in Fig. 19 indicates the level of system safety (red = low; yellow = medium; green = high), whereas the size of the bullets relates to the timeliness of the techniques (large = quick; small = slow). One can see from Fig. 19 that urban surface albedo enhancements like "white roofs" are safe, but lack effectiveness technically and financially. Afforestation, also a safe technique, is affordable, but has a lower effectiveness potential than stratospheric aerosols, which are more risky, are more costly, and take more time. Such comparison charts can help define research priorities.

Results from another, similar study are depicted in Figs. 20 and 21.

Lenton and Vaughan (2009) concludes "only stratospheric aerosol injections, albedo enhancement of marine stratocumulus clouds, or sunshades in space have the potential to cool the climate back toward its pre-industrial state. Strong mitigation, combined with global-scale air capture and storage, afforestation, and bio-char production, i.e., enhanced CO_2 sinks, might be able to bring CO_2 back to its pre-industrial level by 2100, thus removing the need for other geoengineering."

A third study (Goes et al. 2010) which is being presented here has compared four scenarios: BAU (business as usual), CO_2 abatement, intermediate geoengineering (next 50 years), and continuous geoengineering from the present until 2150; see

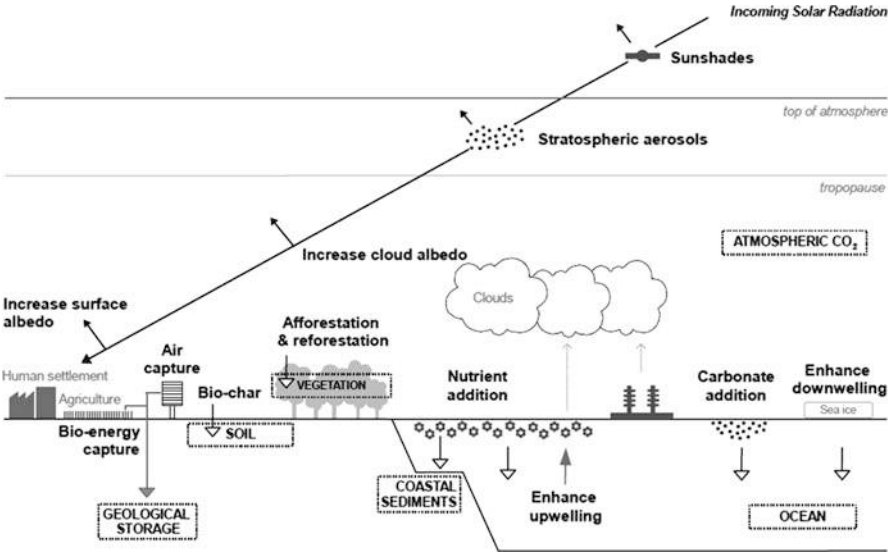

Fig. 20 Schematic overview of the climate geoengineering proposals considered. *Black arrowheads* indicate shortwave radiation; *white arrowheads* indicate enhancement of natural flows of carbon; *gray downward arrow* indicates engineered flow of carbon; *gray upward arrow* indicates engineered flow of water; *dotted vertical arrows* illustrate sources of cloud condensation nuclei; and *dashed boxes* indicate carbon stores (Source: Lenton and Vaughan 2009)

Figs. 22 and 23. The two geoengineering scenarios deploy stratospheric aerosol injection.

CO_2 emissions are assumed to be equally increasing in all scenarios except the abatement one. Two key observations from this study (Goes et al. 2010) are:

- Radiative forcing in the "intermediate geoengineering" scenario would reach the same levels as that in the BAU scenario soon after the geoengineering was stopped.
- Compared to the BAU scenario, a temperature rise of up to 1.5 K per decade, as opposed to less than 0.5 K per decade, would result. Such a strong change might finally be even worse for flora and fauna – and humans than a steady increase.

Figure 23 gives projections on the costs of the four scenarios.

As one can deduct from Fig. 23, damage and total costs of the BAU and intermediate geoengineering scenarios are highest, whereas the continuous geoengineering scenario presents itself as the economically most favorable one. As the authors conclude, aerosol geoengineering for CO_2 abatement can be an economically ineffective strategy. Failure to sustain the aerosol forcing can lead to huge and abrupt changes to the climate: "Substituting aerosol geoengineering for greenhouse gas emissions abatements constitutes a conscious risk transfer to future generations, in violation of principles of intergenerational justice which demands that present

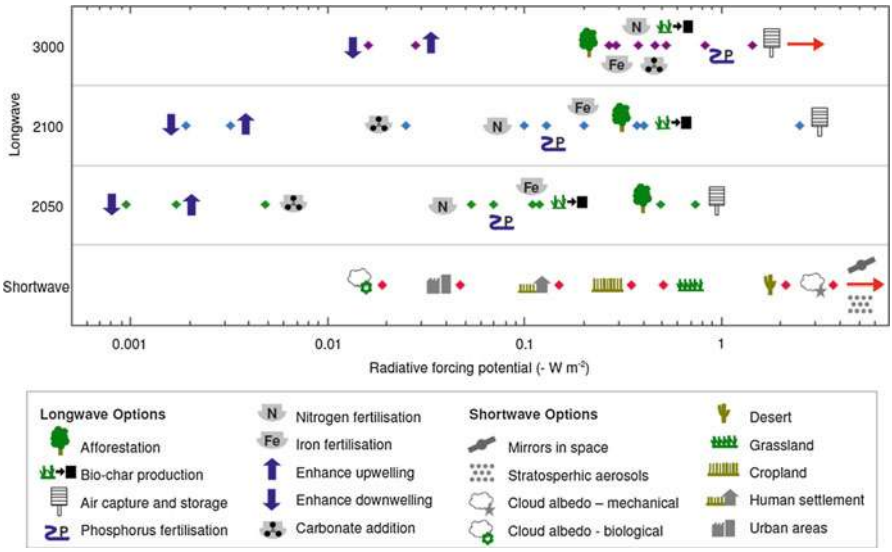

Fig. 21 Summary of estimates of the radiative forcing potential of different climate geoengineering options from Lenton and Vaughan (2009). The potential of longwave (CO_2 removal) options is given on three different time horizons, assuming a baseline strong mitigation scenario. The *rightward pointing arrows*, which refer to mirrors in space, stratospheric aerosols, and air capture and storage on the year 3,000 timescale, indicate that their potential could be greater than suggested by the diamonds (which in these cases represent a target radiative forcing to be counteracted: 3.71 W/m^2 due to 2 × CO_2 = 556 ppm for the shortwave options and 1.43 W/m^2 due to 363 ppm CO_2 in the year 3000 under a strong mitigation scenario) (Source: Lenton and Vaughan 2009)

generations should not create benefits for themselves in exchange for burdens on future generations" (Goes et al. 2010).

Conclusions

As this brief, introductory chapter to geoengineering has shown, several concepts that at first sight look tempting to "quickly fix global warming" have been developed. Ideas range from more tree planting to huge constructions in space, they include techniques to substantially alter the albedo of manmade objects, deserts, or mountains, and they consider injecting vast amounts of chemicals into the ocean and/or the stratosphere. At the present time, the consequences of such measures, and even the magnitude of their very effect, are hard if not impossible to predict, possibly generating huge risks from irreversibly messing up the complex climate system of our Earth for centuries, altering rainfall patterns, and provoking severe military activities, to name but a few possible side effects. Yet, climate engineering poses an option to deal with the impending aggravation of climate change, and once scientists know more about the various options, one or the other of them might in fact become a viable support in global climate change mitigation and adaptation

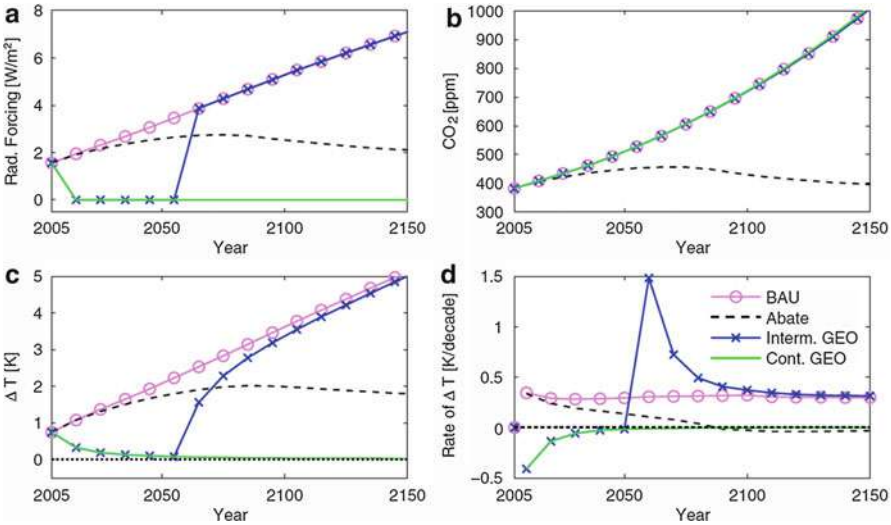

Fig. 22 Radiative forcing (panel **a**), global mean atmospheric CO_2 (panel **b**), global mean surface temperature change (panel **c**), and the rate of global mean surface temperature change (panel **d**) for BAU (*circles*), abatement (*dashed line*), intermittent geoengineering (*crosses*), and continuous geoengineering (*solid line*). Note that these results neglect potential economic damages due to aerosol geoengineering forcing. *BAU* business as usual, *GWP* gross world product (Source: Goes et al. 2010)

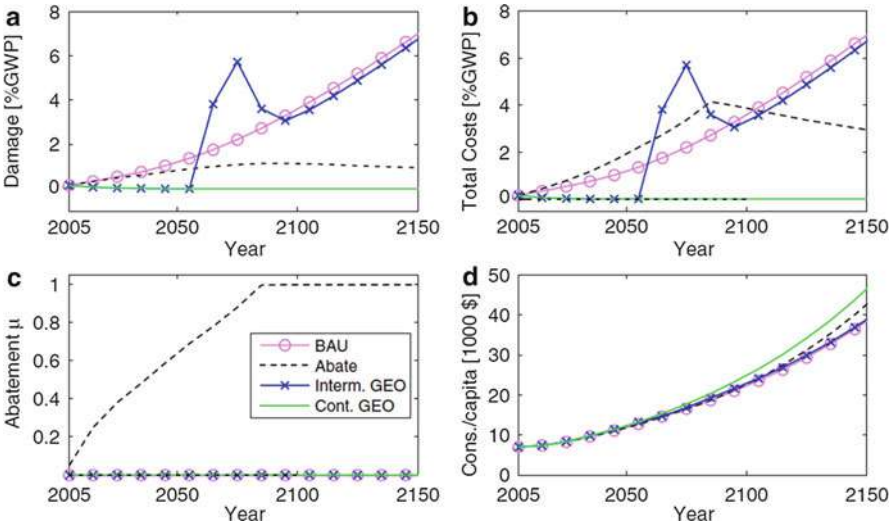

Fig. 23 Economic damage of climate change (panel **a**), total costs (i.e., CO_2 abatement costs and climate change damages cost), abatement, (panel **b**), fraction of CO_2 abatement (panel **c**), and per capita consumption (panel **d**) for BAU (*circles*), optimal abatement (*black dashed line*), intermittent geoengineering (*crosses*), and continuous geoengineering (*solid line*). Note that these results neglect potential economic damages due to aerosol geoengineering forcing. *BAU* business as usual, *GWP* gross world product (Source: Goes et al. 2010)

measures to bring the anthropogenic impacts back under control. On the question of geoengineering ethics, Alan Robock concludes that "in light of continuing global warming and dangerous impacts on humanity, indoor geoengineering research is ethical and is needed to provide information to policymakers and society so that we can make informed decisions in the future to deal with climate change. This research needs to be not just on the technical aspects, such as climate change and impacts on agriculture and water resources, but also on historical precedents, governance, and equity issues. Outdoor geoengineering research, however, is not ethical unless subject to governance that protects society from potential environmental dangers. . .Perhaps, in the future the benefits of geoengineering will outweigh the risks, considering the risks of doing nothing. Only with geoengineering research will we be able to make those judgments" (Robock 2012).

So to conclude, one can say that climate engineering is an interesting topic of research, and CDR techniques that are less risky than SRM techniques might complement conventional climate change mitigation actions. For approaches with global impact, clear governance rules need to be established and enforced.

Outlook

Research of geoengineering should be enhanced, as recommended, e.g., by the UK Royal Society, the American Meteorological Society, the American Geophysical Union, the US Government Accountability Office, and prominent scientists (Robock 2014). Unrealistic and potentially dangerous concepts will be abandoned, and new, innovative ones emerge, possibly providing new options for climate change mitigation and adaptation.

Social Efficiency in Energy Conservation

Patrick Moriarty and Damon Honnery

Contents

Abstract

Global energy use, fossil fuel carbon dioxide (CO_2) emissions, and atmospheric CO_2 levels continue to rise, despite some progress in mitigation efforts. Improving energy efficiency is seen as an important means of reducing emissions, but absolute reductions in global energy use remain elusive because of continued growth in the numbers of important energy-using devices such as transport vehicles, and energy rebound. Limiting the rise in average surface temperature above preindustrial to 2 °C is widely regarded as the limit for avoiding dangerous anthropogenic climate change. Given the magnitude of CO_2 emission reductions necessary for this limit to be met, other approaches are needed for reducing energy use and its resultant emissions. This chapter discusses social efficiency (nontechnical means for reducing energy use) and stresses the social

and environmental context in which energy consumption occurs in various sectors. Three important sectors for energy use, transport, buildings, and agriculture, are used to illustrate the potential for social efficiency in energy reductions. We argue that by focusing more clearly on the human needs energy use is meant to satisfy, it is possible to find new, less energy-intensive ways of meeting these needs.

Introduction

Most studies on energy efficiency focus on technical efficiency measures such as megawatt-hour output of electricity per megajoule (MJ) of primary energy input for a power station, or vehicle-km per MJ of fuel input for a car. While the potential for technical efficiency improvements in energy-consuming devices is large (Cullen et al. 2011) and efficiency gains are expected to be a major factor in future carbon mitigation scenarios (Van Vuuren et al. 2011a, b), the results to date have been disappointing. Many barriers, both technical and socioeconomic, hinder the implementation of energy efficiency policies. Global energy use and fossil fuel CO_2 emissions continue to grow (BP 2015), resulting in a steady climb in atmospheric CO_2 levels.

Further, energy efficiency is subject to the well-known *rebound effect*. Rebound occurs because efficiency improvements (e.g., in light bulbs or passenger cars) lower the cost of operation, either encouraging more use of the energy-using device or allowing the money so saved to be spent on other energy-using goods or services (Druckman et al. 2011; Moriarty and Honnery 2015). A related concept is the demonstration effect of present lifestyles in high-income countries on the

expectations of residents of industrializing countries. If their ownership of energy-intensive goods such as private vehicles or air conditioners rises to levels near those prevailing in high-income countries, any efficiency gains will be swamped by rising global use. Technical energy efficiency is important for carbon mitigation, but needs to be supplemented by nontechnical measures for deep carbon reductions. Energy efficiency measures are discussed in detail in the chapter "▶ Energy Efficiency: Comparison of Different Systems and Technologies".

It is not enough that the energy (or carbon) intensity of economies – primary energy (or carbon) consumed per unit of gross national income – be reduced; absolute levels of fossil fuel energy must also be greatly cut.

As used here in the context of energy conservation, the term *social efficiency* refers to a system-based approach that stresses the social and environmental context in which energy consumption occurs in various sectors. As Haas et al. (2008) have stressed, households and organizations do not use energy for its own sake; they use it to enjoy the *energy services* it provides. Put simply, social efficiency will refer to nontechnical means for reducing energy use. As discussed, technical efficiency improvements are made by getting more output from a given energy input, such as electric output per unit of fossil fuel input energy; social efficiency improvements, on the other hand, are made by getting more social "value" from each unit of the output of an energy-using device (Moriarty and Honnery 1996, 2014).

It is instructive to compare approaches in climate change modeling and energy efficiency studies. Climate scientists have utilized general circulation models for decades and, more recently, coupled carbon-climate models. Such modes have been used to show, for example, that afforestation could exacerbate climate change (Keller et al. 2014). The newly grown forests would decrease the albedo (the fraction of the insolation reflected directly back into space), offsetting the carbon sequestration in the trees. With the exception of the rebound literature, energy efficiency research, in contrast, mostly does not look at effects on other energy sectors.

To illustrate both the approaches used and the potential for social energy efficiency, this chapter focuses on three important energy-using sectors as case studies: transport, both passenger and freight; energy use in buildings, both household dwellings and commercial buildings; and agriculture, particularly for food production. These case studies were chosen not only for their importance for global energy use and greenhouse gas (GHG) emissions but also because they illustrate different aspects of social efficiency.

By examining social efficiency in these three sectors, we hope to point to new ways at looking at energy and GHG emissions reductions. In particular, we stress the need to examine more closely *what energy is used for* (Shove and Walker 2014). As energy researcher Benjamin Sovacool (2014) put it: "Academic researchers frequently obsess over technical fixes rather than ways to alter lifestyles and social norms." The usual, technical approach is to find ways of performing existing tasks more efficiently; instead we ask whether the tasks should be done in the first place and whether the human needs underpinning energy use can be met in a different, less energy-intensive way.

Social Efficiency: Transport

In 2012, the fuel for all modes of vehicular transport, including both passenger and freight, accounted for 27.9 % of global final demand for energy, up from 23.1 % in 1973 (International Energy Agency (IEA) 2014). Transport is heavily reliant on fossil fuels (96.6 % in 2012) and global road vehicle numbers are still rising rapidly. GHG emissions from this sector are thus rising, and it will be very difficult for technical solutions alone to stop further rises, let alone greatly reduce them.

Passenger Transport

The conventional measure of the passenger transport task is passenger-km (p-km). For example, 10 p-km is generated if one passenger travels 10 km or ten passengers each travel for 1 km. Transport efficiency in turn is measured as p-km per MJ of primary fuel. Measures such as miles per gallon and liters per 100 km are still widely used for vehicle efficiency, but suffer from two drawbacks. First, the useful output of passenger travel is p-km rather than vehicle-km (v-km); in other words, the occupancy rate is important. With this measure of output, buses can now be compared with car travel. Second, although liters per 100 km is useful for comparing the efficiency of various petrol or diesel-fueled vehicles, it is not useful for comparing electric-powered vehicles, whether for private or public transport, with vehicles that run on liquid fuels. But p-km/MJ of primary enables fair comparison of all passenger transport modes, regardless of energy source or vehicle carrying capacity (Moriarty and Honnery 2012).

However, even though p-km is a more useful measure than v-km, transport is still mainly a *derived demand*. Although some travel, especially by car, is undertaken for its own sake, in most cases travelers undergo the monetary and time costs required in order to access out-of-home activities such as working, education, or shopping. Access to activities, not mobility, is the real purpose of transport; hence one measure of the social efficiency of passenger transport would be *access* per primary MJ of transport fuel. Obviously, all else being equal, doubling the occupancy rate of all vehicular transport should double the access achieved per primary MJ. Occupancy rates are covered in more detail in the chapter "▶ Reducing Personal Mobility for Climate Change Mitigation".

Of course, it is much easier to measure p-km than it is to measure access, which has a subjective component. As Halden (2011) has stated: "accessibility is an attribute of people and goods rather than transport modes or service provision." Mobility may be easy to measure, but given that travel is mainly a derived demand, he further argued that it is difficult to say whether more travel is better than less.

How can access be improved? The journey to work trip will be used to illustrate the possibilities. First, we need to define two terms, *minimum average work trip length* and *actual average work trip length*. For convenience, we will use the example of cities and assume that all workplaces within the city boundaries are filled by resident workers. The minimum average work trip length for any city will

then be the average distance traveled to work if workplaces are fixed, but workers can change residences such that total travel to work for all city residents is minimized. The actual average work trip length is that calculated from origin-destination studies of citywide work trip patterns. Clearly, total work travel will be less if the actual average distance is close to the minimum.

Studies have shown that, in real cities, there is a large amount of "excess" work travel. For a range of US and Australian cities, actual work travel was found to be roughly twice the minimum. On the other hand, for a sample of Japanese and South Korean cities, actual work travel was much closer to the minimum (Moriarty and Honnery 2013). The much higher densities of the latter cities compared with US and Australian cities, and the accompanying traffic congestion, are important explanatory factors. However, even if excess work travel is very low, overall work travel could still be reduced in some cities. This happens if there is a mismatch between residences and workplaces – if, for example, workplaces are largely located in one area of a city and residents (and thus workers) in other areas. With the rise of the service sector (and the decline in manufacturing jobs) in Organisation for Economic Co-operation and Development (OECD) cities, this potential mismatch is disappearing. Jobs such as those in the education, health, retail shopping, and other service sectors serve a local area and so are found intermingled with residential areas. With manufacturing, in contrast, the intended market for the products is far wider, often national or even international in scope, and so did not need to be close to residential areas. The result of the rising share of service jobs is improvement in the balance of workplaces and resident workers at the local level (Australian Bureau of Statistics (ABS) 2013; Cervero 1996).

For other trip types, access is more difficult to define. For shopping, access is not only a function of distance to the nearest shopping center but also the range of shops available. Authorities can and do improve resident access to services by strategic location of schools, parks, local government offices, and health centers, for example. As discussed in the chapter "► Reducing Personal Mobility for Climate Change Mitigation" (Section 7), if we lower the *convenience* of car travel in an attempt to reduce its external costs (e.g., air and noise pollution, GHG emissions, community disruption, traffic casualties), the balance between private travel and other modes will be fundamentally altered. In particular, nonmotorized modes will now be relatively more convenient, as well as faster and safer. Vehicular trips for different purposes will be combined more often, and preferred destinations for discretionary trips will change. In brief, if we remove the *priority* accorded to vehicular travel, especially by car, overall vehicular travel will fall. But access levels need not decline with reduced (vehicular) travel, since travel patterns and the intensity of use of various local services can be expected to change over time to maintain access levels.

As Gabrielli and von Karman (1950) showed many decades ago, there is a trade-off between speed and energy efficiency. Slower modes of transport are usually more energy efficient. So an important way of lowering the convenience of car travel is by speed reductions. This will not only reduce transport energy use but also traffic-related air and noise pollution. It will also reduce the frequency and severity

of traffic accidents, both for vehicle occupants and for nonmotorized travelers. For the latter group, research has found that at "impact speeds of 32 km/h, only about 5 % of pedestrians are killed and injuries are minor. At 48 km/h, 50 % are killed and many are seriously injured, while at 80 km/h most do not survive the impact" (Moriarty and Honnery 1999, 2008). Similarly, vehicle impacts with other vehicles or roadside objects are reduced in both number and severity. These benefits can be used to justify lower speed levels.

Even before the global financial crisis, land passenger travel per capita had started decreasing in a number of OECD countries (Millard-Ball and Schipper 2011). However, air travel continues its strong growth, except for Japan, where it has been falling since the year 2000 (Statistics Bureau Japan (SBJ) 2014). Globally, Airbus projects air travel to grow at an average rate of 4.7 % over the years 2014–2033, with international tourism a key driver (Airbus 2014). Hence, an important approach to reducing fuel use and GHG emissions in air transport is the substitution of more local for international tourist destinations. Why do so many people feel the need for international holidays and distant travel in general? One reason is the large and rising number of people, often from lower-income countries, working in wealthier countries (OECD 2014), who visit their families or friends in their home country. Another possible reason is the stress of modern industrial life and work, which impels people to take their vacations in distant locations to get away from this situation (Chen and Petrick 2013). What these examples do show is that global social and economic conditions form part of the explanation of the present high levels of travel.

Finally, we need to explore the ways in which the new information technology (IT) affects travel behavior. Although this question has been explored for nearly four decades, no definitive answer has emerged. Dal Fiore et al. (2014) concluded, as others have, that the new IT, especially mobile technology, has the potential to both increase and decrease levels of passenger travel. Given that per capita vehicular travel levels are falling in many OECD nations, it is possible that either IT is now actively decreasing travel levels or that it is at least enabling people to cope with less travel.

Freight Transport

In a similar manner to passenger transport, technical freight transport efficiency can be measured by tonne-km (t-km) of payload freight per MJ of primary fuel. Even more so than for passenger travel, the efficiency of the various freight modes varies by two to three orders of magnitude (Edenhofer et al. 2014), with air transport being by far the least energy efficient (but the fastest) form of freight transport.

Although freight trucks in all weight classes have shown technical efficiency gains in recent years (in terms of t-km/primary MJ), there has also been a trend toward increased use of smaller freight vehicles for delivery. In Australia overall, but especially in urban areas, light commercial vehicles are carrying a rising share of total t-km (ABS 2013). In London, the same trend has been found and is expected

to continue out to the year 2050 (Zanni and Bristow 2010). Such trends undo some of the efficiency gains in truck freight transport. "Just-in-time" logistics is intended to keep parts inventory in manufacturing to a minimum. One consequence is that delivery frequencies have risen, and average loads have decreased. In effect, the private costs of inventory have fallen, but at the expense of increased external costs for highway freight. The list of external costs for road freight vehicles is similar to those already discussed for road passenger travel.

The "occupancy rate," or payload to tare weight ratio, for freight vehicles is just as important as for passenger travel. For specialized transport vehicles, such as oil or liquefied natural gas tankers, return loads are not feasible. For general goods carriers, two-way loadings can often be improved by better logistics planning, resulting in overall energy reductions (Edenhofer et al. 2014). But a prior question should be: is this particular freight transport needed at all? Most tonne-km of freight globally is moved by international ocean vessels. In most OECD countries, large volumes of products are either imported from other countries or from a different region of the same country. Yet similar products are often also made in the importing country or region. Consumer choice may be important; the point that is often overlooked is that the external costs of the necessary freight transport are unpaid, leading to underpricing of the imported goods.

However, social changes already underway could move freight in a more sustainable direction. Recently much attention has been given to "food miles" and a general preference for locally produced goods, such as that sold at farmers' markets. Food miles represent the distance between the point of food production and the point of consumption. Van Passel (2013) has shown that the concept needs to be modified to meet the charge of oversimplification. He argued for its extension to include freight transport externalities and even added that "all relevant economic, social, and ecological aspects should be taken into account." Many existing food products are endorsed as variously being "fair trade," "organically grown," or "dolphin safe" and often have detailed nutritional information on their packets. In the future we could well see information such as the energy costs, kilometers of transport, and transport mode added to labels. Just as many countries worry about energy security, food security could also become more important for consumer preferences. This point is discussed further in the section "Social Efficiency: Agriculture."

As an example of the kind of systems thinking needed about freight, Schewel and Schipper (2012) have examined in detail "retail goods movement" in the USA, which in 2009 accounted for 6.6 % of US energy demand. They start with the point of import or of manufacture, followed by transport of these goods to a central warehouse, then distribution to individual shops, and finally transport, usually by car, of the purchased goods to the consumer's final destination. They point out the conflict that can arise between freight transport energy costs and the final consumer's energy costs. The trend toward fewer, larger stores has improved freight energy efficiency by allowing use of higher capacity trucks, but on the other hand, shoppers have had to drive further to the more widely spaced retail outlets. This retail case study shows that it is not always possible to separate passenger travel energy from freight transport energy.

Social Efficiency: Buildings

According to the Intergovernmental Panel on Climate Change (IPCC), in 2010 "buildings accounted for 32 % of total global final energy use" (Edenhofer et al. 2014). They were also responsible for 19 % of energy-related GHG emissions, or 9.18 Gt CO_2-eq., when electricity-related emissions were included. Further, according to the IPCC, this "energy use and related emissions may double or potentially even triple by mid-century." Although building energy is growing strongly in industrializing countries, in the core OECD countries, and the economies in transition, total building energy, both direct and indirect, has peaked (Edenhofer et al. 2014). But, as pointed out in the chapter "► Nontechnical Aspects of Household Energy Reductions" (Section 2)", research has shown that occupant behavior can make a huge difference in domestic energy use and presumably for commercial buildings as well. Thus, it is becoming increasingly acknowledged that the social context in which building energy use occurs is crucial.

Energy use in buildings is different from energy use in passenger transport in that it can and does occur without a human presence. In many cases, this raises few problems: refrigerators, freezers, and electric clocks are best left running continuously. But lighting and space heating/cooling in buildings, as well as computers, televisions, radios, and other appliances, are often left running, whether or not humans are there to enjoy the energy services provided. Even when not running, their standby energy use can be collectively important. Rather than measuring the power consumption of, for example, a television set, a possible measure of social efficiency might be the number of person-hours of actual viewing per hour the set is operating or per MJ of energy the device consumes.

In OECD countries, by far the most important energy use in buildings is for space heating and cooling. Yet temperature controls for both heating and cooling could be set much closer to ambient levels, if clothing more appropriate to outside temperatures were worn indoors. For offices, it would mean that dress codes would need to change to allow more appropriate clothing for the season. One problem with fixed temperature settings is that it weakens the possibility of *acclimatization* to seasonal temperatures. For example, in hot regions of the world, Auliciems (2009) has reported that inhabitants preferred temperatures of "34 °C or even higher." This seasonal or regional acclimatization can be lost where air-conditioning of buildings is common.

Passive solar energy is in some ways a misnomer, since its use requires a far more active participation by building occupants for space heating or cooling, for example, than does mechanical air-conditioning, which merely requires a thermostat setting. Passive solar can be used for lighting as well as thermal conditioning of buildings. For residences, use of passive solar involves the judicious opening and shutting of windows and blinds for temperature control and lighting and even varying the timing and use of cooking stoves and ovens, depending on whether the heat will add or subtract from thermal comfort. In some situations, it may be worthwhile investigating a change to hours of employment as a means of improving occupant comfort. Passive solar (in the form of wind energy) can also be used for

clothes drying, but in many communities the use of outdoor clothes drying is still banned (Lee 2009), because of the claim that clothes lines are unsightly.

The case study by Pilkington et al. (2011) in the UK showed the importance of occupant behavior for making the most of energy savings from passive solar design. The six terrace houses studied were of identical design, with superefficient insulation and "sunspaces." They found that space heating use per occupant varied by a factor of 14. The main reason for the variation was that the higher energy users kept the internal doors open on winter days. Overall, the approach we advocate here can be contrasted with the "smart buildings" approach. Instead of predetermined settings, even if set by the occupants, we advocate that the building occupants actively respond to changing ambient conditions and adjust openings and shading accordingly.

Just as for passenger transport, the occupancy rate of buildings is important in determining energy use. For residences, the occupancy rate has generally fallen in recent decades in most OECD countries, a consequence of both declining family size and rising incomes (e.g., ABS 2012; SBJ 2014; US Census Bureau 2012). The result is that dwelling space (in m^2) per occupant has also risen, which tends to raise the energy for heating or cooling and lighting energy per occupant. If the trend toward declining household size could be reversed, not only would domestic energy efficiency rise but the occupancy rate for cars, and thus their energy efficiency, would also rise. Possibilities for increase include young adults staying at home longer and multi-family and group households. Both the latter groups are already common in many OECD countries, forming an increasing share of total households (e.g., ABS 2012). However, they have not been able to stem the overall fall in household sizes.

Social Efficiency: Agriculture

Modern industrial agriculture is not only heavily reliant on energy, especially petroleum-based fuels, but is also a major producer of the GHGs methane and nitrous oxide, as well as CO_2. Over the years 2000–2100, the IPCC estimated that average annual emissions of all GHGs from agriculture were in the range 5.0–5.8 Gt CO_2-eq., compared with all-sector global 2010 emissions of 49 Gt CO_2-eq. (Edenhofer et al. 2014). For these reasons alone, a change is needed in the way the world produces its food and fiber. But present agricultural methods also produce a host of other serious environmental problems and costs, including air and water pollution, loss of biodiversity, soil erosion, and soil salinity.

The emphasis in industrial agriculture is on cost minimization per unit of output, given that its products must compete in the marketplace. However, these costs are usually viewed in a narrow accounting sense; the *external costs* (including GHG emissions and the other costs listed above) can often be ignored (Weis 2010), just as they often are for transport. These environmental costs, such as surface water pollution, will incur energy costs for their remediation (Moriarty and Honnery 2011).

Ho and Ulanowicz (2005) investigated the energy return (in terms of food kilojoules) to energy input ratio for three types of agricultural systems: preindustrial, semi-industrial, and full-industrial. They found that the range of energy return ratios for the first two systems was 6.9–11.5 and 2.1–9.7, respectively. For the full-industrial agricultural systems, the ratio was little better than unity. It appears that trying to coax more output per hectare in industrial agriculture is subject to diminishing returns on the largely fossil fuel energy invested (Bos et al. 2013). While it may save land (and for industrial agriculture, land rent, real or imputed, is an important part of production costs), such systems carry higher energy costs, as well as higher general environmental costs.

A narrow technical approach to GHG emissions from agriculture can also lead to conflicts for overall climate mitigation. Emphasis on CO_2 emissions reduction may lead to nitrous oxide emissions from fertilizer being overlooked. And the projected use of corn stover for conversion to liquid fuels runs the risk of increased soil erosion and loss of soil carbon. Using corn stover (and other agricultural wastes) for bioenergy will enable some fossil fuel carbon to be left in the ground, but soil carbon losses could partly or wholly offset this benefit.

Nevertheless, for agriculture, we have to look wider than these biophysical environmental impacts. McMichael (2011), in his article on multi-functionalism in agriculture and the "food sovereignty" movement, stressed that farming is not simply about food production, vital though this is. It is valued also for "its contribution to ecosystem management, landscape protection, rural employment, fostering farming knowledge, rural life, cuisine maintenance, and regional heritage." The recognition of the importance of multi-functionalism means that agriculture has diverse impacts on overall energy use; agriculture's energy use implications go far beyond that involved in food and fiber production, even after the energy costs of environmental damages are taken into account. Whether or not these energy costs incurred in other sectors are greater or less for alternative than for industrial agricultural practices is presently unknown; the important point is that they should be considered in the analysis of the total energy costs of agriculture. Farming is a *social* activity.

When discussing passenger transport in section "Passenger Transport," we emphasized the importance of the question: What is the purpose of transport? Similarly, we need to ask: What is the purpose of agricultural production? What are the products used for? The answer might seem obvious, since food is a basic human necessity, with no substitutes. However, according to the Food and Agriculture Organization (OECD/FAO 2014), in 2014, 34.4 % of the global grain harvest (estimated at 2.461 Gt) was fed to livestock, with a further 6.8 % used for liquid fuel production. The FAO expects the share of these nonfood uses to rise modestly in the future, together reaching 42.3 % of the grain harvest by 2023. Grain provides the bulk of the human diet. Other important agricultural foodstuffs used for feedstock for animals or for fuels include soybeans, oilseeds, and sugarcane. It is true that feedstocks are used to produce meat and dairy produce. However, in many OECD countries, including the USA and Australia, meat and dairy produce consumption is well in excess of the level regarded as producing a healthy diet. Further,

one billion people still suffer dietary deficiencies of various kinds (Conway 2012). If the world shifted to a more vegetarian diet, this deficiency could be remedied.

A related issue is food waste: much of the food that is produced and intended for direct human consumption is not eaten but wasted. For industrializing countries, food losses are greatest in the immediate post-harvest part of the food supply chain. In contrast, for OECD countries, the greatest overall food losses resulted at the food retailer, food services industry, and household levels (Parfitt et al. 2010). Atkinson (2014) has even claimed that half the food supplied in high-income countries is thrown away uneaten. As a solution, Parfitt et al. have called for "[C]ultural shifts in the ways consumers value food" and educating the public on the environmental costs of such food waste.

Urban agriculture could also be an important means for reducing food production energy use. Teng et al. (2011) have estimated that, worldwide, around 800 million nominally urban residents are involved in food production, many of them full time, especially in low-income cities. But food production is also growing in popularity in OECD cities. Growing food in cities for the household's own use reduces the relevant "food miles" discussed in section "Freight Transport" to zero, thus cutting freight energy use. According to Ackerman et al. (2014), urban farms can also potentially produce a range of social and economic similar to rural farms: "Urban agriculture not only provides a source of healthful sustenance that might otherwise be lacking, it can also contribute to a household's income, offset food expenditures, and create jobs." It also helps the environmental sustainability of the city, and larger urban farms can provide job training for underserved populations. Varying diets to match the growing seasons of locally produced fruit and vegetables can also reduce agricultural transport costs.

Future Directions

If efforts at mitigating climate change in the coming decades are no better than those in recent decades, the world could be heading to a 4 °C rise in average surface temperature above preindustrial values by the century's end. Although some adaptative measures will be clearly needed, since further climate change is unavoidable given climate (and social) inertia, adaptation cannot be expected to cope with such a temperature rise. At a 4 °C rise, the broadly linear response so far observed in various climate subsystems may break down (New et al. 2011), resulting in changes difficult to predict. Adaptation efforts would then be continuously aiming at a moving target.

Hence, mitigation is the only long-term solution to climate change, and the later it is postponed, the more drastic will be the changes needed. There are encouraging signs that the world's leaders are starting to appreciate how serious the climate change problem is. The European Union now binds its member states to reduce their GHG emissions by at least 40 % from 1990 levels by 2030, mainly through improved energy efficiency and more renewable energy. The world's largest carbon emitter, China, has recently pledged to stabilize its GHG emissions by 2030, and the

second largest, the USA, has promised that by 2025, its emissions will be 14–16 % less than those in 1990 (Anon 2014; Malakoff 2014). Although technical solutions will doubtless be the preferred approach to meet these targets, the latest IPCC report on mitigation (Edenhofer et al. 2014) has placed far more emphasis on nontechnical approaches than did the earlier IPCC reports.

A key advantage of technical energy efficiency improvements is that they are a much better fit to the existing growth-oriented market economies than the social efficiency approaches discussed here. At present, most of these social efficiency measures are not politically feasible. But, in addition to the GHG reduction targets just discussed, changes are under way which will ensure that, in future, social efficiency is less "unthinkable" than it is today. Rockström et al. (2009) have discussed nine "planetary limits" which Earth is approaching, including climate change, ocean acidification, and the rate of biodiversity loss. To this list must be added the global depletion of fossil fuels, particularly oil, and of key minerals essential for industrial economies.

The official position is still that reserves of fossil fuels are more than enough to sustain rising production for decades to come (BP 2015; Energy Information Administration (EIA) 2014). The IPCC (Stocker et al. 2013) projects that natural gas will be an important component of future energy use, being seen as especially valuable as a transition fuel to a low carbon future, because of its low CO_2 emissions per unit of energy compared with coal or oil.

In contrast to this optimistic position, recent research (Inman 2014) has cast doubt on the long-term future for shale gas, which was thought to have large reserves, particularly in the USA. A fine-grained analysis of US shale formations has found that the "sweet spots" where production is presently occurring are not typical of the formations as a whole. Overall, US natural gas production could peak within a decade and then fall sharply. If the US example serves as a model for shale gas production globally, the decarbonization of the energy supply could even be reversed. More generally, Schindler (2014) and others (e.g., Höök and Tang 2013) have stressed that oil, both conventional and unconventional, will peak soon, and natural gas and even coal will peak within a very few decades as well. If the potential for renewable energy to reduce GHG emissions is also less than anticipated, energy reductions will have to be the main approach for GHG reductions.

In the future, then, we can expect to see greatly increased attention to system approaches to energy use, as well as more research that combines both technical and social approaches to energy, for the following reasons:

- Rising energy costs for producing energy partly offset any gains in device energy efficiency.
- Energy rebound significantly offsets any gains in energy efficiency.
- As evidenced by the continued rise in atmospheric concentrations of CO_2 and GHGs overall, the current emphasis on technical solutions is not working.
- Many of the easily made technical energy efficiency measures have already been implemented; those remaining will be progressively more difficult to implement. In contrast, social efficiency potential has barely been tapped.

This chapter has shown that it is usually very difficult to neatly compartmentalize the various energy sectors. Improving freight energy efficiency may negatively impact on passenger transport efficiency, for example. A large range of social practices impact on energy uses, as shown in this chapter. The efficiency of providing thermal comfort in buildings can be greatly improved by changes to the lifestyles of the occupants, including their clothing choices, and by the active use of passive solar energy. Agricultural practices can affect both transport energy costs and the energy costs of ecosystem maintenance. Choosing a diet with less meat and dairy products can greatly improve the overall energy efficiency of national and global food systems. If the world is to produce the carbon mitigation effort needed to avoid disruptive climate change, the question that will increasingly need to be asked is: What is the energy for? What we have termed social efficiency is an attempt to address this vital question.

Measuring Household Vulnerability to Climate Change

Sofie Waage Skjeflo

Contents

Abstract

This chapter summarizes research on the potential impacts of climate change on households, with a particular focus on contributions from different methodological approaches to understanding impacts for households in developing countries. Agriculture has been a central focus of this literature, both because of the sensitivity of the agricultural sector to a changing climate and also because of the importance of agriculture for the livelihoods of the poor. The literature review shows that developing countries are largely expected to be disproportionally hurt by projected changes in temperature, precipitation, and extreme events. On the other hand, the actual household level response to these changes is not well understood, and there are still gaps in the methodological approaches to understanding these issues. The recent literature reveals promising approaches that may complement and improve existing methods as more data becomes available.

Introduction

Despite remarkable achievements in improving standards of living and reducing the proportion of the world's population living in poverty over the past century (Easterlin 2000; Chen and Ravallion 2010), securing basic needs remains a challenge for a large share of the global population. In 2010, the estimated share of the world's population living in extreme poverty, defined as less than $1.25 per day measured in purchasing power parity terms, was about 20 % (World Bank 2014). In sub-Saharan Africa, the estimated share is almost 50 % (World Bank 2014). The majority of the world's poor live in rural areas and rely on agriculture as their main livelihood (World Bank 2014). In the face of a changing climate, the challenge of improving the livelihoods of the poor may be even greater (IPCC 2014). The physical characteristics of agriculture create a strong link between the climate, agriculture, and poverty (Porter et al. 2014). Understanding the potential impacts of climate change therefore requires knowledge of how the rural poor might be affected, through which channels and how policies to improve livelihoods interact with these impacts.

This chapter aims to give an overview of the literature on climate change impacts in developing countries, with a particular emphasis on agriculture in sub-Saharan Africa. The focus is on the contributions of different methodological approaches to understanding climate change in rural developing countries, as well as empirical findings. After discussing the direct impacts of changing temperature and precipitation trends, the household level response to these impacts is discussed. This requires an understanding of household characteristics and the context in which rural households interact, which is discussed in section Household Heterogeneity and Market Characteristics. The final section concludes with some challenges for future research.

Climate Change Impacts on Agriculture

The most recent report from the Intergovernmental Panel on Climate Change (IPCC) concludes that the climate system is warming and that it is very likely that weather extremes have become more frequent and severe due to climate change (IPCC 2013). Projections show that continued greenhouse gas emissions will cause average temperatures to increase further, and there is high confidence that the near-term increase will be larger in tropical and subtropical regions than midlatitude regions. Projections for average precipitation are less clear. It is likely that precipitation variability will increase, but the projections are uncertain and vary considerably across regions in sub-Saharan Africa (IPCC 2013). Figure 1 shows the trends and projected trends in temperature and precipitation for Africa. The top left panel of the figure shows the trend in temperature from 1901 to 2012, where white areas are areas where there is insufficient data to conclude on any trend. The top right panel shows the projected difference in annual mean temperature between mid- and late twenty-first century and 1986–2005. The projections for the RCP8.5, or the

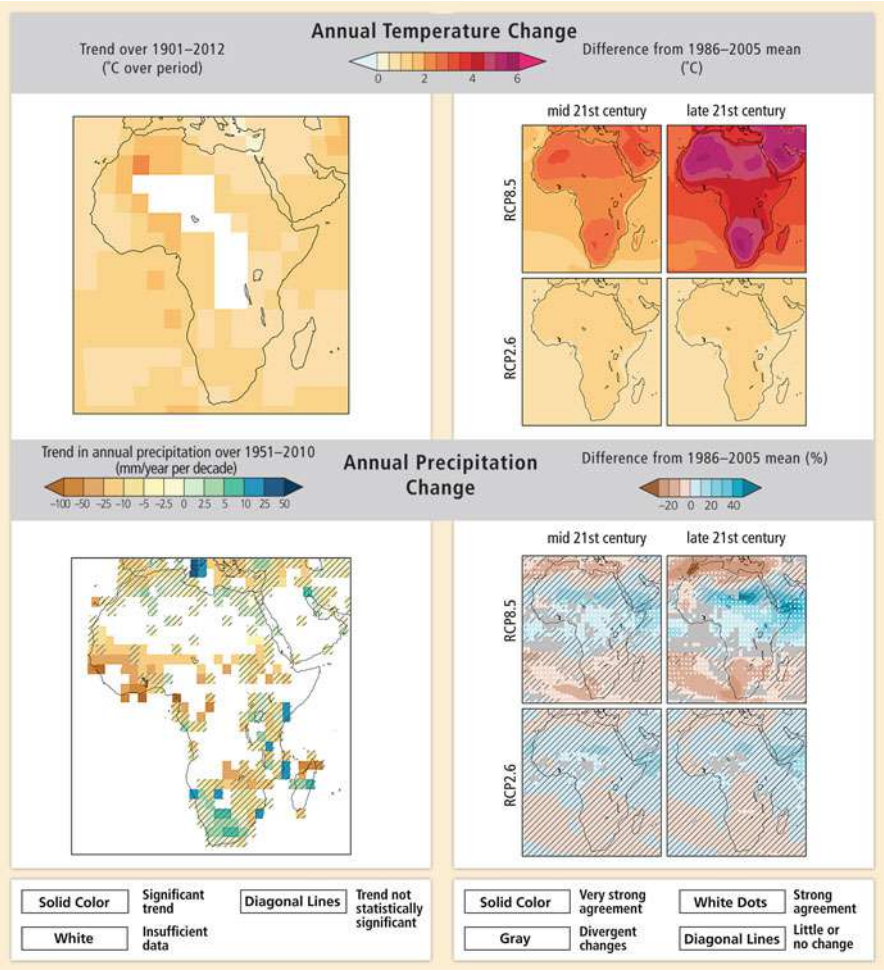

Fig. 1 Observed and projected changes in annual average temperature and precipitation (*top panel*, *left*). Map of observed annual average temperature change from 1901 to 2012, derived from a linear trend [WGI AR5 Figures SPM.1 and 2.21] (*bottom panel*, *left*). Map of observed annual precipitation change from 1951 to 2010, derived from a linear trend [WGI AR5 Figures SPM.2 and 2.29]. For observed temperature and precipitation, trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70 % complete records and more than 20 % data availability in the first and last 10 % of the time period). Other areas are white. *Solid colors* indicate areas where trends are significant at the 10 % level. *Diagonal lines* indicate areas where trends are not significant (*top and bottom panel*, *right*). CMIP5 multi-model mean projections of annual average temperature changes and average percent changes in annual mean precipitation for 2046–2065 and 2081–2100 under RCP2.6 and 8.5, relative to 1986–2005. *Solid colors* indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability (natural internal variability in 20-year means) and >90 % of models agree on sign of change. *Colors* with *white dots* indicate areas with strong agreement, where >66 % of models show change greater than the baseline variability and >66 % of models agree on sign of change. *Gray* indicates areas with divergent changes, where >66 % of models show change

"business-as-usual" scenario, show up to 6° warming by the end of the twenty-first century in some areas of Africa. The RCP2.6 scenario, which is a scenario with aggressive mitigation efforts where emissions are near zero by the end of the century, also shows warming in Africa, highlighting that adaptation efforts may be needed even if emissions are cut dramatically. The bottom two figures show that observed trends and projected changes in precipitation are much less clear, with missing data preventing clear insights on past trends.

Studies of impacts of climate change in developing countries have to a large extent focused on impacts through agriculture, both because of the importance of the agricultural sector in terms of production and employment and because of the sensitivity of this sector to climate change (Arndt et al. 2012).

Early studies of quantitative impacts of climate change on agriculture relied on crop simulation models to simulate the impact of changing temperature, precipitation, and concentration of CO_2 in the atmosphere on crop growth (Kurukulasuriya and Rosenthal 2003). These models capture the effect of genetic factors; climate variables such as solar radiation, maximum and minimum temperatures, and precipitation; as well as soil characteristics and farm management practices on yields (Parry et al. 1999). The models can also take into account the fertilization effect of increased CO_2 concentration in the atmosphere, as explained by Darwin and Kennedy (2000), and different adaptation options can be simulated by exogenously changing planting dates, fertilization, irrigation, and so forth.

Since these models require detailed input and are constructed for separate crops, the applications of crop models for country- or region-level studies of Africa are scarce (Hertel and Rosch 2010; Thurlow et al. 2012). Thurlow et al. (2012) therefore use a less detailed hydro-crop model in their study of impacts of climate variability on Zambian agriculture. Based on climatic and agronomic statistics from the past three decades, their hydro-crop model predicts 14–77 % maize yield losses in the most drought-prone agroecological zone during a severe drought event and up to 48 % yield losses during more moderate drought events.

An application at a more aggregated scale is provided by Jones and Thornton (2003) who use global circulation model (GCM) output to generate weather scenarios for surfaces in Africa and Latin America up to 2055. The authors do not state which emission scenarios the simulations are based on. The GCM output is used to produce daily weather data that is used in the CERES-Maize crop model. The model simulations are run under the assumption of current varieties and farm practices, i.e., without adaptation. The results show that three quarters of the countries in Africa and

Fig. 1 (continued) greater than the baseline variability, but <66 % agree on sign of change. Colors with *diagonal lines* indicate areas with little or no change, where <66 % of models show change greater than the baseline variability, although there may be significant change at shorter timescales such as seasons, months, or days. Analysis uses model data and methods building from WGI AR5 Figure SPM.8 (See also Annex I of WGI AR5. [Boxes 21-2 and CC-RC] Source: page 1207 in Niang et al. (2014))

Latin America can expect declining maize yields. An exception is the Ethiopian highlands which are expected to experience up to 100 % increases in yields.

Nelson et al. (2009) use the DSSAT biophysical crop modeling system to predict impacts of climate change on crop yields under the A2 SRES scenario (Nakicenovic and Swart 2000) simulated with two different climate models. The direct biophysical impact on crop yields is calculated without any adaptation and both with and without the fertilization effect from CO_2 and is reported to be negative for rain-fed wheat, but with mixed results (some increases and some decreases) for rain-fed maize. For sub-Saharan Africa, the direct impact of climate change on maize yields is negative for both climate models, although a precise estimate is not provided. The numerical results reported are highly aggregated for rain-fed and irrigated maize, which makes it difficult to compare these results with the country-level study above. When taking into account farmers' adaptation to price changes due to climate change, for instance, through adapting crop mix and input use, a 10 % decrease in maize production for sub-Saharan Africa is predicted. This estimate is based on the partial equilibrium IMPACT model.

Taking into Account Adaptation

As emphasized by several authors, the direct impacts of climate change on crop yields may not be good predictors of the economic impacts of climate change (Mendelsohn et al. 1994; Mendelsohn and Dinar 1999; Skoufias et al. 2011). First of all, if the estimated impacts have not taken into account farmers' response to changing conditions, they could overestimate the negative impacts, as farmers may adapt to climate change by switching crops and agricultural techniques, diversifying income sources, or migrating (Kurukulasuriya and Rosenthal 2003). To avoid what they called the "dumb farmer bias," Mendelsohn et al. (1994) therefore introduced a "Ricardian approach" – examining the importance of climate for land values – to take into account adaptation by farmers. The Ricardian approach uses cross-sectional data and bases the analysis on returns to land under different climatic conditions, thus capturing that farmers will adapt to climate change by switching to technologies and crops that yield the highest return to their land. This method estimates long-run impacts of climate change, incorporating all available adaptations. Mendelsohn (2008) summarizes recent studies of impacts of climate change for agriculture in developing countries, using the Ricardian approach. Based on cross-sectional farm-level data from eleven African countries, the marginal effect of increased temperature on net revenues is found to be a 6 % decrease, on average. However, the studies reported show large variations of impacts depending on whether it is the impact of mean climate changes or climate variability that is assessed, whether farms are irrigated, geographic locations, and in which season climate variability occurs. Average estimates can therefore hide large variations. For instance, the effect on net revenues on dryland farms is estimated to be −8 %, while it is estimated that irrigated farms can expect a 3 % increase in net revenue from

marginal warming. The impact of decreased precipitation also shows large variations, although both irrigated and rain-fed farming are expected to lose.

Early criticism of the Ricardian approach was raised by Cline (1996) and Darwin (1999), where Cline (1996) argues, among other things, that ignoring relative price changes due to climate change is likely to underestimate welfare losses, considering the price inelastic demand for food. In addition, Hanemann (2000) argues that the Ricardian approach will overestimate the adaptation choices available to the individual farmer. Burke and Lobell (2010) add that this critique is particularly relevant for poor farmers in developing countries, where access to suitable alternative crops for crop switching may be limited and the cost of switching may be high due to risk aversion or strong consumer preferences for a particular crop.

A number of studies investigate the determinants of adapting to climate change in developing countries using cross-sectional data. For instance, Deressa et al. (2009) and Bryan et al. (2009) find that important constraints to adaptation include lack of information, financial constraints, and lack of access to land for households in South Africa and Ethiopia.

Di Falco and Veronesi (2013) investigate the determinants of adaptation and the impact of different adaptation strategies on net crop revenues in Ethiopia. They use cross-sectional data on 941 farm households and spatially interpolated climate data. Survey respondents were asked about what, if any, adjustments they made in their farming practices in response to long-run shifts in temperature and precipitation. Of the farmers that adapted, more than 95 % reported changing crop varieties, soil conservation, and water conservation or water-harvesting strategies. To correct for selection bias when estimating the impact of adapting on farm net revenues, the authors use a multinomial endogenous switching regression, where the choice to adapt is estimated in a first step. As instrumental variables (see, for instance, Wooldridge 2010) for adaptation in the second step, past experience with climate extremes and access to information about farm techniques are used in the regression that estimates the impact of adaptation, along with climate variables, on farm net revenues. The second step corresponds to the Ricardian approach discussed above. From the first stage, the authors find that temperature, rainfall, soil conditions (where those with very fertile soils are less likely to adapt), household size, and past experience with climate extremes are significantly correlated with the decision to adapt using various strategies. The results from the second step are used to estimate counterfactual net revenues, which are used to calculate the treatment effect of various adaptation strategies for farm net revenues. They find no significant effect of adopting adaptation strategies in isolation, but a portfolio of adaptation strategies significantly increases net farm revenues. In line with the previous literature on this subject, they find that switching crops is one of the most rewarding strategies to adapt to climate change, but only when carried out in combination with soil or water conservation. Adopting all three strategies simultaneously does not increase net revenues more than only one of the conservation strategies in combination with crop switching.

An important weakness of the abovementioned studies is the reliance on cross-sectional data. Despite attempts to control for factors that may bias the results, the

decision to adopt is likely to be dependent on unobservable household characteristics that are also correlated with, for instance, farm revenues. Similarly, household unobservables may influence the variables that are correlated with the decision of whether or not to adopt adaptation strategies, as well as the adoption decision itself, thus biasing the estimated coefficient on the determinants of adoption. Using panel data makes it possible to control for time-invariant unobservables by exploiting the variation within households over time, and this approach is increasingly used in recent studies of impacts of climate change and climate variability. Recent studies exploit observed variation in temperature and precipitation to investigate impacts of climate change on economic outcomes, while controlling for time-invariant unobservables by using fixed effects panel data analysis, i.e., exploiting the variation *within* a spatial unit over time, rather than cross-sectional variation. An example from African agriculture is the study by Schlenker and Lobell (2010), who exploit panel data on crop yields for five staple crops in sub-Saharan Africa, coupled with weather data, while controlling for country fixed effects. They use their estimated impacts to predict the effects of various scenarios for future temperature and precipitation and find consistently negative impacts on yields. This holds for all crops except cassava, which the authors argue does not have a well-defined growing season, resulting in a poor model fit (Schlenker and Lobell 2010).

A review of papers using this approach is provided by Dell et al. (2013), who argue that the strength of the literature is to provide causal evidence on the impact of contemporary weather (rainfall, precipitation, and extreme events) on economic outcomes such as agriculture, health, and conflict. They also argue that there are challenges in extrapolating from the impacts of weather to impacts of long-run climate change, which may be larger (due to intensification) or smaller (due to adaptation).

To the author's best knowledge, there are very few studies explicitly looking at farm-level adaptation to climate change in developing countries using panel data. One exception is a working paper by Taraz (2013), who uses panel data on more than 8,000 Indian farm households from three crop seasons between 1970 and 1999, as well as district level agricultural panel data, both coupled with gridded monthly climate data from the University of Delaware. She exploits variation in monsoon regimes, periods of more common droughts or floods, typically lasting three to four decades, to investigate farmer's adaptation to a marginal change in climate. The results show that farmers adapt their crop portfolio as well as investment in irrigation following particularly dry or wet decades, controlling for wealth and time-invariant household characteristics. However, she also finds that this adaptation is only able to mitigate 15 % of the losses farmers are exposed to due to the adverse shift in climate.

In a developed country setting, Burke and Emerick (2013) use variation in longer-term temperature and precipitation in the USA to study whether farmers can adapt to gradual climate change. As argued by the authors, relying on short-run weather variability to say something about adapting to long-run climate change may overestimate adaptation (if short-run strategies are not "sustainable" in the longer run) or understate adaptation (if there is more flexibility in the longer run). They therefore model changes in agricultural outcomes over time as a function of changes

in temperature and precipitation while controlling for country-level time-invariant unobservables and state-level time-variant unobservables, by using fixed effects analysis as discussed above. Their findings indicate very limited adaptation taking place and little or no mitigation compared to impacts of short-run climate variability. Their results imply potentially large negative impacts of projected climate change by mid-century.

Household Heterogeneity and Market Characteristics

A second objection to relying on crop model simulations alone to assess impacts of climate change in rural developing countries is that the distribution of impacts across the population will depend on heterogeneity in terms of productive assets and whether the households are net producers or net consumers of food (Skoufias et al. 2011).

The second aspect is best captured in a model that incorporates price changes due to climate change. In an early study, Rosenzweig and Parry (1994) use results from crop simulation models in a global trade model and find that despite adaptation, cereal prices are expected to increase due to climate change. Their finding is confirmed by more recent studies, for instance, those reviewed by Schmidhuber and Tubiello (2007). Taking into account the likely change in relative prices due to climate change also responds to the critique of the Ricardian approach for being a partial equilibrium.

A computable general equilibrium (CGE) model takes into account autonomous adaptation to climate change, in the sense that changing market prices for goods and factors of production create incentives to reallocate resources (for instance, to increase food production if food prices increase) and substituting between different food crops in consumption. CGE models are, briefly stated, multisector equilibrium models where prices and production are determined simultaneously. As discussed by Arndt et al. (2012), this approach makes it possible to trace the causal links and mechanisms through which biophysical changes (e.g., decreased crop yields) impact the economy.

Several studies have explored impacts of climate change by using CGE models of developing countries. Using the crop yield impacts from the hydro-crop model described above, Thurlow et al. (2012) analyze impacts of climate variability and climate change on growth and poverty in Zambia. They use a dynamic CGE model which is also linked to a microsimulation component to calculate impacts on poverty. The model disaggregates agricultural production into five agroecological zones to take into account the differential impacts of climate variability and change on these subregions. Two sets of simulations are run; impacts of climate variability over a ten-year period are investigated by simulating 32 different rainfall patterns/sequences based on observations from 1976 to 2007. Impacts of climate change are investigated by simulating three different climate scenarios up to 2025, the SRES B1 scenario and two alternative scenarios with 2° warming by 2025 and 15 % decrease in rainfall in one scenario and 15 % increase in rainfall in the other. The

authors find that the impacts of climate variability dominate the impacts of climate change, but in combination, they both have serious impacts on growth and poverty. The mean climate variability impact is a 0.4 % reduction in GDP each year, reduced maize production by 30 kg/capita, and an average change in the poverty rate by 2.25 % over the ten-year period, with a larger increase in urban than rural poverty. The impacts of climate change are sensitive to the assumptions made concerning rainfall changes, but even under the most pessimistic climate change scenario, the impacts are less than half of those resulting from climate variability.

Another CGE study that focuses on climate variability is the study by Pauw et al. (2011), which looks at economy-wide impacts of droughts and floods on Malawi as well as adaptation through adoption of drought-resistant maize varieties. Production losses in agriculture estimated in a stochastic drought and flood model are simulated in a CGE model of Malawi, and the authors find that Malawi on average looses 1.7 % of GDP annually due to droughts and floods. The CGE model disaggregates farm households according to landholding size and region, as well as urban and rural nonfarm households. Farmland is disaggregated according to land size, and labor is disaggregated according to skill level. This allows detailed modeling of the economy with links between production, factor markets, and household incomes and thus a detailed analysis of impacts on household welfare. The changes in expenditures for each household group are combined with household survey data to calculate changes in the poverty rate. The largest increase in poverty is for rural nonfarm households, while the largest impact on earnings is for small-scale farmers. These farmers rely to a large extent on maize, which is vulnerable to droughts, and the increase in crop prices in response to the drought is not sufficient to compensate the production loss. If farmers adapt to climate variability by adopting drought-resistant maize, the overall poverty rate decreases and GDP increases; however, the authors do not discuss how these benefits are distributed across household categories.

Hertel et al. (2010) assess implications of three climate change impact scenarios (resulting in low, medium, and high productivity) for agriculture on a set of 15 developing countries. For instance, the low-, medium-, and high-productivity scenarios for coarse grains for Malawi imply −22, −10, and 2 % changes in yields by 2030. These impact estimates are based on recent studies and are direct yield impacts, i.e., without adaptation. The authors use the Global Trade Analysis Project (GTAP) model with a microsimulation component for poverty analysis to study impacts of the productivity change on world market prices and poverty of household groups in the different countries. The simulations show that average crop prices do not change much under the medium-impact scenario and that average poverty impacts are also small. For coarse grains, world market prices are still expected to increase as much as 15 % in the medium scenario and 62 % in the low-productivity scenario. The results also show that poverty impacts can be disaggregated into effects on costs of living and effects on earnings, where the earnings effect varies considerably depending on which activity households engage in. For some households, the positive earnings effect from increased crop prices may outweigh the effect of increased costs of living. Adding together these effects, the authors find that the median poverty impact

on self-employed agricultural households is positively correlated with the productivity shock, while the opposite is true for the self-employed nonagricultural households. Urban wage earners experience a poverty increase in all cases, but normally constitute a small share of the poor. For African countries, the large negative impact on yields does not permit poverty reduction for the self-employed agricultural households, even in the low-productivity, high-price scenario. The authors conclude that in order to assess impacts on livelihoods and poverty in developing countries, detailed information on earnings and poverty in household groups is needed, and it is necessary to look beyond the most likely impact scenarios.

The results imply that taking into account the likely increase in food prices due to climate change implies a positive "earnings effect" on farm households that sell some of their produce, and accounting for this effect may reverse the negative impact of climate change for some households. Using a static CGE model of Malawi, Skjeflo (2013) shows that negative productivity shocks to maize cause increased domestic maize prices, which are beneficial for large landholders. On the other hand, urban poor and small-scale farmers are hurt by higher food prices because they are net buyers of food and spend a large share of their income on food. This is shown in Fig. 2, where the welfare impact of the negative productivity shock to maize for eight household groups is measured by the equivalent variation as percent of baseline expenditures. The figure shows that small-scale farm households, who constitute the majority of the rural households in Malawi, experience a small welfare decrease

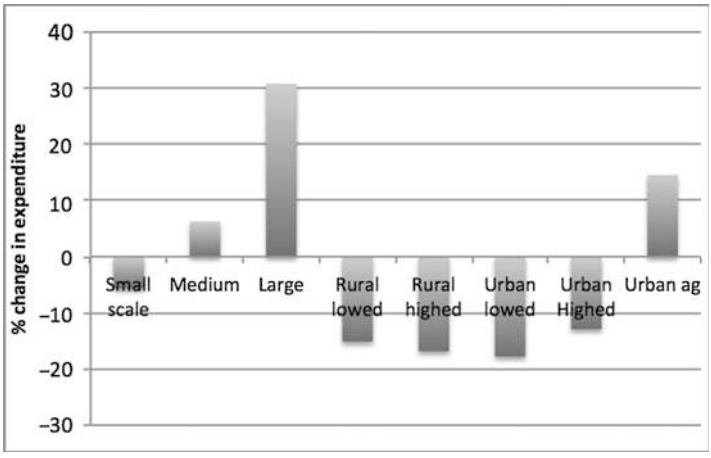

Fig. 2 Welfare impacts of negative productivity shocks to maize due to climate change by 2030 in Malawi. Welfare change measured by the equivalent variation, as percent of baseline household expenditures. Household groups: small scale = small-scale farm households, medium = medium-scale farm households, large = large-scale farm households, rural lowed = rural nonfarm households with low education, rural highed = rural nonfarm households with high education, urban lowed and highed defined similarly, urban ag = urban farm households (Source: page 1698 in Skjeflo (2013))

despite higher maize prices. Farm households with larger landholdings benefit from the productivity shock because of increased crop prices. Urban households, and especially urban households with little or no education, are particularly vulnerable because of the large share of their income that is spent on food.

The CGE studies discussed above are based on aggregate models that assume perfect factor and product markets, while econometric studies have shown numerous constraints to adaptation at the household level, many of them related to market imperfections. As previously mentioned, studies from South Africa and Ethiopia find that access to credit is a main constraint to adapting to climate change among farm households, as well as access to land (in Ethiopia) and information about adaptation options and climate projections (Deressa et al. 2009; Bryan et al. 2009; Di Falco et al. 2012).

The fundamental dependence of agriculture on weather and natural resources creates a strong link between the environment and the rural economy in developing countries. In a seminal paper, Binswanger and Rosenzweig (1986) show how the immobility of land causes spatial dispersion, high transport costs, and synchronic timing of production activities in agriculture, while heterogeneity in input factors contributes to asymmetric information. Weather variability is linked to yield risk, market price risk, and uncertain optimal timing of production activities. Binswanger and Rosenzweig (1986) show how a combination of these factors may explain credit market imperfections, labor and land market imperfections, as well as output market imperfections. The dual role of farm households as producers and consumers of food is therefore also likely to be important when assessing household vulnerability to climate change. This is in line with the basic farm household model by Singh et al. (1986). They also showed that when markets for goods that the farm household both consumes and supplies (such as food or labor) fail, production decisions are no longer independent from consumption decisions. A number of studies have shown the implications of non-separability for farm household behavior, for instance, in terms of low supply response to price incentives (de Janvry et al. 1991) and nonlinear supply (Löfgren and Robinson 1999).

Morton (2007) discusses potential impacts of climate change on smallholder agriculture and mentions lack of market access for smallholders as a non-climatic stressor that increases smallholders' vulnerability to climate change. As previously discussed, market imperfections may also act as constraints to adaptation for farm households, and they are also likely to affect how households respond to planned adaptation policies. Market characteristics will also shape the response of households to increased climate risk due to climate change. To the extent that climate shocks are common shocks that simultaneously affect households in an area, the scope for informal risk-sharing strategies is limited (Dercon 2002). Formal credit and insurance markets are often missing or imperfect in developing countries (Besley 1995), and the effect of increased climate variability on households will depend on their ability to smooth income and consumption through risk management strategies. These strategies may in themselves have important impacts on poverty, by locking poor households in low-risk, low-return agriculture (Dercon 2002). Weather risk may thus contribute to increased inequality.

Future Directions

The studies summarized above show that climate change is expected to harm less developed countries disproportionally. However, as has been extensively discussed in the literature, it is not sufficient to rely on the direct impacts of changing temperatures and precipitation, or more severe and frequent climate extremes, without taking into account households' responses to these changes. An early suggestion to incorporate this important aspect into studies of climate change impacts is the Ricardian approach. This approach has been criticized for failing to take into account the likely impact of climate change on food prices and for overestimating the range of adaptation options available to the individual farmer. Another problem is the reliance on cross-sectional data, causing concerns for omitted variable bias. This is also a concern for the existing studies of farm-level adaptation to observed variation in temperature, precipitation, and climate extremes in less developed countries. As a way of bypassing this problem as well as dealing with the importance of changing prices, a number of studies use CGE models to investigate the impacts of climate change for household groups in developing countries. A valid criticism against this approach is the assumption of well-functioning markets in poor, rural economies. The recent empirical literature that exploits variation in observed weather across time within spatial units seems like a promising approach to improved understanding of climate change impacts. These studies are rare for developing countries, perhaps because of data quality and availability issues, for instance, if one wishes to investigate actual adaptation to gradual changes in climate and not weather variation. However, as more and better data becomes available, this seems like a promising approach. Existing and new approaches should be used to complement each other in order to gain new and robust insights to the potential impacts of climate change for households.

Fracking

Qingmin Meng

Contents

Abstract

Natural gas has gained a dominant role in current world clean energy development due to the significant advances in horizontal drilling and hydraulic fracturing. Hydraulic fracturing, also known as fracking that is now increasing exponentially across the world, is the process of extracting natural gas from shale rock layers or other tight rock formations within the earth. Specifically, horizontal drilling combined with traditional vertical drilling allows injection of highly pressurized fracking fluids into the shale layers to create new channels within the rock, from which natural gas is released at much higher rates than traditional drilling. For example, the USA holds the largest known shale gas reserves in the world. Fracking in the USA has boosted economy and local community growth. However, studies have found that hydraulic fracking threatens water resources, harms air quality, changes landscapes, and damages ecosystems. Furthermore, methane emissions from drilling, fracking processes, and the related natural gas storage and transportation have become a critical issue, which raises the question whether hydraulic fracking can mitigate world climate

change. Some studies have obtained significantly different conclusions of climate mitigation impacts of fracking. More studies and further measuring and observational surveys are needed in order to have a comprehensive understanding of hydraulic fracturing's impacts on climate mitigation.

Introduction

In the media, hydraulic fracturing (fracking) often refers to the two steps applied for extracting natural gas trapped in shale formations. The first step is to drill down to the sedimentary rocks and then drill sideways for a mile or more. This horizontal drilling has been widely practiced since the 1980s to extract conventional oil and gas. In the second step, the producers must deploy hydraulic fracturing; using high pressure, fracking pumps into open fractures in the rocks with millions of gallons of water, sand, and chemicals that allow oil and gas to flow. Fracking was introduced into gas mining as early as in 1940s and then was efficiently combined with horizontal drilling in 1990s.

Fracking has resulted in significant economic hopes and opportunities such as employment, income, and tax revenue growth in shale play regions but with increasing public awareness and concerns about the environmental impacts of hydraulic fracturing. Many studies have talked about the processes of hydraulic fracturing and its environmental impacts including surface and groundwater resources (e.g., Osborn et al. 2011), air pollution (e.g., Howarth et al. 2011a), seismic activities (e.g., seismosoc.org 2015), environmental and the population at risks of fracking (Meng 2015a), and landscape and ecosystem disturbance (Meng 2014). In this chapter, the author summarizes a comprehensive understanding of the conception and technological process of fracking, its development, and its worldwide extent and then focuses on methane emissions and a concise summary of current understanding of its climate impacts.

Hydraulic Fracturing (Fracking)

Instead as a "drilling process" as a lot of media state, hydraulic fracturing in fact is a specific process used after the drilled hole is completed. Hydraulic fracturing or "fracking" is the propagating of fractures in a rock layer caused by a highly pressurized compound fluid creating small cracks, or fractures, in underground geological formations to free unconventional resources of natural gas, oil, and other hydrocarbons captured inside tight sandstones, shales, and other low-permeability geological formations. These geological formations, known to contain hydrocarbons, have served as sources for conventional oil or gas. However, the gas and oil in them were generally be deemed as unrecoverable due to their low porosity and permeability. The advancements of technology in hydraulic fracturing and horizontal drilling have resulted in significant progresses recently (Kuuskraa

et al. 2011), and drilling now can be done kilometers underground and to horizontal distances of 3 km and even more exploring shale, sandstone, and other formations as thick as only 30 m.

A well is hydraulically fractured after horizontal drilling is completed and then the drilling rig is moved off site. Water tanks and water-hauling trucks come to the well site. The fracking operation is to start when the sand haulers, pump truck, blender, and control van arrive. After all pieces of equipment are joined together, they will be connected to the wellhead with high-pressure hoses. Then, the equipment is tested before the actual fracture stimulation will start. This fracking operation may need several hours to even several days, which depends on the geological characteristics and the number of fracture zones. There is then typically a very high-level noise and truck traffic becomes the most noticeable signal in the operation process. Generally, 8000–80,000 m^3 (2–20 million gallons) of water and proppants including sand and chemicals are pumped underground into the horizontal or directional wells at high pressures (69,000–138,000 kPa), which are sufficient to fracture impermeable rock formations. Rock fractures induced by high-pressure, high-volume hydraulic fracturing allow natural gas and oil to flow from the formation to the well and up through the well to the ground surface. In this process, chemical- and sand-laden watery fluid will be pumped down into the well and the watery gas or oil will eventually be collected. Therefore, in order to prevent the fluid from entering the water supply, steel surface or intermediate casing needs to be inserted into the well. Additionally, cement needs to be filled into the annulus and the space between the casing strings and the drilled hole. Once the cement has set, the drilling continues from the bottom of the surface or intermediate cemented steel casing to the next depth. Using smaller steel casing each time, this process is repeated until the gas and oil-bearing reservoir is reached often between 1900 and 4000 m in depth.

Fracturing fluids, typically including water, sand, and proprietary chemical mixes, are injected down the well bore into the impermeable rock formations. The fluids that create the initial fractures are then mixed with thicker fluids that include sand and gelatin. When the fluids flow back up, sand remains in the fractures and props the rock open, which maintains open pathways to the well. This allows the gas or oil to seep from the rock into pathways, up and through the well and till the ground surface for collection. According to volume of fracturing fluids used, one can classify fracking into low-volume and high-volume hydraulic fracturing. Up to 20 million liters of water for an individual well can be needed for high-volume hydraulic fracturing applied to the completion of tight gas and shale gas fracking. Low-volume fracking used to stimulate high-permeability reservoirs typically needs 75,000–300,000 l of fluid per well. One also needs to understand that 15–80 % of the fluid returns to the ground surface and is often called wastewater, when the fracking procedure is completed. The wastewater often contaminates fracturing chemicals and subsurface constituents, which include toxic organic compounds, heavy metals, and naturally occurring radioactive materials. Remaining untreated or not adequately secured, this wastewater can result in harmful environmental and health effects.

A larger fracking field is needed to take into account the space for equipment and material storage for fracture stimulation. A typical fracking site is about 4–5 acres,

which is used to hold the numerous truck-mounted pumps, temporary storage tanks, and fracture-treat large tractor trailer trucks, and the original landscape is totally changed (Meng 2014). Once a vertical hole is drilled, a downhole drilling motor is inserted into the hole to begin horizontal drilling. For instance, it takes over 350 pieces of pipe for a 3000 m horizontal well. Production casing is inserted into the full length of the wellbore when the target distance is completed. Casing wells is a critical process because it permanently secures the wellbore and it prevents hydrocarbons form seeping out, and at this point, a temporary wellhead is installed. A perforating gun is lowered by wire line into the casing and an electrical current is sent down and sets off a charge that shoots small holes through the casing and cement. Then, the well will be fracked and a permanent wellhead is installed once fracking is completed with a built pipeline to transport the gas to the pipeline network.

Biocides are widely used in fracking since bacterial colonies can clog or obstruct fracking wells and make it hard to extract gas after fracturing. However, people do not have a complete list of the biocides currently used in fracking. While biocides are a small portion of fracking fluid, we need to understand that up to $>$ 500 mg/L and, given total fluid volumes surpassing 10 million L per horizontal well, a total amount of biocides per fracking event can exceed 1000 gal (McCrudy 2011; Nicot and Scanlon 2012; Aminto and Olson 2012). Many of the biocides are degradable through abiotic and biotic especially aerobic processes, but some can potentially transform into severe or persistent compounds, while the understanding of biocides' degradation and sorption in high pressure and salt and organic matter concentrations is very limited (Kahrilas et al. 2015). Some of the fluids stay underground, and some return to the surface as wastewater and are collected for disposal, which are often injected into deep ground that are called wastewater wells.

Gas yield per well can be much different across shale plays, but currently there is limited available statistics about production of fracking wells. In Marcellus Shale region, USA, an average yield of a gas well is between 5700 to 290,000 m^3 per day. In the first and second year, the yield can be 57,000–114,000 m^3 per day; in the third and fourth year, the yield can be 28,000–56,000 m^3 per day (Marcellususa.com).

Fracking Across the World

Many countries, including but not limited to Algeria, Argentina, Australia, Brazil, Canada, China, France, Libya, Mexico, Poland, Russia, South Africa, the USA, and Venezuela, are estimated to possess at least $\sim 3 \times 10^{12}$ m^3 [$\sim$100 trillion ft^3 (Tcf), or 1×10^{14} ft^3] of recoverable shale gas (Kuuskraa et al. 2011; Schulz et al. 2010). In Fig. 1, the US Energy Information Administration (EIA) has summarized and compared the technically recoverable shale gas and oil resources of the whole world between the USA and the regions outside the USA. Global estimates for recoverable shale gas are $\sim 206 \times 10^{12}$ m^3, which is for at least 60 years of current global usage in 2013, and global estimated shale oil resources are now 345 billion barrels (Bbbl; one barrel = 42 US gallons) (US Energy Information Administration

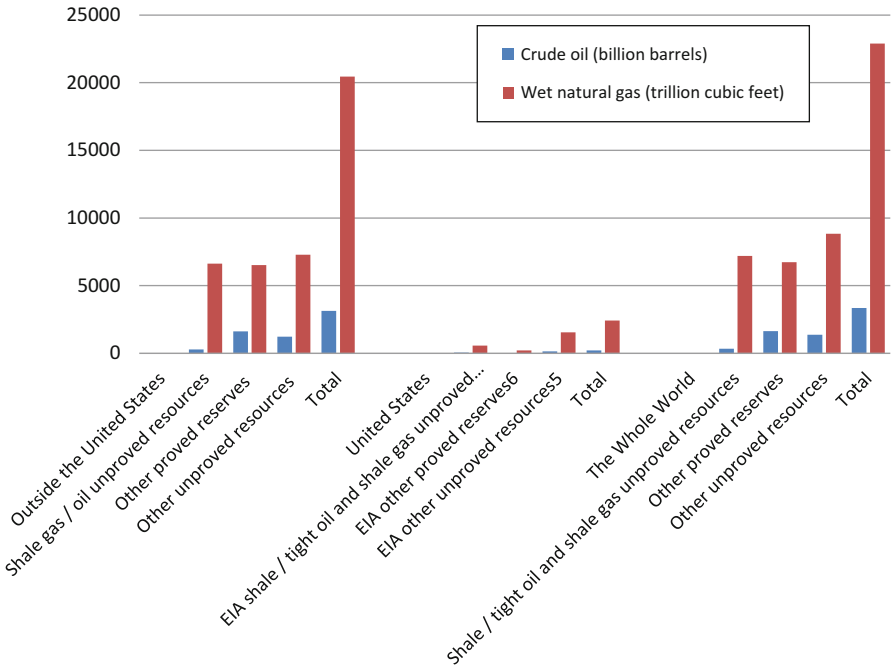

Fig. 1 Technologically recoverable shale gas and shale oil resources across the world. They are plotted using the data estimated by the US Energy Information Administration (2013)

2013). In the USA, average estimates of the technically recoverable shale gas resource doubled to 600–1000 Tcf (17–28 $\times$ 10^{12} m^3) in 2013, and the technically recoverable shale oil resource rose by 40 % to 58 Bbbl (US Energy Information Administration 2013). However, these are only substantial resource estimates, which are a type of guesses because large-scale production of shale and other unconventional gas and oil resources is currently in its introduction phase (Meng 2015b).

Fracking has been applied in the whole world for about 60 years, but in the various countries, the fracking processes can be different. In the USA, one early type of fracking called slickwater fracking was used to extract natural gas in the Barnett Shale in Texas in 1998. This fracking technique was made possible by integrating microseismic three-dimensional imaging supported by federal agencies such as the Department of Energy and recent advances in directional drilling (Shellenberger and Nordhaus 2011). Drilling into shale now accounts for about 30 % of the US gas production (Dopp 2012). Today, fracking often means the combination of advanced high-pressure, high-volume hydraulic fracturing and horizontal drilling, which in fact employs cutting-edge technologies and now is mostly responsible for surging natural gas or petroleum production. In the USA, fracking has been involved in safe applications to shale, but other tight rock formations have also been explored by drilling about 2 km or more below the surface before gradually turning horizontal (Fig. 2). Compared to shale gas, tight gas is produced from reservoir rocks with

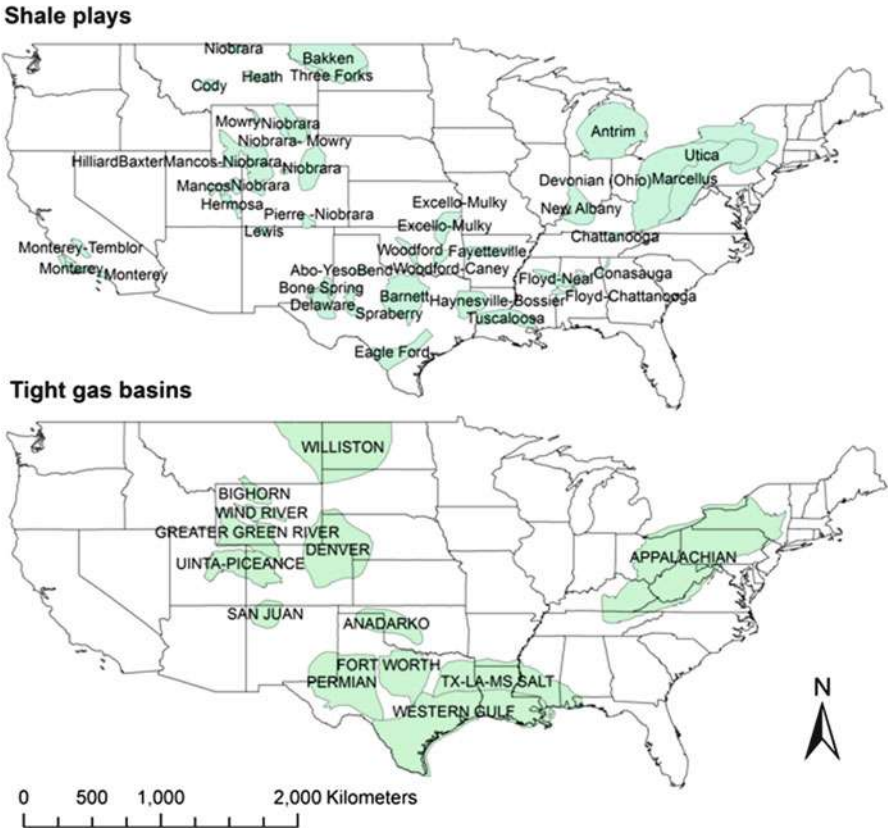

Fig. 2 Shale plays and tight gas basins in the USA

much lower permeability so that massive hydraulic fracturing is needed to create fractures in the reservoirs less than 0.1 millidarcy matrix permeability and less than 10 % matrix porosities (Law and Spencer 1993; Sharif 2007). When a well is drilled, cased, and cemented, small perforations are made in the horizontal portion of the well pipe, and in reality, a single surface site/fracking pad often accommodates a number of wells. A typical mixture of water (90 %), sand (9.5 %), and chemical additives (0.5 %) is pumped at high pressure through the well into tight rock formations in order to create microfractures, which are held open by the grains of sand. Chemical additives play a number of roles, such as to reduce friction and prevent pipe corrosion.

From at least the mid-1960s, fracking has been widely used by the petroleum industry in Canada (Milne and Howie 1966). Massive fracking has been used across Alberta from the late 1970s to regain natural gas from the Spirit River Formation, which is a typical low-permeability sandstone formation (Cant and Ethier 1984). Fracking currently is applied to the development of the fields Cardium, Duvernay,

Montney, and Viking in Alberta, Bakken in Saskatchewan, Montney, and Horn River in British Columbia.

Germany began to apply fracking to gas wells in tight sandstone in 1975, and it quickly became a common technology in the period 1978–1985, when more wells used fracking than in any other European country. Most fracking used water- or oil-based gels in Germany (Mader 1989), and the Rotliegend Sandstone is the most popular target formation for fracking, which has been the source of most of German natural gas production (Koehler 2005).

In the UK, fracking has been used commonly in North Sea gas and oil fields from the late 1970s (Mader 1989) and has been used in about 200 British onshore gas and oil wells since the early 1980s. However, fracking did not attract public attention until it was proposed for onshore shale gas wells in 2007 (British Geological Survey 2012).

Fracking also has been recently used in developing countries. The South African government strongly campaigns for fracking in order to extract enough natural gas across the country, which is treated as a "bridge-fuel" between coal and alternative fuels in this country. However, people recognized that the significant amount of loss of methane to the environment in the process of fracking through leakage from fracking sites is considerable. A temporary moratorium on hydraulic fracturing for shale gas in South Africa's Karoo region was imposed in 2011 due to the public pressure, examining concerns about environmental degradation and particularly groundwater safety (Hweshe 2012). China completed its first horizontal shale gas well in 2011. A global shale gas study has indicated that China's technically recoverable shale gas reserves could be almost 50 % higher than those of the USA (Watts 2011).

Methane Emission from Fracking Process

According to estimations by the US Environmental Protection Agency (EPA), methane (CH_4) is the second most prevalent greenhouse gas (GHG). CH_4 is mainly emitted in the USA from human activities. CH_4 accounted for about 9 % (equivalent to CO_2) of all US greenhouse gas emissions from human activities (EPA 2010). Methane is emitted from sources such as wetlands and human activities such as leakages from natural gas systems and the raising of livestock. Although methane's lifetime in the atmosphere is much shorter than that of carbon dioxide (CO_2), CH_4 is more efficient at trapping radiation than CO_2. The impact on climate change for CH_4 is over 20 times greater than CO_2 over a 100-year period. Globally, over 60 % of total CH_4 emissions come from human activities (EPA 2010).

Methane is emitted from industry, agriculture, and waste management activities. According to EPA's overall green gas emissions' estimation, the largest source of CH_4 emission is natural gas and petroleum systems in the USA (Fig. 3). Methane is the primary component of natural gas. Most often CH_4 is emitted to the atmosphere in the processes of production, processing, storage, transmission, and distribution of

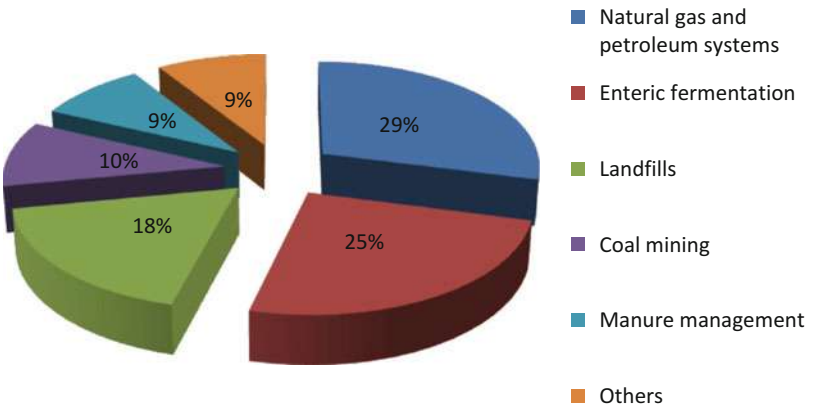

Fig. 3 Methane emission sources in the USA

natural gas. Methane emission from hydraulic fracking is more complex than that from conventional gas mining.

During fracking well completion, natural gas starts flowing up the well, accompanied by some of the water and chemicals used to crack the rock. In fracking processes, completion practices and regulations differ from region to region and by companies. The flowback water, also called wastewater, is most often pumped into an open wastewater pit dug on site, where methane and volatile organic compounds (VOCs) directly flow into the air. Flowback mixtures sometimes are also contained in tanks, either open or closed and thus with vapors vented or flared too. When a fracking well has been completed, production operations become similar to conventional natural gas extraction.

There are also potential methane emissions during production and fracking processes. Potential emissions include incomplete combustion during flaring, fugitive emissions of natural gas from equipment leaks, and intentional venting from oil and wastewater storage tanks or ponds. Natural gas produced with fracking liquids and oil will be richer in VOCs than a well producing mostly natural gas. Natural gas-powered compressor engines, flaring units, and centralized processing and compression facilities at fracking pad sites also contribute CO_2, CO, NOx, and VOCs such as formaldehyde, PM (soot), and polycyclic aromatic hydrocarbons. Fugitive emissions encompass the GHG methane and varying amounts of VOCs including aromatics such as the carcinogen benzene and the hazardous air pollutant toluene.

Actual gas emissions are different from region to region. This depends on natural gas and oil composition, separation requirements, and different state regulations (Moore and Bar-Ilan 2013). Some estimates of the fraction of natural gas production vented or flared on federal lands in the Western USA ranged from 0.34 % to 5 % of the total production volume (US Government Accountability Office 2010). However, 29 % to 36 % of the natural gas extracted from the Bakken Shale in North Dakota was vented or flared between May 2011 and December 2012, which is mainly due to a

lack of infrastructure such as access to pipelines and other processing infrastructure (US Energy Information Administration 2014). As the official Colorado inventory for the Denver basin indicated, more than 70 % of total VOC emissions from all sources in the region resulted from 6000 more oil and condensate storage tanks, even with stringent controls in place (Wells 2012). However, the state estimate of total VOC emissions from gas and oil operations was only half the estimate obtained from actual field measurements in the Denver Basin (Pétron et al. 2014).

Regional and national estimations of total methane emissions associated with hydraulic fracking remain uncertain and are an important topic of considerable research (Howarth et al. 2011b). Official EPA estimates of annual methane emissions from natural gas production operations have varied greatly in the last decade, which ranged between about 0.2 % (US Environmental Protection Agency 2010) and 1.5 % (US Environmental Protection Agency 2011, 2012) of the national gross natural gas production. Similarly, a study indicated that national emissions from natural gas production operations in 2011 were 0.42 % of gross production (Allen et al. 2013), which is very close to the estimate of 0.49 % according to the 2013 EPA inventory and EIA (Energy Information Administration, USA) production statistics.

Research is also needed to examine methane leakage during natural gas transmission and distribution. In the USA, there are about 2.2 million miles of natural gas distribution mains and hundreds of thousands of miles of higher-pressure transmission pipelines. According to the US EPA inventories, losses during transmission and distribution are about 0.7 % of total production, which is the largest loss of any step in the natural gas supply chain (US Environmental Protection Agency 2013). Other estimates of the amount of gas lost in the process of natural gas transport are 1.4 % for Russia (Lelieveld et al. 2005) and 5.3 % for the UK (Mitchell et al. 1990). Although new methane mapping technologies have allowed to check and map pipeline leakage of natural gas across cities (Jackson et al. 2014; Phillips et al. 2013), it is still a grand challenge to regionally and nationally assess natural gas leakage during transport.

Unlike these bottom-up emission measurements and inventory estimates, substantially larger regional-scale leakage rates have been found by recent atmospheric studies using airborne and tall-tower measurements in the western USA. Karion et al. (2013) estimated that 55,000 $\pm$ 15,000 kg CH_4 per hour leaked into the atmosphere in the Uintah Basin, which amounts to a rate of 6.2–11.7 % of total natural gas production in the region. Pétron et al. (2014) measured 4 % leakage in the oil- and gas-producing Denver Basin, Colorado. In these two basins, aggregated methane emissions seem significantly larger than the US EPA 2013 estimated 1.4 % total leak rate. A recent synthesis suggests that total methane emissions from anthropogenic activities in the USA, including oil and gas production, were 50 % higher than EPA estimates (Brandt et al. 2014; US Environmental Protection Agency 2013). The emissions from gas and oil can be underestimated by as much as a factor of five in the South Central USA according to a recent study (Miller et al. 2013). It is apparent that more research work is needed, and a common understanding that methane losses are larger than current EPA estimates is acceptable.

Climate Mitigation?

Unfortunately, whether methane emissions are large enough to offset the advantage in methane's combustion efficiency compared to coal in electricity generation is still unclear (3.2 % lost gas in total) (Alvarez et al. 2012). If it is so, people believe that better information on the sources of leaks and advanced gas transport technology can significantly reduce future leakage and fugitive greenhouse gas emissions, and therefore improve local and regional air quality in the future. How much hydraulic fracturing and unconventional resource extraction reduce total GHG emissions in the future is unknown. Current lower energy prices from increased supply would probably increase energy consumption and encourage users to natural gas from other energy sources including coal, nuclear, and renewables.

Using the data of the National Energy Modeling System projections from the US Energy Information Administration (EIA), Newell and Raimi (2014) showed that in the USA, gas and oil price would fall significantly under a "high natural gas and oil resource" scenario compared with a reference scenario. While total energy use would be about 3 % higher as a result, total GHG emissions could remain about 0.5 % lower than in the reference scenario, which could be mainly because of the natural gas displacement of coal for electricity generation. Likewise, other researchers concluded that increased natural gas supply such as hydraulic fracturing might decrease GHG emissions slightly in the USA and globally, but it seems impossible to change global GHG concentrations substantially (Newell and Raimi 2014; Energy Modeling Forum 2013; Edmonds and McJeon 2013).

On the other hand, an increase of the total GHG emissions is still possible, which partially depends on the extent to which cheaper natural gas and oil reduce the market penetration of other green energy sources, such as renewables and nuclear power. Large emissions with an average of 34 g CH_4/s (2.937 t/day) per well from seven hydraulic fracking pads were checked and quantified in the drilling phase (Caulton et al. 2014). Howarth et al. (2011a) also concluded that 3.6–7.9 % of lifetime shale gas production migrates to the atmosphere through venting or leaking over the lifetime of a well and that 1.9 % of the total gas production is emitted as methane through well completion.

Furthermore, Schneising et al. (2014) used the SCIAMACHY (Scanning Imaging Absorption spectroMeter for Atmospheric CHartographY) satellite remote sensing to quantify methane emissions from the Bakken and Eagle Ford formations that are the fastest growing oil production regions in the USA. They found that methane emissions in the Bakken and Eagle Ford formations have increased by 990 $\pm$ 650 kt CH_4 $years^{-1}$ and 530 $\pm$ 330 kt CH_4 $years^{-1}$ between the periods 2006–2008 and 2009–2011. These emission estimates correspond to leakages of 10.1 % $\pm$ 7.3 % and 9.1 % $\pm$ 6.2 % in terms of energy content, which directly puts fracking's immediate climate benefit in question and therefore indicates that current inventories very likely underestimate the fugitive emissions from Bakken and Eagle Ford. This remote sensing-based top-down estimate is calculated using long-term satellite data, which complements previous measurement-based results of other regions. For example, these estimates are similar to the earlier results of an average of 4.0 %

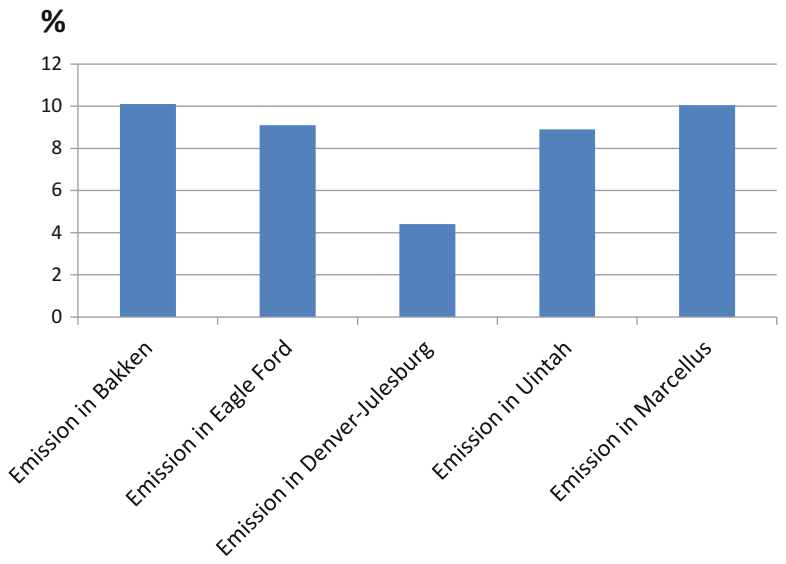

Fig. 4 High methane emission rates (%) in different hydraulic fracturing regions in the USA

(2.3–7.7 %) for the Denver-Julesburg (Pétron et al. 2012), 8.9 % (6.2–11.7 %) for the Uintah Basin (Karion et al. 2013), and a possible range of 2.8–17.3 % for the Marcellus shale formation (Caulton et al. 2014), which are described in Fig. 4. We also need to understand that it is possible to reduce methane emissions by adopting green completion technology, which could considerably lower leak rates to the EPA inventory estimates at selected fracking sites in the Appalachian, Gulf Coast, Midcontinent, and Rocky Mountain regions in the USA (Allen et al. 2013).

Future Directions

Currently, public concerns and scientific research mainly focus on risks to surface water and groundwater resources, the air impacts, and the induced seismicity. Minimal research has been carried out exploring fracking's impacts on ecosystem and landscape disturbance and local and global climate changes. The author believes that some challenging research questions and topics in climate mitigation can include:

1. To establish reliable and standard ways to accurately measure fracking-caused methane emissions. Independent state and federal efforts are needed to evaluate and improve current emission inventories in order to increase accuracy.
2. To develop long-term emission inventory and monitoring systems. Short period intensive studies are also needed to supply independent measurements and to support long-term monitoring adjustments.

3. To locally, regionally, and globally estimate methane emissions and to estimate and model the local, regional, and global climate impacts of fracking. To understand and model the relationship between methane emissions and climate changes is another challenging topic in fracking and climate mitigation.
4. To create national and worldwide spatial and temporal databases for fracking and its methane emissions and make them publically available.

temperatures and increased ambient CO_2 concentrations during the last century. The man-made CO_2 emissions are primarily from burning of fossil fuels for energy production and transportation. To limit the emissions, CO_2 sequestration has been applied to inject CO_2 into various deep surface formations after capturing CO_2 from the flue gases. The topic of transport through porous media in this chapter is to summarize investigations of migration of CO_2 after sequestration, gas transport through coal particles during oxy-combustion, and oxygen transport in membranes during air separation. A general mechanism has been provided first in the introduction to briefly explain transport through porous media. The following sections, respectively, include a general review of recent literatures on the subjects of CO_2 migration after sequestration, CO_2-oxygen transport in oxy-combustion, and oxygen transport in membrane at high temperatures. Understanding the fundamental mechanisms and processes of the transport through porous media allows mathematical models to be used to evaluate and optimize the performance and design of these systems.

Introduction

Gas transport in porous media occurs in a number of important applications including environmental remediation of contaminated sites (Xiang et al. 2013), drying of industrial and food products (Sam Saguy et al. 2005), coal-based oxy-combustion (Edge et al. 2011), and carbon sequestration (Ho and Webb 2006). Understanding the fundamental mechanisms and processes of the transport through porous media allows mathematical models to be used to evaluate and optimize the performance and design of these systems.

Readers can understand the topic from three aspects: the processes and models, measurements and monitoring, and some applications. The focus of this chapter is on climate change-related gas transport in porous media, and a few important examples include CO_2 migration after sequestration, CO_2-oxygen transport in oxy-combustion, and oxygen transport in membranes at high temperatures.

Processes and models present fundamentals associated with gas transport in porous media like mass, momentum, and heat transport mechanisms. Interactions between gas and the media surface or between species in the continuum phase may occur and affect the transport of the gas. Figure 1 illustrates the porous medium containing a two-phase system: γ-phase, the liquid or gas phase, and the κ-phase, the impermeable solid phase (Ho and Webb 2006). Two types of averages in terms of the average volume, V (illustrated in Fig. 1), should be defined in order to develop the local volume-averaged equations.

The first of these is the *superficial average* of some function ψ_γ which is defined according to

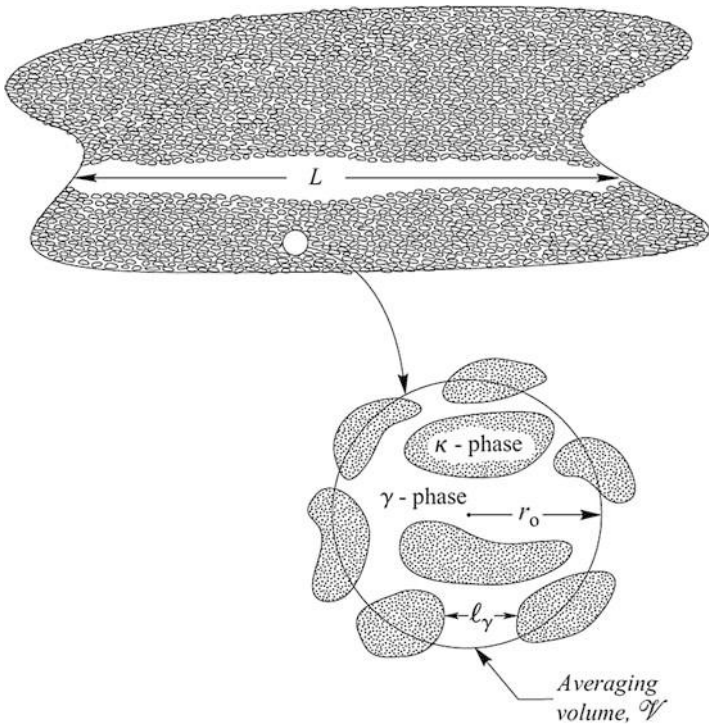

Fig. 1 The porous medium containing a two-phase system: γ-phase, the liquid or gas phase, and the κ-phase, the solid phase (Reproduced by permission)

$$\langle \psi_\gamma \rangle = \frac{1}{\mathscr{V}} \int_{V_\gamma} \psi_\gamma \mathrm{d}V \tag{1}$$

while the second is the *intrinsic average* which is defined by

$$\langle \psi_\gamma \rangle^\gamma = \frac{1}{V_\gamma} \int_{V_\gamma} \psi_\gamma \, \mathrm{d}V \tag{2}$$

These two averages are related according to

$$\langle \psi_\gamma \rangle = \varepsilon_\gamma \langle \psi_\gamma \rangle^\gamma \tag{3}$$

in which ε_γ is the volume fraction of the γ-phase defined explicitly as

$$\varepsilon_\gamma = \frac{V_\gamma}{\mathscr{V}} \tag{4}$$

The application of the two types of averages was demonstrated in section "General Transport Mechanism" to develop the local volume-averaged equations.

Various methods have been used to measure gas transport processes and parameters at the laboratory and field scales. Measurements of the diffusion coefficient, permeability, flow rate, constituent concentration, and mass flux of gas were described in this chapter with the three applications of CO_2 migration after sequestration, CO_2-oxygen transport in oxy-combustion, and oxygen transport in membrane at high temperatures.

Literature review has been given separately for the three applications as well as a summary of transport fundamental studies in the porous media. This chapter provides a general review of the different processes, models, and experimental methods associated with the three applications of gas transport in the porous media. The author hopes that readers can develop an understanding of the topics and an appreciation for the three applications covered in this chapter.

General Transport Mechanism

Momentum Transfer

The momentum transfer in the porous media also includes the continuity equation and the linear momentum equation. The former has been given by Ho and Webb (2006) as

$$\frac{\partial \rho_\gamma}{\partial t} + \nabla \cdot \left(\rho_\gamma \mathbf{v}_\gamma\right) = 0 \tag{5}$$

When the density can be treated as a constant, this reduces to

$$\nabla \cdot \mathbf{v}_\gamma = 0, \tag{6}$$

and the local volume-averaged form is given by

$$\nabla \cdot \left\langle \mathbf{v}_\gamma \right\rangle = 0 \tag{7}$$

This form of the continuity equation is an attractive approximation for the case of dilute solution mass transfer. For non-dilute solutions, the approximation given by Eq. 7 may not be acceptable.

Ho and Webb (2006) also demonstrated the development of the linear momentum equation in the form of the superficial velocity, and the final form was given by

$$\left\langle \mathbf{v}_\gamma \right\rangle = -\frac{\mathbf{K}}{\mu_\gamma}\left[\nabla\left\langle p_\gamma \right\rangle^\gamma - \rho_\gamma \mathbf{g} - \underbrace{\left(\mu_\gamma/\varepsilon_\gamma\right)\nabla^2\left\langle \mathbf{v}_\gamma \right\rangle}_{\text{Brinkman correction}}\right] - \underbrace{\mathbf{F}\cdot\left\langle \mathbf{v}_\gamma \right\rangle}_{\text{Forchheimer correction}} \tag{8}$$

in which **K** and **F** have been deliberately chosen to produce a momentum equation containing the *superficial average* velocity rather than the *intrinsic average* velocity and $\mu_\gamma/\varepsilon_\gamma$ is sometimes referred to as the *Brinkman viscosity*. When values of the Brinkman viscosity are different from $\mu_\gamma/\varepsilon_\gamma$, it means that this term is being used as an empirical correlating factor.

The deduction of Eq. 8 began with the governing equation for $\boldsymbol{v}_\gamma$ given by

$$\frac{\partial}{\partial t}\left(\rho_\gamma \mathbf{v}_\gamma\right) + \nabla \cdot \left(\rho_\gamma \mathbf{v}_\gamma \mathbf{v}_\gamma\right) = \rho_\gamma \mathbf{g} - \nabla p_\gamma + \mu \nabla^2 \mathbf{v}_\gamma \tag{9}$$

in which variations in the density and viscosity in the viscous term have been ignored.

Mass Transfer

Ho and Webb (2006) have developed a convenient form of the general mass transfer equation in the porous media:

$$\underbrace{\varepsilon_\gamma \frac{\partial \langle c_{A\gamma}\rangle^\gamma}{\partial t}}_{\text{accumulation}} + \underbrace{\nabla \cdot \langle c_{A\gamma}\, \mathbf{v}_{A\gamma}\rangle}_{\text{transport}} = \underbrace{\langle R_{A\gamma}\rangle^\gamma}_{\text{homogeneous reaction}} \underbrace{- a_v \frac{\partial \langle c_{As}\rangle_{\gamma\kappa}}{\partial t}}_{\text{adsorption}} + \underbrace{a_v \langle R_{As}\rangle_{\gamma\kappa}}_{\text{heterogeneous reaction}} \tag{10}$$

where C_{As} represents the surface concentration of species A (moles per unit area) and R_{As} represents the molar rate of production of species A owing to heterogeneous reaction (moles per unit area per unit time). A connection between the surface concentration, C_{As}, and the bulk concentration, $C_{A\gamma}$, is required in order to obtain a solution for $C_{A\gamma}$ and therefore the intrinsic concentration, $\langle C_{A\gamma}\rangle^\gamma$. The two classic connections are the linear interfacial flux relation given by

$$\left(c_{A\gamma}\, \mathbf{v}_{A\gamma}\right) \cdot \mathbf{n}_{\gamma\kappa} = k_{A1}\, c_{A\gamma} - k_{-A1} c_{As}, \text{ at the } \gamma - \kappa \text{ interface}, \mathrm{A} = 1, 2, \ldots, \mathrm{N} \tag{11}$$

and the approximation of local adsorption equilibrium (Whitaker 1986; 1999). For a linear adsorption isotherm, this latter connection is given by

$$c_{As} = K_{\mathrm{eq}}\, c_{A\gamma}, \text{ at the } \gamma - \kappa \text{ interface}, \quad \mathrm{A} = 1, 2, \ldots, \mathrm{N} \tag{12}$$

A more convenient form of Eq. 10 has been given by Ho and Webb (2006):

$$\varepsilon_\gamma \frac{\partial \langle c_{A\gamma}\rangle^\gamma}{\partial t} + \nabla \cdot \left(\langle \mathbf{v}_\gamma\rangle \langle c_{A\gamma}\rangle^\gamma\right) = \langle \nabla \cdot \mathbf{J}_{A\gamma}\rangle + \underbrace{\nabla \cdot \langle \widetilde{\mathbf{v}}_\gamma \widetilde{c}_{A\gamma}\rangle}_{\text{dispersive transport}} + \langle R_{A\gamma}\rangle^\gamma - a_v \frac{\partial \langle c_{As}\rangle_{\gamma\kappa}}{\partial t} + a_v \langle R_{As}\rangle_{\gamma\kappa} \tag{13}$$

in which the volume average velocity has been expressed in terms of the superficial average, $\langle \boldsymbol{V}_\gamma \rangle$, rather than the intrinsic average, $\langle \boldsymbol{V}_\gamma \rangle^\gamma$.

In the following sections, we will provide a general review of the different processes, models, and experimental methods of the gas transport in the porous media associated with the three applications of CO_2 migration after sequestration, CO_2-oxygen transport in oxy-combustion, and oxygen transport in membrane at high temperatures.

CO_2 Migration After Sequestration

Introduction

Global warming and climate change have been linked to man-induced carbon dioxide (CO_2) emissions due to the correlation between raised global surface temperatures and increased ambient CO_2 concentrations during the last century (Oelkers and Cole 2008; Lackner 2003). The man-made CO_2 emissions were on the order of 3.45×10^{10} tonnes/year in 2012 (Olivier et al. 2013) and are primarily from burning of fossil fuels for energy production and transportation. To put the number in comparison, the total anthropogenic CO_2 emissions are on the order of 2.7×10^{10} tonnes/year in 1999 (Reichle et al. 1999). To limit the emissions, CO_2 sequestration has been applied to capture CO_2 from the flue gases and to inject CO_2 into various deep surface formations through underground geological storage, ocean storage, and mineral carbonation of carbon dioxide (Lackner 2003; Metz et al. 2005). In addition, the captured CO_2 can be stored as biomass in forests and soils (Oelkers and Cole 2008). If sequestration is to achieve this goal, it must operate on a multiterawatt scale while sequestering almost all produced CO_2, and it must also be safe, environmentally acceptable, and stable (Lackner 2003).

Called geologic carbon sequestration, this process aims to prevent CO_2 from entering the atmosphere by storing it permanently in three main target formations, specifically, depleted oil and gas reservoirs, brine formations, and deep unmineable coal seams (Kaszuba et al. 2003; Lackner 2003; Metz et al. 2005). An impermeable cap rock is essential because CO_2 density is generally less than that of water, so buoyancy tends to drive CO_2 upwards, back to the surface (Oelkers and Cole 2008). CO_2 sequestration through ocean storage means the injection of captured CO_2 into the ocean, usually at depths greater than 1000 m, where it would be isolated from the atmosphere (Adams and Caldeira 2008). Mineral carbonation aims to create stable carbonate minerals such as magnesite ($MgCO_3$) and calcite ($CaCO_3$) by reacting CO_2 with silicate minerals containing magnesium and calcium (Oelkers and Cole 2008). Such minerals are stable over geologic timescales, so sequestration by this method would minimize risk of later leakage back to the atmosphere. Storing CO_2 in forests and soils is a potential alternative to the above industrial sequestration methods. The use of forests for CO_2 storage will require (1) that forests be managed to grow continuously and

(2) that the carbon harvested from forests not be returned to the atmosphere (Johnson 1992). The potential for forests to sequester CO_2, however, is limited (Nilsson and Schopfhauser 1995) due to the limited hectares of trees available worldwide for afforestation.

Of the potential target formations for geologic carbon sequestration, depleted natural gas (CH_4) reservoirs appear to be obvious targets for initial utilization for several reasons. First, depleted gas reservoirs have a proven record of long-term gas containment and capacity as evidenced by their exploitation for CH_4 production. Second, there is an infrastructure of wells and pipelines, knowledge of the local subsurface conditions, and history of industrial activity at gas fields that favor implementation of CO_2 injection. Third, natural gas reservoirs are typically depleted and uneconomic even though 10–40 % of the original gas in place is still in the reservoir. Thus, the possibility exists to inject CO_2 into depleted gas reservoirs to increase reservoir pressure and produce additional CH_4 for economic benefit. Oldenburg (2006) has provided a detailed review on the CO_2 transport through porous depleted natural gas (CH_4) reservoirs.

Among several alternatives for CO_2 removal through geologic carbon sequestration, sequestration of CO_2 in coal seams has also been proposed as a promising strategy because of high gas storage capacity of coal. This technique also has a scientific and technological advantage compared to other proposed techniques for CO_2 sequestration due to the knowledge and experience gained in the area of gas production from coal seams over the years (Karacan and Mitchell 2003). White et al. (2005) reviewed the storage of captured CO_2 in coal seams with a methane recovery process. The review topics include an evaluation of the coal seam properties relevant to CO_2 sequestration, such as density, surface area, porosity, diffusion, permeability, transport, rank, adsorption/desorption, shrinkage/swelling, and thermochemical reactions; a leak detection using direct measurements, chemical tracers, and seismic monitoring; a discussion of gaps in our knowledge base that will require further research and development; etc.

Once injected, CO_2 will be in a supercritical fluid state at depths greater than approximately 800 m (2600 ft) and will be in either a liquid or gaseous state at lesser depths (Schnaar and Digiulio 2009). In all cases, CO_2 will be less dense than native groundwater and will migrate vertically due to density and pressure differentials and laterally due to pressure differentials. This section of the book chapter focused on gas transportation through porous media after sequestration in the coal seams, and review of the literature was limited to the mathematical modeling and simulation of gas transport and to the techniques measuring the chemical and physical properties of gas and subsurface.

Modeling and Simulation

Schnaar and Digiulio (2009) have provided a detailed review of the computational modeling of the geologic sequestration of carbon dioxide. Existing studies demonstrate the use of modeling in project design, site characterization, assessments

of leakage, and site monitoring. Particularly informative components of existing modeling studies include parameter sensitivity analyses, evaluation of numerical artifacts, code comparison, and demonstrations of model calibration to site monitoring data. Modeling the injection and sequestration of CO_2 bears unique challenges, such as the need to properly characterize CO_2 transport properties across a large range of temperatures and pressures and the need to couple multiphase flow, reactive transport, and geomechanical processes. In addition, the volumes of CO_2 that may be injected are largely unprecedented, and an appropriate amount of site characterization across the potentially impacted area will be difficult.

A coal bed (known as coal seams in Europe) contains a natural system of orthogonal fractures known as the cleat, which imparts some permeability to it (Holloway 2001). Although the solid coal does not contain a significant amount of conventional porosity, it does contain micropores of 20°A in diameter and mesopores of 20–500°A in diameter. The mesopores account for most of the pore volume and the micropores for most of the internal surface area (Jones et al. 1992). These commonly contain a natural gas known as coalbed methane (CBM). CO_2 has a greater affinity to be adsorbed onto coal than methane. Thus, if CO_2 is pumped into a coal seam, not only will it be stored by becoming adsorbed onto the coal, it may displace any methane at the adsorption sites (Gunter et al. 1996).

Several subsurface processes, collectively referred to as trapping mechanisms, may promote long-term sequestration of CO_2 (Metz et al. 2005). These include physical containment beneath low-permeability, high-entry-pressure strata (i.e., caprock), trapping as a residual, nonmobile fluid phase in formation pore space (i.e., capillary trapping), dissolution into resident groundwater, precipitation of C-bearing minerals, and sorption of CO_2 onto mineral surfaces. Modeling the transportation of CO_2 through porous media after sequestration in the coal seams includes some of these subsurface processes.

A wide variety of modeling exercises have been reported in the peer-reviewed literature for geologic sequestration of CO_2 (Schnaar and Digiulio 2009). Here listed some reports related to fate of CO_2 after sequestration in coal seams. Simulations have been conducted considering enhanced coalbed CH_4 production with CO_2 sequestration and consideration of CO_2 sorption to coalbed seams (Bromhal et al. 2005). Simulations including mineral precipitation and dissolution reactions have been conducted for injection into fractured caprock (Gherardi et al. 2007). The impact of relative permeability hysteresis and residual fluid trapping by capillary forces in three-dimensionally heterogeneous media has also been considered (Juanes et al. 2006; Flett et al. 2007; Doughty 2007). Subsurface flow of CO_2 has been coupled to a simplified atmospheric flow model to examine the fate of CO_2 that reaches the ground surface (Oldenburg and Unger 2004). To summarize, subsurface fluid flow models used for CO_2 sequestration activities vary in complexity and may include routines for multiphase flow, heat transport, reactive transport, and geomechanical processes. Traditionally, models have been developed as separate entities to simulate these processes. At best, present-day simulators address and couple a subset of these processes.

Use of Modeling to Design Geologic Sequestration Systems

Schnaar and Digiulio (2009) have summarized the use of modeling to design geologic sequestration systems. Computational models can be used to aid in the siting and design of geologic sequestration operations. For example, models can be used to optimize the number, depth, orientation (i.e., vertical, horizontal, or angled), flow rate, and maximum injection pressure of injection wells to maximize CO_2 trapping processes. Keith and others (Keith et al. 2004; Leonenko and Keith 2008) demonstrated that CO_2 dissolution can be accelerated by optimizing the geometry of injection wells and the pump age of brine to maximize the CO_2-brine interface. Several studies have demonstrated the use of modeling to assess design strategies for geologic sequestration during enhanced hydrocarbon recovery (e.g., Jessen et al. 2005; Kovscek and Cakici 2005).

Models can be used to demonstrate how formation heterogeneity can be taken advantage of to increase capillary trapping and dissolution. Simulations reported by Doughty et al. (2001) and Doughty and Pruess (2004) demonstrated that the interplay between geologic heterogeneity and buoyancy-driven flow is crucial in determining where and how effective structural and stratigraphic traps are and how CO_2 is distributed in space. They reported that the presence of discontinuous low-permeability lenses resulted in sinuous, vertically extensive plumes that increased the interfacial contact area and contact time between CO_2 and groundwater compared with a homogenous case. Therefore, there was an increased potential for CO_2 trapping via dissolution, capillary trapping, and mineral precipitation for the heterogeneous case.

Use of Modeling to Inform Site Monitoring

Schnaar and Digiulio (2009) summarized an example of how numerical modeling can be used to compare the spatial resolution and sensitivity of various geophysical monitoring techniques. The study used three-dimensional, multiphase-flow, numerical modeling and rock-property relations developed from log data at the Schrader Bluff field on the North Slope of Alaska (Hoversten and Gasperikova 2004). The analysis considered the application of electromagnetic and seismic geophysical techniques, as well as other techniques, for monitoring injection at a site on the North Slope. Results showed that there would be a clear change in seismic amplitudes and the amplitude vs. offset signature associated with changes in water and CO_2 saturation, both of which could be used to make quantitative estimates of saturation changes. An electromagnetic surface technique was evaluated as a method to quantitatively measure changes in brine saturation in the reservoir. Simulation results suggested that the injected CO_2 would result in changes in the electrical field of an order of magnitude above the background electrical noise.

Modeling Leakage of Carbon Dioxide to the Vadose Zone and Atmosphere

In the event of CO_2 leakage, the vadose zone is the last subsurface domain that CO_2 would traverse as it moves toward the root zone, the atmosphere, and the indoor air of buildings, where it could pose a threat to ecosystems and human health at

relatively low concentrations (e.g., Lewicki et al. 2006). Schnaar and Digiulio (2009) have summarized the modeling leakage of carbon dioxide to the vadose zone and atmosphere. In the vadose zone, leaking CO_2 would be in a gaseous form and CO_2-air mixtures would be denser than the surrounding air. Simulations reported by Oldenburg and Unger (2003), however, suggested that pressure differentials caused by leakage of CO_2 at the water table could result in upward vertical movement of CO_2 and release to the atmosphere. The magnitude of this pressure differential was shown to increase with leakage rate and decrease with the radius of the source zone (i.e., larger source zones are associated with diffusing leakage relative to direct leakage from wells). Simulations also suggested that attenuation due to CO_2 dissolution into infiltrating water was minimal in cases where CO_2 leakage was ongoing and that barometric fluctuations had little impact on time-averaged CO_2 atmospheric release rates. Sensitivity analyses demonstrated several scenarios wherein CO_2 concentrations at the soil surface were large enough (i.e., mole fraction >0.3) to cause adverse ecological impacts.

Oldenburg and Unger (2004) coupled subsurface and surface-layer transport models to further evaluate subsurface-atmospheric interactions. The above-ground surface layers were established in a numerical code by setting a porosity equal to unity and permeability values to mimic a logarithmic wind velocity profile. Simulation results were consistent with earlier simulations in that relatively large CO_2 concentrations were observed in vadose-zone air (i.e., a CO_2 mole fraction approaching unity); however, CO_2 concentrations in the surface layers were orders of magnitude smaller than in the subsurface due to dilution in wind. Lower CO_2 concentrations in the surface air were observed in simulations with greater wind speeds.

Simulations also suggested that some CO_2 would reenter the subsurface in the direction downwind of surface release due to dissolution in infiltrating water. In the event that significant leakage occurs from the injection zone, remediation may be required in groundwater and the vadose zone. Vadose-zone remediation strategies for gaseous CO_2 would probably be similar to those currently used for volatile organic compound contaminated sites, which are primarily based on soil vapor extraction (SVE) systems. Zhang et al. (2004) evaluated several design strategies for SVE-based remediation of CO_2. Two-dimensional radial simulations demonstrated that the use of a vertical well SVE system provided modest improvements to remediation efficiency when compared with natural attenuation or passive strategies. The use of an impermeable cover did not improve remediation removal rates. Three-dimensional simulations suggested that the use of complementary vertical and horizontal wells in the SVE system may improve remediation efficiency compared with strictly vertical or horizontal well cases.

Existing Codes

Several codes have been developed for multiphase flow and transport problems (Schnaar and Digiulio 2009). Codes reported in the literature used for the modeling of CO_2 sequestration can also be applied or modified to simulate CO_2 migration after sequestrating in the coal seams. The codes include those developed primarily

for petroleum reservoir engineering (STARS, Law and Bachu 1996; ECLIPSE, Zhou et al. 2004; Juanes et al. 2006; CHEARS, Flett et al. 2007; and CMG-GEM and CMG-IMEX) and codes developed at the US Dep. of Energy national labs for a range of multiphase flow and transport problems (CRUNCH, Knauss et al. 2005; TOUGH series, Finsterle 2004; Xu et al. 2006; Doughty and Pruess 2004; Doughty 2007). These codes vary not only in the physical processes and governing equations but also in numerical techniques such as the spatial discretization methods, iteration approaches, and gridding routines.

Measurements

Measurements of chemical and physical properties include collecting site information and monitoring the migration of CO_2 after sequestration. X-ray CT and SEM were used to observe the gas storage and transport in a coal sample from Zonguldak Basin (Turkey) (Karacan and Okandan 2001; Karacan and Mitchell 2003). In these studies, a coal sample was placed in an X-ray transparent core holder that enables applying confining pressure and gas pressure separately. Images were processed and quantified to calculate the porosity and gas adsorption rate at different local positions. These data, together with SEM pictures at the same local points, revealed that different lithotypes show different rate behaviors in consolidated sample. These data were also used to study the equilibrium isotherm parameters and to investigate the kinetics of the adsorption process for calculating the diffusivity of CO_2 in different microlithotypes.

Monitoring of geologically sequestered CO_2 is required to protect the environment as well as the health and safety of the public. White et al. (2005) reviewed the monitoring and verification of geologically sequestered CO_2. Migration of CO_2 can be monitored using a variety of techniques. The simplest monitoring method is to measure the pressure (White et al. 2005). To monitor the possible leakage of CO_2 and CH_4 to the surface, it is necessary to determine the flux of these gases emanating from the earth above the coalbed on a seasonal basis before CO_2 is sequestered (Klusman 2003). A monitoring technique that allows determination of a slow and/or intermittent leak of CO_2 to the surface is required. This can be done using a tracer. A tracer is an extraneous substance that is added to the CO_2. White et al. (2005) summarized the use of tracer to determinate such kind of leakages.

Geophysical methods represent another major category of monitoring tools that will be applied to monitor the fate and integrity of geologically sequestered CO_2. Interested readers can refer to the literature review by White et al. (2005).

Summary

Gas transport through porous media is a very important topic in CO_2 sequestration and migration. Storage of CO_2 in the coalbed has been proposed as a promising strategy because of high gas storage capacity of coal. However, mathematical

modeling studies in this subject are very limited though much more experimental work was reported in the literature. Since modeling and simulation can be used to evaluate and optimize the performance and design of these systems, researchers could put more effort in modeling CO_2 injection and migration for the sequestration process in the coal seams.

CO_2-Oxygen Transport in Oxy-Combustion

Introduction

Oxy-fuel combustion is currently considered to be one of the major technologies for carbon dioxide capture. A book (Zheng 2011) has focused on the development of oxy-fuel combustion technologies using coal as fuel. Coal plays a very important role in our day-to-day lives. In a comprehensive report published in 2008, the International Energy Agency (IEA) predicted that the demand for coal will surpass oil in absolute terms between 2030 and 2050 and will become the predominant fuel for the world (IEA, 2008–1). Coal as an energy source has a number of negative environmental impacts, including (but not limited to) the release of particle matter, oxides of sulfur and nitrogen, carbon monoxide (CO), and trace metals such as mercury. Therefore, it is necessary to develop clean coal technology.

Currently, there are three major CO_2 capture technologies that have reached the level of industrial-scale demonstration: post-combustion capture, precombustion capture, and oxy-fuel combustion (Shaddix 2012). Oxy-fuel combustion is a very elegant approach for CO_2 capture that uses oxygen instead of air for combustion. By eliminating nitrogen from the oxidant gas stream, it is possible to produce a CO_2-enriched flue gas ready for sequestration after water has been condensed and other impurities have been separated out. Oxy-fuel combustion for CO_2 capture incorporates three main components: the air separation unit that provides oxygen for combustion, the furnace and heat exchangers where combustion and heat exchange take place, and the CO_2 capture and compression unit. The heat transfer characteristics and its impacts on boiler design were studied for furnaces of various sizes under oxy-fuel operation, and it is concluded that an oxy-fuel-fired furnace can have the same heat transfer rate as an air-fired one with lower furnace exit temperature and higher gas emissivity. Therefore, current boiler design principles and operational practice can be easily adopted for oxy-fuel combustion (Tan et al. 2006; Wall et al. 2005).

Research into oxy-fuel combustion of coal has involved a diverse set of experiments and modeling studies, from the most fundamental aspects to pilot-scale experimental testing and full-scale boiler CFD modeling (Shaddix 2012). Pulverized coal combustion represents the vast majority of the installed power plant capacity, and most of the oxy-fuel combustion research to date has focused on applications of diluting the oxygen to produce similar radiant and convective heat transfer profiles as existing in conventional air-fired coal boilers. Since CO_2 has higher volumetric heat capacity than N_2, the average mixture of oxygen and

recycled flue gas (predominately CO_2, with high concentrations of moisture, in some cases) must be composed of approximately 28 % O_2. Consequently, coal particles in the oxy-fuel boilers are igniting and burning in vastly different chemical and thermal environments than in conventional air-fed boilers. This has motivated a revisit of fundamental studies of coal particle ignition and char combustion phenomena in a CO_2 bath gas, which provide key information for CFD modeling and oxy-fuel burner design. This section of the chapter focuses on the transport phenomena through the porous coal particles in the oxygen-fed boilers during the oxy-combustion.

Modeling and Simulation

For oxy-combustion with flue gas recirculation, elevated levels of CO_2 and steam affect the heat capacity of the gas, radiant transport, and other gas transport properties. A topic of widespread speculation has concerned the effect of gasification reactions of coal char on the char burning rate. To assess the impact of these reactions on the oxy-fuel combustion of pulverized coal char, Hecht et al. (2012) computed the char consumption characteristics for a range of CO_2 and H_2O reaction rate coefficients for a 100 μm coal char particle reacting in environments of varying O_2, H_2O, and CO_2 concentrations using the kinetics code SKIPPY (Surface Kinetics in Porous Particles). Their results indicate that gasification reactions reduce the char particle temperature significantly (because of the reaction endothermicity) and thereby reduce the rate of char oxidation and the radiant emission from burning char particles. However, the overall effect of the combined steam and CO_2 gasification reactions is to increase the carbon consumption rate by approximately 10 % in typical oxy-fuel combustion environments. In addition, the gasification reactions have increasing influence as the gas temperature increases (for a given O_2 concentration) and as the particle size increases. Gasification reactions account for roughly 20 % of the carbon consumption in low-oxygen conditions and for about 30 % under oxygen-enriched conditions.

Chen et al. (2012) reviewed the oxy-fuel combustion of pulverized coal in the aspects of characterization, fundamentals, stabilization, and CFD modeling. The technical review of oxy-coal combustion covered the most recent experimental and simulation studies. Numerical models for subprocesses were used to examine the differences between combustion in an oxidizing stream diluted by nitrogen and carbon dioxide. The review introduced the evolution of this technology from its original inception for high temperature processes to its current form for carbon capture, followed by a discussion of various oxy-fuel systems proposed for carbon capture. The review also discussed the characteristics of oxy-fuel combustion in the context of heat and mass transfer, fuel delivery and injection, coal particle heating and moisture evaporation, devolatilization and ignition, char oxidation and gasification, as well as pollutants formation. Further, the review included advances in sub-models for turbulent flow, heat transfer and reactions in oxy-coal combustion

simulations, and the results obtained using the CFD modeling. It was summarized that distinct characteristics in oxy-coal combustion necessitate modifications of CFD sub-models because the approximations and assumptions for air-fuel combustion may no longer be valid. Based on the review, research needs in this combustion technology were suggested.

Geier et al. (2012) reported on the development and application of an extended single-film reaction model that includes both oxidation and gasification reactions. The traditional single-film nth-order Arrhenius char oxidation model was extended by including additional heterogeneous reactions of char with CO_2 and H_2O, as is required to accurately predict char particle temperatures and char consumption rates in both conventional and oxy-combustion environments. The performance of the model has been systematically interrogated in comparison to experimental data for two US coals (a Powder River Basin subbituminous coal and a low-sulfur, high-volatile bituminous coal) for a variety of model assumptions. The analysis with the extended single-film model showed that incorporation of both steam and CO_2 gasification reactions is required to maintained reasonable values for activation energy of the reactions. The modification of the traditional single-film char burnout model achieved the goal of improving CFD predictions of oxy-fuel combustion of pulverized coal char particles by focusing on the model performance in predicting experimentally observable data (particle temperature) of char particles burning in N_2 and CO_2 baths with different contents of O_2.

Kim et al. (2014) used burnout simulations of coal char particles with apparent char reactivity and a single-film model that includes the Stefan flow effect on mass and energy transfer, to study the impact of CO_2 gasification on the oxy-combustion of pulverized coal chars. The simulations revealed that gasification reaction by CO_2 improves the char burnout time and carbon consumption and decreases the char particle temperature. Also, the simulations indicate the gasification reaction has a greater influence on the char burnout time and the relative contribution to carbon consumption in an oxygen-deficient environment and a greater influence on the particle temperature in an oxygen-enriched environment. However, this tendency according to oxygen level is also influenced by the gas temperature. In addition, the influence of the gasification reaction on char combustion increases as the gas temperature increases and as the particle size increases. Although more reliable rate parameters and insight of the influence of boundary layer heat release are needed, the simulation study shows that it is important to include gasification reaction by CO_2 when simulating char combustion in the oxy-fuel combustion environments.

Measurements

In order to fully understand the results of pilot-scale tests and to accurately predict scale-up performance through CFD modeling, Murphy and Shaddix (2006) have measured the combustion rates of two pulverized coal chars in both conventional

and oxygen-enriched atmospheres. The study used a combustion-driven entrained flow reactor equipped with an optical particle-sizing pyrometry diagnostic and a rapid-quench sampling probe. Oxygen-enriched combustion was found to significantly increase the char combustion temperature and to reduce the char burnout time, as expected. The optical kinetic data, interpreted with a single-film oxidation model, demonstrate increasing kinetic control in enriched-oxygen combustion, despite the faster particle combustion rates. Char burnout rates and char particle temperatures are predicted reasonably well when applying a char burnout model with the derived kinetics.

Gonzalo-Tirado et al. (2013) determined the kinetics of CO_2 gasification for coals of different ranks under oxy-combustion conditions. Combustion reactions were performed in a flow reactor consisting of a cylindrical, externally heated tube (1.6 m long, 78 mm inner diameter), in which the fuel particles are pneumatically injected by means of an insulated gun. Samples of partially burnt particles were collected at increasing distances from the injection point with an isokinetic probe. Higher activation energies and lower char reaction rates (in the conditions explored) were found for char gasification than for oxidation, and the coal rank influenced both sets of kinetics.

Kim et al. (2014) applied a new experimental approach to directly measure the CO_2 gasification rate of a subbituminous coal char at high temperatures and atmospheric pressure. Sandia National Laboratories' laminar entrained flow reactor facility was employed for this study, and char particle size-temperature statistics were measured using a particle-sizing pyrometer, i.e., the velocity, diameter, and temperature of individual burning char particles. A water-cooled sampling probe with helium-quench gas dilution was used to collect char samples at selected heights for determination of char burnout.

Summary

Computational fluid dynamic (CFD) simulations traditionally rely on the computational efficiency of single-film global kinetic oxidation models to predict char particle temperatures and char conversion rates in pulverized coal boilers. In oxy-fuel combustion with flue gas recirculation, char combustion occurs in the presence of elevated CO_2 levels and, frequently, elevated water vapor levels (when employing wet flue gas recirculation). Also, local oxygen concentrations can be quite high in the vicinity of oxygen injection lances. The suitability of existing approaches to modeling char combustion under these conditions has been unclear. In particular, previous work has shown that both boundary layer conversion of CO and gasification reactions of steam and CO_2 need to be included to give reasonable agreement with the experimental measurements, for particles over 60 μm in size. Large physical domain sizes and high computational complexity dictate the use of fairly coarse meshes for the spatial domain and application of simplified coal combustion models, which inevitably reduces the range of process conditions for which the simulation software produces reliable results.

Oxygen Transport in Membrane at High Temperatures

Introduction

It was introduced in section "CO_2-Oxygen Transport in Oxy-Combustion" that oxy-fuel combustion for CO_2 capture incorporates three main components: the air separation unit that provides oxygen for combustion, the furnace and heat exchangers where combustion and heat exchange take place, and the CO_2 capture and compression unit. This section of the book chapter focused on the technology of oxygen separation using membrane at high temperatures. The use of selective membranes to separate certain components from a gas stream, for example, separating oxygen from nitrogen in the oxy-fuel combustion system is a relatively novel capture concept (Mondal et al. 2012). Membranes are semipermeable barriers able to separate substances by various mechanisms (solution/diffusion, adsorption/diffusion, molecular sieve, and ionic transport). These are available in different material types, which can be either organic (polymeric) or inorganic (carbon, zeolite, ceramic, or metallic) and can be either porous or nonporous.

Oxygen separation technologies currently include polymer membranes, pressure swing adsorption (PSA), vacuum swing adsorption (VSA), cryogenics, chemical looping combustion (CLC), and ceramic autothermal recovery (CAR) (den Exter et al. 2009). Polymeric membranes are used for oxygen enrichment or depletion of air, and the polymers are commonly based on among others polyphenyloxide (Parker Gas Separation) and polyimides (air products). The separation is based on preferred dissolution and diffusion of oxygen over nitrogen in these materials, but the operating temperature is limited by the thermal stability of the polymers used. The PSA and VSA technologies are based on the preferred absorption of nitrogen in, for example, zeolite beds. Cryogenics is currently the most developed mature large-scale oxygen production technology, and this technology can also be used to produce nitrogen and argon. In CLC, a metal or metal oxide is oxidized by air in one reactor and transferred to a reduction reactor that is fed with, for example, syngas. The CAR concept uses a set of two or more batch reactors alternating between oxidation and reduction cycles, containing a perovskite material that is cycled between two oxygen contents.

High-temperature oxygen transport membranes (OTMs) have been proposed for plants using high purity O_2 for fuel conversion. These include both plants that partially oxidize feedstocks to produce syngas and power plants with CO_2 capture based on oxy-fuel combustion (Chiesa et al. 2013). The optimal OTM operating temperature is between 800 °C and 900 °C when integrating as a permeator in a gas turbine of an integrated gasification combined cycle (IGCC) plant and is between 700 °C and 900 °C for heavy fuel oxy-combustion. All these applications require high operation temperatures of the OTMs.

den Exter et al. (2009) clearly identified that the high-temperature ceramic membranes that selectively transport oxygen are the high-temperature oxygen transport membranes (OTMs). They are referred to with several acronyms of

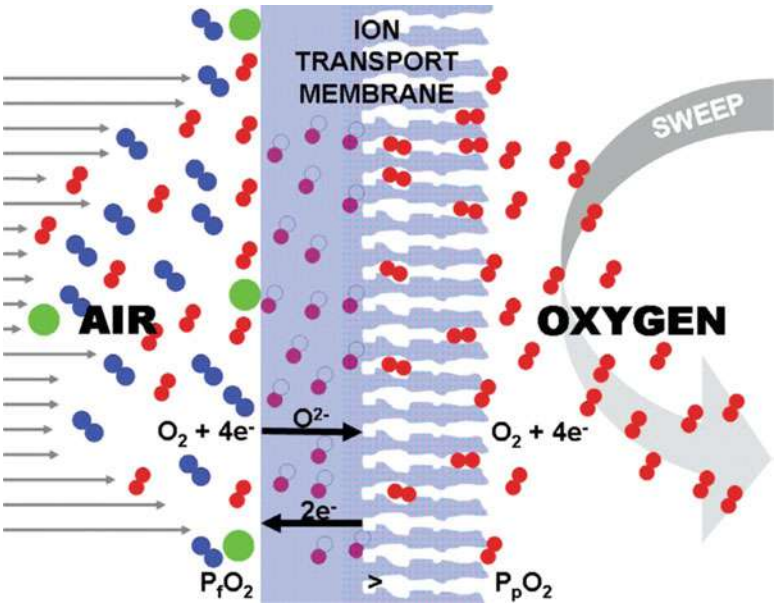

Fig. 2 Schematic representation of the transport of oxygen through an ion transport membrane consisting of a dense (*left*) and porous (*right*) part. The sweep can be either "inert," for example, CO_2 or H_2O, or "fuel," for example, CH_4 (den Exter et al. 2009)

which OTM (oxygen transport membranes), ITM (ion transport membranes), and MIEC (mixed ionic electronic conducting) membranes prevail. They also pointed out the two main applications of high-temperature membrane technology are the production of high purity oxygen as a valuable chemical and as a reactant for various (partial) oxidation processes such as methane conversion. Most OTM materials are only permeable to oxygen at temperatures above 700 °C (975 K) (Foy and McGovern 2005). OTM technology integrates O_2 separation and combustion in one unit. A schematic representation of the air separation process using OTM as a whole is presented in Fig. 2 (den Exter et al. 2009). The driving force for the transport of oxygen is a difference in partial oxygen pressure (p_{O2}) between the feed and permeate side of the membrane. Figure 2 also demonstrates that the OTM consists of an inert porous support (*right*) coated with a dense gas separation layer (*left*).

There are three main types of ceramics with ion transport capabilities: perovskite, fluorite, and mixed (Foy and McGovern 2005). OTM reactors supply pure oxygen through the membrane to the sweep side where a fuel is introduced and oxidized. Examining the fundamentals of catalytic fuel conversion and how they couple with oxygen permeation and gas-phase reactions requires detailed and complex models (Hong et al. 2013a, b). Due to the coupling between catalytic fuel conversion and oxygen permeation, and the high operation temperature,

a detailed analysis is needed to account for the coupling of oxygen permeation, gas-phase flow and transport, and homogeneous and heterogeneous chemistry in terms of the local thermodynamic state on both sides of the membrane surface.

The modeling of the flow process considers a numerical solution of the conservation equations of mass, momentum, energy, and species in the axisymmetric flow domain (Ben-Mansour et al. 2012). The oxygen permeation across the membrane depends upon the prevailing temperatures and the oxygen partial pressure at both sides of the membrane. In the following section, modeling and simulation studies of the flow process were summarized.

Modeling and Simulation

Understanding the theory of the OTM is very important for the modeling and simulation studies. Foy and McGovern (2005) provided a summary of the theory. There are a number of factors that affect the passing of oxygen through the membrane. Firstly the oxygen must reach the membrane. It is possible that due to transport in the flow of gas on the feed side of the membrane, the flux could be limited. After the oxygen reaches the membrane, it is adsorbed onto the surface. Surface exchange effects can be identified by a difference in the normalized values for different thicknesses of the same material. Once the oxygen has reached the surface and been adsorbed onto it, it is transported through the ceramic by bulk transport through the ceramic lattice, which contains oxygen ion vacancies. The oxygen flux across the membrane is given by the Nernst-Einstein equation above 700 °C (975 K) where the flux is directly proportional to the absolute temperature and inversely proportional to the thickness of the membrane. The flux is also proportional to the natural log of the ratio of oxygen partial pressures across the membrane. This explains why the flux can be much higher when an oxygen-consuming reaction occurs on one side of the membrane.

Modeling studies conducted so far have rarely related the heterogeneous chemistry for perovskite oxygen transport membranes to the local thermodynamic state and have not resolved its coupling with the oxygen permeation and gas-phase transport and reactions in detail (Hong et al. 2013a, b). Akin and Lin (2004) assumed different permeation mechanisms and two limiting oxidation kinetics: either extremely fast reaction or no conversion. Using a simple reactor model such as a continuously stirred tank reactor (CSTR), they examined how the oxidation reaction rates, the reducing gas flow rate, and the feed-side oxygen partial pressure influence the oxygen permeation rate. Based on the same CSTR model, Rui et al. (2009) investigated the effect of the finite chemical kinetic rates on the oxygen permeation rate. Results from these studies have shown that chemical reactions and their kinetic rates have substantial influence on the oxygen permeation. These models considered a CSTR and assumed arbitrary reaction rates. Wang and Lin (1995) estimated catalytic kinetic parameters assuming that perovskite membranes behave catalytically in a way similar to Li/MgO membranes and

applied them to the CSTR model, while Tan et al. (2008) used the kinetic parameters of perovskite membranes with a plug flow reactor (PFR) model.

Hong et al. (2013a, b) developed a physical model that resolves spatially the gas-phase flow, incorporates detailed homogeneous chemistry, and accounts for oxygen permeation. Hong et al. (2013a, b) further revised this model to incorporate heterogeneous chemistry on the membrane surface. The surface and bulk species and their reactions are coupled with the local thermodynamic state near the membrane in the gas phase. Using spatially averaged, i.e., reactor level, measurements available in the literature, numerical simulations have been used to develop the heterogeneous chemistry that resolves both oxygen surface exchange and catalytic fuel conversion.

Computational fluid dynamics was also applied to model the oxygen transport in a lab-scale experimental setup for permeation testing of oxygen transport membranes using finite element analysis (Gozálvez-Zafrilla et al. 2011). The modeling considered gas hydrodynamics and oxygen diffusion in the gas phase and vacancy diffusion of oxygen in a perovskite disk-shaped membrane at 1273 K. In a first step, the model was set to obtain the diffusion coefficient of oxygen. The parametric study showed that the setup geometry and flow rate in the air compartment did not have major influence in the oxygen transport. However, very important polarization effects in the sweep-gas (argon) compartment were identified. The highest oxygen permeation flux and the lowest oxygen concentration on the membrane surface were obtained for the following conditions (in increasing order of importance): (1) a large gas inlet radius, (2) a short gas inlet distance, and (3) a high gas flow rate. The computational fluid dynamics method has also been applied by Habib et al. (2013a, b), and the solver of the Fluent software was used with a series of user-defined functions (UDFs) in a Cartesian coordinate system.

To summarize, the modeling of the flow process considers a numerical solution of the conservation equations of mass, momentum, energy, and species in the axisymmetric flow domain. A representative OTM flow schematic for modeling study has been given by Hong et al. (2013a, b) and was reproduced in Fig. 3. The flow process couples the gas-phase flow, transport and chemical reactions, and oxygen permeation flux and heat flux across the membrane.

Conservation of Mass

According to the configuration in Fig. 3, Hong et al. (2012) used the following as the continuity equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial V}{\partial y} + \rho U = -\frac{\rho}{T}\frac{\partial T}{\partial t} - \sum_{k=1}^{N} \frac{\rho \overline{W}}{W_k}\frac{\partial Y_k}{\partial t} + \frac{\partial V}{\partial y} + \rho U = 0 \tag{14}$$

where ρ is the density, V is the normal velocity, U is the transverse velocity, W is the mixture molecular weight, W_k is the molecular weight of species k, and N is the number of gas-phase species.

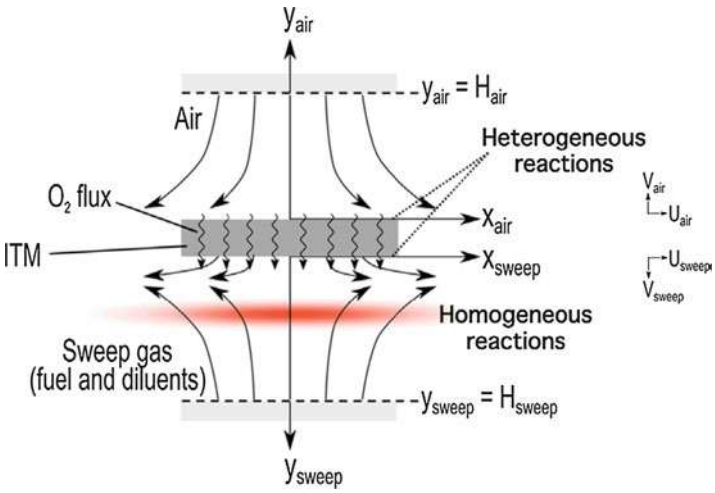

Fig. 3 Planar, finite-gap stagnation flow configuration of the OTM flow schematic for modeling study (Hong et al. 2013)

Conservation of Momentum

According to the configuration in Fig. 3, Hong et al. (2012) proposed the conservation of momentum in the x-direction and used the following equation:

$$\rho\frac{\partial U}{\partial t}+V\frac{\partial U}{\partial y}+\rho U^2+\Lambda_x-\frac{\partial}{\partial y}\left(\mu\frac{\partial U}{\partial y}\right)=0 \tag{15}$$

where ρ is the density, V is the normal velocity, U is the transverse velocity, $\Lambda_x=\frac{1}{x}\frac{dp}{dx}$ and is the scaled transverse pressure gradient (kg/m^3/s^2), and μ is the dynamic viscosity.

Conservation of Energy

Hong et al. (2013) coupled the thermal energy balance of the membrane in their mathematical models and considered the conductive, convective, and diffusive heat transfer with the gaseous domain and the heat release from the surface reactions as well as the thermal radiation between the membrane and the reactor walls. According to the configuration in Fig. 3, Hong et al. (2012) used the following as the conservation of energy equation:

$$\rho\frac{\partial T}{\partial t}+V\frac{\partial T}{\partial y}+\frac{1}{c_p}\left[\sum_{k=1}^{N}\hat{h}_k\dot{\omega}_k+\sum_{k=1}^{N}j_k c_{p,k}\frac{\partial T}{\partial y}-\frac{\partial}{\partial y}\left(\lambda\frac{\partial T}{\partial y}\right)\right]=0 \tag{16}$$

where ρ is the density, V is the normal velocity, $\dot{\omega}_k$ is the molar production rate of species k, c_p is the mixture specific heat, $c_{p,k}$ is the specific heat of species k, $\hat{h}_k$ is the molar enthalpy of species k, λ is the mixture thermal conductivity, N is the number of gas-phase species, and j_k is the flux of species k in the y direction.

Conservation of Species

Hong et al. (2013) distinguished three domains for the conservation of species with heterogeneous chemistry. The three domains were illustrated in Fig. 4 as gaseous, surface, and bulk domains. The gaseous and bulk domains are volumetric domains, whereas the surface domain is an interface domain between these two volumetric domains. The transport-chemistry interaction in each domain is modeled using the appropriate form of the differential equations, and the surface reactions are used to connect them. The bulk species concentration in the direction of the membrane thickness is governed by bulk diffusion, and the control volume approach is used to relate the volumetric bulk domain with the interface domain. The species conservation within the surface domain is accounted for by surface reaction without species transport or mass fluxes. When coupling the heterogeneous kinetic mechanism, the species concentration at and immediately below the surface domain is used.

Ben-Mansour et al. (2012) specified the binary mass diffusion coefficient of the component i in the component j to determine the diffusion coefficient. The corresponding diffusion coefficient in the mixture is computed by

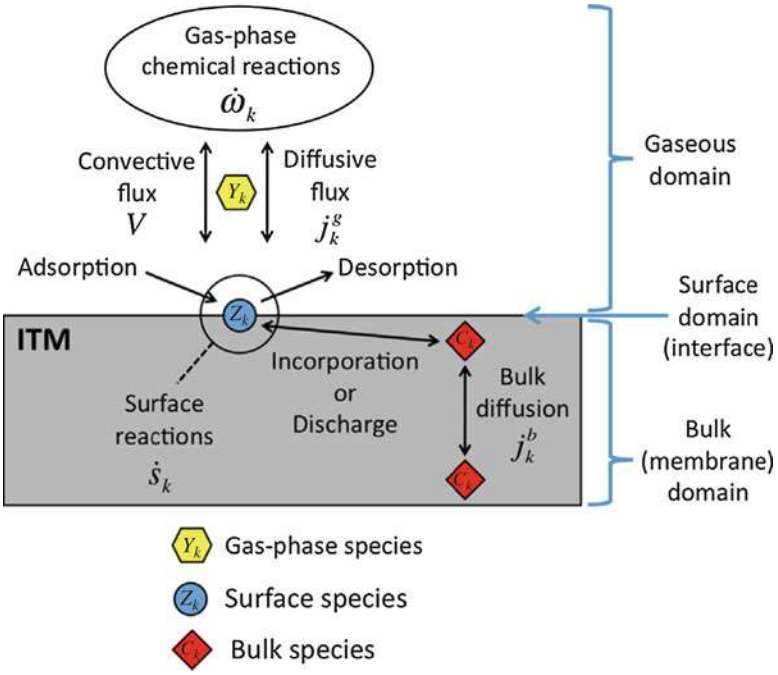

Fig. 4 Three domains (i.e., gaseous, surface, and bulk domains) and the species belonging to each domain (i.e., Y_k = gas-phase species in the gaseous domain, Z_k = surface species in the surface domain, and C_k = bulk species in the bulk domain). The gaseous and bulk domains are volumetric domains, whereas the surface domain is an interface domain between these two volumetric domains (Hong et al. 2013)

$$D_{i,\mathrm{m}} = \frac{1 - X_i}{\sum_{j,j\neq i}\left(\frac{X_i}{\mathrm{D}_{i,j}}\right)} \tag{17}$$

Gozálvez-Zafrilla et al. (2011) modeled the transport of oxygen in the membrane by a Fickian diffusion mechanism of oxygen vacancies in the structure. The transport depends on the concentration gradient of oxygen vacancies and a diffusion coefficient which is a material property.

Measurements

Chemical and Physical Properties

Zeng et al. (2009) applied the Archimedes method using mercury to obtain the relative density of the ceramic membrane. They also analyzed the phase composition of the membrane intermediate material by X-ray diffraction (XRD), measured the O1s XPS spectra of the powders with VG ESCALAB MKII, and analyzed with the Gaussian peak software.

Park et al. (2008) applied SEM to measure the morphologies of the calcined powder and membrane. They painted the rectangular specimens with silver paste to measure the electrical conductivity with a *dc* four-probe method as a function of temperature (100–900 °C) in 80 % N_2-20 % O_2 and in 1 % O_2/N_2 atmosphere at a flow rate 100 mL · min^{-1}.

Transport Properties

Oxygen permeation tests were performed by numerous researchers (Zeng et al. 2009; Park et al. 2008; Tan et al. 2012; Sunarso et al. 2009; Wang et al. 2014). Gas phase chemistry detection was involved in all these studies. In this section of the book chapter, we only representatively listed two studies.

Zeng et al. (2009) measured the oxygen permeation through the membranes using the experimental setup: one side of a disk-shaped membrane was exposed to atmospheric air and the other side was swept with flowing helium or pure CO_2 to carry away the permeated oxygen. The total flow rate on the feed side of the membranes was set to be 100 mL · min^{-1} and the flow rate on the permeate side to 50 mL · min^{-1}. To verify the O_2/CO_2 production concept, a one-end closed membrane tube was sealed in an alumina tube by silver to form a permeation cell. The shell side of the tube was exposed to a pressurized air (3 bar), and the core side was swept with a flowing CO_2 injected through an alumina tube. The effluent from the permeated (lower p_{O2}) side of the membrane was analyzed with online gas chromatography.

Park et al. (2008) measured the oxygen permeation using the setup shown in Fig. 5. The membrane permeation cell was assembled with the membrane, alumina tube, and sealant. Prior to oxygen permeation test, the cell part was purged with He gas to remove the air in permeation cell tube and to confirm

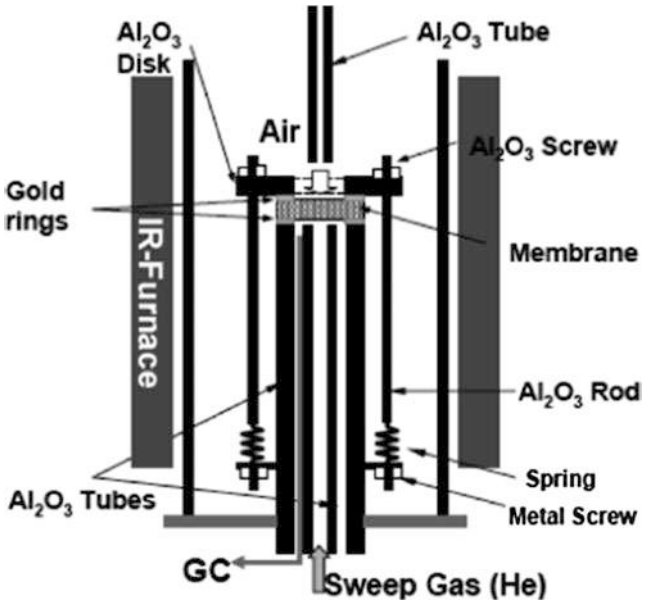

Fig. 5 The schematic diagram of a permeation test cell (Park et al. 2008)

sealing of the assembly consisted of alumina tubes, membrane, and sealant for 20 h. The leakage through membrane during oxygen permeation test was also measured for all runs at each temperature, and the oxygen permeation fluxes were corrected on the basis of the measured leakage. Permeation study was performed within the temperature range of 750–950 °C. The oxygen content in the permeate stream was measured with a gas chromatograph, and the oxygen flux was determined by:

$$J_{O_2}[\mathrm{mL/min\,cm^2(STP)}] = \frac{F_{\mathrm{total}}[\mathrm{mL/min}]\, y_{O_2}[v\%] - \text{leakage correction}}{A\,[\mathrm{cm^2}]} \tag{18}$$

where F_{total} is corresponding with the total flow rate of the permeation stream in which the oxygen concentration is y_{O2}, A is the effective membrane surface area, and *leakage correction* means the calculating oxygen flux from leakage.

Thermal Properties

Thermogravimetric analysis (TA) was carried out for the OTM materials. Tan et al. (2012) reported to use TA with 500 mg of the crashed hollow fiber sample in a sample holder. The sample was heated 25–950 °C at a rate of 10 °C · min^{-1} in CO_2 or nitrogen (flow rate = 50 mL · min^{-1}).

Summary

Numerous reports have been on the study of the oxygen transport membrane, and the OTM technology has been proved a popular topic. However, due to the complexity of the flow process through the membrane system, much further effort is still required to understand the fundamentals and to improve the performance of the OTM at high temperatures.

Future Directions

In this book chapter, the author first listed the general mechanism to briefly explain transport through porous media. Then, a general review was given of the different processes, models, and experimental methods of the gas transport in the porous media associated with the three applications of CO_2 migration after sequestration, CO_2-oxygen transport in oxy-combustion, and oxygen transport in membrane at high temperatures. Due to the broadness of the topic, the author suggested readers to further refer to the listed references of each topic if interested.

The topic of oxygen transport at high temperatures is popular recently. Many efforts have been put in exploring new materials for OTM, while less efforts have been made in understanding the transport mechanism. Due to the high working temperature, the OTM requires materials having strict properties so that it is very popular for researchers to study materials with high performance. It is very important to understand the transport mechanism in order to develop the new materials.

Abstract

The efficient use of energy, or energy efficiency, has been widely recognized as an ample and cost-efficient means to save energy and to reduce greenhouse gas emissions. Up to 1/3 of the worldwide energy demand in 2050 can be saved by energy efficiency measures. In this chapter, several important aspects of energy efficiency are addressed. After an introduction and definition of energy efficiency, historic development and state-of-the-art and future trends of energy efficiency are presented in the light of life cycle assessment and total cost of ownership considerations. Energy efficiency in the sectors energy production, energy transmission and storage, transportation, industry, buildings, and appliances is reviewed. Concurrent measures such as recycling or novel materials are also discussed and touched upon. Energy conservation is covered in the final section of this chapter. References for deeper study are provided with an emphasis on guidelines on how to improve energy efficiency. Given the breadth of the subject, only exemplary coverage can be aimed for. The purpose of this chapter is to highlight the significance of energy efficiency and to provide cross-learnings from achievements in different sectors so that energy efficiency in the readers' own facilities and installations can be assessed and improved with cost-effective means as a contribution to climate change mitigation, cost savings, and improved economic competitiveness.

Introduction

Energy in the everyday world is a range of commodities, for instance, thermal or electrical. It is a scalar physical quantity that is defined by the amount of work that can be done by a force. Energy comes in different forms: Classical mechanics distinguishes between kinetic and potential energy. In the everyday world, one can see chemical, thermal, gravitational, light, and electrical energy, to name but a few. These forms of energy can be transformed into each other. The SI unit of energy is joule [J], with other common units being kilowatt hour [kWh], tonne of oil equivalent [toe], and British thermal unit [btu, BTU]:

$1\ J = 1\ kg\ m^2\ s^{-2} = 1Ws$
$1\ kWh = 3.6*10^6\ J$
1 toe = 41.868 GJ = 11,630 kWh
1 btu = 1.060 kJ; 1 quad = 10^{15} (1 quadrillion) btu = 1.06×10^{18} J

The worldwide energy consumption is on the order of 500 exajoules (5×10^{20} J) per year, which corresponds to an average consumption rate of 15 terawatts (1.5×10^{13} W).

Energy efficiency, i.e., the efficient use of energy, describes the use of less energy to achieve the same level of energy service. Energy efficiency is a universally applicable concept relevant for consumers and industry alike. It can be achieved by a more efficient technology, an improved process, or a change of individual behavior. Energy efficiency can, according to the IEA's World Energy Outlook 2014, "close the competitiveness gap caused by differences in regional energy prices" (IEA 2014a).

The International Energy Agency (IEA) promotes energy security amongst its 29 member countries through collective response to physical disruptions in oil supply and provides research and analysis on energy. The annual World Energy Outlook is the IEA's "flagship" publication, which is widely recognized as an authoritative source for global energy projections and analyses. It provides medium- to long-term energy market projections, ample statistics, and recommendations for governments and the energy business.

Obstacles toward the introduction of energy efficiency are often not imposed by technical or economic reasons but rather by the habits, norms, and mindset of our social institutions, often termed "market barriers." Therefore, apart from increasing research and development (R&D) to create and improve energy-efficient technologies and appliances, one has to address the issue from other angles such as policy-making (Blok et al. 2004), too. The proliferation of energy-efficient technologies requires stimuli outside the scope of technical, and economic, logic arguments.

Also, it has to be noted that the proliferation of technically and economically superior technology is a gradual one (Jaffe and Stavins 1994). Subsidies can have an important effect on the penetration rate of new energy technologies (Lund 2006), as can industry agreements (Grossman and Krueger 1991).

In its most current World Energy Outlook (IEA 2014a), released in November 2014, the International Energy Association (IEA) has compared the "central scenario," a kind of baseline or BAU (business as usual or reference) scenario, to its suggested course of action to control climate change, which is termed "for 2 °C target" scenario. In the WEO 2009, it was called "450 scenario", as a limit of 450 ppm of $CO_{2\text{-eq}}$ in the atmosphere would limit temperature increase to 2 °C. In the reference scenario, worked out for the period to 2040, the world is set for a rise in temperature of up to 6 °C, leading to severe global challenges in terms of irreversible environmental damage and energy security. The notion that energy security can be an issue has existed since the OPEC oil embargo of 1973 (otherwise known as the oil crisis), followed by the second energy crisis 6 years later. It was recently revived in

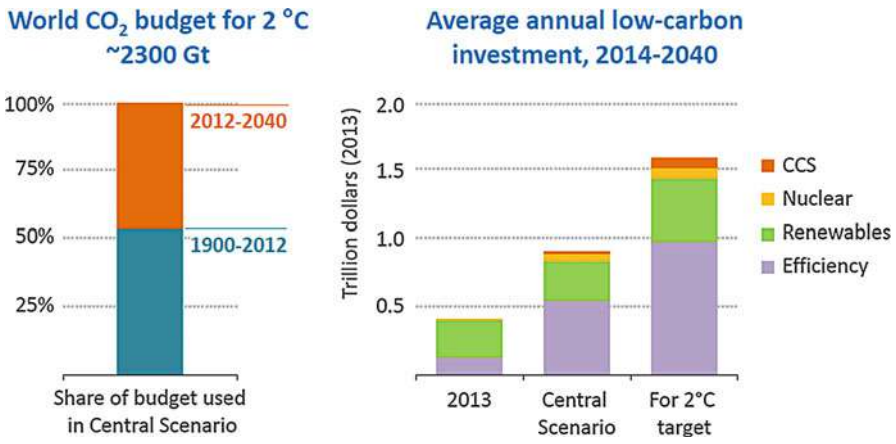

Fig. 1 In the central scenario of WEO's Energy Outlook 2014, the entire global budget of $CO_{2\text{-eq}}$ to 2100 is used up by 2040 (*left*). Investments to achieve the 2 °C target are ~2/3 in the energy efficiency domain (*right*) (Source: IEA 2014b)

Central Europe in the winters of 2006 and 2009 (Gow 2009; Hollinger 2014) due to natural gas supply cuts.

Globally, crude oil prices exceeding for the first time 100 USD per barrel in the same year have also led to concerns about energy security in terms of affordability and sustainability. There is no straightforward definition for energy security. In Kruyt et al. (2009), indicators based on availability, accessibility, affordability, and acceptability were created. With depleting fossil fuel sources and concentration of these in fewer regions, not all of which are considered politically stable, it can be anticipated that fossil fuel prices will go up and will fluctuate more strongly, partly driven by speculation. Today, the world relies to approx. 80 % on fossil fuels for primary energy production.

The IEA "450 scenario" demands for fossil fuel consumption to peak by 2020 and for energy-related CO_2 emissions to be cut from 28.8 Gt in 2007 to 26.4 Gt in 2030 (IEA 2009). In the "for 2 °C target," the world's CO_2 budget is given as 2,300 Gt, of which more than 50 % was emitted from 1900 to 2012; see Fig. 1.

As it can be seen in Fig. 1, the largest contribution to CO_2 abatement – approx. 2/3 – can be made by energy efficiency measures. Another strong contribution comes from changes in the mix of power generation technologies.

Table 1, based on IEA (2009), shows the worldwide energy-related CO_2 emissions.

Similar results, focused on the USA, were found in Granade et al. (2009). As a conclusion, one can say that energy efficiency has a huge potential. In this chapter, several aspects of energy efficiency for climate change mitigation are highlighted. Complete coverage of the topic cannot be provided within the scope of this chapter, so a selection has been made to present some of the most relevant areas related to energy efficiency.

Table 1 Global CO_2 emissions in the "reference scenario" and the "450 scenario" in the 2009 World Energy Outlook of the IEA, compare Fig. 1 (Source: IEA 2009)

CO_2 emissions	1990	2007	2030, reference scenario	2030, 450 scenario
Total	20.9 Gt	28.8 Gt	40.2 Gt	26.4 Gt
Per capita	4.0 t	4.4 t	4.9 t	3.2 t
Power generation	36 %	41 %	44 %	32 %
Transport	22 %	23 %	23 %	29 %
Industry	19 %	17 %	15 %	17 %
Buildings	14 %	10 %	8 %	10 %
Others	10 %	10 %	9 %	11 %

What Is Energy Efficiency

Energy efficiency is, as the term implies, the efficient use of energy, i.e., using a lower amount of energy to achieve the same level of energy service (Patterson 1996). It can be achieved by improved behavior or by more efficient technology.

Thermodynamics teach that energy can only be transformed. According to the first law, energy can neither be created nor destroyed. A change in the internal energy of a system, U, can be achieved by adding heat Q or work W:

$$\mathrm{d}U = \mathrm{d}Q - \mathrm{d}W \tag{1}$$

where $\mathrm{d}Q$ and $\mathrm{d}W$ are incremental changes in heat and work, respectively (the minus denotes that positive work is being done by the system).

Equation 1 can be rewritten as

$$\mathrm{d}U = T\mathrm{d}S - p\mathrm{d}V \tag{2}$$

where the work done by the system during expansion is $p\mathrm{d}V$. The amount of heat added to the system can be described by $\mathrm{d}Q = T\mathrm{d}S$ with T being the temperature and S the entropy. In a heat engine, thermal energy is converted to mechanical energy by exploiting a temperature gradient between a hot and a cold reservoir for an energy transfer. The efficiency of such a heat engine is given by the ratio of useful power to heat energy input. It can be derived as follows:

$$\mathrm{d}W = \mathrm{d}Q_\mathrm{c} - (-\mathrm{d}Q_\mathrm{h}) \tag{3}$$

$\mathrm{d}W = -p\mathrm{d}V$, i.e., the work done by the engine.
$\mathrm{d}Q_\mathrm{h} = T_\mathrm{h}\mathrm{d}S_\mathrm{h}$, i.e., the heat energy taken from the high-temperature reservoir.
$\mathrm{d}Q_\mathrm{c} = T_\mathrm{c}\mathrm{d}S_\mathrm{c}$, i.e., the heat energy delivered to the cold-temperature reservoir.

In the reversible Carnot heat engine cycle ($\mathrm{d}S_\mathrm{c} = \mathrm{d}S_\mathrm{h}$, i.e., no net change in the entropy), the maximum efficiency is

Table 2 Efficiencies of power plants (Source: Curzon and Ahlborn (1975), Callen (1985))

Power plant	Technology	T_c (°C)	T_h (°C)	η (Carnot)	η (endoreversible)	η (observed)
A	Coal fired	25	565	0.64	0.40	0.36
B	Nuclear power	25	300	0.48	0.28	0.30
C	Geothermal power	80	250	0.33	0.178	0.16

$$\eta_{\max} = 1 - \frac{\mathrm{d}Q_c}{\mathrm{d}Q_h} = 1 - \frac{(T_c \mathrm{d}S_h)}{(-T_h \mathrm{d}S_h)} = 1 - \frac{T_c}{T_h} \tag{4}$$

The Carnot efficiency is a theoretical one, because it considers an infinitesimally small temperature change. As for "real" heat engines such as internal combustion engines or power plants, one is typically after a sizeable power output, which is an irreversible process. Therefore, the ideal, reversible Carnot process does not well describe the efficiency of a technical system. Taking the concept of endoreversible thermodynamics (Hoffmann et al. 1997) into consideration, the efficiency of a heat engine operating in irreversible mode can be obtained as

$$\eta = 1 - \sqrt{\frac{T_c}{T_h}} \tag{5}$$

This expression is known as the endoreversible efficiency or Chambadal-Novikov efficiency (Chambadal 1957; Novikov 1958). It allows a more realistic estimation of the efficiency of a heat engine, which can be termed semi-ideal. The endoreversible efficiency takes the destruction of **exergy** in an irreversible process into consideration. Exergy is the highest possible useful work during a process that brings the system into equilibrium with a heat reservoir (Perrot 1998; Dewulf et al. 2008; Demirbas et al. 2000; Wall et al. 1994; Prins et al. 2004). It was introduced by Gibbs as a special form of the Gibbs available energy. Exergy is the **work potential** of a system. It can be potential (gravitational or magnetic force field), kinetic (velocity), physical (pressure, temperature), or chemical (composition) (Dewulf et al. 2008). Exergy analysis can be used to determine inefficiencies.

Table 2, compiled from Curzon and Ahlborn (1975) and Callen (1985), shows the comparison of the Carnot and Chambadal-Novikov efficiencies of three power plants to their actual ones.

From the above table, it can be seen that the endoreversible efficiency predicts the observed one well. In Cullen and Allwood (2010), theoretical efficiency limits for energy conversion devices are reviewed.

The combination of energy efficiency and renewable energy is often referred to as **sustainable energy**. Sustainability was defined in 1983 by the UN World Commission on Environment and Development as follows: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs."

Energy productivity, similar to energy efficiency, has a narrower scope. It is defined as ratio of output divided by energy consumption, e.g., GDP/energy consumption in terms of liter oil equivalent of that economy from its energy balance table (GDP = gross domestic product).

Another aspect related to energy efficiency in the context of climate change mitigation is the concept of **greenhouse gas emission factors**. Apart from CO_2, other greenhouse-active gases can be emitted, such as CH_4, N_2O, or halocarbons. Office of Energy Efficiency, Natural Resources Canada (2002), provides an overview.

There is a huge potential for energy efficiency improvements. Three recent studies on this topic are Electric Power Research Institute (EPRI) (2015) and Granade et al. (2009), making projections until 2020, and IEA (2009), which extends its forecasts to 2030. It needs to be stressed that such impressive potentials can only be turned into reality if significant initiatives are launched. Program costs have to be catered for, too. Different approaches to measure energy efficiency in industry are shown in Phylipsen et al. (1997). Indicators of energy efficiency are discussed in Bor (2008) and Ang (2006). Another important consideration in energy efficiency is the entire life cycle of a product. **Life cycle energy efficiency** (Malça and Freire 2006) not only considers actual use of a piece of equipment but also its production and disposal (see section "Life Cycle Assessment (LCA)" later). **Energy efficiency trading** can only be mentioned here. It is discussed in Mundaca (2009). A detailed overview on energy efficiency is provided in McLean-Conner (2009).

Significance of Energy Efficiency

There is – unfortunately – no such thing as a perpetuum mobile. As a consequence, energy can only be transformed from one form into another one, which happens under certain losses (see also above). Users of mobile phones, notebooks, and any other mobile device will naturally and subconsciously appreciate energy efficiency – because energy is obviously a scarce resource in these applications. Service life and hence usefulness will depend on the efficiency and energy density of the gadget (Mitsos et al. 2007). However, energy efficiency is a much broader topic.

Energy is the leading source of anthropogenic greenhouse gas emissions, approx. 65 % (IEA 2009), and hence needs to be at the core of climate change mitigation actions. In the IEA's reference scenario, the global energy demand is set to increase by 40 % from 2007 to 2030, reaching 16.8 billion toe (IEA 2009). 90 % of this increase is predicted to happen in non-OECD countries, with India and China accounting for half (IEA 2009). Global electricity demand is projected to grow by even 76 % from 2007 to 2030, requiring 4,800 GW of additional capacity. This is five times the existing US capacity (IEA 2009).

In the proposed course of action, the "450 scenario," more than 50 % of all (necessary) energy savings are realized by energy efficiency measures. The target is an energy-efficient and low-carbon economy. By 2050, energy efficiency measures could cut the total worldwide energy consumption by as much as 1/3 (IEA 2009).

Energy efficiency has a large-scale effect. Apart from addressing global warming, energy security and fossil fuel depletion are tackled, alongside solid savings for individuals, enterprises, and nations at large.

Air quality, particularly in urban areas and in developing countries, can also be improved by energy efficiency measures. There are other environmental co-benefits, too, from implementing energy efficiency measures.

By focusing on energy efficiency rather than on increasing energy production, a cost-effective, "soft" energy path is followed. The term "negawatt" was coined two decades ago to describe electricity that "*wasn't created due to energy efficiency*" (Joskow and Marron 1993).

Energy efficiency has been widely recognized as a vast, low-cost energy source (Granade et al. 2009). The reason why this unused potential is so large stems from the multitude of barriers that impede energy efficiency today (Granade et al. 2009; Schleich 2009; Jaffe and Stavins 1994). Unlike the production factors of labor and capital, which have been seen impressive optimization since the industrial revolution, energy is far from being at the lowest possible level.

Energy efficiency has become part of the political agenda in many countries (Al-Mansour et al. 2003). Monitoring energy intensity is common practice since the 1973 oil crisis. How policies can increase energy efficiency is shown in Geller et al. (2006) for the OECD countries (OECD = Organization for Economic Co-operation and Development; 34 member countries, which are considered highly developed) and in Vine (2002) for the state of California, a leading region for energy efficiency as will be referred to in this chapter of the handbook.

For corporations, energy efficiency is an important pillar for the "triple bottom line," i.e., their performance in economic, social, and environmental aspects. Businesses and consumers alike start taking energy considerations into account for decision making. It is estimated that energy is a strategic factor for 40 % of all global revenue (McKinsey & Company, Inc. 2009). Unpredictable volatility in fuel prices, driven by depletion of crude oil and speculation, places a burden on companies and economies as a whole, which they feel needs to be controlled. Stern (2007) provides an overview on the economic aspects of climate change. With energy efficiency being the easiest way to save energy, it is highly relevant to mitigate climate change effects and their detrimental consequences.

Benefits of Energy Efficiency

Energy efficiency offers several direct and indirect benefits, some of which are obvious. The reduction of pollution and greenhouse gas emissions aids the environment. For businesses, reduced energy bills will translate into competitive advantages. Also, energy efficiency measures can lead to higher worker productivity and reduced sick leave rate (Granade et al. 2009) as concurrent benefits. Consumers can enjoy increased comfort levels (Jaffe and Stavins 1994), particularly those living in low-income households. Indirect benefits, as an example, also related to health (less drafty and damp rooms after the implementation of energy efficiency measures in

private homes such as insulation upgrading). As a nation, a key benefit is an improvement in energy security, another one that reduced exposure to volatility in energy prices. There has also been a wide discussion on job creation by the quest for energy efficiency. While it is true that energy-intensive production processes are shifted toward developing countries, leading to job losses in countries of the European Union and the USA, for instance, there should be a net positive effect from the job market stimuli provided by energy efficiency. For instance, the market for building insulation is estimated at 10–12 billion USD for the USA alone (Granade et al. 2009).

An overview on the market size for energy efficiency in the USA is provided by Ehrhardt-Martinez and Laitner (2008).

Some considerations on actual and potential job creation by energy efficiency improvement programs are provided by Granade et al. (2009), where the potential for the USA is estimated to lie between 600,000 and 900,000 jobs over the next decade in direct, indirect, and induced jobs.

Energy efficiency will not be the sole solution. There will still be a need for new, additional power plants, partly to meet increased demand, partly to replace old ones. Also, there might be additional demand that is now unaccounted for, e.g., to power electric vehicles (Granade et al. 2009) that are likely to replace traditional cars to some extent. A national commitment to green buildings has the potential to generate 2.5 million and to support 8 million American jobs (US Green Building Council 2015), with similar prospects being offered in other countries. The job market potential of clean energy is reviewed in Wei et al. (2010).

Downside of Energy Efficiency

While energy efficiency as such is indisputably a good thing, there are several aspects that have to be considered to avoid detrimental overdoing. First, the **economics** have to be considered. In a competitive landscape, corporations will only implement energy efficiency measures that "pay for themselves" (see also later). High upfront investments are one of the barriers toward better energy efficiency. Apart from costs, **complexity** is another aspect to consider. In order to improve the efficiency of a plant or an engine, advanced control systems are required, which need to be maintained. Capable technicians and additional resources have to be provided to that end. The most economic process might not be the most reliable one. As **operability** of technical equipment, particularly in the capital-intensive process industry, is of utmost importance, some concessions to energy efficiency are sometimes well accepted from a process point of view. For many production plants, 1 day of additional, unplanned shutdown per year will mean the difference between profit and loss. Also, plant personnel might focus on other aspects than energy efficiency when operating a unit or equipment (Moore 2005) to safeguard "trouble-free" operation or simply be too busy to concentrate on continuously optimizing energy usage. Another extreme, hypothetic example of an inefficient energy saving attempt

would be a person having an accident at home because of not turning on the light when fetching something from the cellar or during the night.

For these reasons, it might happen and even be advisable not to squeeze out the last bit of energy efficiency from a given system, but rather to act with commonsense.

Energy Efficiency Versus Energy Demand: The Rebound Effect

The effect that energy efficiency improvements on the microlevel (i.e., machines and individual plants in industry) do not fully translate into the expected energy savings on the aggregate level (such as the economy) is termed **rebound effect** or **Jevons paradox**. It is also called the **Khazzoom-Brookes postulate**. The rebound effect can be direct or indirect. If it is >100 %, it is called "backfire" (Sorrell 2009). Simply put, energy efficiency makes energy services cheaper, so demand tends to increase. This concept is called "elasticity of demand." A more economic car might tempt its owner to drive faster and further, thus partially offsetting potential energy savings. A car producer can decide to install more electronic devices for increased driver comfort in a car that has been made more fuel efficient, thanks to the use of lightweight construction materials and a better engine.

The extent of the rebound effect depends on the elasticity of demand, which tends to be stronger with consumers than with industrial plants (Sorrell 2009).

William Stanley Jevons studied the rebound effect during the industrial revolution (Sorrell 2009). In his 1865 book *The Coal Question* (Jevons 2008), he was pondering over the question whether efficiency measures would really lower actual coal consumption, based on empirical evidence that after efficiency improvements with steam engines and in steel production, the actual energy consumption had soared. For more information, see Saunders (1992) and Herring and Sorrell (2009).

Energy Intensity

Intensity is an ambiguous term. In physics, it is power per unit area [W/m^2], a time-averaged energy flux. In heat transfer, intensity commonly denotes the radiant heat flux per unit area per unit solid angle [$W \cdot m^{-2} \cdot sr^{-1}$].

Here, energy intensity is an economic concept as a measure of the energy efficiency of a nation's economy. It is calculated as units of primary energy consumption per unit of GDP or value added, measured in [MJ/$] or [toe/$]. The energy intensity of a country is influenced by many factors, for instance, the climate. Economic productivity and standards of living contribute as well as the energy efficiency of buildings and appliances, traffic patterns (public transportation vs. individual cars), and the way energy is being produced (EIA 2015).

Energy intensity can hence be used as a surrogate for aggregate energy efficiency. Countries differ strongly by energy intensity, and within countries, there are marked differences amongst regions. In the USA, a state with superior energy efficiency

performance is California, which has established leadership in, e.g., per capita energy consumption (Rosenfeld 2008; Vine et al. 2006). The energy efficiency of different countries is assessed in Utlu and Hepbasli (2007). The term "energy intensity" can also be applied to a production process as a synonymous expression for specific energy consumption, based on quantity [kg] or value added [$] or [€]; see also section "Energy-Intensive Industries."

Emission Intensity (Carbon Intensity)

Another concept is the emission intensity. It is the average emission rate of a given pollutant from a given source related to the intensity of a specific activity, e.g., grams of CO_2 per MJ of energy produced [g/MJ]. The term emission intensity is often used interchangeably with "**carbon intensity**" and "**emission factor**" in the climate change discussion. Other greenhouse gases and pollutants can be considered, too, by calculating CO_2 equivalents (CO_2-eq). Table 3 provides an overview on emission intensities, compiled from Bilek et al. (2008).

The subscripts in Table 3 stand for "thermal" and "electric." In combined heat and power (CHP, cogeneration), both heat and power are produced from a combustion process, boosting overall efficiency (see later).

Historical Development of Energy Efficiency

A proverb says "Things that cost nothing have little value." In this sense, as long as easy access to energy is available, there are few incentives to use it wisely. History tells several lessons here. Visitors to Greek islands will witness testimony of one such unsustainable practice exercised centuries ago, i.e., chopping down trees to build ships without reforestation. There are countless other examples of unsustainable acts related to resource and energy efficiency in the past, some of which have even led to the extinction of a local human population (Bologna and Flores 2008). The global oil crises in the 1970s were an event that has triggered several measures for energy efficiency on a large scale, e.g., the creation of the DoE (Department of Energy) in the USA. In the following decade, when crude oil prices

Table 3 Emission intensities (Source: Bilek et al. 2008). The ratio of H/C is 4 in natural gas, which is higher than in oil and especially coal, leading to lower CO_2 emissions per kWh

Fuel/resource	Electric g(CO_2-eq)/kWh_e
Coal	863–1,175
Oil	893
Natural gas	587–751
Nuclear power (U)	60–65
Hydroelectricity	15
Photovoltaics	106
Wind power	21

went down again, there was reduced motivation to focus attention on energy efficiency in many areas. The industrial sector has improved its energy efficiency continuously over the last 30 years, partly in order to reduce variable production costs and to improve competitive advantage (one also has to take into account that a significant part of energy-intensive production facilities was transferred to low-labor-cost countries in, e.g., Asia). Economic growth, a trend toward increased personal mobility and toward larger homes and the use of more and more appliances, amongst others, has led to a steady increase of absolute energy demand in most industrialized countries.

As a result, the overall energy intensities in the USA have declined as follows between 1980 and 2005 (Granade et al. 2009):

Residential sector	−11 %
Commercial sector	−21 %
Industrial sector	−42 %

While the national per capita energy consumption in the USA has grown by 1.3 % per year from 1977 to 2007, which means a doubling, it remained almost constant in California.

In the EU, the average efficiency of gas-fired power plants has increased from 34 % in 1990 to 50 % in 2005 and is expected to increase to 54 % by 2015 (Graus and Worrell 2009). For coal-fired power plants, the efficiency, also based on the lower heating value, went up from 34 % in 1990 to 38 % in 2005 and is expected to increase to 40 % by 2015. These trends are visualized in Fig. 2.

As the developed world has built its industry, specific energy consumption was constantly improved. Yet the largest share of historic and current global emissions comes from developed countries. Many people now fear that while other countries race through their development, they might expel "their share," i.e., high amounts of pollutants, into the atmosphere. China, for instance, has been able to maintain economic growth of greater than 9 % from 1980 to 2000, while the energy demand only increased by 3.9 % per year (Lin 2007). This shows that energy demand does not necessarily have to outpace economic growth during the early stages of industrialization and development (Lin 2007).

A word of caution: Many scientific publications, as well as the public opinion, believe in decreasing energy intensity over time. This hypothesis is often only an assumption, which needs to be proven. In Le Pen and Sévi (2010), the authors conclude that many energy efficiency trends on a national level follow a stochastic nature; see Fig. 3.

In Schipper et al. (2005), historic developments and future trends of energy efficiency are discussed. Megatrends (Naisbitt 1985) will also have an impact on energy efficiency. How they are perceived can differ strongly (Atilla Oner et al. 2007).

In general, there have been strong improvements in certain areas with respect to energy efficiency, some of which were countered, though, by rebound effects.

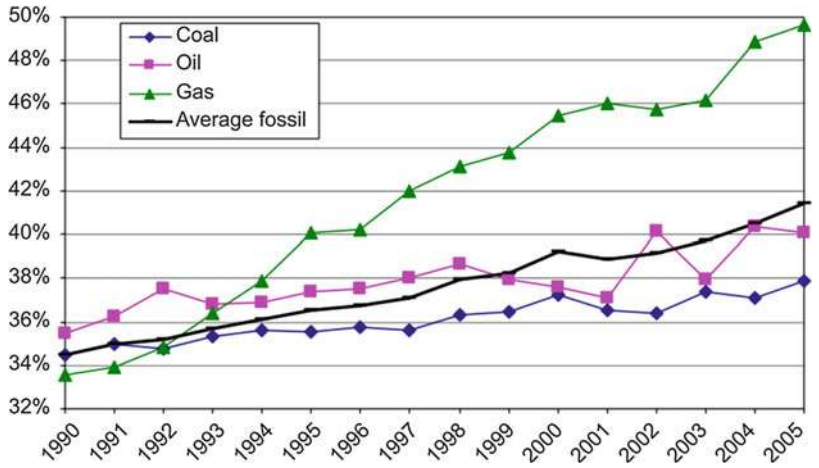

Fig. 2 Energy efficiency trends of fossil fuel combustion in the EU27 (Reprinted with permission from Elsevier from Graus and Worrell (2009))

Assessing Energy Efficiency Improvements

Energy efficiency improvements can be achieved by technological progress or by changes in behavior. They can be measured.

However, for a correct assessment, the following factors have to be taken into account:

- Erosion of part of the improvements by the rebound effect (see above)
- Comparability of data (same year, same boundary conditions)
- Selection of a proper baseline

The baseline for measuring energy efficiency is of utmost importance to avoid wrong conclusions. This is elaborated with an example from the transportation industries below, viz., the fuel consumption of aircraft over time. Figure 4 shows a data compilation of how fuel efficiency of commercial aircraft was improved over the last decades.

Taking the Comet 4 as a baseline, fuel consumption was reduced by 70 % in modern aircraft. Approx. 40 % of the improvements are attributed to engine efficiency improvements, and 30 % to airframe efficiency improvements (IPCC 2000).

The **de Havilland Comet** was the world's first commercial jet airliner (Davies and Birtles 1999).

Figure 4 was taken from an IPPC report. The IPCC (**Intergovernmental Panel on Climate Change**) is a renowned, scientific intergovernmental body established to evaluate the risk of climate change caused by human activity (Intergovernmental

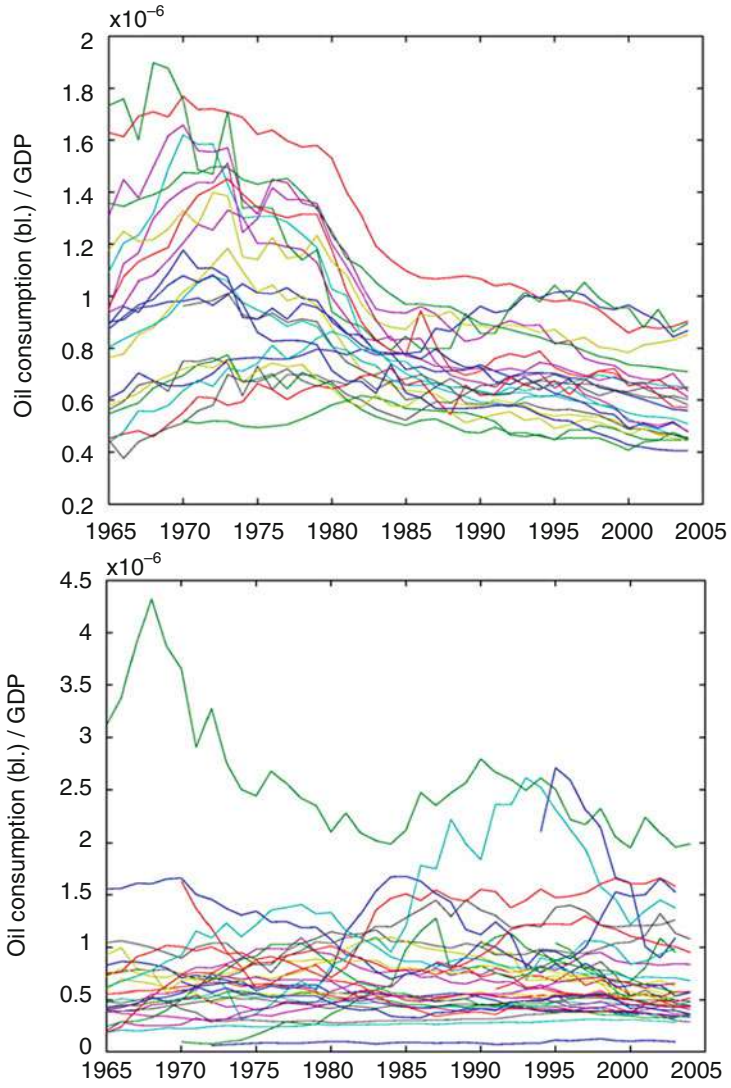

Fig. 3 Stochastic movement of energy consumption. *Left*: oil consumption per unit of GDP for OECD countries from 1965 to 2005. *Right*: same data for non-OECD countries (Reprinted with permission from Elsevier from Le Pen and Sévi (2010))

Panel on Climate Change (IPCC) 2015). It was awarded the 2007 Nobel Peace prize together with Al Gore. In Peeters et al. (2005), the authors argue that the pre-jet era was ignored in the above IPCC discussion and that the Comet 4 is an unsuitable baseline. From the conclusions of that report (Peeters et al. 2005):

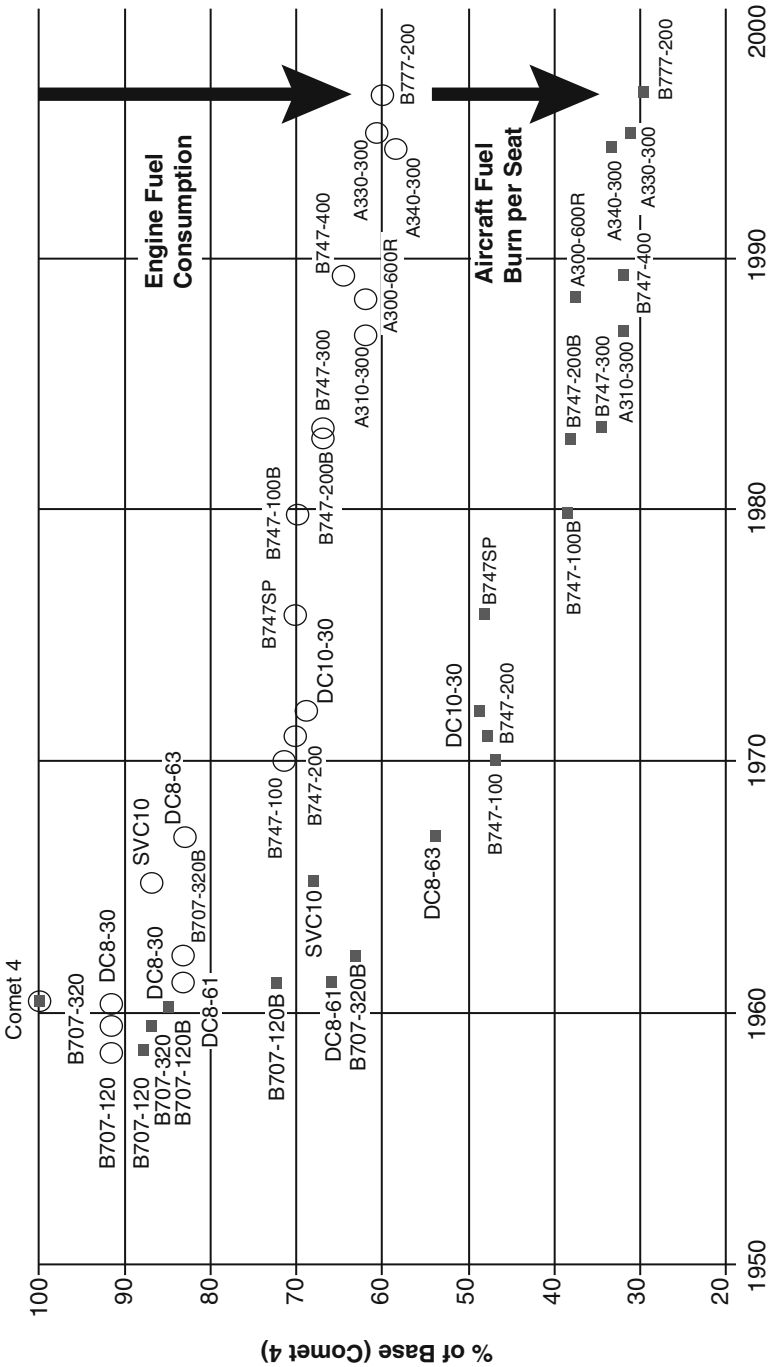

Fig. 4 Fuel efficiency of commercial aircraft over the last 50 years. See text for details. Reprinted with permission (Source: IPCC 2000)

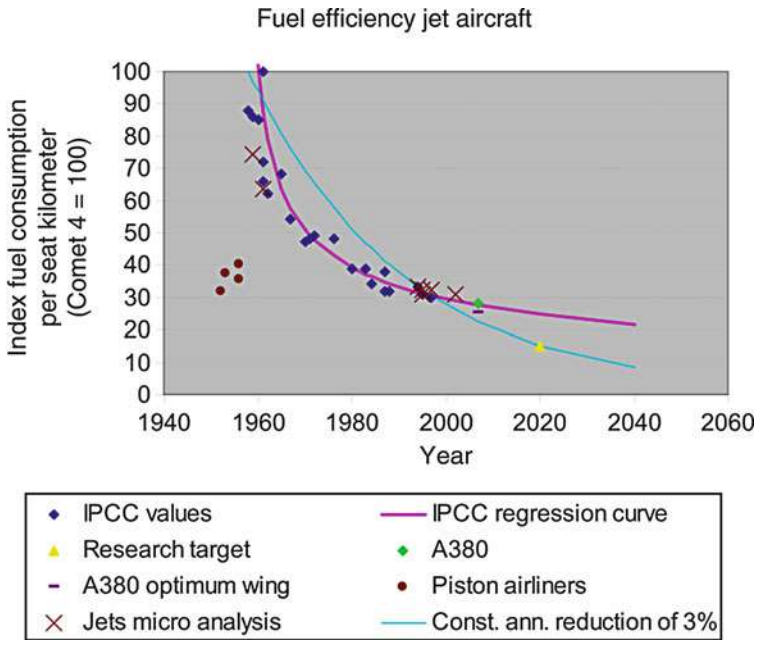

Fig. 5 IPCC graph with additional data (Reprinted with permission from Peeters et al. (2005))

> The later piston-powered airliners were at least twice as fuel-efficient as the first jet-powered airliners; If, for example, the last piston-engine aircraft of the mid-fifties are compared with a typical turbojet aircraft of today, the conclusion is that the fuel efficiency per available seat-kilometre has not improved. . .. The last piston-powered aircraft appear to have had the same energy efficiency per available seat-kilometre as average modern jet aircraft. The most modern jet aircraft (such as the B777-200 or B737-800) are slightly more efficient per available seat-kilometre.

The findings from this study are depicted in Fig. 5.

As it can be seen in Fig. 5, slight changes in the assumptions will lead to strong deviations in the results. This has to be borne in mind when assessing and comparing energy efficiency studies presented by various interest groups.

Innovation and New Technologies for Energy Efficiency

In order to increase energy efficiency, innovation (Christensen et al. 2001) is needed. By innovation, either of the following energy efficiency improvements can be achieved:

- Carrying out the same task or process with less energy
- Utilizing the same amount of energy to produce more output or higher value
- Redefining the task or process so that the new way consumes less energy

Innovation can take place in incremental steps or in a disruptive way, when a new technology is developed, for instance. The electric light bulb, being condemned as energy inefficient today, was one such disruptive innovation, which has been around for more than a century. So in order to innovate, engineers and researchers might be tempted to search and build more knowledge in their own area of expertise and to innovate as much as possible in their very own fields. This strategy has proven successful – take the famous Bell Labs (Gehani 2003) as an example. Fifty years ago, the Bell Labs were generating every new technology that the telephone business needed, and the telephone business, in turn, was using all of Bell Labs' innovations. Bell Labs were virtually unbeatable. However, the rules of innovation have changed somehow over time. The Bell Labs invented the transistor, which clearly is one of their greatest discoveries. However, Bell Labs did not recognize the value of the transistor, and they gave it away for little money. The transistor, hence after, was extremely successful, but with the main use not being in the telecommunications industry. On the other hand, the very innovation that revolutionized the telecommunications industry – the fiberglass cable – was developed outside that industry. This phenomenon has been observed in many industries over the last 50 years (Drucker 2003) – the major innovations with the biggest impact for an industry are not likely to come out of the industry itself but will rather be "born" in a different area.

The significance of this development for the realm of energy efficiency is as follows: Energy efficiency can be improved in many ways. In a passenger car, for instance, an advanced engine, lightweight plastics components instead of steel or tires causing less rolling friction will all serve the same final purpose of energy efficiency.

Innovation takes time until its full potential is being realized, though. In Lund (2006) the market penetration rates of new energy technologies were studied. It is concluded there that the time for a takeover of market share from 1 % to 50 % varies from less than 10 years to 70 years, with takeover times below 25 years being associated with end-use technologies. Long investment cycles render the energy production industry inert to change.

Typical Energy Efficiencies

The energy of photosynthesis is on the order of 1 %, with a fraction of approx. 0.2 % being stored as biomass. Sugarcane exhibits peak storage efficiencies of up to 8 % (Hall and Rao 1999). The first steam engines, designed as external combustion engines, had efficiencies on the same order of magnitude.

To visualize the energy balance, i.e., the energy efficiency, of a process or machine, a Sankey diagram can be used. For exergy, Grassmann diagrams (Hinderink et al. 1999) are deployed (though both terms are sometimes used interchangeably in the literature).

An example for a Grassmann diagram for nitric acid production is shown in Fig. 6 (Hinderink et al. 1999).

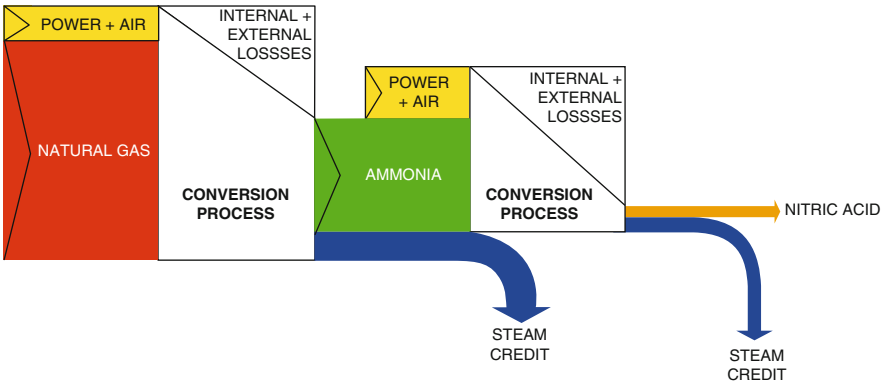

Fig. 6 Simplified Grassmann diagram for the production of nitric acid (Hinderink et al. 1999) (Reproduced by permission of the Royal Chemical Society (*RCS*))

The Grassmann diagram can be seen as an energy flow diagram, visually explaining which fraction of the total, initial energy ends up in the final product.

In order to obtain typical energy efficiencies, or reference energy efficiencies, a benchmark is deployed. The benchmark in energy efficiency is given by the state-of-the-art and so-called BAT (best available technology) values. However, BAT values are often difficult to obtain, as corporations tend to keep them secret and patents do not always provide full disclosure.

The energy efficiency and carbon intensity of a given process depend on the system boundaries that are considered and on the energy path. For instance, whether electricity for a hybrid car has been produced in a coal-fired power plant or by solar cells will heavily impact the overall efficiency (see also section "Life Cycle Assessment (LCA)").

Actual efficiencies will depend on a large number of factors such as the condition of a given system or appliance. Examples are the load of an engine, maintenance on motors, and usage patterns. This is obvious for every car owner who wants to reach the "official" fuel consumption of his/her car.

When energy efficiency potentials are presented in the literature, one has to be careful not to overestimate or mix up the various potentials, which are:

- Technical potential
- Economic potential
- Maximum achievable potential (considering factors such as demographics, market conditions, and regulatory factors)
- Realistic achievable potential (taking historic data into account)

People adapt to change at different rates. Take popular technologies as an example. Even for microwave ovens and mobile phones, it took 10–15 years for market penetration. Therefore, the realistically achievable potential is never equal to

the full technical potential. Also, the effort to obtain a large part of any potential saving will increase along the way.

For energy efficiencies of various technologies, processes, and appliances, the reader is referred to the respective chapters of this handbook and to the specialized, referenced literature.

Benchmarking of Energy Efficiency

There are no useful reference data for absolute energy efficiency from a thermodynamic or theoretical point of view. Rather, one can only compare a given process or technology route, device, or method to other solutions in the lab or in the field, so that the best available technology (BAT) or state of the art can be determined empirically. Such a benchmarking exercise focused on energy efficiency will yield interesting results. In Phylipsen et al. (2002), for instance, it was found that the energy consumption of the steelmaking plants in several countries was 25–70 % above the best plant. In the cement industry, the average consumption was 2–50 % higher than the very best plant energy efficiency.

Benchmarking can be used by operators of industrial plants to compare their energy efficiency, and ultimately their competitiveness, to that of their contenders.

Consumers can use relative indications of energy efficiency, such as the Energy Star® label, to easily spot energy-efficient appliances as a guide for purchase decisions.

It needs to be mentioned that comparing like with like is crucial. If, for instance, steelmaking plants in two countries are to be compared, sectoral differences must be taken into account (Phylipsen et al. 2002) (if, e.g., there is plenty of secondary steel available, energy efficiency will "automatically" be higher). Also, regional differences in feedstock quality (Worrell et al. 2000a) or climatic conditions will affect the energy efficiency of a given plant. More information of reliable reference data for energy efficiency comparisons on a national level can be found in Doukas et al. (2008).

In mature industries, energy efficiency differences from plant to plant are not expected to be very large, because improvements tend to be incremental.

Generally, there is a lack of energy efficiency benchmark standards for industry at large and factories in various sectors (Yang 2010), secrecy and antitrust legislation being important impeding factors. There exist corporate benchmarks in some companies that operate multiple plants or sites. Several consultants carry out benchmarking studies in various industries, e.g., Solomon Associates for steam crackers, Phillip Townsend Associates for polymerization plants, Plant Services International for ammonia and urea plants, and PDC (Process Design Center) for more than 50 petrochemical processing plants (The International Energy Association in Collaboration with CEFIC 2007), to cite a few examples. These benchmarks present generalized and anonymized data with which the energy efficiency and the competiveness of one's own plant can be compared to the industry average.

Energy Efficiency World Records

A world record in energy efficiency of a car was set in 2005 as 5,134 km per liter of gasoline equivalent, operating on a hydrogen-powered PEMFC (polymer electrolyte membrane fuel cell) (Santin 2005) during the Shell Eco-Marathon. It challenges students around the world to design, build, and drive the most energy-efficient car and has three annual events in Asia, America, and Europe. On the website of the competition (Shell Eco Marathon 2015), additional records on energy efficiency are highlighted, e.g., an equivalent of 3,771 km with 1 l of fuel with a combustion engine-powered car in 2009 (5 years earlier, the record was 3,410 km). These figures, equally impressive and irrelevant for current practical road transportation, show that there is plenty of potential left to increase energy efficiency, even beyond current imagination.

Some Not-So-Energy-Efficient Inventions and Practices

Here are some examples of low-energy-efficient appliances and habits, most of which might soon astonish people that they even existed in our times:

- Incandescent light bulbs
- Huge private cars such as SUV with single occupancy
- Standby function on electrical appliances in households
- Patio heaters to warm open areas outside the house
- Melting snow in cities such as New York City to dispose of it
- Flaring of hydrocarbons in petroleum refineries
- Room temperature regulation by opening and closing a window, while keeping the heater switched on
- Water ring pumps to produce an industrial vacuum

In a typical household, appliances on standby use up 10 % of the total amount of electricity consumed. This is equivalent to 400–500 kWh annually, virtually wasted with no energy service rendered.

Barriers to Energy Efficiency

There is no doubt about the fact that energy efficiency offers cost-effective energy savings. However, the full potential has barely been tapped into. There are several barriers, associated with financial limitations, uncertainty, or others. They can also be classified as structural and behavioral and related to availability (Granade et al. 2009).

Though businesses and households are responsible for implementing most energy efficiency investments, it is their governments to provide the right bordering conditions to catalyze investments in energy efficiency by offering tax incentives,

Table 4 Estimated persistence of energy efficiency measures (Source: Climate Action 2015)

Years following implementation (installation)	Remaining energy efficiency impact	
	Electricity-related measures (%)	Fuel-related measures (%)
1	99.69	100
2	95.97	99.46
3	89.59	98.51
4	85.14	97.84
5	84.02	97.11
6	78.32	89.75
7	78.22	89.75
8	78.22	89.75
9	74.58	89.70
10	66.73	87.45

education, or other facilitation. One reason why the potential for energy efficiency has not yet been realized to its full extent is the fact that high upfront investments are often necessary, whereas the savings accrue incrementally over the subsequent years (Granade et al. 2009). Also, the energy efficiency improvement potentials are highly fragmented (Granade et al. 2009). Apart from low awareness, the difficulty to measure energy efficiency improvements in several areas contributes to slow progress. Barriers to energy efficiency are discussed in Granade et al. (2009), alongside the following potential actions to break down these barriers:

- Information and education
- Incentives and financing
- Codes and standards

Experience shows that consumers are particularly hostile toward funding of energy efficiency measures, compared to businesses, even if the economics are reasonable. They apply hyperbolic discounting, meaning that immediate value is regarded significantly higher than future one.

Barriers toward energy efficiency improvements in industrial settings are reviewed in Schleich (2009).

Another interesting question is the durability of energy efficiency measures, which was studied in Climate Action Team (2015), the results of which are given in Table 4.

The percentages in Table 4 reflect the portion of the first year energy savings that remain throughout the full lifetime of the studied energy efficiency measures. A distinction was made between measures focused on saving electrical energy and measures to save fuel. It can be seen that already after a few years, considerable losses from the initial gains are encountered, which can be explained by various factors depending on the efficiency measure. "Hard-wired" energy efficiency initiatives will generally be lasting longer than those based on behavioral changes (see also below).

An example on how energy efficiency can stagnate if the economic and organizational conditions are not in favor of it, such as prevailing low electricity prices, is shown for the Swedish building industry in Nässén and Holmberg (2005) and Nässén et al. (2008).

Aspects of financing energy efficiency, another prominent barrier, are outlined in Taylor et al. (2008), Lee et al. (2003), Jechoutek and Lamech (1995), and Clark (2001). Barriers to energy efficiency in general are reviewed in Sorrell et al. (2004).

Levels of Energy Efficiency: From Process to Behavior

Energy efficiency can be achieved by various means.

A product can be manufactured in a way that energy is used efficiently, either during its production or during its use. A process can be energy efficient by itself, or it can produce energy-efficient outcomes. The same applies for services. Here are some examples of more and less efficient products and processes:

- Office lighting by compact fluorescent lights/LED versus traditional incandescent light bulbs
- Modern compact passenger car versus older, mid-sized model
- Cement production by the dry process versus the wet process
- Air separation by pressure swing adsorption versus air separation by cryogenic air cooling and fractionated distillation
- Steel manufacture from scrap metal versus ore

It is desirable to have efficient equipment and processes in place. However, these can be operated in very inefficient ways. The magnitude of loss in energy efficiency by "bad" operation can be as large as the difference between competing processes and equipment items (Moore 2005). Some examples of these "bad" operation aspects are:

- Excessive speeding with a car, which strongly increases fuel consumption/km
- Neglected maintenance on insulation of window frames in a private home
- Keeping office lights on overnight when they are not needed
- Operating plant utilities at full capacity during idle production times
- Not repairing leakages on compressed air pipelines

In contrast to the installation of new, more energy-efficient equipment, or the design of a more energy-efficient process, operation thereof requires constant attention (compare also the table above, showing the stunning erosion of energy efficiency gains over a few years' time). By continuously working on a mindset toward energy efficiency, for instance, by having employees turn off idle equipment and by fostering continuous improvement, also small, individual savings can add up.

In Moore (2005), some aspects of why operators in control rooms do not always give utmost importance to energy efficiency are listed:

- Lack of urgency, little incentives to value long-term performance versus the short term
- Preference of steady-state operation versus short-term optimization efforts
- Comfort, trading economy against less effort
- Individual work history and anecdotes making risk perception highly personal
- Different levels of skills and knowledge
- Instinct to preserve assets rather than maximize their utilization
- Little effect of administrative control measures alone
- Focus drift due to distraction

The most economic mode of operation of a plant in the process industries, for instance, is not always the most convenient one (Moore 2005). This will lead operators to at least partly refrain from energy efficiency optimization.

Such "human factors" can be improved by considering the **usability** of processes and equipment. Whereas the usefulness of a man-made tool or installation is related to user satisfaction, the term us(e)ability denotes the ease with which it can be deployed. In general, usability can be defined as a measure of the ease with which a system can be learned or used; its safety, effectiveness, and efficiency; and attitude of its users toward it (Jordan et al. 1996). In Nachreiner et al. (2006) and Nishitani et al. (2000), two examples of the successful application of usability and **usability engineering** in process control systems and industrial plants are given.

Energy Efficiency Investments

As energy-efficient technologies often have higher initial investment costs than older, less advanced ones, economic considerations will determine the extent to which energy efficiency is considered for new investments and for retrofits alike. The TCO (total cost of ownership) approach will clearly recommend energy efficient, but typically more expensive installations, in many cases. Investing in "the right technology," if it is not supported by a sound business case of yearly energy bill savings, will be easier during the construction of a new building or factory than when one wants to apply for funds, corporate and federal alike, later on. In industry, one can distinguish between:

- Pure capacity investments
- Pure energy efficiency investments
- Hybrid capacity and energy efficiency investments

Common appraisal methods for investment projects in industry are:

- Payback period
- Net present value (NPV)

- Internal rate of return (IRR): discount rate where NPV = 0
- Strategic fit

Approval can be based on an evaluation of several of these parameters, by a ranking or by fulfilling a certain cutoff criterion. To test the validity of the profitability calculation of such a project, a sensitivity analysis can be carried out by varying the most important parameters. Monte Carlo simulation enhances the quality of such simulations (Lackner 2007). Real options (Rugman and Li 2005) can also be used. While debottlenecking investments, which increase production capacities, usually have short payback periods and high IRRs, often exceeding 50 %, energy efficiency investments sometimes cannot make it over the 10 % hurdle. If the funds for investment projects are limited, naturally those with higher IRR will be preferred. Energy efficiency investments can be carried out at a lower IRR than a corporation's normal hurdle rate (IRR), because the associated risk is generally lower than for a capacity investment (energy savings can be predicted more reliably).

Often, when "selling" an energy efficiency project in a corporation, one had to better avoid the term "energy" and describe potential projects as "efficiency" or "productivity" improvement projects when presenting them to decision makers.

Energy has a different importance for various sectors. Those industries which are energy intensive will suffer more from high and volatile energy prices than the ones incurring only a small percentage of their costs from energy bills. It is estimated that out of the total global economic activity (according to the International Monetary Fund (IMF) US$77.609 trillion (GDP) or US$106.998 trillion (purchasing power parity, PPP) for 2014), 40 % comes from companies where energy plays a strategic role (McKinsey & Company, Inc. 2009). The sectors concerned are transportation, building and construction, energy-intensive industries, engineering, IT (information technology), and the energy industry. For companies in these sectors, energy can have a direct or indirect effect, i.e., on their own production costs or on the acceptance of their products.

On the other side, there are industries, such as education, retail, insurance, and healthcare, which do not depend as much on energy competitiveness.

Introducing Energy Efficiency Programs

It is estimated that most organizations have a potential for 10–20 % energy efficiency improvement, which will materialize in the bottom line. In order to improve energy efficiency in a company or another larger institution, an **energy survey** or an **energy audit** can be a first step to map out the saving potential. More information on such energy audits can be found in Sustainable Energy Ireland (SEI) (2015) and Carbon Trust (2015). They consist of data collection ("hard facts" such as electricity consumption and interviews on common practices) and internal and external benchmarking. There is currently a lack of qualified energy auditing staff (Yang 2010). Checklists can help to uncover inefficiencies in processes and equipment.

In the EU, Directive 2012/27/EU of 25 October 2012 on energy efficiency has introduced compulsory energy audits for large corporations in an attempt to foster energy consumption reduction.

Using off-peak hour electricity is an option to shrink the electricity bill. How to manage energy efficiency in a corporation is described in Russell (2009). To which extent agreements foster energy efficiency is analyzed in Rietbergen et al. (2002).

Combustion

Combustion plays a critical role in energy efficiency considerations, as approx. 80 % of global primary energy is produced by combustion processes. Combustion processes have the single largest human influence on climate with 80 % of anthropogenic greenhouse gas emissions (Quadrelli and Peterson 2007). Fuels can be fossil or renewable (biomass). They are gaseous, liquid, and solid.

Combustion is used in power plants for electricity and heat production, transportation, and other areas (see sections below for details). Figure 7 shows the global trend in CO_2 emissions over the last 140 years (source: Quadrelli and Peterson 2007).

As it can be inferred in Fig. 7, the increase in anthropogenic, combustion-derived CO_2 emissions has almost been an exponential one. For the impact on climate change, not only the efficiency of a combustion process itself but also emissions generated during fuel production and transportation have to be considered. For instance, for every kg of mined coal, 1.2–16.5 g of the greenhouse gas methane (GWP = 21) are emitted (Office of Energy Efficiency, Natural Resources Canada 2002).

Combustion can be carried out in furnaces (see section "Power Plants and Electricity Production" below) and boilers, in internal and external combustion engines, and in gas turbines (Pilavachi 2000; Boyce 2006; Farzaneh-Gord and Deymi-Dashtebayaz 2009).

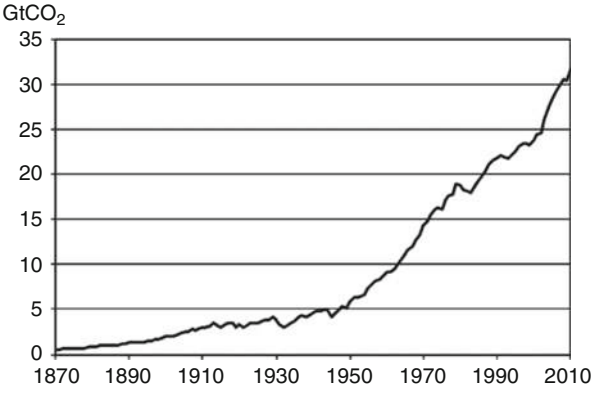

Fig. 7 Trend in CO_2 emissions from fossil fuel combustion (Source: Carbon Dioxide Information Analysis Center, Oak Ridge National Laboratory, US Department of Energy, Oak Ridge, TN, USA). Units: Gigatons of CO_2 (Reprinted with permission from International Energy Agency (2014))

Pyrolysis and gasification are special cases of combustion. These processes can be used to obtain gaseous or liquid fuels from biomass or coal in conjunction with a Fischer-Tropsch (van Vliet et al. 2009; Prins et al. 2004) or other synthesis processes. Due to the removal of moisture and ash and the effect of deoxygenation, liquid hydrocarbons derived from biomass have a threefold energy density and are hence more advantageous for transportation and storage (Demirbas et al. 2000). See also chapter "► Gasification Technology" in this handbook.

Heat recovery from flue gases is a particularly energy-efficient measure. For steam systems, for instance, 1 % of fuel can be saved for every 25 °C reduction in exhaust gas temperature (Galitsky 2008).

In Quadrelli and Peterson (2007), recent trends on CO_2 emissions from fuel combustion are reviewed. For combustion in general, see Lackner et al. (2010) and Lackner et al. (2013).

Power Plants and Electricity Production

12 % of man's total energy is made up by electricity, a fraction that is expected to rise to 34 % until 2025 (Ibrahim et al. 2008).

Energy efficiency in electricity production can be defined as the energy content of the produced electricity divided by the primary energy input, with reference to the lower heating value (Graus and Worrell 2009).

The lower heating value (LHV, or net calorific value) assumes that the water formed in combustion remains as vapor.

In **cogeneration**, the overall efficiency can be increased, because the (by-product and formerly waste) heat is used. Cogeneration is also dubbed **CHP** (combined heat and power).

Power production is carried out by (large) public power and CHP plants and by so-called **autoproducers**. These are users such as chemical factories which produce their own power and heat. In the EU, autoproducers account for 8 % of the total power generation (Graus and Worrell 2009). Electricity production plants have an efficiency of around 30–40 %, whereas combined heat and power (CHP, cogeneration) yields up to 90 % (Office of Energy Efficiency, Natural Resources Canada 2002). For the installed base of CHP, see CHP Installation Database (2015).

In the EU, the energy efficiencies for coal-fired power production range from 28 % (Slovak Republic) to 43 % (Denmark). On a global scale, the spread for oil-fired power plants is an efficiency of 23 % for the Czech Republic and 46 % for Japan (Graus and Worrell 2009).

The efficiency of a given power plant is dependent on its age. The younger a plant, the higher its energy efficiency was (intuitively) found to be (Graus and Worrell 2009). These findings are in line with another study (Phylipsen et al. 2002), which revealed that the least energy-efficient plants are not always located in developing countries. Apart from the age of a plant, its fuel mix, size, and load account for the big differences in efficiencies mentioned above (see also section "Cross-Cutting Technologies" below).

State-of-the-art power plants based on coal and gas have energy efficiencies of 46 % and 60 %, respectively (Graus and Worrell 2009).

It is estimated that the replacement of inefficient coal-fired power plants by more efficient coal- or gas-fired ones, particularly in China and in the USA, can reduce global CO_2 emissions by 5 % (IEA 2009). In Canada in 1988, according to the Canadian Industry Program for Energy Conservation (CIPEC), the average CO_2 emissions in electricity production were 0.22 t/MWh, with a spread of 0.01 in Quebec to 0.91 in Alberta (Office of Energy Efficiency, Natural Resources Canada 2002).

Demand side management (DMS) can help to level peak electricity demand (Loughran and Kulick 2004). This will be even more important as more renewable energy plants (wind, solar) are installed, where electricity production and consumption hardly coincide.

Energy is increasingly being produced **from waste**. Methane can be extracted from landfills for power production in gas engines. Waste incineration uses the energy content of waste and converts it to a low-volume, inert residue. While previously the focus of waste incineration plants was on low-emission combustion to get rid of the waste, today the energy efficiency of these plants has become important, too. In Bujak (2009), an incineration plant for medical waste is presented. It is equipped with a heat recovery system and can extract 660–800 kW of usable energy from 100 kg/h of medical waste with an energy efficiency between 47 % and 62 %. New and innovative pyrolysis and gasification technologies for energy-efficient waste incineration are presented in Malkov (2004). In Dijkgraaf and Vollebergh (2004), waste incineration is compared to landfilling, and in Cherubini et al. (2009), a life cycle assessment (LCA) (Guineé 2002) of waste management strategies is performed.

Energy Transmission and Distribution

Today, electricity production is centralized, with large power plants being coupled to a complex distribution network.

Energy transmission and distribution cannot be performed in a totally loss-free way (leaving apart superconductivity, where electrical resistance is exactly zero). In Europe, they typically amount to 4–10 % and hence reduce the overall efficiency of power supply by several percent points (Graus and Worrell 2009).

For the USA, EIA estimates that national electricity transmission and distribution losses are approx. 6 % (FAQ and US Energy Information Administration). In India, losses are estimated at 32 %, which is significantly above the global average of 15 % (Joshi and Pathak 2014).

Transporting the fuel to end users is more cost effective yet also consumes substantial amounts of energy (see sections below). Natural gas, for instance, is being pumped across long distances, because placing a gas power station next to the gas field and transmitting the electricity and heat would result in a considerably lower overall efficiency than compressing and moving the gas through pipelines.

Globally, Russia is the largest producer and transporter of natural gas. Methane emissions from the Russian natural gas long distance network are estimated at approximately 0.6 % of the natural gas delivered (Lechtenböhmer et al. 2007).

Energy Storage

The need for more and cleaner energy leads to an increase in distributed generation (DG) and renewable energy sources (RES) (Hadjipaschalis et al. 2009). Since such sources like wind power are not as reliable and as simple to adjust to demand fluctuations as conventional power plants, they could be coupled with energy storage systems.

Power demand by (end) users fluctuates strongly. Typically the lowest consumption during a 24-h period is nearly half the peak demand (compare Fig. 8).

Today, with a mainly centralized electricity production scheme, there is only a small storage capacity available, amounting to approx. 90 GW or 2.6 % of the total production of 3,400 GW (Ibrahim et al. 2008). With DG and RES on the increase, it is expected that energy storage, more specifically electrical energy storage, will gain significance on a local (small) and regional (large) level.

Energy can be stored in various ways, for instance, as:

Potential energy	Pumped hydro storage (PHS, i.e., pumping water up into a reservoir, so that it can later drive a turbine) or compressed air energy storage systems (CAES, i.e., compressing gas in a cylinder)
Kinetic energy	Accelerating a flywheel
Chemical energy	Batteries (Rydh and Sandén 2005), fuel cells (H_2)
Thermal energy	Use of sensible or latent heat (Ibrahim et al. 2008), e.g., of NaOH

Lead batteries are well known for the storage of energy; however, they are heavy and inapt for high cycling rates. Rydh and Sandén (2005) discuss the energy efficiency of batteries.

In Ibrahim et al. (2008) and Hadjipaschalis et al. (2009), an overview on current and future energy storage technologies is given. They differ in their maturity, target use (e.g., portable or fixed, long- or short-term storage), specific power (power density) [W/kg] and specific energy (energy density) [Wh/kg], the lifetime (number of cycles), the self-discharge rate, and the costs per installed kWh. Hydrogen storage options are reviewed in Hirscher and Hirose (2010).

In Ibrahim et al. (2008), the energy efficiencies of various energy storage technologies are compared.

An interesting option for electrical energy storage is power to gas (P2G, PtG) (Gahleitner 2013).

Energy storage (and conversion) is always associated with losses.

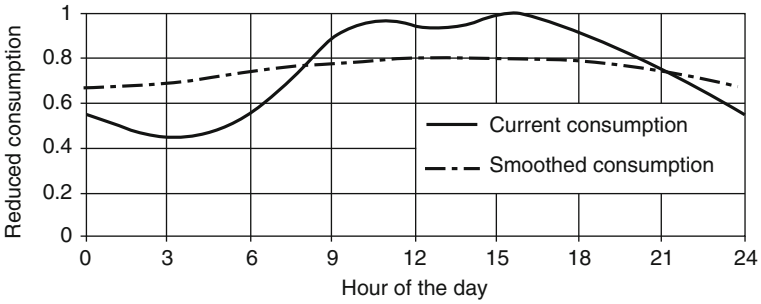

Fig. 8 Average daily power consumption in France (Reprinted with permission from Elsevier from Ibrahim et al. (2008)). Peak demand happens in the morning and afternoon, with the lowest demand being met in the early morning hours

Life Cycle Assessment (LCA)

Life cycle assessment (LCA) (Guineé 2002), also called life cycle analysis, is a holistic view on a product or service. As the name implies, all steps from its raw material production, manufacturing, transportation, distribution, use, and disposal are considered to determine the overall effect that a given product has on the environment. LCA is rooted in the ISO14001 environmental management system standard, more specifically in ISO 14040, 14041, 14042, and 14043 (ISO 2015). The ISO standard for energy management is ISO 50001.

Variants of life cycle analysis are:

Cradle-to-grave analysis	(Full life span)
Cradle-to-cradle analysis	(Including recycling)
Cradle-to-gate analysis	(Partial process)
Gate-to-gate analysis	(One step)
Well-to-wheel analysis	(Used in the automotive industry; see below)
Wire-to-water efficiency	(Used for pumps; see later)

Eco-balance is a synonymous expression for LCA.

An illustrative example for the value of LCA is the use of plastic materials for insulation purposes. Within 4 months of use, the energy savings can equal the energy needed for production, with a service life of up to over 50 years (The International Energy Association in Collaboration with CEFIC 2007).

In transportation, LCA is typically done as well-to-wheel (WtW) analysis, which is an overall fuel efficiency calculation (there are also the standard LCA studies for cars, ranging from production to use and disposal). **WtW efficiency**, detailed in Braungart et al. (2007), van Vliet et al. (2009), Svensson et al. (2007), and Hekkert et al. (2005), is a similar concept as **life cycle energy efficiency** (Malça and Freire 2006). Both concepts can be understood as overall efficiencies of a process chain, calculated as the product of the individual efficiencies.

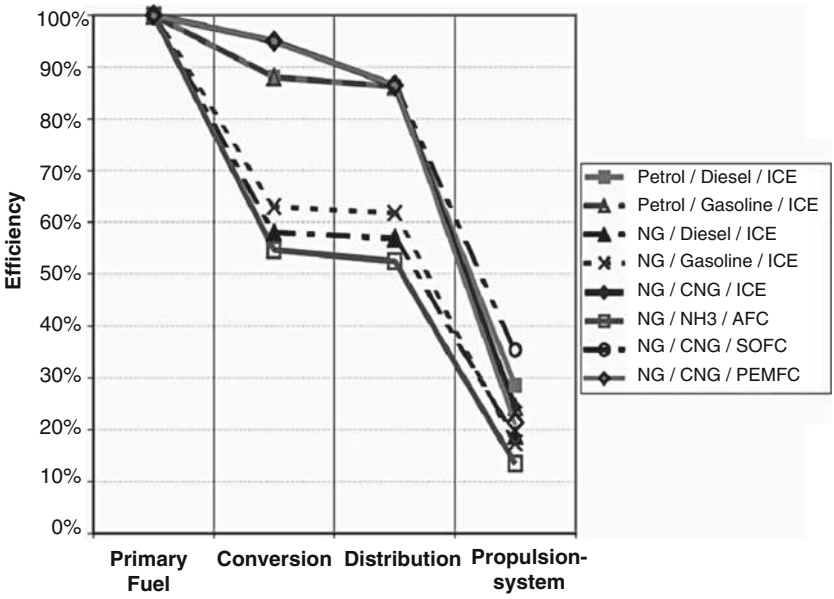

Fig. 9 Well-to-wheel efficiencies under hot starting conditions (Reprinted with permission from the Society of Automotive Engineers (*SAE*) from Ellinger et al. (2001)); *ICE* internal combustion engine, *NG* natural gas, *CNG* compressed natural gas, *AFC* alkaline fuel cell, *SOFC* solid oxide fuel cell, *PEMFC* polymer electrolyte membrane fuel cell

WtW efficiencies allow meaningful comparisons between different technologies, for instance, internal combustion engines (ICEs) versus fuel cell (FC) vehicle technologies. They provide for a fair comparison. Figure 9, taken with permission from Ellinger et al. (2001), shows the efficiency chain for different automotive propulsion systems under hot start conditions.

In Fig. 9, the WtW efficiency is calculated as the product of conversion efficiency η_c, distribution efficiency η_t, and propulsion system efficiency η_p as shown in equation 6:

$$\eta = \eta_c \eta_t \eta_p \tag{6}$$

The conversion efficiency η_c for gasoline and diesel production in a refinery is quoted as 88 % in Heitland et al. (1990) and as 63 % for their production from methanol according to the Lurgi process (20 years ago), and the distribution efficiency η_t as 97–98 % in The International Energy Association in Collaboration with CEFIC (2007).

In Fig. 9, it can be seen that the CNG-SOFC (compressed natural gas-solid oxide fuel cell) combination achieved the best overall efficiency of around 35 %, with the best internal combustion engine performance being 29 % for diesel from crude oil (the International Energy Association in Collaboration with CEFIC 2007).

The **eco-balance** of biodiesel, for instance, has to consider the consumption of fossil fuels and materials for its production, e.g., the use of lubrication oil. Another important term is that of the **energy path**. The production process will strongly impact energy consumption. Methanol, for instance, can be produced via a path starting from sugarcane (1st-generation biofuel), from lignocellulosis (2nd-generation biofuel), or from natural gas (traditional), which will yield different eco-balances.

An interesting website on LCA is run by the US Environmental Protection Agency (EPA) (http://www.epa.gov/nrmrl/std/lca/lca.html 2015).

A related concept to LCA is the **embodied energy** (Venkatarama Reddy and Jagadish 2003). It is often used for buildings (see later). Also in other industries, significant amounts of energy are "stored" in the final product. In the case of the petrochemical and chemical industries, which consume 30 % of global industrial energy, more than half of the energy is locked up in the final products (the International Energy Association in Collaboration with CEFIC 2007) and can be recaptured at the end of their lifetime.

The total life cycle of a product can not only be assessed with regard to energy use and environmental aspects but also from an economic point of view – in terms of costs. In this case, one speaks about **life cycle costs** (**LCC**) or total cost of ownership (TCO).

Recycling is an important aspect of life cycle assessment. The primary energy demand for "new" materials is often considerably higher than that needed to recycle them from waste. For instance, if aluminum cans are recycled, the energy consumption will only be 5 % of the energy needed to make them from virgin bauxite ore. Scrap metal, glass, paper, and plastics should be recycled to make best use of their "energy content," as primary production tends to consume more energy than secondary one. In the case of plastics, "thermal recycling" is an advantageous, final use if other types of recycling are not feasible. The 3Rs (**reduction, reuse, recycling)** are approaches to limit the quantity of primary raw material demand, hence contributing to sustainability.

Total Cost of Ownership (TCO)

The total cost of ownership (TCO) concept acknowledges the fact that the use of any equipment has two types of costs associated with it:

- Initial investment costs
- Running costs over the entire useful lifetime (energy, maintenance, disposal, etc.)

For industrial pumps, for instance, which are typically in service for 15–20 years, the initial investment cost is often less than 5 % of total incurred costs (Tutterow et al. 2002). For a majority of industrial assets and facilities, the lifetime energy will dominate the life cycle costs, which is also the case for many equipment items in private homes. More information on TCO can be found in Braun and Leiber (2007),

US Department of Energy (2005), and Sorrell et al. (2004), with the latter two providing ample coverage of economic evaluation of energy efficiency.

Energy Efficiency in Various Sectors

In the following sections, energy efficiency in various areas is discussed. As is shown in Fig. 1 and Table 1, major consumers of energy are end users, power plants, transportation, industry, buildings, and others, each of which showing potential for cost-effective energy efficiency improvements.

Agriculture and Food

Agricultural activities make a strong contribution to anthropogenic climate change.

Greenhouse gas emissions from this sector account for 22 % of global total emissions, which is similar to the contribution level of industry and greater than that of transportation. Livestock production (including transport of livestock and its feeding) accounts for nearly 80 % of the sector's emissions (McMichael et al. 2007). The two strong greenhouse gases (GHG), methane and nitrous oxide (which are closely linked with livestock production), contribute much more to this sector's warming effect than does carbon dioxide (McMichael et al. 2007). Emission factors of CO_2 and CH_4 for livestock are estimated at 36–3,960 and 0.01–120 kg per head and year, respectively (Office of Energy Efficiency, Natural Resources Canada 2002). Agricultural operations not only put strain on global climate by CH_4 emissions from cattle but also by energy consumption, which is concentrated in the areas of irrigation, process heat applications, and refrigeration. Irrigation pumps, refrigerated warehouses, greenhouses, and postharvest processing offer various potentials for energy efficiency improvements. A nice example is provided by some Dutch greenhouses, which are heated by gas engines, the CO_2 from which is fed into the greenhouses to fertilize the plants and to boost their growth (Lugt et al. 1996). In Oude Lansink and Bezlepkin (2003), different heating methods for greenhouses are compared. In Ramírez et al. (2006a), the energy efficiency of the Dutch food industry is reviewed, and in Ramírez et al. (2006b) that of the European dairy industry. Additional case studies of recent improvements in energy efficiency in the agricultural industry are discussed in Swanton et al. (1996).

The energy use for the production of various agrichemicals, such as herbicides, growth regulators, and fungicides, ranges from 120 to 550 MJ/kg of active ingredient (Saunders et al. 2006), taking production, packaging, and transportation into account (Saunders et al. 2006). The application rate of these chemicals further determines the total energy consumption per kg of agricultural product.

Food miles are a very simplistic concept relating to the distance food travels as a measure of its impact on the environment (Saunders et al. 2006). While a lower number of "food miles" will generally render a product more energy efficient, because transportation ways are shorter, a food commodity that is produced with

high energy efficiency, e.g., by low use of fertilizers, and that has a long mileage to the consumer can still have a lower environmental impact that foodstuff manufactured close to the end customer in an otherwise inefficient way. This simple example shows that energy efficiency aspects are closely interwoven and often difficult to compare, not only in the agricultural industry. Globalization affects the food industry as much as it does high-tech goods.

Ecuador is the world's largest banana exporter. The carbon footprint of Ecuadorian export bananas was found to range from 0.45 to 1.04 kg CO_2-equivalent/kg banana (Iriarte et al. 2014).

In Wang (2008), energy efficiency in the food industry is treated in detail.

Transportation and Logistics

Our world has become global, so that people and goods are being transported between countries and continents on a large scale. The IEA predicts significant improvements in energy efficiency in transportation; however, these will be more than offset by increased travel (IEA 2009) and further globalization.

Fuel efficiency in transportation ranges from a few megajoules per kilometer and passenger for a bicycle to several 100 MJ for a helicopter. Approx. 1/3 of the energy consumption in transportation is used for freight movement (Sorrell et al. 2009), which accounts for 8 % of total anthropogenic CO_2 emissions. Most of these emissions stem from trucks (heavy goods vehicles, HGV), which account for most freight activities in most countries, e.g., 68 % of all tonne kilometers in the UK (Sorrell et al. 2009). Ample road networks make cargo distribution by HGV convenient and efficient in terms of time and costs.

Externalities are the costs or benefits that affect parties who did not choose to incur that cost or benefit (Buchanan and Stubblebine 1962). An example for such a negative externality is air pollution or climate change by transportation: The costs are born neither by car producers nor by motorists. For a discussion of freight and transportation externalities, see Ranaiefar and Amelia (2011).

For details on transportation and climate change, see the subsections below and also chapter "▶ Fuel Efficiency in Transportation Systems" in this handbook.

Road Transportation and Internal Combustion Engines

Although rail and ship transportations are more efficient and environmentally benign than road transportation, trucking is still heavily used for reasons of flexibility, costs, and timeliness, not only in weakly developed areas, to move goods and people.

Most vehicles on the road today are powered by internal combustion engines (ICE).

Engine and propulsion system selection for cars is based on various criteria such as driving performance, range, and safety. ICE burn gasoline and diesel, the latter being primarily for trucks. In some countries, cars and trucks with natural gas-, ethanol-, and hydrogen-propelled engines constitute a fleet fraction next to those

with alternative systems such as electrical batteries or air buffer tanks. In Brazil, ethanol fuel has become popular. It is mostly produced from sugarcane, whereas the USA use corn as feedstock. For biodiesel, the Americas use soybean, whereas Europe mainly deploys rapeseed (1st generation biofuels). Hydrogen is chiefly obtained by water electrolysis.

Internal combustion engines have become more efficient over the last decades. The largest losses in gasoline engines are encountered by throttling the engine (Ellinger et al. 2001).

Taylor (2008) estimates that over the next decade, an efficiency improvement of another 6–15 % is feasible. Various optimizations such as direct fuel injection, variable valve timing, supercharging, downsizing, exhaust gas recirculation, onboard fuel reforming, and powertrain improvements, e.g., on the gearbox, are being tested and implemented (Ellinger et al. 2001). The reuse of losses also offers significant potentials, for instance, recuperative braking or the extraction of heat from exhaust gases, as it is a state of the art in power plants (economizers).

Stationary engines, such as large gas engines for power backup or landfill gas use, can be operated in steady mode at optimum efficiency. Combustion engines in mobile machines have to perform well over a wide range of load, which yields poorer overall efficiency.

A novel, promising combustion technology for engines is HCCI (homogeneous charge compression ignition) (Zhao 2007). HCCI is a hybrid between an auto-ignited diesel engine and a spark-ignited Otto engine in that it deploys auto-ignition of a homogeneous fuel-air mixture. Alternative ignition systems (Lackner 2009) such as laser ignition are also expected to improve fuel economy. For a discussion on internal combustion engines for future cars, see Lackner et al. (2005).

Passenger Cars

It is estimated that by 2030, 60 % of all new cars sold will be **hybrids**, plug-in hybrids, and **electric vehicles**, as opposed to 1 % today (IEA 2009). Hybrid cars combine an electric engine and an internal combustion engine. Dual fuel concepts (natural gas and diesel, for instance) are also feasible. The CO_2 intensity of the passenger car fleet in 2030 is estimated to be 90 g of CO_2/km, compared to 205 g/km in 2007, as a worldwide average. In OECD countries, it should reach 80 g, in the EU 70 g, and in India and China 110 and 90 g, respectively, in 2030, the latter ones down from 225 and 235 g, respectively, in 2007 (IEA 2009). On the other hand, a large increase in the global number of cars is anticipated, particularly in developing nations such as China and India.

Hybrids use regenerative breaking to recapture energy that would otherwise dissipate. The effect on fuel economy of such cars is particularly pronounced in stop-and-go city traffic.

Fuel economy of private cars is governed by the following aspects:

- Technology advances of the car, e.g., weight reduction or better engine
- Driving habits (use of air-condition, cruising speed, payload in the car, etc.)

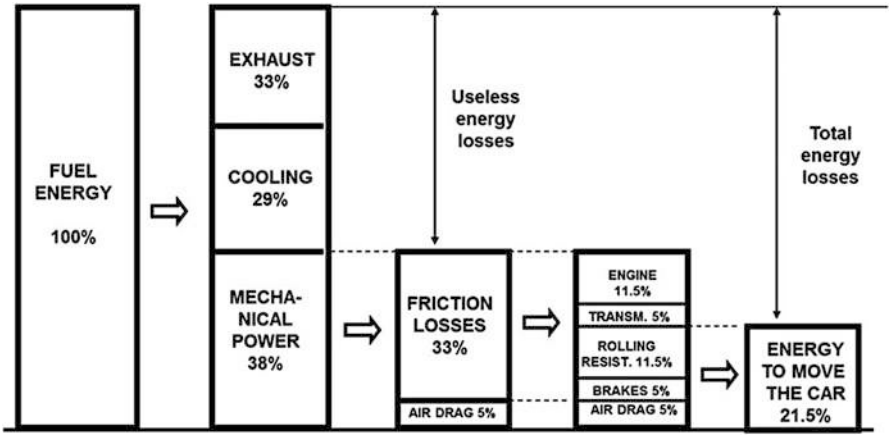

Fig. 10 Energy losses in passenger cars (Reproduced with permission from Elsevier from Holmberg et al. (2012))

- Maintenance (no clogged air filters, correct tire pressure, etc.)
- Weight (lightweight construction materials can save fuel over the entire lifetime)

Figure 10 shows the breakdown of passenger car energy consumption (Holmberg et al. 2012).

In passenger cars, one-third of the fuel energy is used to overcome friction in the engine, transmission, tires, and brakes. The direct frictional losses, without braking friction, are 28 % of the fuel energy. In total, only 21.5 % of the fuel energy is used to move the car.

Potential solutions to reduce friction in passenger cars include the use of advanced coatings and surface texturing technology on engine and transmission components, new low-viscosity and low-shear lubricants and additives, and tire designs with reduced rolling friction (Holmberg et al. 2012).

There is plenty of information available for consumers who want to pick an energy-efficient car, e.g., one website run by the US EPA (http://www.fueleconomy.gov/ 2015).

In California, **partial zero emission vehicles (PZEVs)** were introduced to satisfy part of the state's **zero emission vehicle** (ZEV) program (Collantes and Sperling 2008).

In Johansson and Åhman (2002), options for carbon-neutral passenger transport are reviewed.

Thomas (2009) compares fuel cell and battery electric vehicles. The primary energy efficiencies of alternative powertrains in vehicles are discussed in Åhman (2001)). In Ellinger et al. (2001), the energy efficiency of internal combustion engines and fuel cells for automotive use with different fuels is assessed. It is concluded there that fuel cells have an advantage during hot start conditions, but suffer from efficiency losses during cold starts (Ellinger et al. 2001).

Although the energy efficiency of a fuel cell-powered car is not the best, the environmental performance of a vehicle burning hydrogen from solar generation in a low-noise, virtually emission-free fuel cell is outstanding. It is expected that the fraction of fuel cell cars will increase over the next decade, with an accompanying growth of the necessary infrastructure.

Ships

Nifty percent of the world's trade is carried by the international shipping industry, supported by 50,000 merchant ships (http://www.ics-shipping.org/publications/ 2015). Over the last four decades, total seaborne trade is estimated to have quadrupled, from just over 8,000 billion tonnes-miles in 1968 to over 32,000 billion tonnes-miles in 2008 (http://www.ics-shipping.org/publications/ 2015). In 2011, figures were 42.8 billion tonnes-miles or 8.7 billion tonnes according to UNCTAD (United Nations Conference on Trade and Development) and the ITF (International Transport Forum 2013).

Seaborne shipping is one of the most energy-efficient means of transportation, especially for large, bulky goods.

Here is a comparison of energy efficiency of different transportation modes, taken from a study by the Swedish Network for Transport and the Environment (Table 5) (http://www.ics-shipping.org/publications/ 2015).

It has to be noted that the table above is slightly biased in favor of sea transportation, as the aircraft mentioned is an outdated one used on a short-haul flight.

Ships can be driven by different technologies (Schneekluth and Bertram 1998) with diesel engines being most common. The resistance of the ship's hull, the design or the propeller, and the tonnage are important factors for its energy efficiency as well. The impact of shipping on the atmosphere and on the climate is discussed in Eyring et al. (2010). The auxiliary powering of ships by kitelike devices is discussed in Burgin and Wilson (1985) and Kim and Park (2010). Spinning vertical rotors installed on a ship to convert wind power into thrust based on the Magnus effect, so-called Flettner rotors, are another option to increase energy efficiency. Microbubbles as a means of reducing skin friction on ships are studied in Kodama et al. (2000). Different propulsion systems for LNG carriers are discussed in Chang et al. (2008). LNG (liquefied natural gas) is expected to gain an increasing importance.

Table 5 Energy consumption in different transportation modes (dwt is the deadweight tonnage (also known as deadweight, DW or dwt), a measure of how much weight a ship can safely carry. It is the sum of the weights of cargo, fuel, ballast water, crew, etc.) (Source: http://www.ics-shipping.org/publications/ 2015)

Mode	Air	Road	Sea	Sea
Comment	B727-200 (1,200 km flight)	Medium-sized truck	Cargo ship, 2,000–8,000 dwt	Cargo ship, >8,000 dwt
Energy consumption	4.07 kWh/(ton*km)	0.49 kWh/(ton*km)	0.08 kWh/(ton*km)	0.06 kWh/(ton*km)

Rail Transportation

Intuitively, rail transportation of people and cargo is amongst the most environmentally friendly modes of movement. Technological progress has increased energy efficiency in rail transportation, too. According to Kemp (1997), aerodynamic drag per seat at 150 km/h was cut by half over 30 years. Train speed determines energy efficiency. The energy consumption for a high-speed train from London to Edinburgh increases from 30 to almost 60 kWh/seat as the speed goes up from 225 to 350 km/h (Kemp 1994). The American railway corporation Amtrak reported an energy use of 2,935 BTU per passenger-mile (1.9 MJ/passenger-km) in 2005 (Amtrak 2015).

A critical factor in energy efficiency of trains is the occupancy. If a train is only 25 % loaded, the fuel consumption per passenger and seat can be worse than with economic cars and modern aircraft as shown in Kemp (2004).

For a discussion on the potential role of high-speed trains in future sustainable transportation, see Kamga and Yazici (2014).

Air Transportation

Aviation has helped shape our current business dealings and lifestyles significantly. Virtually any point on the globe has got into easy reach within 24 h. Air transportation is used for cargo and people. It has contributed approx. 3.5 % to global greenhouse gas emissions in 1990 with a projection of 15 % or more in the future (Penner et al. 1999). The impact of aviation on climate change is not only driven by CO_2 emissions but also by H_2O emissions at high altitude (Williams et al. 2002). Due to the long residence time of water vapor at aircraft cruising altitude, it can disproportionally contribute to global warming by reflecting and retaining infrared radiation (compare the effect of natural clouds). Biofuels for aviation (Marsh 2008) were already tested in a proof-of-concept study (BBC 2008), provoking mixed feelings amongst critics. Winglets (Marks 2009) and lightweight materials (Marsh 2007) are two commonly known concepts to increase fuel efficiency of aircraft, hence increasing energy efficiency. See also Figs. 4 and 5.

The impact of service network topology on air transportation efficiency is discussed in Kotegawa et al. (2014).

In a recent study on the impact of airline mergers and hub reorganization on aviation fuel consumption, it was found that a typical airline merger in the USA has a fuel saving potential of 25–28 % (Ryerson and Kim 2014). Renewable fuels in aviation are discussed in Winchester et al. (2013).

Pipeline Transportation

Pipelines (Ellenberger 2010), i.e., conduits of pipe, can be used to transport liquids, gases, and slurries. The Romans built aqueducts for water transportation some 2,000 years ago. An early industrial pipeline was installed in Austria in 1595 to transport brine from Hallstatt to Ebensee for salt production (Bedford and Pitcher 2005). Today, pipelines are commonly used to transport petroleum, natural gas, and other commodities over large distances. A comparison of natural gas transportation by

LNG tankers and pipelines is made in Elvers (2007). LNG compression and regasification consume 7–13 % of the original amount of natural gas, as well as roughly 0.15 % per day of marine transport, which adds about another 1 % to overall energy losses. Pipeline transportation of natural gas results in energy losses of approx. 1 % per 1,000 km. Therefore, an intercontinental 8,000 km pipeline would involve energy losses of roughly 10 %, which is approx. half the amount of transportation by LNG tankers over the same distance (Elvers 2007). The transportation of liquids in pipelines versus onboard of trucks is compared in Pootakham and Kumar (2010) and (Ghafoori et al. (2007). The conveying of coal as slurry in pipelines is assessed in Kania (1984). In industrial plants, pneumatic conveying (dense phase or dilute phase conveying of a solid in air) and hydraulic conveying (solids in liquid carrier media) are used to transport materials between various processing sections. Variable speed drives (VSD) for pneumatic conveying blowers are a means of enhancing energy efficiency versus blowing off excess air at low conveying capacities for the transportation of solids in the gas phase. Kumar et al. (2007) review the transportation of biomass in pipelines. It is concluded that long distances and high throughput rates make such systems economic, as is generally the case with pipeline transportation.

Industry

Industry accounts for a high fraction of the global energy consumption; see Table 1. The energy intensity varies strongly from 52.3 end-use BTUs per USD of value added in cement production to 0.4 end-use BTUs per USD in computer assembly (Granade et al. 2009). Ten end-use BTUs per USD can be set as limit for energy-intensive industries as done in Granade et al. (2009).

There is a huge potential for energy savings in industry, yet the biggest opportunities for optimization are not easily known to the people involved (Yang 2010).

Approximately 2/3 of the energy saving potential can be found in specific process steps of energy-intensive industries, whereas 1/3 resides in various areas of nonenergy-intensive ones. Savings can be realized by more efficient processes or by more efficient equipment.

Crosscutting Technologies

Equipment which is used in different sectors of industry, such as lighting, motors, boilers, and pumps, is subsumed as crosscutting technologies. For these, best practices (see, e.g., US Department of Energy 2010) and general recommendations can be formulated that are valid for several branches and sectors of industry. Generally, there exist untapped-into saving potentials in:

- Waste heat recovery
- Steam systems
- Motor systems
- Pumps (Tutterow et al. 2002)

- Lighting
- Buildings
- Utilities

For quantifying energy efficiency potentials, there are various methods (Phylipsen et al. 1997).

Here are some aspects of energy efficiency that are relevant for many industries:

Process design: The largest contribution to energy efficiency is made during the design of a process. If a product, for instance, has to be heated up and cooled down several times, chances are high that the process is not energy efficient. Also, an implemented production process is difficult to change.

Overcapacity: Design capacity should meet the needs for a process in terms of vessel size, engine power, etc. Overdesign always costs money – not only in the investment phase but most likely also later on, when energy consumption is higher than necessary. Overcapacities of process equipment should normally not exceed 10 % of the overall design capacity.

Debottlenecking: If a plant can be deblottlenecked, i.e., the output can be increased by making some small modifications, one typically has a highly profitable project. Also from an energy efficiency perspective, debottleneckings frequently lower the specific energy consumption of a product, thus making it more energy efficient.

Measuring, monitoring: In order to be able to track energy efficiency measures, it is necessary to measure accurately and regularly actual consumption values of electricity and other utilities such as compressed air or cooling water. Only by monitoring them actively will deviations be spotted.

Automatic controls: Automatic process control is generally faster and more accurate than a manual one and also less prone to errors. Therefore, a production process can be carried out in the most energy-efficient way if it is automatically controlled (Szentennai and Lackner 2014). Automation will be more economic for large processing plants where the investment costs can be diluted over the volume.

Compressed air: Leaks of air from pipes can easily lead to 20–50 % efficiency loss of a compressed air system. Preventive maintenance and the timely repair of leaks will help to minimize running costs. A pressure reduction of the entire system can often be considered, as instrument air (plant air) typically only needs to have ~6 bar pressure, which is less than the design pressure of many compressor systems. If the operating pressure is reduced by just 1 bar, energy savings of over 5 % can result.

Maintenance: If industrial assets are not properly being taken care of, their energy consumption tends to increase. Advanced maintenance techniques such as risk-based maintenance, preventive maintenance, thermography, and others will help to keep energy efficiency up. Cutting costs on maintenance can bring short-term gains at the expense of increased risk and deferred costs. A typical yearly maintenance budget for industrial plants would be 2 % of the investment value, depending of course on the process.

Cogeneration: Production sites that produce their own electricity should seriously consider combined heat and power (CHP). If there is no need for heat in the installation itself, there might be an opportunity to sell the heat, e.g., for district heating purposes. Cogeneration will use the heat which would otherwise be wasted, thereby increasing the energy efficiency. For details, see Raj et al. (2011) and Çakir et al. (2012).

Motors and drives: It is estimated that 2/3 of all electricity consumption in industry is used to drive various motors (US Department of Energy 2010), so there is a huge optimization potential. The "motor challenge" is a recent program to improve motor efficiency (Energy Efficient Motor Driven 2010). Typical energy efficiencies of motors are 80–90 %, with advanced models reaching 97 % (Office of Energy Efficiency, Natural Resources Canada 2002).

Variable speed drives: An engine's energy consumption can be matched to the load by using a variable speed drive (VSD). VSDs can be realized with a frequency converter coupled to an engine. Up to 50 % of energy can be saved. Today, only an estimated 10 % of all engines in industry are equipped with VSD. A large number of motors are still controlled by throttling valves in pump systems or vanes in fan applications. By throttling, a part of the produced output immediately goes to waste. Speed control with intermediate transmission such as belt drives, gearboxes, and hydraulic couplings adds to the inefficiency of the system and requires the motor to run at full speed. Another drawback is that such systems typically require more maintenance. They can be noisy, too.

Pumps: It is estimated that pumps consume 25 % of the electricity in US manufacturing facilities (Galitsky 2008). Industrial pumps have a lifetime of 20 years and longer. Pump efficiency is defined as the pump's fluid power divided by the input shaft power and is influenced by hydraulic effects, mechanical losses, and internal leakages. Pump manufacturers have devised many ways to improve pump efficiencies. For example, the pump surface finish can be made smoother by polishing to reduce hydraulic losses. A "good" efficiency for a pump will vary depending on the type of the pump. A more useful efficiency term is the **wire-to-water efficiency**, which is the product of the pump and motor efficiency. An even better measure of efficiency for analysis purposes is the **system efficiency**, which is defined as the combined efficiency of the pump, motor, and distribution system. See also Tutterow et al. (2002) and "Life Cycle Assessment (LCA)" above.

Blowers and fans: Fans move air as pumps move liquids. They can often be optimized for energy efficiency, e.g., by adding a VSD. For details, see, e.g., Gunner et al. (2014).

Energy management system: An energy management system (EMS) is the energy equivalent of an environmental management system. Generally, industrial sites or units that consume more than 1,000 toe/day should have a dedicated **energy manager**, who will "pay himself/herself" by economizing on energy bills. A guideline for energy management is provided by Office of Energy Efficiency, Natural Resources Canada (2002). The standard ISO 50001 can serve as guidance.

Several smaller units instead of large one: Instead of one large pump which is controlled with a bypass, several smaller pumps might be more energy efficient, matching power consumption to the process needs. The same consideration might work for air compressors, etc.

Energy audit and energy survey: These tools were mentioned already earlier in this chapter in the context of the EU Directive 2012/27/EU of 25 October 2012 on energy efficiency. Energy audits and energy surveys can be administered by internal or external staff. Generally speaking, it is vital for the success of an energy efficiency program in a corporation to have the support of a senior, recognized executive and to make the effort lasting by introducing energy performance indicators, which can be linked to employee's targets and performance management.

Load shifting (using off-peak electricity) (Favre and Peuportier 2014): If energy-intensive production processes can be concentrated in off-peak hours, the energy bill will be lower. This will also have positive effects on the environment, as peak electricity demand often needs to be produced in a not-so-efficient way.
For details, see, e.g., demand side management in smart grid operation in López et al. (2015).

Load shedding (Kanimozhi et al. 2014): By reducing peak electricity consumption, energy costs can also be reduced.

Insulation: Process insulation can be optimized for energy efficiency. A waterlogged insulation transfers heat 15–20 times faster than a dry one, and one filled with ice even 50 times faster (Office of Energy Efficiency, Natural Resources Canada 2002)!

Using waste heat: Heat losses are a major sink for energy. Process heat in general can be upgraded using **absorption heat pumps (AHP)** (Wei et al. 2014). Heat losses in flue gases are a particularly large term: If flue gases exist and the chimney too hot, significant amounts of heat are wasted (up to 1 % of fuel savings for 25 °C colder flue gas temperature (Galitsky 2008)); see also cogeneration. As for **heat exchangers**, cleaning and optimization can bring additional energy efficiency gains (Wang et al. 2009).

An overview on energy efficiency improvement potentials in industry is given in Rajan (2002) and Bannister (2010), the latter focusing on mechanical systems. Industrial energy efficiency in Asia, where a large part of global energy-intensive industry has settled, is treated in United Nations (2006).

Steam and Boilers

Steam engines are gone; however, still 37 % of the fossil fuel burned in the US industry is used to produce steam (Einstein et al. 2001). Steam is the working fluid in steam turbines for electricity production. It is used in various industries to transfer and to store heat, as it is a capacious reservoir for thermal energy because of the high heat of vaporization of water.

The chemical industry uses significant amounts of steam as process heat, one reason being that steam is generated as a by-product in some processes in integrated

chemical production sites. Steam in general can be produced efficiently in cogeneration plants. In contrast to district heating networks to heat private homes, cogeneration plants in industry can be operated at full capacity all year round. Steam is produced in **boilers**. Energy efficiency measures for boilers include:

- Improved process control
- Reduced excess air
- Improved insulation
- Maintenance
- Recovery of heat from flue gas
- Recovery of steam from blowdown
- Optimization of fuel mix

For steam distribution systems, the following measures are effective:

- Improved insulation
- Improved steam traps
- Steam trap monitoring
- Leak repairs
- Condensate return

In Einstein et al. (2001), information on steam systems in industry and their energy use and energy efficiency improvement potentials are outlined. Detailed information on boilers is given in Heselton (2004).

Energy-Intensive Industries

There are certain "heavy industries" that consume a large fraction of total energy output. In China, for instance, the top 1,000 energy-intensive enterprises consumed 30 % of China's total energy and 50 % of the total industrial energy in 2007 (NDRC 2007). Energy intensity is a specific quantity, expressed as kWh/kg of product or as kWh/monetary unit (value added, often in USD). Above an arbitrary threshold of ten end-use BTUs per USD, one can speak about energy-intensive industries (Granade et al. 2009). This classification is valid for the production of:

Cement	(Calcination process, clinker production)
Steel	(Coke consumption)
Aluminum	(Primary metal production by electrolysis)
Ores	(Mining operations)
Pulp and paper	(Mechanical pulping)

These industries have a strong effect on global energy consumption, because they are not only energy intensive as such but because they produce high amounts of materials per year. The global steel production, for instance, is in excess of one million tonnes (Lackner 2010). The IEA predicts big improvements in energy efficiency in industry, which are expected to be more than offset by higher output

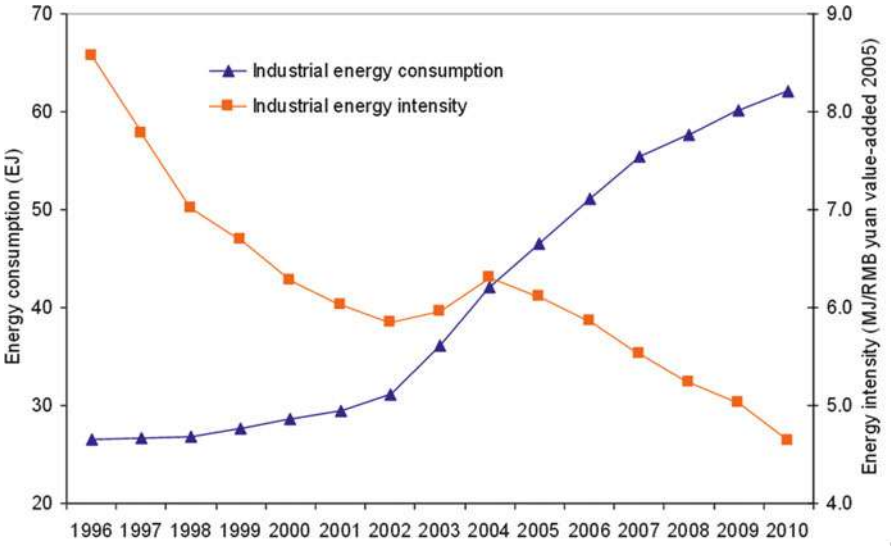

Fig. 11 China's industrial energy consumption and intensity from 1996 to 2010 (Reproduced with permission from Ke et al. (2012))

of steel and cement (IEA 2009), especially in the developing world, to which countries like Brazil, Russia, India, China (BRIC), Mexico, and South Korea belong. Figure 11 shows the trend in China's industrial energy consumption and intensity from 1996 to 2010 (Ke et al. 2012).

The industrial energy consumption of China increased significantly from 1996 to 2010, especially after 2002.

By 2010, China's industrial energy intensity had decreased 46 % below the 1996 level (Ke et al. 2012).

Energy production in China is largely based on coal combustion, with efficiencies being approx. 10 % lower than in Europe or the USA (Nuo and Gaoshang 2008). The CO_2 emissions from coal combustion are naturally higher than those from other fuels with a lower C/H ratio. Several technology options to reduce energy consumption and CO_2 emissions in energy-intensive industries are reported in Yudken and Bassi (2009); see also below.

Iron and Steel

In the iron and steel industry, as the name implies, iron production and steel production are the main processes (Berns et al. 2008). Iron can be produced along different routes. The classic path is the production of pig iron from ore and coke in the blast furnace, which is then further processed into steel in the basic oxygen furnace (BOF) or the open hearth furnace (OHF), the first one being more energy efficient. Smelt reduction and direct reduction (DR) are two other, advanced routes to iron. The electric arc furnace (EAF) is used to produce secondary steel from scrap.

Table 6 Potential technologies to make energy-intensive production processes more efficient (Source: Yudken and Bassi (2009) from IEA, DOE, AISI, Aluminum Association, Korean Energy Institute)

Technology option	Description	Time frame
Pulverized coal and plastic waste injection	Pulverized coal is already used by more than 50 % of all US BOFs	ST-MT
New reactor designs	Uses coal and ore fines (COREX™, FINEX™)	MT
Paired straight hearth furnace	Substitutes coal for coke in blast furnaces, lower costs, uses 2/3 energy	MT-LT
Molten oxide electrolysis	Produces iron and oxygen, no CO_2	LT
Hydrogen flash melting	Uses hydrogen in shaft furnaces, no CO_2	MT
Geological sequestration and steelmaking		MT-LT

ST short term (2010–2015), *MT* medium term (2015–2030), *LT* long term (2030–2050)

In China, the energy consumption per tonne of steel has declined from 1.43 to 0.52 toe between 1980 and 2005 (Wei et al. 2007). Integrated steel plants have a specific primary energy consumption ranging from 19 to 40 GJ/t of steel (Gale and Freund 2014), with minimills that use scrap steel being more efficient. Technology options for reducing energy use and CO_2 emissions in the iron and steel industry are tabulated in Table 6, reproduced from Yudken and Bassi (2009).

Aluminum

Worldwide primary aluminum production is projected to increase from 23 to 38 million tonnes by 2020 (Gale and Freund 2014). The primary aluminum (Moors 2006) production, starting from bauxite via electrolysis (Hall-Héroult process), is a very energy-intensive process, contributing 1 % of total anthropogenic greenhouse gas emissions in 1995 with about 364 million tonnes/year CO_2-equivalent (Gale and Freund 2014).

Secondary aluminum production (Li et al. 2006) consumes approx. 5 % of the energy needed for primary production. Existing and potential future processes for bauxite processing are reviewed in Smith (2009). Technology options for reducing energy use and CO_2 emissions in primary aluminum are summarized in Table 7, reproduced from Yudken and Bassi (2009).

Other Primary Metals

Generally, one can distinguish between pyrometallurgical and hydrometallurgical processes. The ore content of a deposit influences energy efficiency as the chosen process does. The energy demand for comminution is described in Tromans (2008). Energy efficiency of a lead smelter is discussed in Morris et al. (1983), and energy efficiency of copper and magnesium production in Alvarado et al. (2002) and Cherubini et al. (2008), respectively. Processes for the production of steel, aluminum, copper, lead, and zinc are reviewed from an energy perspective in Stepanov

Table 7 Potential technologies to make energy-intensive production processes more efficient (Source: Yudken and Bassi (2009) from IEA, DOE, AISI, Aluminum Association, Korean Energy Institute)

Technology option	Description	Time frame
Wetted, drained cathode technology		MT-LT
Alternative cell concepts	Combines inert anode, drained cathodes	LT
Carbothermic and kaolinite reduction process on commercial scale	Alternatives to the Hall-Héroult process	LT

ST short term (2010–2015), *MT* medium term (2015–2030), *LT* long term (2030–2050)

and Stepanov (1998). Sintering processes and their energy efficiencies are discussed in Musa et al. (2009) for one system, and scale-up in metallurgy in general in Lackner (2010).

Pulp and Paper

The pulp and paper (P&P) industry is a very energy-intensive one.

Pulp is being produced from wood by the kraft process, with electricity as additional input and output, plus steam as an output. An efficient kraft pulp mill can be a net exporter of heat and electricity (Jönsson and Algehed 2010).

Industry practice shows that in the past, most energy-efficient measures were limited to low-investment, high-return projects, with typically 5 % energy savings with a 1-year payback time (Costa et al. 2007), with a lot of potential still untapped into.

In current paper mills, steam savings of up to 30 % are deemed feasible (Kilponen et al. 2001; Costa et al. 2009; Axelsson et al. 2008; Nordman and Berntsson 2009; Lutz 2008).

Energy efficiency savings can be obtained from the use of different fuels, which are typically wood, bunker oil, and black liquor (Costa et al. 2007), the latter being a by-product of the transformation of wood chips into pulp. Typical energy efficiencies in the industry for bark combustion are 67 % (based on the higher heating value) and 80 % for bunker oil combustion, respectively (Costa et al. 2007).

In Jönsson and Algehed (2010), the utilization options for excess steam and heat at kraft pulp mills are studied. Traditional ways are increased electricity production and district heating, whereas increased sales of biomass as bark and/or extracted lignin and carbon capture and storage (CCS) are new pathways.

There is a trend toward additional products, complementing the traditional pulp and paper output, by biofuels, pellets, lignin, carbon fibers, and other specialty chemicals (Jönsson and Algehed 2010) from pulp and paper plants.

In Costa et al. (2007), the economics of **trigeneration** in a kraft pulp mill are discussed. In trigeneration, pulp production, waste heat upgrading, and power production are simultaneously carried out (compare **polygeneration**). Absorption heat pumps (AHP) can be used to cool waste heat streams and to extract energy from them.

Table 8 Potential technologies to make energy-intensive production processes more efficient (Source: Yudken and Bassi (2009) from IEA, DOE, AISI, Aluminum Association, Korean Energy Institute)

Technology option	Description	Time frame
Black liquor gasification	In demonstration, R&D; commercially available 2030; 15–23 % gain	MT-LT
Efficient drying technology	R&D now; commercial demo, 2015–2030; commercial, 2030 onward	MT-LT

ST short term (2010–2015), *MT* medium term (2015–2030), *LT* long term (2030–2050)

Technology options for reducing energy use and CO_2 emissions in the paper and paperboard industry, reprinted from Yudken and Bassi (2009), are summarized here in Table 8.

Recycling is another option to increase energy efficiency of paper products. For details on energy efficiency options in the pulp and paper industry, see Worrell et al. (2001).

Cement

The cement industry, already 15 years ago, exceeded 1.5 billion tonnes of annual output, making it a huge consumer of energy. For cement production, first clinker has to be made, which is then blended with approx. 5–70 % additives such as gypsum and fly ash to yield cement. This first step is the most energy-intensive one. Limestone ($CaCO_3$) is burnt with silicon oxides, aluminum oxides, and iron oxides. There is a wet process and a dry process, the latter one being more energy efficient. As cement plants (Deolalkar 2009) consume significant amounts of energy, approx. 4 GJ/t of cement produced (Khurana et al. 2002), energy efficiency programs have been extensively applied to various plants (da Graça Carvalho and Nogueira 1997; Utlu et al. 2006; Mandal and Madheswaran 2010; Worrell et al. 2000a; Doheim et al. 1987). For each t of cement, approx. 0.5 t of CO_2 are generated (Office of Energy Efficiency, Natural Resources Canada 2002).

In Worrell et al. (2000a), potentials for energy efficiency improvements in the US cement industry are discussed, and in Liu et al. (1995) those for China.

CO_2 and energy intensity reductions in cement production can be achieved by:

- Modification of the product composition (less clinker)
- Use of alternative cements (e.g., mineral polymers)
- Improving the energy efficiency of the process and process equipment
- Introduction of a different process (e.g., change from wet to dry process)
- Replacement of high-carbon fossil fuels by low-carbon fossil fuels

A trend in the cement industry is the use of waste fuels such as tires. Recommendations on energy efficiency and cost saving opportunities for the cement industry can be found in Worrell and Galitsky (2008).

Glass Production

Glass is a ubiquitous material that comes as sheet glass (produced in the float glass process), hollow glass (for glass containers), automotive glass, optical glass, and other glasses such as glass fiber and glass wool. Its production is an energy-intensive process. According to Sheredeka et al. (2001), 74 % of production costs are typically raw materials, fuels, and electricity. Recycling of glass offers a good way of increasing energy efficiency. One recycled bottle can save approx. 0.1 kWh (Glass Manufacturing Industry Council (GMIC) 2015). In http://www.osti.gov/glass/bestpractices.html (2015), best practices for energy efficiency improvements in the glass industry are provided. A detailed treatise of energy efficiency potentials in the American glass industry can be found in Worrell et al. (2008).

Petroleum Refining

In a petroleum refinery (oil refinery) (Fahim et al. 2009), crude oil is processed into various petroleum products such as naphtha, gasoline, diesel, and liquefied petroleum gas (LPG). Refineries are complex, chemical plants that are usually highly integrated. Crackers, for instance, can produce lightweight hydrocarbons as basic feedstock for the petrochemical industry (see also below).

Energy efficiency in a petroleum refinery can be tackled from various angles. Like in industry in general, there is usually optimization potential in cogeneration, steam systems, heat transfer systems, and motors; see also Coletti and Macchietto (2009a, b), Bevilacqua and Braglia (2002), Wenkai et al. (2003), Fath and Hashem (1988), Najjar and Habeebullah (1991), and McKay and Holland (1981) for details reported in the literature. Worrell et al. (1994a) estimated the energy saving potential for refineries to be around 15 %.

The determination of the energy efficiency of a certain process is a somewhat tricky task, as it depends on boundary limits to be drawn. Alireza Tehrani Nejad (2007) attempts to allocate CO_2 emissions in petroleum refineries to various petroleum products. One aspect of the petrochemical and chemical industry in general that has to be noted here with respect to energy efficiency is that the energy contained in the feedstock is partly converted to heat and power but also remains in the final products to some extent, providing potentials for recycling at the end of the various materials' lifetimes (feedstock recycling or thermal recycling).

Recommendations on energy efficiency and cost saving opportunities in refineries can be found in Worrell and Galitsky (2005).

Petrochemicals

Petrochemicals are products derived from petroleum (Meyers 2004) other than fuels for combustion. The petrochemical industry consumes approx. 8 % of total oil production for the manufacture of various products (The International Energy Association in Collaboration with CEFIC 2007) ranging from plastics, rubbers, and solvents to various fine chemicals. Two important upstream processes are **cracking** (fluid catalytic cracking, steam cracking) for the production of olefins such as ethylene and propylene and **reforming** (catalytic reforming) for the production of aromatics.

Table 9 Potential technologies to make energy-intensive production processes more efficient (Source: Yudken and Bassi (2009) from IEA, DOE, AISI, Aluminum Association, Korean Energy Institute)

Technology option	Description	Time frame
High-temperature furnaces	Able to withstand more than 1,100 °C	MT-LT
Gas turbine integration	Higher-temperature CHP for cracking furnace	MT-LT
Advanced distillation columns		MT-LT
Combined refrigeration plants		MT-LT
Biomass-based system options	Feedstock substitution	LT

ST short term (2010–2015), *MT* medium term (2015–2030), *LT* long term (2030–2050)

Worldwide, more than 10^7 t of propylene, $6.5*10^6$ t of ethylene, and $7*10^6$ t of aromatics are produced per year. From these primary petrochemicals, to which also synthesis gas can be counted, a wide range of chemical products is made. Energy efficiencies of a steam cracker are reported in Tuomaala et al. (2010) and Ren et al. (2008). Naphtha crackers are estimated to consume 31.5 GJ/t of energy (Worrell et al. 2000b).

The gross energy requirement (GER) for major petrochemical products such as ethylene, propylene, butadiene, and benzene is reviewed in Worrell et al. (1994a).

Technology options for reducing energy use and CO_2 emissions for petrochemicals are shown here in Table 9, from Yudken and Bassi (2009).

Below, details on some petrochemical products with respect to energy efficiency are reviewed.

Polymers

The polymer industry has ramped up plastic production between 1950 and 2007 from 1.5 to 260 million tonnes (Johansson 2015) worldwide, which corresponds to an annual growth rate of more than 9 %, making plastics ubiquitous and versatile construction materials. Today, plastic production has reached 300 million tonnes per year (http://www.essentialchemicalindustry.org/processes/recycling-in-the-chemical-industry.html 2015). Polyolefins are the most common plastics, with polyethylene (PE) and polypropylene (PP) accounting for the largest fraction, followed by polyvinylchloride (PVC), polystyrene (PS) and expanded polystyrene (EPS), polyethylene terephthalate (PET), polyurethane (PUR), and others, e.g., engineering plastics such as polycarbonate (PC).

Polymers can be produced with different technologies, ranging from radical reactions (high-temperature and high-pressure processes such as for high-density polyethylene (HDPE)) to catalytic processes (at more moderate conditions), which show varying energy efficiencies.

The gross energy requirements for the production of low-density polyethylene (LDPE), PP, PS, and PVC are 69.8, 61.6, 81.5, and 55.7 GJ/t, respectively (Worrell et al. 1994a). Plastic production uses 8 % of the world's oil production, 4 % as feedstock and 4 % during manufacture (University of York 2010).

Cogeneration and heat recovery in polymerization processes are discussed in Budin et al. (2006).

In Europe, the recycling rate of plastics has reached 51.3 % (21.3 % recycling and 30.0 % energy recovery, i.e., combustion) (Johansson 2015).

Worrell et al. (1994a) investigated potential energy savings in the production of plastics. That study found that the technical potential for energy efficiency savings varies from 12 % for PE to 25 % for PVC. Further information on energy use in plastic production can be found in Patel and Mutha (2004).

Alternative feedstocks, biopolymers, and feedstock recycling (Scheirs 2006) are emerging trends in the industry with impact on energy efficiency.

Chemical Industry

The chemical industry uses crude oil, natural gas, and coal, apart from electricity, both as raw materials and as fuels to produce more than 50,000 different products. More than half of the energy used by the chemical industry is processed as feedstock, which means that it is transformed into various products such as chemicals or polymers. Most energy is consumed by the production of a few small, intermediate compounds. In the chemical industry, energy costs account for 10–15 % of total manufacturing costs (Bieling 2007). For some processes such as electrolysis, energy costs can exceed 50 % of production costs. The DOE estimates potential energy savings within the chemical industry to be approximately 20 %.

Strategies to improve energy efficiency in the chemical industry are process improvements, cogeneration, integration, and the introduction of energy management systems (EMS).

Integration means that rather than producing a single chemical, a production location should strive to use its feedstock to make the desired final product, while utilizing by-products as well. If several production steps, such as crude oil distillation, cracking, and polymerization, can be done in one location, costly and wasteful transportation and storage steps can be avoided (compare the German concept of an integrated chemical complex, the "Verbund." At the largest chemical Verbund site, BASFs, Ludwigshafen, synergies amount to 500 million € per year, 150 million € out of which are attributed to energy savings (The International Energy Association in Collaboration with CEFIC 2007)).

Process design is also an important consideration for energy efficiency, as different unit operations (McCabe et al. 2004) have varying energy demands.

In Worrell et al. (2000b), energy use and energy intensity of the US chemical industry are analyzed. A general review on sustainability and energy efficiency in the chemical industry is provided by de Swaan Arons (2010).

Below, some details on various products of the chemical and process industries with respect to energy efficiency are compiled.

Actual energy consumption values for the production of chemicals are significantly higher than the theoretical demand stipulated by thermodynamics.

A "clean-sheet redesign," not considering cost-effectiveness, would offer a potential for energy savings in chemical production of up to 95 % (Granade et al. 2009; Hinderink et al. 1999).

Catalysts, as they lower the activation energy, can generally increase energy efficiency, particularly enzymatic catalysts for several particular reactions.

Process intensification and **polygeneration** are two emerging technologies that could reduce energy demand in the chemical industry.

By process intensification (Etchells 2005), more compact and efficient plants can be designed. Polygeneration using natural resources is detailed in Serra et al. (2009).

An overview on energy efficiency in the chemical industry is provided in Worrell and Blok (1994) and Worrell et al. (1994a, b, 2000c). **Green chemistry** is discussed in Poliakoff et al. (2002) and Anastas and Warner (2000).

Ammonia

Ammonia is one of the inorganic chemicals with the highest yearly production volume. Its global consumption is in excess of 10^7 t. NH_3 is the precursor to most industrially produced nitrogen-containing compounds. More than 80 % of ammonia is processed to fertilizers. Ammonia production consumes more than 1 % of all man-made power (Max Appl 2006). CO_2 emissions in ammonia production are estimated to be 1.58 t for each t of the product (Office of Energy Efficiency, Natural Resources Canada 2002). Energy consumption is quoted as 39.3 GJ/t for feedstock (natural gas) plus 140 kWh/t electricity, totaling to 40.9 GJ/t (based on higher heating value, corresponding to 37.1 GJ/t based on lower heating value) (Worrell et al. 2000b). Without considering the natural gas, the primary energy consumption for ammonia production is 16.7 GJ/t (Worrell et al. 2000b).

For energy efficiency studies and improvement potentials in ammonia production, see Panjeshahi et al. (2008) and Rafiqul et al. (2005). The use of ammonia as a fuel is described in Zamfirescu and Dincer (2009).

The specific energy consumption for the production of urea is estimated at 2.8 GJ/t (1994) (Worrell et al. 2000b).

Fertilizers

Nitrogen-bearing fertilizer production is a very energy-intensive industry. Ammonia is the most important intermediate chemical compound here (see also above). Table 10 shows the energy use and emission intensity for the production of various fertilizer components, reprinted from Wells (2001):

An early review on energy efficiency in fertilizer production is provided by Mudahar and Hignett (1985). Energy efficiency in the fertilizer industry is reviewed in Ladha et al. (2005), Abdul Quader (2003), Kumar (2002), Mudahar and Hignett (1985), and Fadare et al. (2010).

Nitrogen fertilizer production has an additional impact on climate change, mainly via N_2O emissions (Stuart et al. 2014).

Table 10 Energy requirements to manufacture fertilizer components plus associated CO_2 emissions (Source: Wells 2001)

Component	Energy use [MJ/kg]	Emissions [kg CO_2/MJ]
N	65	0.05
P	15	0.06
K	10	0.06
S	5	0.06
Lime	0.6	0.72

Methanol

Methanol can be produced by steam reforming from methane (Rosen and Scott 1988). It can also be obtained from coal (Li et al. 2010) and various biomass products (Hamelinck and Faaij 2002) such as sugarcane. Methanol has seen increased interest for its use in:

- Direct methanol fuel cells (Jiang et al. 2004)
- Fuel for combustion engines (Agarwal 2007)
- Feedstock for chemical industry (Olah et al. 2009)

In 1994, the specific energy consumption for the production of methanol was 38.4 GJ/t (based on higher heating value) (Worrell et al. 2000b). Best practice in 2013 was 9.0–10.0 GJ/t.

Figure 12 shows today's energy losses in the chemical industry for the major chemicals, amongst them methanol. Catalysis bears a great potential for further energy reduction (DECHEMA 2013).

Industrial Gases

A wide variety of gases is industrially produced and sold in compressed or liquid state. Apart from air, oxygen and nitrogen are amongst the most commonly used industrial gases (Häring et al. 2007), others being argon (welding), carbon dioxide, and methane. Oxygen and nitrogen have traditionally been produced through cryogenic air separation where air is cooled and pressurized until it becomes a liquid with

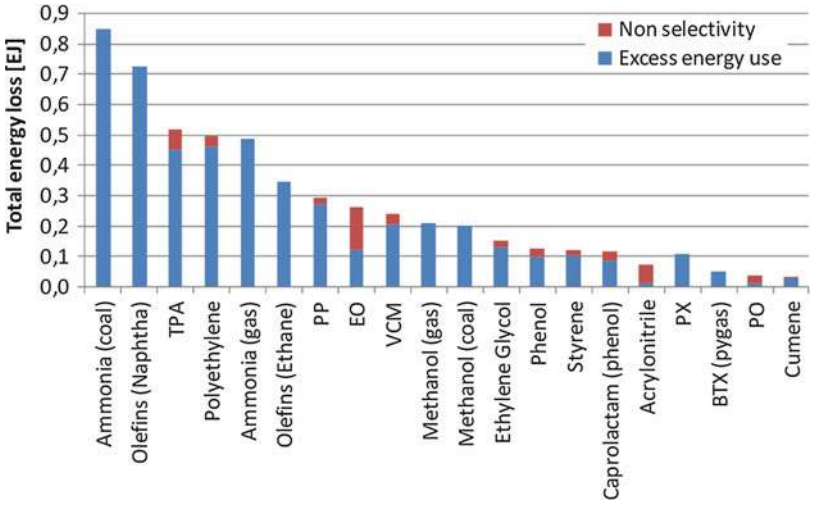

Fig. 12 Cumulated theoretical total energy loss for major chemical processes based on 2010 production volumes (Source: DECHEMA 2013). *TPA* terephthalic acid, *PP* polypropylene, *EO* ethylene oxide, *VCM* vinyl chloride monomer, *PX* paraxylene, *BTX* benzene, toluene, xylene, *pygas* pyrolysis gasoline, *PO* propylene oxide

the various gases being extracted through fractionated distillation. The associated energy consumption is estimated to be 1.8–2.0 GJ/t of oxygen or nitrogen (Worrell et al. 2000b).

Other energy-efficient technologies such as pressure swing adsorption (PSA) (Sharma 2009) and membrane separation (Koros and Fleming 1993) are increasingly used.

For a comparison of cryogeny versus membranes for oxygen-enriched air (OEA) production, see Belaissaoui et al. (2014).

Methane can be produced through anaerobic fermentation (biogas) and methanogenesis (through bacteria). Also, hydrogen can be produced by bacteria (Xia et al. 2014); see also below.

An article on energy efficiency gains in gas production (thermal gasification) is given by Kumar et al. (2010).

Chlorine

Chlorine is produced through electrolysis of a salt solution (brine), which is an energy-intensive process requiring between 3,065 and 3,960 kWh/t (Worrell et al. 2000b). The coproducts caustic soda (sodium hydroxide, NaOH) and hydrogen gas (H_2) are obtained, with the major markets for chlorine being PVC (polyvinylchloride) manufacturing, inorganic chemicals, propylene oxide, water treatment, and organic chemicals.

The chlorine industry is reviewed in Johnston and Stringer (2001).

Technology options for reducing energy use and CO_2 emissions in chlor-alkali manufacturing are summarized from Yudken and Bassi (2009) in Table 11.

Hydrogen

Hydrogen is regarded as an interesting option, as transportation fuel, and as storage medium for electricity, being produced from renewable resources. The "hydrogen economy" (Ball and Wietschel 2009) is often seen as a straightforward solution to many issues around pollution and global warming. Despite all the potential that lies in the technical exploitation of hydrogen, it needs to be borne in mind that the hydrogen – as clean as it is as such – has to be produced. Hydrogen from nuclear power is treated in Hori (2008) and Yildiz and Kazimi (2006).

It is the overall energy efficiency (system efficiency) that will determine whether hydrogen will be used on a large scale as energy carrier. For details, see Page and Krumdieck (2009).

Table 11 Potential technologies to make energy-intensive production processes more efficient (Source: Yudken and Bassi (2009) from IEA, DOE, AISI, Aluminum Association, Korean Energy Institute)

Technology option	Description	Time frame
Convert mercury process and diaphragm process plants to membrane technology	Combined electrolytic cell with a fuel cell, using hydrogen by-product	MT-LT

ST short term (2010–2015), *MT* medium term (2015–2030), *LT* long term (2030–2050)

A comparison of thermochemical, electrolytic, photoelectrolytic, and photochemical solar-to-hydrogen production technologies is made in Wang et al. (2012).

Pharmaceutical Industry

The US pharmaceutical industry has energy expenses of approx. one billion USD per year (Galitsky 2008), which, being only a small fraction of total production costs, is still significant, given the fact that energy savings will translate into direct and predictable earnings. In the pharmaceutical industry, there are three overall stages:

- R&D
- Production of bulk pharmaceutical substances
- Formulation of the final products

Table 12 shows the distribution of energy use (Galitsky 2008) in this sector.

Twenty-five percent of the total energy is used for plug loads and processes, 10 % for lighting, and 65 % for HVAC (heating, ventilation, and air-conditioning). The biggest potential can hence be found in R&D and bulk manufacturing.

Public Sector and Community Infrastructure

The public sector is another area where energy efficiency potential exists.

Awareness of energy efficiency and conservation is a major topic. In a typical office, nearly 40 % of the electricity consumption occurs after closing hours (Danish Ministry of Transport und Energy 2005). In China, the energy consumption in the building sector is 25 % of total energy consumption. The energy use in urban buildings in megacities like Beijing and Shanghai are about 90 % of the whole energy consumption in buildings (Jiang 2011). It was found that amongst these urban buildings, the energy use in **public buildings** is higher than in other building sectors (Jiang 2011). China's Ministry of Construction has issued six energy efficiency design standards to the building sector since 1995, where the latest one is the design standard for energy efficiency in public buildings, aiming at a 50 % reduction of energy consumption in new and refurbished public buildings. Beijing and

Table 12 Pharmaceutical industry and energy use (Source: Galitsky 2008)

Area	Distribution of energy use (%)
R&D	30
Offices	10
Production of bulk pharmaceutical substances	35
Formulation, packaging, and filling	15
Warehouse	5
Miscellaneous	5
Total	100

Shanghai governments have also issued their local energy saving standards for public buildings with 65 % and 50 % of energy saving, respectively (Jiang 2011).

Government institutions can apply energy-efficient procurement and create awareness for energy savings. Public buildings (see also next section) offer energy efficiency increase potential, as does, for instance, the lighting infrastructure of public roads.

For enhancing energy efficiency in public buildings, local energy audit programs were found to be successful (Annunziata et al. 2014).

Energy efficiency in **public lighting** is discussed in Radulovic et al. (2011).

Desalination plants are important in several parts of the world. Their energy efficiencies for different technologies are assessed in Mesa et al. (1997), Tay et al. (1996), Al-Kharabsheh (2006), Gomri (2009), and Charcosset (2009).

Another important infrastructure is **data centers**. Their energy efficiency is discussed, e.g., in Todorovic and Kim (2014).

Buildings

Buildings have a strong and long-lasting impact on global energy consumption, because they are constructed for typically 50–100 years. In 2005, 39 % of the total energy consumption in the USA stemmed from commercial and residential buildings (US Green Building Council 2015). They accounted for as much as 70 % of total electricity consumption (US Green Building Council 2015). There is hence a huge potential for what is known as **green buildings**.

The residential sector in the USA is expected to account for 29 % of the US energy consumption in 2020 (Granade et al. 2009), driven by population growth, larger homes, and more electric and electronic gadgets in private households. The specific energy use for heating of buildings, a major parameter for their energy efficiency, is given in kWh/(m^2*year).

Key determinants for energy efficiency of buildings are:

- Location and surroundings
- Insulation
- Heating technology

Sealing of ducts, basement insulation, and improved heating equipment are seen as major efficiency opportunities in private homes in the USA (Granade et al. 2009).

Heat pumps are particularly energy efficient. There are three types of heat pumps: air to air, water source, and ground source. Ground source heat pumps typically use four times less electrical energy than direct electrical heaters.

Deviations in energy efficiency from the design requirements to actual performance may come from:

- Errors in the design
- Errors in the construction

- Incorrect operation
- Lack of maintenance
- Changed use of the building

Various tools, such as an **energy survey** or an **energy audit**, can help uncover efficiency potentials.

On average, heating and cooling account for almost half of a typical utility bill. Drafty rooms can be improved by checking windows and doors. The HVAC (heating, ventilation, air-conditioning) system often offers potential for improvement and so does the lighting. Compact fluorescent lights (CFL) are more efficient than electric bulbs.

Passive buildings (Miller et al. 2009) and **zero net energy (ZNE) buildings** (Hernandez and Kenny 2010; Elkinton et al. 2009) are more energy efficient than traditional ones. For ZNE buildings, **embodied energy** (Venkatarama Reddy and Jagadish 2003) can be considered. This is the quantity of energy required to manufacture and transport the materials utilized for their construction.

According to Venkatarama Reddy and Jagadish (2003), the total embodied energy of load-bearing masonry buildings can be reduced by 50 % when energy-efficient/alternative building materials are used.

Landscaping around private homes can also bring measurable energy savings. Carefully positioned trees can save up to 25 % of a household's energy consumption for heating and cooling. They can, apart from giving a nice appearance, provide shade and shelter from wind. Payback times for such planting measures can be as low as several years (DOE 1995).

Microgeneration for individual houses is another interesting technology option for the energy savvy.

A small combined heat and power (CHP) system to produce electricity and heat for a community or a single household is known as microgeneration (Entchev et al. 2004). The most promising technologies are Stirling engines and fuel cells in a size range of approx. 1–10 kW_e. Total efficiencies can be typically 80–88 % (Entchev et al. 2004).

It is estimated that in US buildings, 1/3 of the total energy consumption can be saved at a cost of 2.7 $c/kWh (Brown 2008); see also for natural gas savings there. Figure 13 shows the electricity saving potential for the residential area, and Fig. 14 the same scenario for the commercial sector.

It can be seen in Fig. 13 that in the residential area, a huge potential exists for TV sets, lighting, and space cooling, with freezers already being rather optimized. Figure 14 takes a look at the commercial sector.

In the commercial sector, space cooling and lighting offer large potential, with the most cost-effective opportunities residing in space heating and ventilation. Energy efficiency in the residential area is covered in International Energy Agency (2008). A guide on energy efficiency for home owners can be found in Krigger and Dorsi (2008).

Smart metering has been suggested for enhancing residential energy efficiency (Anda and Temmen 2014).

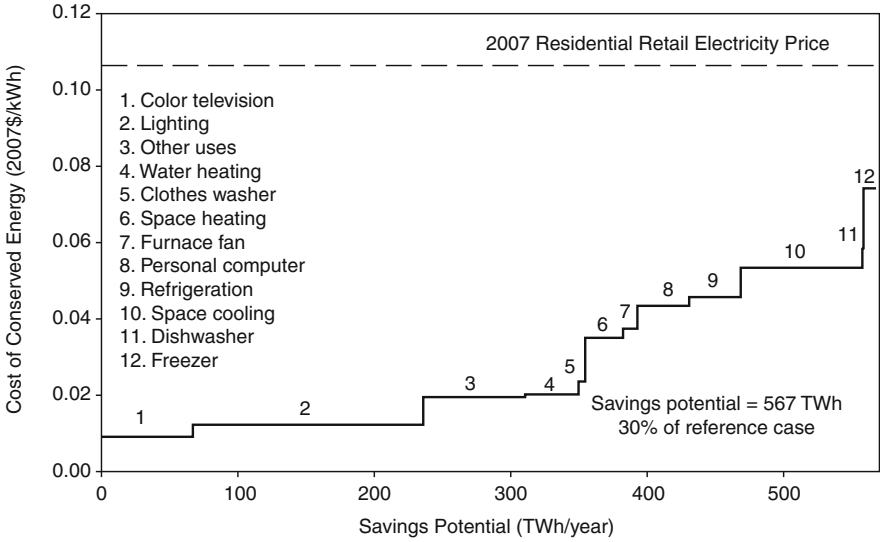

Fig. 13 Residential electricity saving potential in the year 2030 (Reprinted with permission from Brown (2008))

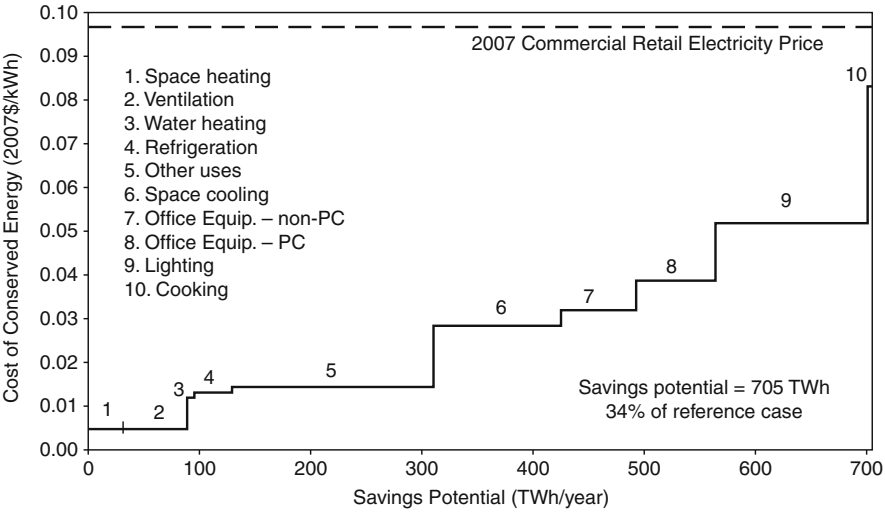

Fig. 14 Commercial electricity saving potential in the year 2030 (Reprinted with permission from Brown (2008))

Appliances

Appliances are a collection of electrically powered devices, which can be found in nearly every household. They account for approx. 20 % of a typical household's energy consumption, with refrigerators, washing machines, and dryers at the top of the consumption list. A "cheap" device can become very costly over its entire lifetime of up to 10 or 20 years (see TCO concept above).

In 1978, California took a leading national role in the USA by establishing the first building and appliance standards in the country. Nearly 85 % of all dishwashers in California are Energy Star™ compliant (see later), and 50 % of refrigerators and washing machines conform to these standards, too. What is even more impressive, however, is that this increase in market share occurred within no more than 7 years; see Fig. 15, reprinted with permission from Next 10's California Green Innovation Index (2010).

Typical renewal cycles of appliances in industrialized countries, here the USA, are shown in Fig. 16, reprinted from Okura et al. (2006).

Modern appliances consume significantly less energy than older ones.

Lighting

Lighting has played a large part in the public discussion on energy efficiency. As traditional incandescent bulbs, which have an efficiency on the order of 1 % to produce light, are being phased out in many countries, mild panic-buying could be observed in 2009 (Jamieson 2009). Some consumers oppose the compact fluorescent lights (CFL), which typically cost four times as much as traditional bulbs. The fact that their energy consumption is one-fifth and that payback times are typically short has not convinced all consumers (yet). There are reservations against the hue of the

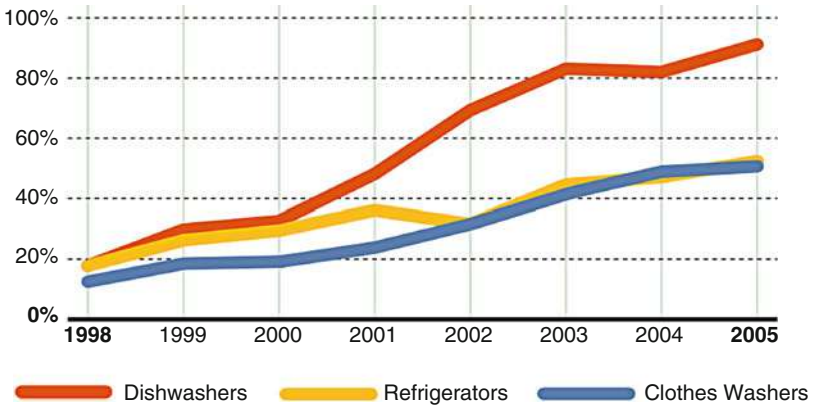

Fig. 15 Market share of Energy Star™ appliances in California (Reprinted with permission from Next 10's California Green Innovation Index (2010))

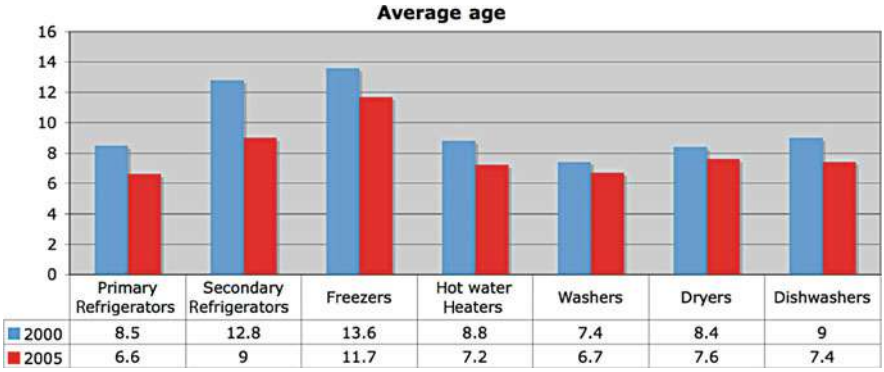

Fig. 16 Appliance renewal cycles (Reprinted with permission from Okura et al. (2006))

Table 13 Number luminous flux emitted by common light sources (Reproduced with permission from Gan et al. (2013)). Lumen is the SI unit of luminous flux, a measure of the total quantity of visible light emitted by a source

Lamp	Lamp wattage	Lumens
Incandescent lamp	75 W	950
Compact fluorescent lamp	15 W	810
Fluorescent lamp	36 W	2,400
LED	18 W	1,600

CFL's light. CFL that work in dimmers tend to cost more than standard CFL. In Techato et al. (2009), a life cycle analysis of CFL is made. An alternative to CFL is light-emitting diodes (LED) (Principi and Fioretti 2014; Gan et al. 2013). For a comparison of typical light sources, see Table 13.

Consumers

Up to 2/3 of household energy use is for space heating, water heating, and refrigeration (Granade et al. 2009) with lighting playing a lesser role. Another significant share is held by the "**plug load**". "Plug load" is a collective term for electrical devices and small appliances. These are virtually hundreds of small devices in private homes, consuming electricity. The biggest shares are held by TV sets (22 %), DVD players (5 %), PCs (5 %), and microwave ovens (3 %) (Granade et al. 2009). **Standby power consumption** is a huge energy waster. In Japan, the annual per household standby electricity consumption could be reduced from 437 to 308 kWh from 2002 to 2005 (Granade et al. 2009). Figure 17 shows typical energy expenditures for Swedish households, reproduced from Nässén et al. (2008).

It is assumed that with a tripling of energy prices, energy use of private households would decrease by 30 % (Nässén et al. 2008). Energy consciousness of consumers has increased over the last years, partly induced by various initiatives such as Energy Star™; see also below.

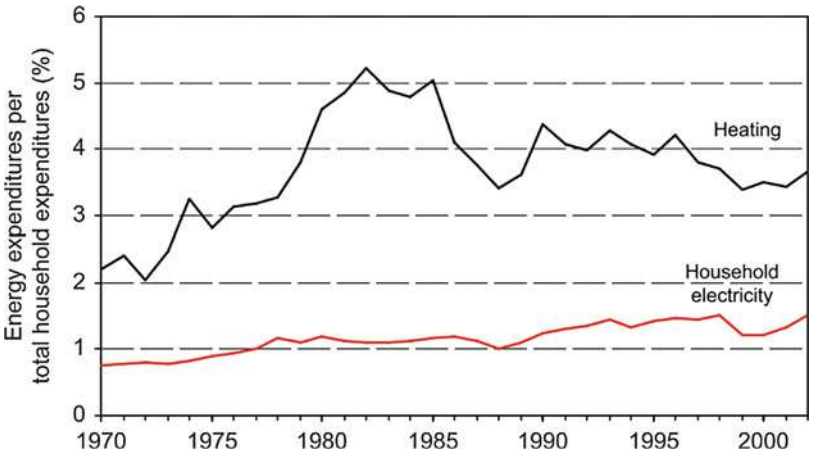

Fig. 17 Annual average of expenditures of households on energy for heating and electricity (Reprinted with permission from Elsevier from Nässén et al. (2008))

Tips and Tricks for Consumers

There are plenty of tips and tricks in various organizations' and authorities' brochures and Internet pages for consumers on how to lower their utility bills. Most of them are commonsense, but it is worthwhile to take a look at them to capture some fast savings. Here are a few examples of often unused potential in private homes:

- The temperature of the refrigerator is too low.
- The refrigerator is positioned in a confined space.
- The washing machine is operated half empty with too warm water temperature.
- Open food is stored in refrigerators (liquids need to be covered, and food should be wrapped to avoid moisture release).
- Untight windows.
- Time is not considered (peak electricity is most costly).

Ample advice on how to save energy (energy conservation and energy efficiency) in the household can be found in the internet, e.g., from governmental sites such as (http://energy.gov/energysaver/articles/energy-saver-guide-tips-saving-money-and-energy-home 2015) or organizations like the OECD (http://www.oecd.org/greengrowth/40317373.pdf 2015).

Initiatives for Energy Efficiency

Energy efficiency improvements do not come "naturally", at least not at the desired speed. In order to overcome the known barriers toward energy efficiency, which were outlined above in this chapter, government action can help. Numerous programs and initiatives to educate people about and to promote energy efficiency have

been started by governments, NGOs (nongovernmental organizations), NPOs (non-profit organizations), for-profit entities, and visionary individuals such as business owners and public celebrities. One such initiative is **Energy Star™**.

The Energy Star® label is used to identify energy-efficient appliances. It was initiated by the DOE (US Department of Energy) and the EPA (US Environmental Protection Agency). Products with the Energy Star™ label usually exceed minimum efficiency standards by a substantial amount.

More information on Energy Star® can be found at (http://www.energystar.gov/ 2015) and (http://www.eu-energystar.org/ 2015). The impact of agreements on energy efficiency is reviewed in Grossman and Krueger (1991).

Other Aspects

There are countless areas for hidden or for indirect energy efficiency improvements, some of which are being touched upon here.

Advanced **packaging**, for instance, can save substantial amounts of materials to achieve the same level of good protection. Lightweight packaging will make transportation over long distances more energy efficient. One example is the replacement of bulky glass bottles by composite containers of (recycled) cardboard and plastics.

In **information technology** (IT), there is often an untapped potential for energy savings and efficiency improvements. Anyone who has witnessed the large air-conditioning systems for server rooms will immediately see the potential offered by what has become known as **green computing**. More details can be found in Minas and Ellison (2009) and Namboodiri (2009).

The **service sector** can also contribute to more energy efficiency. **Electronic banking, video telephony,** and **teleconferencing** (Liang et al. 2007), **telecommuting** (Nelson et al. 2007; Rhee 2008), and **fleet management** (D'Agosto and Ribeiro 2004) are just a few examples where energy for traveling can be economized.

In general, shifting employment and economic activity from manufacturing to the service sector saves energy and cuts greenhouse gas emissions, because the service sector is much lower in energy intensity.

Energy efficiency potentials in hospitals are discussed in Sloan et al. (2009).

Energy efficiency under extreme conditions is reviewed in Tin et al. (2010).

Energy Conservation

Being a broader term than energy efficiency, energy conservation is about using less energy, with a lower energy service being delivered. Sometimes, it is used synonymously with energy efficiency. Energy saving is without doubt the quickest, most effective, and most cost-efficient way for reducing greenhouse gas emissions, as well as improving air quality, especially in developing countries and in densely populated areas. An example of energy conservation on a private level is, for instance, driving

less with one's car. An organization can study its office lighting setup to remove costly over-illumination, for example.

For more information on energy conservation, see Thumann and Dunning (2008), Patrick et al. (2007), Chirarattananon and Taweekun (2003), Jin et al. (2009), Markis and Paravantis (2007), Lin (2007), and Al-Mofleh et al. (2009).

Further Study and Reading

In this section, a few terms that are related to energy efficiency were compiled as a starting point for further exploration by the interested reader.

Dematerialization: By this expression, one can understand the decline of weight and "embedded energy" (cf. embodied energy) of materials in industrial end products over time or, more broadly speaking, the absolute or relative reduction in the quantity of materials required to serve economic functions (Wernick et al. 1996; Tapio et al. 2007). On the one hand, one can observe a decline in weight of certain good such as PCs; on the other hand, people tend to use more materials as their comfort level increases (e.g., larger homes, larger cars). Trends of dematerialization are reviewed in Wernick et al. (1996). A similar term is **ephemeralization**, which was coined by R. Buckminster Fuller. It is the ability of technological advancement to do "*more and more with less and less until eventually you can do everything with nothing*" (Buckminster Fuller 1973).

Industrial Ecology: Being defined as a "systems-based, multidisciplinary discourse that seeks to understand emergent behaviour of complex integrated human/natural systems" (Allenby 2006), industrial ecology strives at sustainability and eco-efficiency. More information on the topic can be found in Frosch and Gallopoulos (1989).

Eco-efficiency: According to the World Business Council for Sustainable Development (WBCSD), it is expressed as:

- Reduction in the material intensity of goods or services
- Reduction in the energy intensity of goods or services
- Reduced dispersion of toxic materials
- Improved recyclability
- Maximum use of renewable resources
- Greater durability of products
- Increased service intensity of goods and services

More information can be found in World Business Council for Sustainable Development (WBCSD) (2000).

Water efficiency: Water efficiency is closely linked to water conservation. It can be defined as the accomplishment of a function, task, process, or result with the minimal amount of water feasible. Effluent reuse is one important means of achieving water efficiency (White and Howe 1998). It is estimated that each m^3 of water utilized in the industrial and service sectors generates at least 200 times more wealth

than it does in the agricultural sector (Beaumont 2000). This suggests that water-intensive production will be shifted from arid regions to those with more water (compare the shift of CO_2-intensive production to certain areas). Here, the concept of **virtual water** (Allan 2005; Chapagain 2006) steps into place. Virtual water, also called **embedded water, embodied water**, or **hidden water**, refers to the water needed to manufacture a good or service.

Yearly individual water consumption is on the order of 1 m^3 for drinking, 100 m^3 for domestic use, and 1,000 m^3 embedded in food. This shows that the concept of virtual water is closely linked to water efficiency and ultimately to energy efficiency.

Other burning topics related to energy are the **affordability** of energy and **access** to **energy**, which are both not secured for a high number of people.

Conclusions

This chapter has taken a look at energy efficiency in industry, transportation, the private sector, and other areas, exploring a topic of high relevance for climate change mitigation. Energy use efficiency is the cheapest and easiest source of energy, with a huge unused potential. It is estimated that up to 1/3 of the worldwide energy demand in 2050 can be saved by energy efficiency measures.

In its "International Energy Outlook 2014," the EIA (US Energy Information Administration) mentions a growing energy efficiency in the transportation sector, which, in OECD Europe, already induced a decline in consumption of liquid fuels (EIA (US Energy Information Administration) 2014). Energy efficiency has started to proliferate, and there is still a lot of potential.

In this chapter, aspects of energy efficiency from various sectors were presented, spanning historic data, current levels, and future trends. An emphasis is placed on providing brief information and references on how energy efficiency improvements can be realized.

Fuel Efficiency in Transportation Systems

Maximilian Lackner, John M. Seiner, and Wei-Yin Chen

Contents

Abstract

Transportation of people and of goods plays an important role in modern life. It is a major source of anthropogenic CO_2. This chapter, after introducing some fundamentals of natural climate fluctuations as described by Milankovitch cycles,

describes the causes and consequences of man-made climate change and the motivation for increased fuel efficiency in transportation systems. To this end, contemporary and future ground-based and air-based transportation technologies are discussed. It is shown that concepts that were already given up, such as turbine-driven cars, might be worthwhile for further studies. Alternative fuels such as hydrogen, ethanol and biofuels, and alternative power sources, e.g., compressed air engines and fuel cells, are presented from various perspectives. The chapter also addresses the contribution of CO_2 emissions of the supply chain and over the entire life cycle for different transportation technologies.

Introduction

The purpose of this chapter is to introduce current concepts being examined to increase fuel efficiency in transportation systems in order to reduce their impact on unfavorable climate change. This is a daunting task that will take the cooperation and sacrifice of most of the entire human population to avoid a premature catastrophic event. Now, other chapters of this handbook reveal the salient scientific reasons for climate change, and the reader is encouraged to consult these chapters. However, here it is only necessary to establish that global warming or cooling has continually occurred by natural causes since Earth's formation. This can be deduced from examining the so-called Milankovitch cycles (Kukla and Gavin 2004).

Transportation of people (passengers) and goods (freight, cargo) can be done on the land, the sea, and the air. Approx. 50 % of all transportation emissions are from passenger transport (Lipscy and Schipper 2013). One can distinguish between individual transportation (e.g., cars, bikes) and mass transportation (e.g., trains, planes, buses). Land-based transportation is achieved on highways and on railroads. Travel intensity and choice of transportation mode depend on personal preference, income, and country (Lipscy and Schipper 2013). Trip distance, e.g., to work for commuters, is also an important driver (Muratori et al. 2013). Goods can also be moved in pipelines. With the globalization of the economy and shifts in lifestyle habits, transportation has become more and more important over the last 100 years, both in the industrial and the developing world. Figure 1 below, in an exemplary fashion, shows the increase in energy consumption for transportation in China.

According to Zhang et al. (2011a), highways have become the dominant mode of transportation in China. The energy consumption in this mode increased from 1980 to 2006 from 36.4 % to 61.5 %. Other economies have seen similar developments. As Fig. 1 shows, other transportation systems have seen more and more usage as well.

Transportation systems are mainly driven by fossil fuels, predominantly those made from crude oil. The reason is that liquid fuels such as gasoline and diesel have high energy content that are safe and convenient to handle at low costs.

Energy efficiency of transportation systems can be defined as the amount of energy needed for a certain task, e.g., the transportation of one passenger or one unit of cargo over a certain distance. Transportation and energy is reviewed in

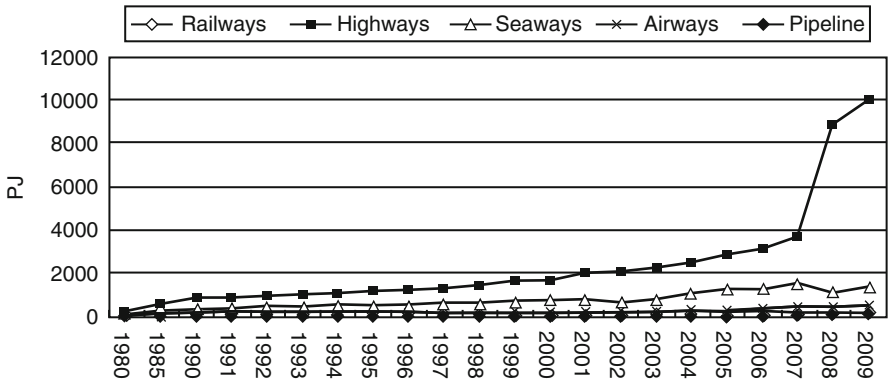

Fig. 1 Chinese transportation sectors and their energy consumption from 1980 to 2009 (Reproduced with permission from Zhang et al. 2011b)

Greene (2004). Energy efficiency is the most economic way for climate change mitigation (Kamal 1997). Therefore, efforts need to be taken to improve energy efficiency of transportation systems.

Since the year 2000, the world production of gasoline (petrol) has matched consumption of this product. This has led to sporadic shortfalls of gasoline at the pumps along with elevated costs. Beyond the uncertainty of future fuel costs, the predictions for effects of global warming on the planet are very severe, and it is important that mankind addresses the issue of how transportation systems contribute to this problem. Today there are over one billion vehicles in the world, and within 20 years, the number will double (Sperling et al. 2010), largely a consequence of China's and India's explosive growth. Figure 2 takes a look at the projected number of cars in China. An impressive increase is expected over the next years (Hao et al. 2011).

Figures 1 and 2 depict the situation in China, which was chosen as a showcase example here, as China is currently one of the world's major emitters of anthropogenic CO_2.

At the present time, as shown in this chapter, there are only partial solutions to reduce the impact of transportation systems on global warming. Energy conservation by avoiding travel is one option. Technical improvements to transportation systems are another approach.

Readers will note that the production of CO_2, a by-product from the combustion of carbonaceous fuels such as gasoline with air, has been linked to a global increase in temperature. With an increase in the Earth's temperature comes melting of the ice caps and a rise of sea level on coastal cities. Of most concern is an accompanying change in composition of the Earth's fragile atmosphere. Millions of years ago the Earth had a very different atmosphere than it does today, where ice caps were melted and instead had lush forests. The percentage of O_2 was over 30 %, a level that would support large mammals, as it did, but not the present human population. Therefore, it is imperative that economical methods be found to reduce the emission of CO_2 if mankind is to have a sustainable future. Tim Flannery (2006) (http://www.

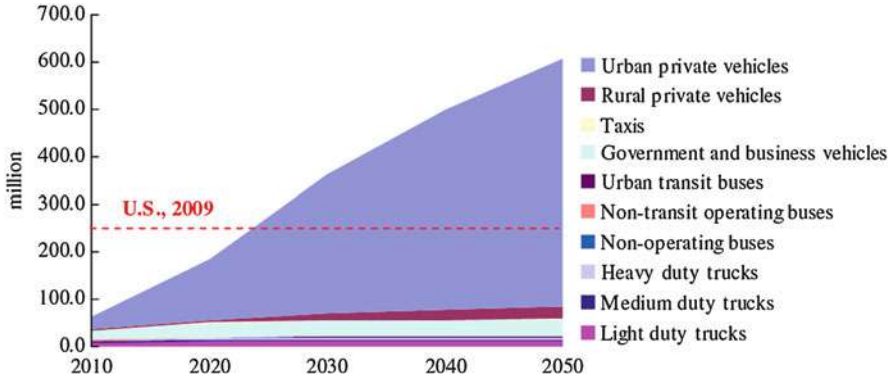

Fig. 2 Projection of China's vehicle population through 2050 (Reproduced with permission from Hao et al. 2011)

theweathermakers.org/) pointed out in his book that to stay below the threshold for melting of the ice sheets in Greenland and West Antarctica, it would be needed to reduce CO_2 emissions by 80 % from today's levels. This corresponds to no more than 30 lb of CO_2 per person per day. Further, Flannery predicts that if progress in reaching the above goal is not enough, only 20 % of the present world population will reach the year 2050. Professor Tim Flannery is an Australian mammalogist, paleontologist, environmentalist, and global warming activist.

In this chapter, the case for the reduction of CO_2 emissions from transportation systems is made. Solutions to efficient reductions are an evolutionary process where incremental change may represent mankind's only solution. With this viewpoint prior automotive designs that were introduced years ago and that failed to gain acceptance but may deserve another evaluation will be discussed. Present-day automotive engines utilize fuel injection systems instead of carburetors and represent the main reason for increased fuel mileage. Consequently, this chapter will also examine various engine cycles. Other measures such as lightweight construction materials, car pooling, and traffic management can also reduce fuel consumption. There is also a need to consider alternate fuels not only for emissions, but also reduction of the dependence on oil. Thus, the use of biofuels and hydrogen as substitutes for oil will be discussed. This is such a broad effort that this chapter will only be able to introduce a few concepts for automotive applications. Concepts for other landborne plus air- and seaborne transportation will be touched upon. The authors will also briefly discuss fuel cells, hybrid vehicles, and electric vehicles. Aircraft with respect to fuel efficiency will shortly be addressed. There is no question that aircraft play an important role in contemporary lifestyle, but they require significant energy to perform their mission. Thus it will be necessary to introduce radical designs that would substantially reduce the fuel burn rate.

The Issue

Since Earth's formation, the atmosphere's composition and temperature has changed dramatically due to the Earth's cooling. However, there is another factor that affects the temperature of the atmosphere that is related to gravitational attraction between the planets and the sun. This gravitational attraction produces an eccentricity of the Earth's orbit, obliquity of the Earth's axis, and precession of the Earth's axis of rotation. These effects have various periods as was first noted by Milankovitch who observed the following periods of the Earth's axis: Wobble cycles of 19,000 and 23,000 years, tilt cycle of 41,000 years, and cycles of 100,000 and 400,000 years to the Earth orbit around the sun (Kukla and Gavin 2004). The Earth's orbit transitions periodically between a circular and an elliptical orbit. When on an elliptical orbit, the Earth's distance to the Sun has periods where it is the greatest, and the Earth's atmosphere is cold (i.e., ice age). Currently, the Earth is in a more circular orbit, and the Earth's temperature is warmer. These Milankovitch cycles are of course natural events that mankind cannot interfere with. During previous periods the ice caps were melted, and in the USA, alligators extended as far north as Denver. Data gathered from the Antarctica ice shelf allow researchers to infer the air temperature of the Earth at that location going back 400,000 years from analysis of cores drilled into the ice. Further analysis of these cores also permits one to estimate the percentage of CO_2 in the atmosphere during this period of time. One can also deduce that during nearly circular orbits, the Earth's temperature is the warmest, and during elliptical orbits, the Earth's temperature is the coldest. The temperature spikes around 320,000, 210,000 and 130,000 years before today's time and now have elevated contents of CO_2 in the atmosphere. The warming periods that occurred beyond present day were controlled by natural events. However, during the present cycle that includes the Industrial Revolution, there appears to be a large increase in the percentage of CO_2 that is significantly higher than recorded for previous cycles: the CO_2 concentration in the atmosphere is elevated by 100 ppm due to human action. During the warm periods where the Earth's orbit is nearly circular, the peak concentration of CO_2 has been in the order of 275 ppm CO_2. Today (January 2015) it has spiked to just under 400 ppm (The Keeling Curve et al. 2015), about 40 % higher than in preindustrial times and higher than in any other period in at least 800,000 years. The level of atmospheric CO_2 is rising at a rate of approximately 2 ppm/year. This increase can be attributed to the presence of humans on Earth and their rapid consumption of energy, i.e., by the combustion of fossil fuels. A fair question to ask is what are the major contributors to CO_2 production and how the CO_2 concentration is related to Earth's average temperature. From Fig. 3, one can see that there are three main contributors to the production and emission of CO_2 in the atmosphere from burning fossil fuels, cement production, and land use change. The figure, reproduced from the 5th IPCC Assessment Report (2013), also shows the CO_2 sinks. These represent the areas where technology developments to reduce CO_2 are needed.

The question then is how this increase in concentration of CO_2 modifies the average temperature of the planet.

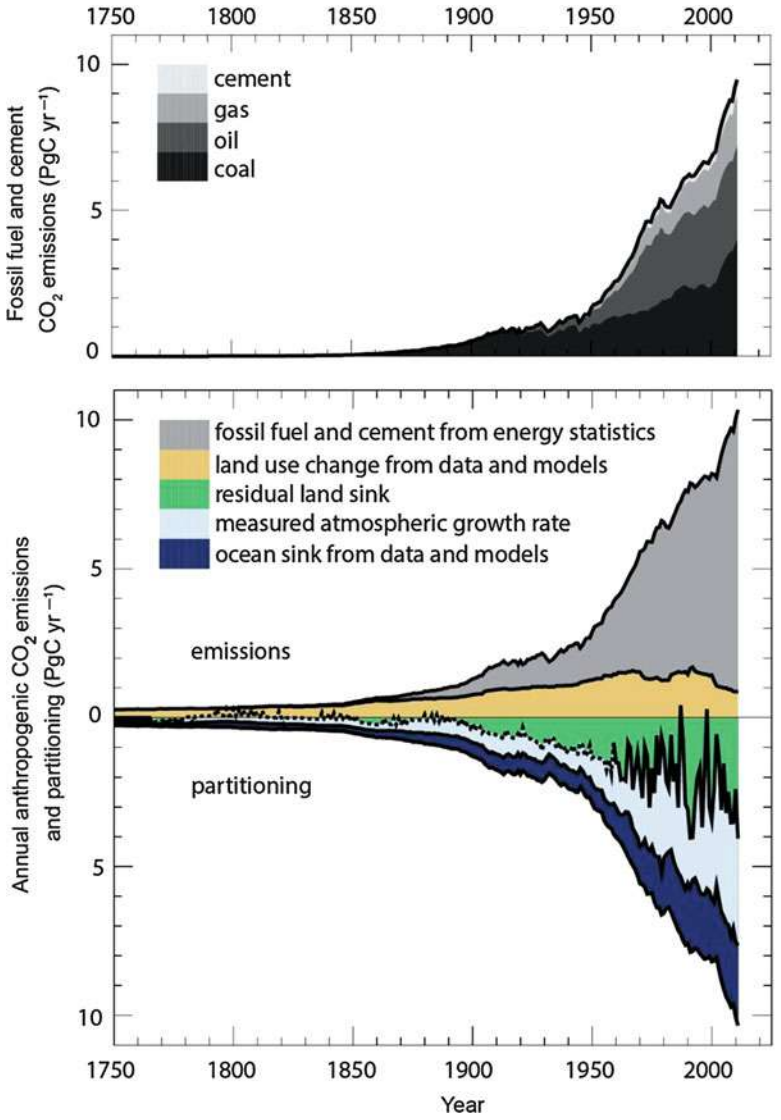

Fig. 3 Leading contributors to production of CO_2 and sinks (Reproduced from IPCC 2013)

Note that CO_2 is not the only anthropogenic greenhouse gas, but also the most important one. Most of the natural greenhouse effect is caused by water vapor.

Other important greenhouse gases are CH_4, N_2O, and SF_6. CH_4 emissions are also produced by the transportation sector, e.g., as losses from natural gas (and biogas) production and distribution and as unburnt hydrocarbon emission from the combustion process.

It is very surprising how small an increase in CO_2 concentration contributes to the average temperature around the globe. Now, the atmosphere has reached a level of said ~400 ppm. This means that the world has seen a nearly 2 °C increase in temperature over that of preindustrial times. Even with this small increase in average temperature, many today can recall changes that have occurred and are noteworthy (for more information on narrative research in climate change, see, e.g., (Paschen and Ison 2014). In the early 1900s, people would drive their cars across Lake Ontario to Toronto, Canada, on the frozen ice sheet. This lake has not frozen over for more than 50 years. In Southern Virginia, James River used to freeze over as late as the 1950s, but no longer. Predictions by Flannery are that if an atmospheric CO_2 concentration between 900 and 1,000 ppm is reached, in the future only one in five people would survive. Now, aside from observations that have occurred with an increase in global temperature, one can observe that the ice sheets have already begun to melt. Figure 4 shows the extent of the Arctic sea ice averaged over the period 1979 to 2007 for the months May to September. Following Fig. 5, one can see that the ice shelf does not restore itself until September. In a typical year the ice sheet would begin to grow again in August, but now in August it is still melting. With melted ice sheets, the Earth's thermal energy balance is changed since more heat from the Sun is absorbed by the Earth rather than being reflected back into space. Thus, the cycle is intensified.

Figure 5 below shows the thickness of the ice sheet north of Greenland in the 1950s and the prediction by NOAA (National Oceanic and Atmospheric Administration) for the year 2050, which shows the ice sheet is predicted to be reduced to half its previous size.

Therefore, there is a strong motivation to increase the fuel efficiency of transportation systems for people and freight to mitigate anthropogenic climate change. Several aspects will be discussed below.

Carbon Emissions by Light Duty Vehicles

It can be seen that since the beginning of the Industrial Revolution, the planet's atmosphere has increased in temperature by almost 2 °C. Not a large increase, but big enough to start significant melting of the ice caps. One can see that the temperature increase can be linked to a large increase in CO_2 in the atmosphere. Combustion of solid (coal), liquid (gasoline, diesel), or gaseous (natural gas) fuels, to a significant fraction for transportation purposes, is the major contributor to the production of anthropogenic CO_2. Natural gas has a higher H/C ratio than diesel or gasoline. Therefore, it is more climatically benign when being burnt in engines (note that the greenhouse warming potential [GWP] of CH_4 is ~20 times that of CO_2, so CH_4 emissions are to be avoided).

A natural question to ask at this point is what percentage of CO_2 production is due to transportation and which countries are the major contributors. DeCicco et al. provide a graphic illustration of each sector's contribution in Fig. 6. The estimates shown in this figure only include the use of fossil fuel. As can be seen,

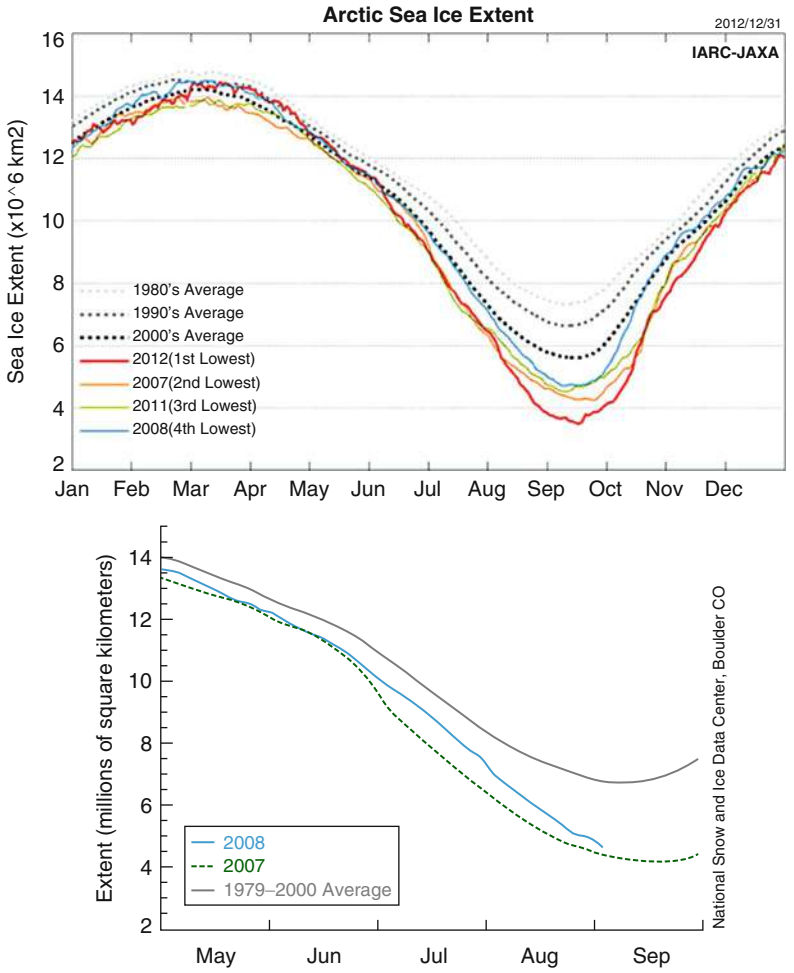

Fig. 4 Annual cycle of the Arctic sea ice extent for 2012 (*red*), 2007 (*orange*), 2011 (*green*), and 2008 (*blue*). *Dashed lines* show decadal means for the 2000s (*black dashes*), 1990s (*gray dashes*), and 1980s (*light-gray dashes*) (Source: IARC/JAXA Sea Ice Monitor, http://www.ijis.iarc.uaf.edu/en/home/seaice_extent.htm) (Walsh 2014)

over 40 % of the CO_2 emissions are from the production of home electricity and heat. Light-duty vehicles only account for 10 % of the production, and almost half of that is produced in the USA with a significant nearly a quarter from Europe. One observes that only a little over 2 % occurs in China and India. In the next 20 years, China and India are expected to grow and consume an amount equal to the USA (compare also Figs. 1 and 2).

A substantial growth in CO_2 production by light-duty vehicles would require additional refineries throughout the world, or extreme shortages at the pump would

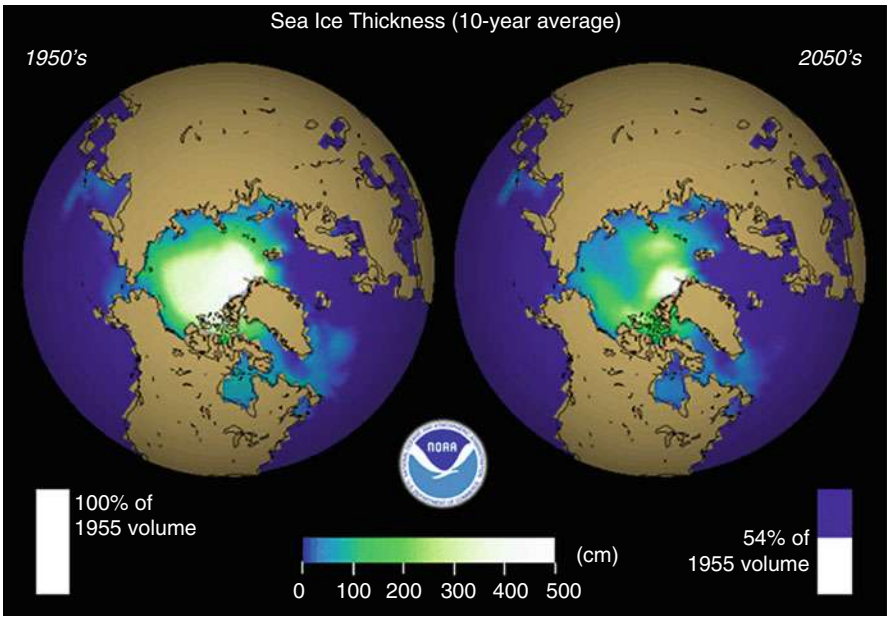

Fig. 5 Melting of the polar ice cap (Reprinted with permission from the National Snow and Ice Data Center 2015)

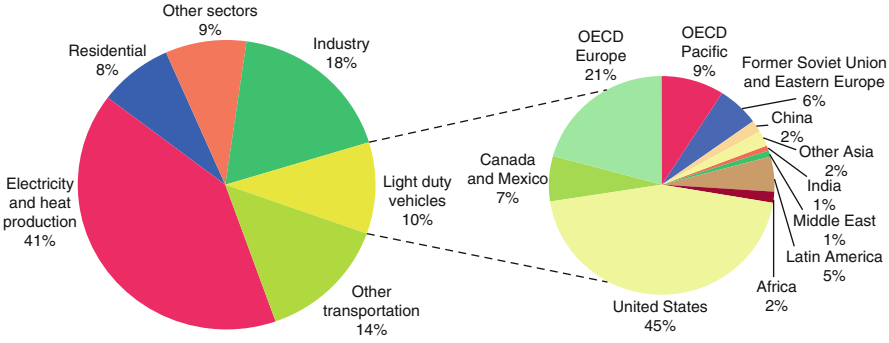

Fig. 6 Estimates for CO_2 production by sector and light-duty vehicles. *Left*: Global carbon emissions by sector (6,814 $*10^6$ t). *Right*: Light-duty vehicle carbon emissions by region ($680*10^6$ t). (Reprinted with permission from DeCicco et al. 2015)

occur. Energy conservation will play a more realistic role in the future to avoid the problem of fuel shortage, but this cannot be expected to take effect until existing vehicles are replaced with ones using new technology. DeCicco also addressed this issue, and in Fig. 7a, one can see that old SUVs dominate the carbon burden share

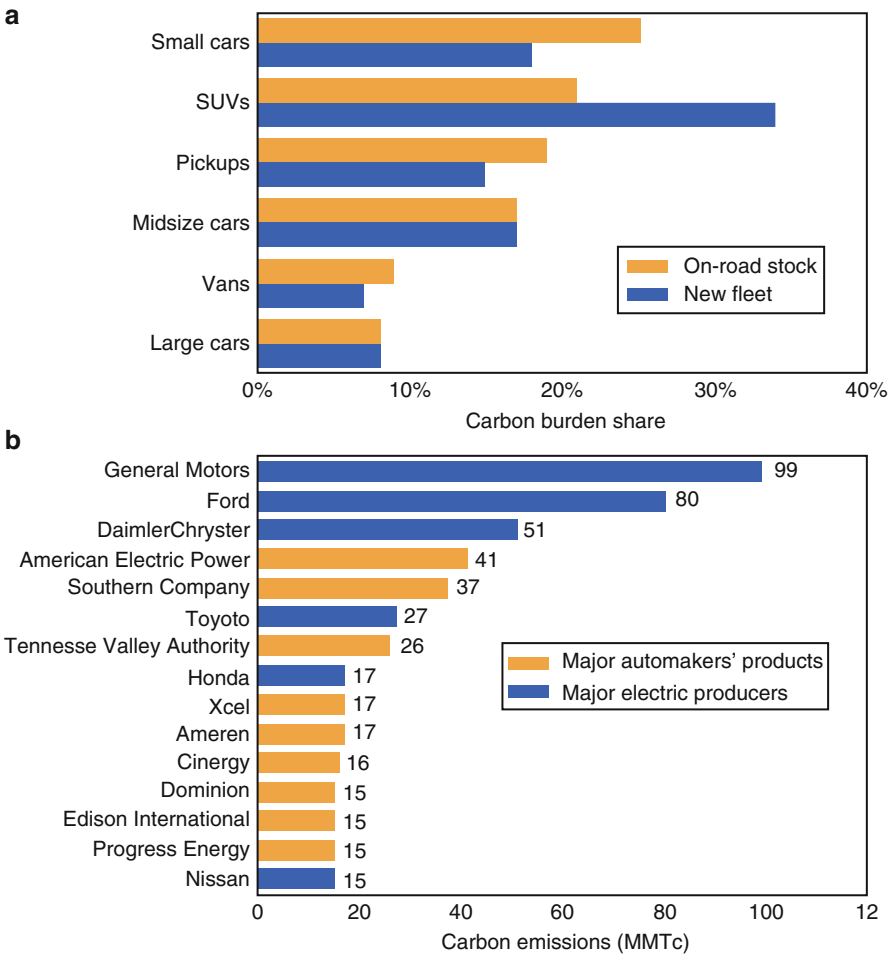

Fig. 7 Carbon emissions by new versus old vehicles and electric producers. (**a**) CO2 pollution as % of new & old vehicles. (**b**) Carbon emissions: auto & electric producers DeCicco et al., Global Warming on the Road (DeCicco et al. 2015)

and that both new and old midsize cars contribute equally. Carbon emissions by cars dominate those associated with electric producers, see Fig. 7b. These statistics indicate that there is a need to adopt a policy to retire existing vehicles as soon as possible and, in particular, SUVs.

DeCicco et al. point out that there are three factors that govern the production of carbon dioxide in the transportation sector. The first is related to travel demand, the second to automotive efficiency, and the third to carbon content per gallon of fuel. Aside from reducing the distance travelled per year by car or light-duty truck, it is of interest to know how alternate means for ground transportation compare to decide which mode to emphasize. Table 1 shows a compilation of results by the US

Table 1 Efficiency of various transportation systems 1 gal (~3.7854 l) of gasoline contains approximately 114,000 BTU (120 MJ) of energy. MPGe = miles per gallon gasoline equivalent. This measure of the average distance travelled per unit of energy consumed compares the energy consumption of alternative fuel vehicles. 1 MPGe ≈ 0.0182 km/kW · h ≈ 0.005 km/MJ

Transport mode	Average passengers per vehicle	Efficiency per passenger	
Vanpool	6.1	1,322 BTU/mi	2.7 l/100 km (87 MPGe)
Motorcycles	1.2	1,855 BTU/mi	3.8 l/100 km (62 MPGe)
Rail (Amtrak)	20.5	2,650 BTU/mi	5.4 l/100 km (43 MPGe)
Rail (transit light and heavy)	22.5	2,784 BTU/mi	5.7 l/100 km (41 MPGe)
Rail (commuter)	31.3	2,996 BTU/mi	6.1 l/100 km (38 MPGe)
Air	96.2	3,261 BTU/mi	6.7 l/100 km (35 MPGe)
Cars	1.57	3,512 BTU/mi	7.2 l/100 km (33 MPGe)
Personal trucks	1.72	3,944 BTU/mi	8.1 l/100 km (29 MPGe)
Buses (transit)	8.8	4,235 BTU/mi	8.7 l/100 km (27 MPGe)

Department of Energy (DOE) for the efficiency of various transportation systems in terms of energy expended per passenger with an estimate of an equivalent number of liters per 100 km. The efficiency in Table 1 is estimated in terms of BTU/mile and also in miles per gallon.

Table 1, from the US Department of Energy in 2008, clearly indicates the value of carpooling with a van that would carry six passengers. On a per passenger basis, the vanpool achieves 87 $MPGe_{US}$, an efficiency that would be hard to match by an automobile with a single passenger. Only motorcycles nearly match the vanpool. Personnel trucks are listed as one of the most inefficient modes of transportation with cars, only slightly better. Transit buses are the worst form primarily due to the constant stopping and starting needed to pick-up and let off passengers.

Carbon Generated by Combustion with Air

Each barrel contains 42 gal (159 l) of crude oil and consists of various petroleum products as shown in Fig. 8. As one can observe, only about half a barrel of crude can be refined into gasoline (after fractionated distillation, several processes in a refinery such as cracking can shift the product mix).

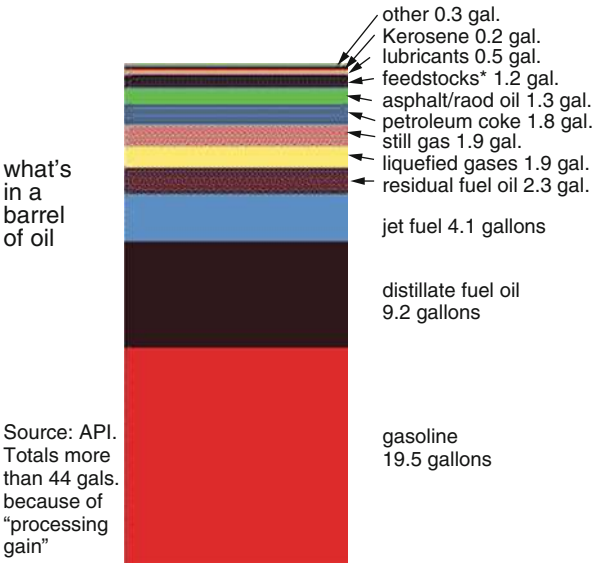

Fig. 8 Products obtained from refining a crude barrel of oil (Reproduced with permission from Gibson Consulting 2015). *API* American Petroleum Institute

The amount of CO_2 emitted per gallon is governed by the Code of Federal Regulations (40CFR600.113) (Title 40 2015). The carbon content of gasoline per gallon is 2,421 g, whereas the carbon content of diesel fuel per gallon is 2,778 g.

Recall the words of Tim Flannery who said that to prevent the ice sheets from melting, every human had to be on a diet of 30 lb or less of carbon a day. So each person could only use about a gallon and a half of gasoline each day. The ability to use only a gallon and a half each day strongly suggests an elusive goal. While one may not be able to meet this goal, earnest conservation steps can ease the way into the inevitable. One of the first conservation steps one can take is to consider engine thermodynamic cycles to see if there is any advantage. Toward this purpose, the bare essentials associated with the spark and compression ignition engines are discussed.

The four-stroke engine cycle was first patented by Eugenio Barsanti and Felice Matteucci in 1854. An illustration of the four-stroke cycle, reproduced from Obert (1973), is shown in Fig. 9. There, one sees the position of the cylinder head, intake valve, exhaust valve, and spark ignition for one entire cycle. Figure 10a, b show that the thermodynamic model for either SI (spark ignition) or CI (compression ignition) during intake and exhaust is considered to be an isentropic process (=constant entropy). During cycles of heat in or out, the thermodynamic model is far from isentropic. Note that for compression ignition engines, during combustion, the process takes place at constant pressure.

For the ideal combustion, the efficiencies associated with the stoichiometric combustion of these fuels with air are illustrated in Fig. 10. For gasoline, this is given by

$$C_8H_{18} + 12^{1/2}O_2 + 47N_2 \rightarrow 8CO_2 + 9H_2O + 47N_2$$

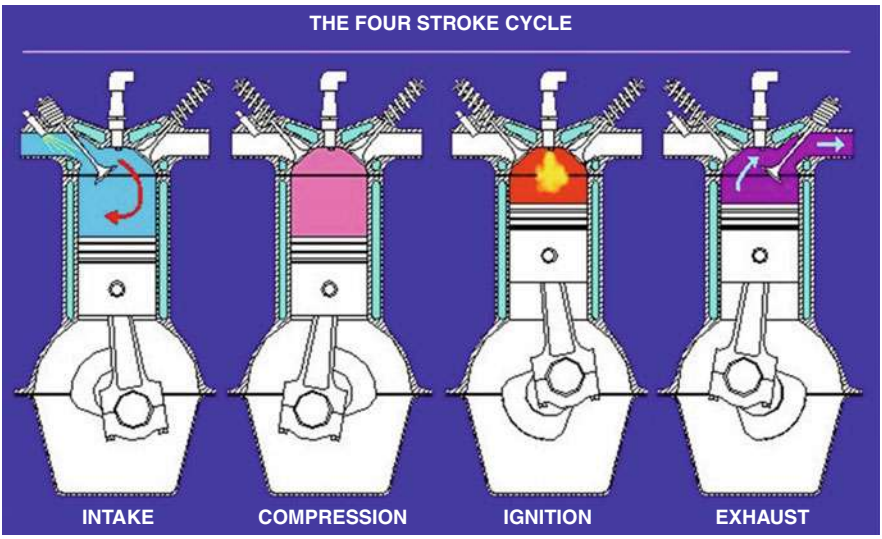

Fig. 9 Graphic illustration of four-stroke compression ignition engine (Reproduced from Obert 1973)

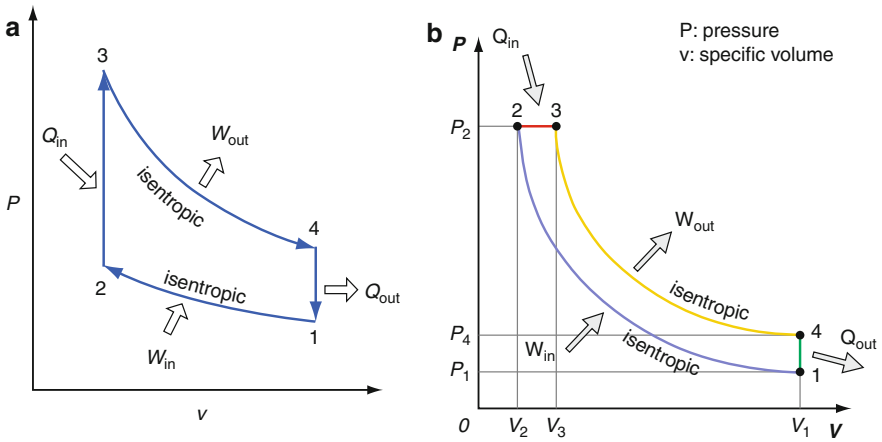

Fig. 10 Idealized four stroke for SI and CI combustion models. (**a**) Otto cycle Pv Diagram. (**b**) Diesel cycle Pv Diagram(Reproduced from Obert 1973). *P*, pressure; *v*, volume; *W*, work; *Q*, heat; *SI*, spark ignition; and *CI*, compression ignition

where following Fig. 10a one can note

$$Q_{Arev} = c_v(T_3 - T_2) \quad \eta_t = \frac{Q_A + Q_R}{Q_A} = 1 - \frac{T_1}{T_2} = 1 - \frac{1}{r_v^{\gamma-1}}$$
$$Q_{Rrev} = c_v(T_1 - T_4)$$

where r_v is the engine compression ratio. As an example, consider the following: engine compression ratio, $r_v = 8$; ambient temperature, $T_a = 540\ ^\circ R$ (300 K); ambient pressure, $P_a = 14.7$ psia (101.3 kPa = 1.014 bar); and then one has that

$$\eta_t = 1 - \frac{1}{r_v^{\gamma-1}} = 1 - \frac{1}{8^{0.4}} = 0.565 = 56.5\%$$

Factoring in transmission and drive train, the overall gasoline-powered automobile efficiency is approx. 17 % (Obert 1973). Quite remarkable, about 83 % of the available energy is wasted on the gasoline-powered internal combustion engine. Even the thermal efficiency of the four-stroke ideal diesel engine cycle appears more attractive. Consider the Pv diagram shown in Fig. 10b, which shows air coming into the system at constant pressure and air being discharged from the system at constant pressure. Based on this cycle one can derive that the reversible heat added and discharged is given by

$Q_{Arev} = c_v(T_3 - T_2)$
$Q_{Rrev} = c_v(T_1 - T_4)$, and since $\left(\frac{T_3}{T_2}\right)^\gamma = \left(\frac{T_4}{T_1}\right)$, the thermal efficiency is given by

$$\eta_t = \frac{Q_A + Q_R}{Q_A} = 1 - \left(\frac{1}{\gamma}\right)\left(\frac{T_4 - T_1}{T_3 - T_2}\right) = 1 - \frac{1}{r_v^{\gamma-1}}\left[\frac{r^\gamma - 1}{\gamma(r-1)}\right]$$

Typical values for the diesel cycle are compression ratios near 25 to ensure auto ignition. A diesel engine takes in just air, compresses it, and then injects fuel into the compressed air. The heat of the compressed air lights the fuel spontaneously. A typical thermal efficiency computed from the above equation using a compression ratio of 25 is a value $\eta_t = 0.264$. Note: Diesel engines are in general 30–35 % more efficient than gasoline-powered vehicles; however, efficiency strongly depends on the vehicle load.

The energy efficiency of alternative power trains in vehicles is discussed in Åhman (2001).

Otto and diesel engines are most commonly used in transportation. The Wankel engine is another concept with less proliferation. It operates without pistons. The Mazda RX-8 is one example of a car that deploys a Wankel engine. Table 2 shows some aspects of Wankel engines.

Experiments with turbine-powered cars were carried out in the USA around 1960. The following pros and cons were identified (Table 3).

Gas turbines are very efficient at high speeds and constant load. They need time to reach optimum operating conditions, and they produce thrust rather than torque. The problem with vehicles is that they are operated in several load conditions and often only for short distances.

Although the concept of turbine cars was abandoned soon after their appearance, they might still offer an interesting route to future efficient cars, so new research is carried out in this area, for instance, on micro-gas turbines (MGT) to recharge battery packs, in particular, for electric vehicles (EVs) (Sim et al. 2013).

Table 2 Assessment of the Wankel engine (Reproduced with permission from Hege 2006)

Pros	Cons
High power output/unit weight	Rotating seals reduce engine compression ratio
Good fuel/air mixing	Large fraction of unburned fuel lowers the efficiency
Even combustion	Excessive noise due to rotating seals

Table 3 Assessment of turbine-powered automobiles (Reproduced from Hege 2006)

Pros	Cons
Low maintenance Long engine life expectancy Reduction of number of parts by 80 % No warm-up period, easy low-temperature start No stall at sudden overload Hot but clean exhaust gases Low oil consumption Operation on wide fuel variety	High fuel consumption at idle due to high rpm throttle lag from idle as the engine spools up. High temperature of exhaust gases, low efficiency High noise emissions Expensive

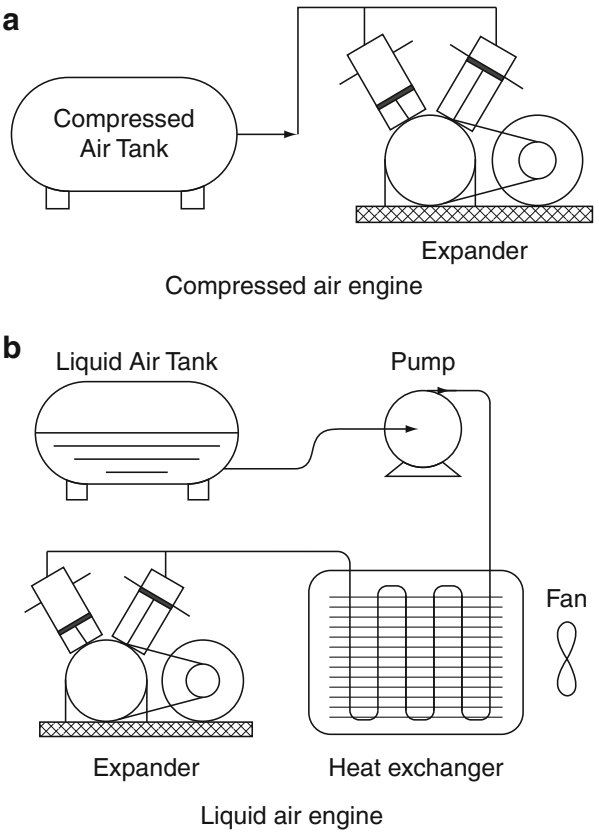

Fig. 11 Air-fuelled engines (Reproduced with permission from Chen et al. 2011)

Another technology is the "air fuelled engine." It can be operated by compressed air (Miller et al. 2010) or by liquid air, yielding zero tailpipe emissions (Chen et al. 2011), compare Fig. 11.

Due to the high energy consumption of air liquefaction plants, the compressed air-powered engines have a better energy efficiency than the liquid air ones (28.3 % to 36.0 % vs. 12.8 % to 17.0 % for the setups studied in Chen et al. 2011). Compared to liquid hydrocarbon fuels, compressed air has a lower energy density.

A novel concept for internal combustion engines is HCCI (homogeneous charge compression ignition) (Zhao 2007). It is a kind of hybrid between a compression ignition and a spark ignition engine, in that a homogeneous fuel/air mixture is brought to autoignition. This combustion mode resembles the typical "knocking" in gasoline engines. It is fast and hard to control. However, HCCI offers the potential of low-pollution and high-efficiency automotive engines.

Alternative Fuels

With depleting fossil fuel resources, costs go up and supply shortages might occur, apart from the emission of CO_2 into the atmosphere from the burning of these fuels. Alternative fuels can be unconventional fossil fuels (such as those derived from shale gas (Mallapragada et al. 2014), methane hydrate, fracking, etc.) and "renewable" fuels. This section focuses on renewable fuels, which are produced directly or indirectly from sunlight, without the need to turn to fossil fuels. The following energy carriers have been envisaged as fuels for combustion engines and/or fuel cells:

- Hydrogen
- Ethanol
- Ammonia (Zamfirescu and Dincer 2009)
- Methane
- Methanol

These fuels can be produced via various routes, both from fossil and renewable resources. Methane is also the main constituent of biogas. There are so-called flexible-fuel (flex fuel) vehicles that can run on several fuels, e.g., ethanol. A blend of gasoline and 85 % ethanol is called E85. Flex-fuel vehicles (FFV) have been produced since the 1980s. Ethanol (von Blottnitz and Ann Curran 2007) and biodiesel (Ticker 2003) are two common "biofuels." Fischer Tropsch synthesis and biomass gasification are important processes to obtain fuels from biomass, apart from anaerobic digestion and fermentation. Fuels from waste are also considered biofuels. Oil crops yield fuels from extraction and pressing of suitable plants (Tickell 2000). Also, aquatic biomass such as certain algae can be used, e.g., for biodiesel production.

There is also some controversy around biofuels. Two issues associated with biofuels are

- Potential competition over farmland with food crops
- Water consumption associated with their production (see concept of virtual water, Allan 2011)

One can distinguish between 1st, 2nd, and 3rd generation of biofuels.

First-generation biofuels are made from foodstuff (ethanol from corn, biodiesel from soybean, or rapeseed via transesterification). They are mature and available on the market.

Second-generation biofuels are produced from lignocellulose. There are thermal and enzymatic processes to break of the biopolymers into smaller units.

There are also "1.5 G" biofuels, which utilize the full plant of 1G fuels.

The first 1.5G and 2G biofuel commercial production plants are on stream. Their advantage is that no competition over arable land with food crops exists. Also, 2G biofuels can be grown on marginal land.

Third-generation biofuels target algae for "green" fuel production, as they are expected to yield more biomass per area than land-based fuels. They could use sewage as nutrient, and avoid land usage (land use change, e.g., through deforestation to produce cropland), which also contributes to climate change.

Energy produced from biomass was initially considered carbon neutral because biomass is renewable through photosynthesis. Controversies, however, have emerged about the various impacts of promoting the use of first-generation biofuels. Major concerns about using bioethanol as fuel include the following issues:

- Corn is a food source, and corn ethanol production will reduce food availability. Developing countries that depend on the corn donation from the west have already experienced food shortages.
- Fertilizer is required in corn production; both cost and energy consumption are incurred during fertilizer production. Moreover, unprecedentedly large scale use of fertilizer alters the natural nitrogen cycle and induces other ecological/environmental problems that have already been identified as threats.
- About 5 gal of water are needed in the production of each gallon of ethanol in a plant; this does not consider the amount of water it takes to grow the corn. So potable water shortages might result from excessive bioethanol production.
- Bioethanol production requires energy input. Ethanol purification by distillation is energy intensive and usually involves consumption of natural gas, which, in turn, produces CO_2 from fossil fuel. As a result, while bioethanol utilization reduces fossil fuel dependence, it is not a completely carbon neutral process.

Widespread adoption of bioethanol will cause redistribution of the world's natural resources and wealth. The actual environmental and societal costs of bioethanol are likely to be much higher. A good starting point for a healthy debate on this issue can be found at (Schulz 2007).

The transportation of energy carriers also consumes, naturally, energy. In Hamelinck et al. (2003), the energy consumption of biofuel transportation from production site to point of use is discussed, so that biofuels are not entirely carbon

Table 4 Energy density of various fuels

Fuel	Volumetric (Wh/l)	Gravimetric (Wh/kg)
Diesel	10,942	13,762
Gasoline	9,700	12,200
LPG (liquefied petroleum gas)	7,216	12,100
Propane	6,600	13,900
Ethanol	6,100	7,850
Methanol	4,600	6,400
Liquid hydrogen	2,600	39,000
Hydrogen (150 bar)	405	39,000
Nickel-metal hydride	100	60
Lead acid battery	40	25
Compressed air	17	34

neutral or even carbon negative. The carbon balance of several biofuels is even worse than that of gasoline or diesel. A detailed life cycle assessment is necessary.

When assessing biofuels, next to climate change, abiotic depletion, acidification, eutrophication, and human toxicity (Petersen et al. 2015) need to be considered.

Second- and third-generation biofuels hold promise for CO_2 emission savings.

The share of biofuels is expected to increase significantly over the next decade. An important aspect of alternative fuels, apart from their specific costs, is the energy density (see Table 4).

From the above Table 4, one can see that compressed air has a low energy density both in terms of volume and weight. The energy density is important for the range of a vehicle. Gases can be stored in compressed form, as hydrides or as a liquid in cryogenic conditions. Liquefaction can consume a considerable amount of energy. For hydrogen, one can define the gravimetric storage density. It is the weight of hydrogen being stored divided by the weight of the storage and delivery system. A typical value is 2–4 %. Storage has to be achieved in a safe, cost-effective, and efficient way. Alanates are a promising material class for hydrogen storage (Gross et al. 2002). Hydrides, this is chemically bond hydrogen in a solid material. This storage approach should have the highest hydrogen-packing density. However, storage media have to meet several requirements:

- Reversible hydrogen uptake/release
- Lightweight with high capacity for hydrogen
- Rapid kinetic properties
- Equilibrium properties (p, T) consistent with near-ambient conditions

There are two solid-state approaches:

- Hydrogen absorption (bulk hydrogen)
- Hydrogen adsorption (surface hydrogen)

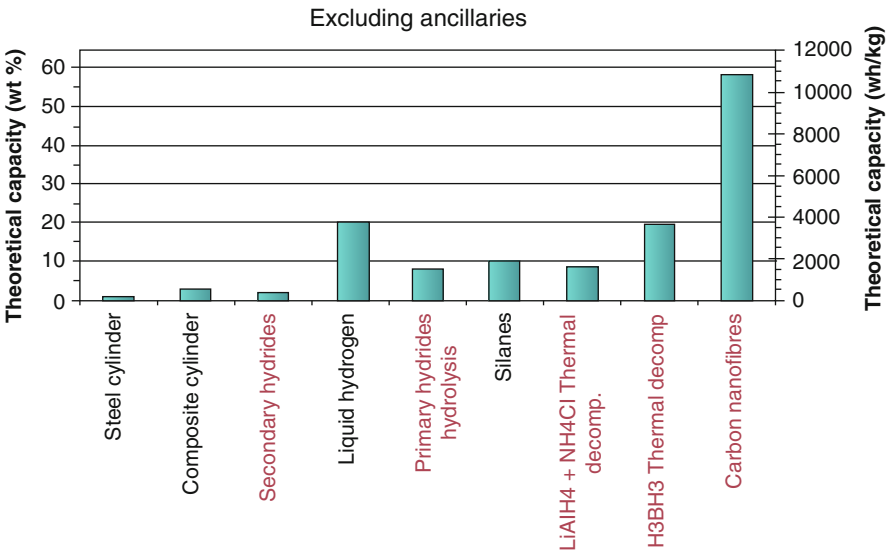

Fig. 12 Graphic illustration of hydrogen storage methods. *Red color* indicates that the technologies have not reached maturity yet (Reproduced from Obert 1973)

For details on hydride storage, see Agresti (2010).

Figure 12 compares several storage methods for hydrogen. Hydrogen can be produced, e.g., by electrolysis (solar power) or gasification.

Renewable energies for sustainable development are discussed in Lund (2007).

Alternative Power Sources

Electric cars come as battery-powered and fuel-cell-powered models. For a comparison on "well-to-wheel" energy pathways, see, e.g., (Eaves and Eaves 2004). So-called hybrid vehicles use a combination of an internal combustion engine (ICE) plus an electric motor (van Vliet et al. 2010).

Air Transportation

According to Chèze et al. (2011), world air traffic should increase by about 100 % between 2008 and 2025. The world jet fuel demand is expected to increase by about 38 % during the same period (Chèze et al. 2011). Aircraft manufacturers have reduced the specific fuel consumption of their equipment over the last decades, e.g., by using more efficient turbines, lightweight construction materials, and improved design. More radical concepts might help lower specific fuel consumptions further. Blended-wing-body (BWB) aircraft are promising constructions currently being studied. Their benefits are 10–15 % less weight and 20–25 % less fuel

consumption. Challenges today are the integration of the propulsion system into the airframe, aerodynamics, and control. An important aspect for the fuel efficiency of aircraft is the so-called aerodynamic efficiency. It determines its range with all other parameters kept constant. For details, see Qin et al. (2004).

CO_2 emissions and energy efficiency of aircraft are treated in Lee (2010), Babikian et al. (2002), Lee et al. (2004), and Morrell (2009).

Cargo

Freight transportation is a huge industry. Goods are moved by sea, air, and land, where seaborne transportation has the highest share with over 30,000 billion tonne-miles per year. Sea transportation aboard large container ships has a particularly advantageous energy efficiency compared to other modes. Because of concerns for the air quality in harbors and port cities, the emissions from ships have recently received more attention. For details on CO_2 emissions from shipping activities and their mitigation, see Fitzgerald et al. (2011), Villalba and Gemechu (2011), Cadarso et al. (2010), Geerlings and van Duin (2011), Heitmann and Khalilian (2011), Schrooten et al. (2009).

Means of Energy Efficiency

Energy efficiency improvements can be achieved in various ways.

By training staff, an "energy saving mindset" can be created. It can yield fuel savings directly, without the need for significant investment costs. However, the impact will not be as long lasting as technical improvements. Building upon the above idea of different means to achieve energy efficiency gains, the following Fig. 13 below highlights four energy conservation strategies for road transportation and their monetary impact, reproduced with permission from Litman (2005).

In Parry et al. (2014), an analytical framework for comparing the welfare effects of energy efficiency standards and pricing policies for reducing gasoline, electricity, and carbon emissions is discussed.

Comparison of Different Transportation Technologies

A key question related to energy efficiency in transportation is how various modes compare to each other. This is shown in an exemplary way for the greenhouse gas emissions (g CO_2 equivalents) per PKT (PKT = passenger kilometer travelled). In that paper (Chester and Horvath 2009), it is concluded that the total life cycle energy inputs and greenhouse gas emissions for road, rail, and aircraft transportation on top of the tailpipe emissions are 63 %, 155 %, and 31 %, respectively. This means that in the case of rail transportation, the major part of CO_2 emissions does not occur during the use of the vessel for a journey, but rather in related areas such as infrastructure

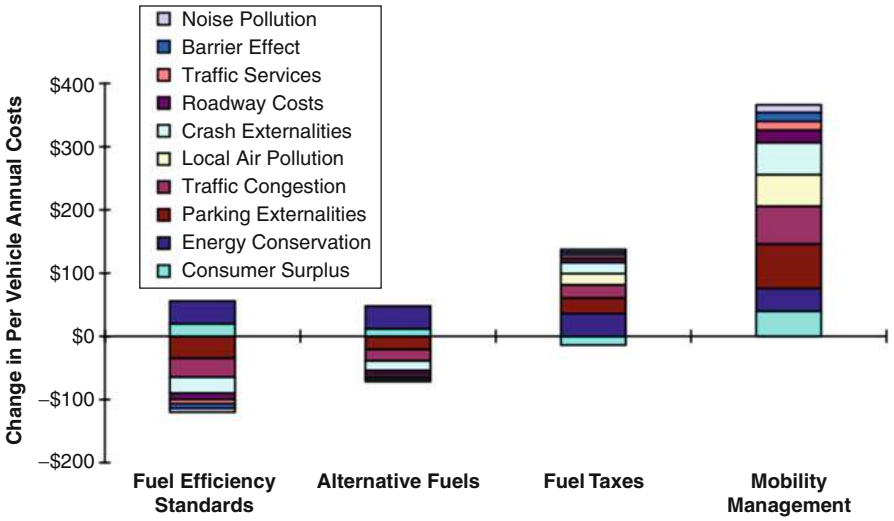

Fig. 13 Cost impact of four different strategies for energy conservation. Above the 0 line, benefits are shown, and below costs. The barrier effect refers to delays that motorized traffic causes to other modes of transportation. In Litman (2005), it is valued at 0.7 cent per vehicle kilometer. For more details, the reader is referred to Litman (2005)

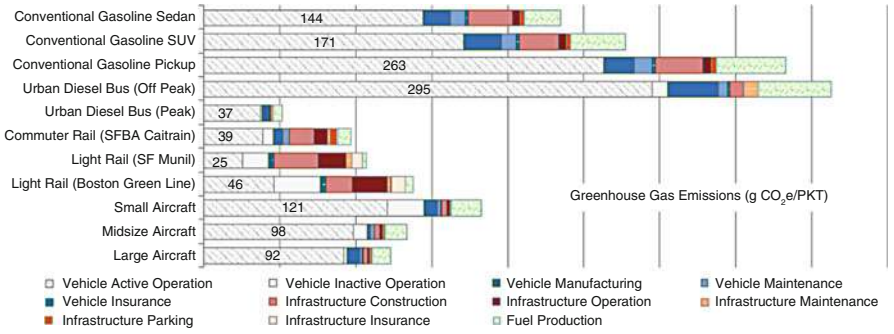

Fig. 14 Total GHG (greenhouse gas) emissions per PKT (passenger kilometer travelled). The components of vehicle operation are depicted in *grey*, while other vehicle components are shown in *blue shades*. Infrastructure components are shown in *red* and *orange*. Fuel production components carry *green* color. All components appear in the order of the legend (Reproduced with permission from Chester and Horvath 2009)

construction and infrastructure operation. The infrastructure for railways is more complex than that of large aircraft, for instance.

As can be seen from Fig. 14 above, it is important to consider infrastructure and supply chain aspects when comparing different transportation modes for their energy efficiency. The (assumed) passenger occupancy is one parameter that strongly affects the results of such studies.

Energy efficiency of rail transportation is detailed in Miller (2009); of buses in Ally and Pryor (2007); and of aircraft in Lee (2010), Babikian et al. (2002), Lee et al. (2004) and Morrell (2009).

Future Directions

Over the last years, a "green" development has emerged, and sustainability has become a buzzword also among consumers and in the transportation industries. In Utlu and Hepbasli (2007), the energy efficiencies of different sectors in several countries are compared (see Fig. 15 below). One can spot that they range from 35 % to 70 %. There is a big potential for savings in all sectors, and it is largest in the transportation area, followed by utilities, residential/commercial, and industrial sectors.

The efficiency of vehicles on US roads from 1923 to 2006 is discussed in Sivak and Tsimhoni (2009). In Romm (2006), Joseph Romm ponders on the car and fuel of the future, and in Azar et al. (2003), global energy scenarios in transportation until 2100 are developed. By looking at Fig. 15, one can assume that the transportation sector offers plenty of potential for energy efficiency improvements. An interesting study (Åkerman and Höjer 2006), which is partly reproduced below, has attempted to quantify these potentials, see Tables 5 and 6.

For cargo transportation, airships might be an energy-efficient means of transportation in future (Liao and Pasternak 2009).

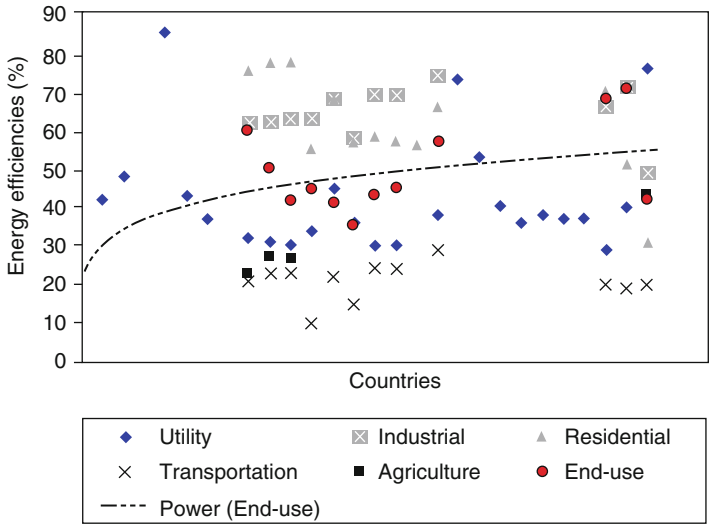

Fig. 15 Energy efficiencies of different countries by sector. In transportation, the potential for improvement seems biggest (Reproduced with permission from Utlu and Hepbasli (2007))

Table 5 Potential to reduce the energy use per passenger-km in Sweden from 2000 to 2050. The occupancy and speed are kept constant (Reproduced with permission from Åkerman and Höjer 2006) (see there for details)

	kWh/ passenger-km, 2000	Potential change by 2050 (%)	kWh/ passenger-km, 2050
Car, combustion mode, 1,2 pass/car (<100 km)	0.75	−75	0.20
Car, electric mode (<100 km)			0.10
Small electric city vehicle			0.07
Car, combustion mode, 2 pass/car (>100 km)	0.32	−65	0.12
Bus (<100 km)	0.22	−60	0.09
Bus (>100 km)	0.13	−40	0.07
Ferry (20 knots)	0.60	−30	0.42
High-speed ferry (40 knots)	1.80	−30	1.30
Rail (<100 km)	0.16	−50	0.08
Rail, 200 km/h (<100 km)	0.11	−50	0.05
Air	0.57	−44	0.32

Table 6 Potential to reduce the energy use per tonne-km in Sweden from 2000 to 2050. The load factor and speed are kept constant (Reproduced with permission from Åkerman and Höjer 2006) (see there for details)

	kWh/tonne-km, 2000	Potential change by 2050 (%)	kWh/tonne-km, 2050
Lorry (<100 km)	0.70	−40	0.42
Lorry (>100 km)	0.25	−30	0.17
Light lorry (<3.5 t)	–	−45	–
Rail	0.05	−30	0.20
Ferry (20 knots)	0.20	−30	0.14
Cargo ship	0.05	−30	0.04
Air	3.00	−44	1.68

Future energy-efficient transportation systems can be developed based on new radical approaches such as blended-wing-body aircraft or by revisiting “old” ideas such as turbine cars.

It is expected that energy efficiency in the transportation sector will increase in the coming years, also driven by cost-saving attempts, see Fig. 16 as an example (Iran).

One can see that there was a fluctuation in both the energy and exergy efficiencies in the period between 1998 and 2009, and the minimum value of energy and exergy efficiencies occurred in the previous year. Some socioeconomic and political reasons, such as the increase and decrease in the export of petroleum and import of petroleum products, the establishment of new refineries, national subsidies, international sanctions, and war are considered as the main reasons for changes in the

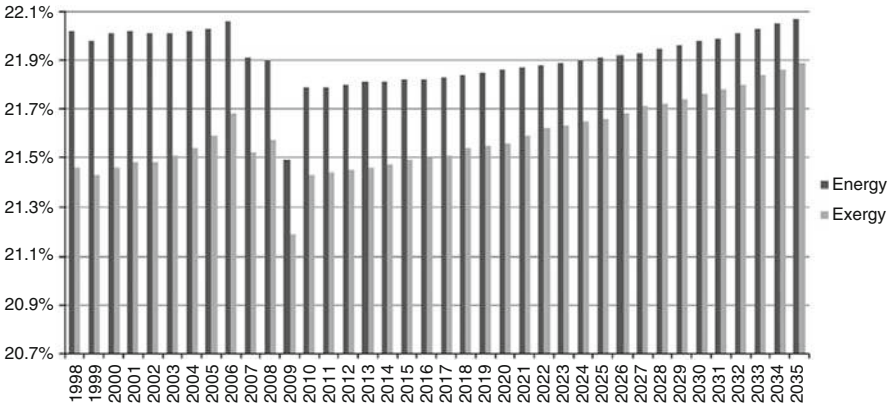

Fig. 16 Overall energy and exergy efficiencies in Iran between 1998 and 2035 (Source: Zarifi et al. 2013)

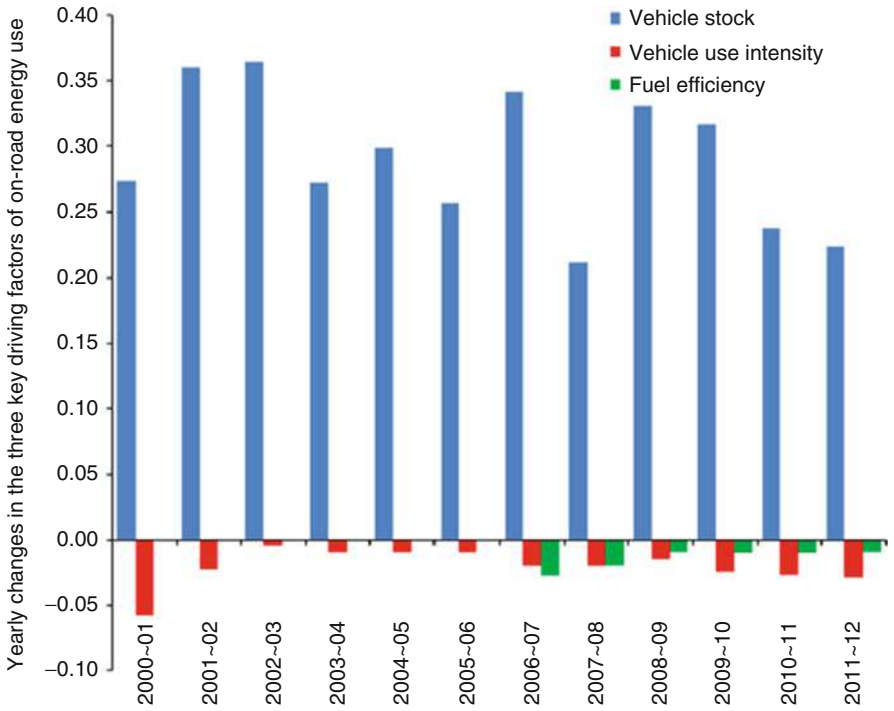

Fig. 17 Relative changes in the three driving factors behind energy use in the road transport sector in China (Source: Wu and Huo 2014)

contribution of each fuel and, consequently, change in the overall energy and exergy efficiencies during the previous years (Zarifi et al. 2013).

It has to be borne in mind that efficiency improvements in transportation can be offset by increased mobility, see Fig. 17 (example of China).

In this chapter, several aspects of energy and fuel efficiency on the transportation industries were touched upon. For comparisons, well-to-wheel (WTW) efficiencies need to be considered (Mallapragada et al. 2014). For further reading, see the cited references and also the chapter "Energy Efficiency" in this handbook. For an in-depth discussion of alternate fuels, see the following chapters in this handbook: Biochemical Conversion of Biomass to Fuels, Hydrogen Production, Conversion of Syngas to Fuels, and Integrated Gasification Combined Cycle (IGCC). Another interesting, promising approach is onboard reforming of fuels (Martin and Wörner 2011).

Thermal Insulation for Energy Conservation

David W. Yarbrough

Contents

Abstract

The use of thermal insulations to reduce heat flow across the building envelope has been an accepted energy conservation strategy for many decades. Materials available for use as building insulation include naturally occurring fibers and particles, man-made fibers, reflective systems, cellular plastics, evacuated systems, aerogels, and hybrid insulations that combine two or more types of insulation. This chapter discusses the basic theory of insulation and the way they are evaluated. Performance limitations are identified, and discussion of the performance of building elements that represent combinations of insulation and other building material is contained in this chapter. The importance of air infiltration and moisture control is discussed. The language associated with thermal insulation technology and key thermal properties have been included to help the reader use the vast literature associated with building thermal insulation.

Introduction

The objectives of modern building design are to provide a comfortable living environment with minimum use of external energy for heating and cooling. In fact, the present target is the construction of "zero energy buildings" that provides conditioned living space, light, and utilities without net energy from exterior sources. This is accomplished by optimum use of wind energy, solar energy, and ground coupling combined with building envelope design that limits heat flow across walls, ceilings or roof cavities, and floors using thermal insulation, reduction of air infiltration, advanced window design, and reduction of thermal bridging. These objectives are major items of interest in the field of building science. This chapter will start with a discussion of thermal insulation: properties, evaluation, and use. This will be followed by observations related to thermal bridging, air infiltration, and new materials.

This chapter discusses the reduction in heat flow by low thermal conductivity materials (insulations). The control of air movement and moisture transport across the building envelope (wall, ceiling, and floor) are additional factors to be considered. Fibrous or particulate insulations seldom provide significant resistance to air infiltration caused by wind-induced pressure differences between the inside and outside of the structure. When these materials are used, additional steps such as caulking and sealing or housewraps are used to provide a barrier to air infiltration. Materials such as cellular plastic insulation (closed cell) can provide a barrier to airflow when installed without cracks or defects. Thermal insulation also plays a role in controlling moisture transport and accumulation. Condensation within the building envelope occurs when the temperature at a location is equal or less than the "dew-point" temperature. The dew-point temperature depends on the actual air temperature (dry-bulb temperature) and the relative humidity. The temperatures within the building envelope depend on the interior temperature, the exterior temperature, and the materials including insulation that are present in the building envelope. Condensation and accumulation of water depend, as a result, on bulk movement of air through the building envelope, diffusion of water vapor through the construction materials, and the temperature profile in the building envelope.

Thermal Insulation Use in Buildings

Heat moves across the building envelope by three mechanisms: convection, conduction, and radiation. Thermal insulations are designed to reduce heat flow by radiation and convection without significantly increasing conduction. There are also insulations that reduce conductive heat transfer by altering the gas phase. The various types of insulation change each type of heat flow by different amounts. Heat transfer of convection can occur within porous materials if buoyant forces resulting from density differences overcome the friction between the moving gas (air, in most cases) and bounding surfaces, fibers, or particles. This "free" convection is eliminated in most cases by insulations such as fiberglass, rock wool, or cellulose.

Air moving within a porous material or region will absorb energy from the warm side of a region and reject it to the cool side of the region. Air moving through a leaky insulated region due to a pressure difference caused by wind or fans, forced convection, means that exterior air is being exchanged for interior air. Airflow into the building is matched by air moving out of the building. In addition, air moving through a porous or fibrous insulation changes the temperature profile within the insulation, and the resulting heat flow by conduction and radiation is changed (Anderlind and Johansson 1983; Yarbrough and Graves 1997). Thermal insulations designed to reduce radiation by the use of reflective (low thermal emittance) surfaces often have a significant amount of internal convection, and as a result, the performance of enclosed reflective air spaces depends on the direction of heat flow (down, up, or horizontal). The convective contribution to the overall heat flow is taken into account when reflective insulation is evaluated and labeled.

A large number of building insulations rely on the low thermal conductivity of air for their performance. This type of insulation includes most of the fibrous materials like fiberglass, rock wool, cellulose, polyester, wool or cotton, and open-cell cellular plastic. A second large class includes closed-cell cellular plastics that contain a gas with a thermal conductivity lower than air with correspondingly high thermal resistance values. The performance of closed-cell insulations requires that the low-conductivity gas remains in the cells unchanged. In general, these insulations are evaluated for average long-term thermal resistance since there are inevitable changes in the cell-gas composition due to air entering the cells or outward loss of the low thermal conductivity gas. There is also a type of insulation that contains fibers or cells that are so small that they interfere with the collisions between gas-phase molecules and consequently reduce the thermal conductivity below that of the gas under normal conditions. The thermal conductivity of a gas depends on both temperature and pressure and is the result of gas molecule collisions. If the gas-phase molecules do not collide, then heat flow through the gaseous part of the insulation is reduced or eliminated. This occurs when the average distance between collisions is greater than the average dimensions of the space available. One type of super-insulation is based on the use of evacuated regions (elimination of the gas phase). All of these concepts are presently represented by commercial products. Table 1 contains a listing of some insulations that are available for use in buildings. Insulation manufactured as batts is usually dimensioned to fit standard construction, while loose-fill insulation is pneumatically installed using especially designed equipment or poured in place. Table 2 contains thermal resistance values for selected building materials and thermal insulations. These are example values not intended to represent any specific product.

There are a wide variety of natural materials mostly fibrous or particulate that are used around the world as insulations. References such as the *ASHRAE Handbook of Fundamentals* (ASHRAE 2009), AIRAH (2007), and Materials for Energy Conservation in Buildings (Hall 2010) contain tables of physical properties for insulating materials and detailed discussions about the use and evaluation. Table 3 contains qualitative information about the relative performance for commonly encountered conditions for the insulations in Table 1.

Table 1 Building insulations

Insulating material	Type	Examples
Air	Fibrous	Fiberglass – batts and loose fill
		Rock wool – batts and loose fill
		Cellulose – batts and loose fill
		Cotton – batts
		Polyester – batts
		Wool – batts
	Cellular plastic	Spray-applied polyurethane (open cell)
		Expanded polystyrene (board or slab)
		Polyisocyanurate (board stock or slab)
	Particulate	Perlite
		Vermiculite
	Reflective	Reflective insulations
		Radiant barriers
Gas other than	Cellular plastic	Spray-applied polyurethane (closed cell)
		Extruded polystyrene (board or slab)
		Polyisocyanurate (board or slab)
		Phenolic
		Gas-filled panels
Reduced pressure	Particulate	Evacuated panels containing silica
		Evacuated panels containing perlite
Nano-materials		Aerogels
		Nano-fibers

Table 2 Thermal resistivity values for selected building materials at 75 °F (24 °C)

Material	R for 1-in. thickness (ft^2 h °F/Btu)	RSI for 25-mm thickness (m^2 K/W)
Wood	0.8–1.4	0.14–0.25
Concrete		
High density	0.1	0.018
Low density	0.5–1	0.09–0.18
Fiberglass batt	3.1–4.2	0.55–0.74
Fiberglass loose fill	2.0–2.4	0.35–0.42
Cellulose loose fill	3.5–3.7	0.62–0.65
Cellular plastic		
Open cell	3.0–3.5	0.53–0.62
Closed cell	5.0–6.5	0.88–1.15

Several entries in Table 3 indicate an increase in conduction because solids such as glass, rock, paper, plastic, or wood have much greater thermal conductivity than air. If air is displaced by a solid particle or fiber, then the heat flow by conduction will increase.

Table 3 Relative performance of commonly used building insulations

Type of insulation	Free convection	Conduction	Radiation
Fiberglass, rock wool, and cellulose	Eliminates	Increases	Reduces
Cellular plastics – air	Eliminates	Increases	Reduces
Cellular plastics – gas	Eliminates	Decreases	Reduces
Reflectives	Reduces	Increases	Greatly reduces

Fibrous materials such as fiberglass, rock wool, cellulose, or open-cell plastics present some resistance to airflow resulting from a pressure difference but do not perform as "air barriers." Closed-cell plastic insulation can perform as an air barrier material in sufficiently thick and without cracks or holes due to shrinkage or weathering. Reflective insulations have an effect on convection when they divide the space they occupy into discrete regions with reduced temperature differences and increased surface area to resist the movement of the enclosed air.

Horizontally applied porous insulation can exhibit a loss in thermal resistance due to upward convection (Graves et al. 1994; ASTM C 1373 (2014)). This phenomena occurs in cold climates where there is a large temperature difference across the insulation that create significant air density differences in the air.

Thermal Performance Evaluation of Building Insulation

The thermal performance of building insulation is commonly characterized by its thermal resistance designed by "R (ft^2 h °F/Btu)" or "RSI (m^2 K/W)" depending on the system of units being used. The thermal resistance is defined by Eq. 1 where the denominator is referred to as "apparent thermal conductivity." This terminology is used since the equation used to describe heat flow by conduction (Fourier's law) is used to describe heat flow by all mechanisms:

$$R = t/k_a \tag{1}$$

- [t] is thickness in inches.
- [k_a] is apparent thermal conductivity in Btu in./ft^2 h °F.
- [R] is thermal resistance in ft^2 h °F/Btu.

$$RSI = t/\lambda$$

- [t] is thickness in meters.
- [λ] is apparent thermal conductivity in W/m K.
- [RSI] is thermal resistance in m^2 K/W.

Another property called thermal resistivity, R^* or RSI^*, is related to thermal resistance as shown by Eq. 2. Equation 1 indicates that R or RSI scales linearly

with thickness. This is valid as long as k_a or λ has been determined using test specimens thick enough to avoid surface effects (the thickness effect) (Fine et al. 1981):

$$R^* = R/t \quad \text{or} \quad 1/ka \tag{2}$$

[R^*] has units ft^2 h °F/Btu in.

$$RSI^* = RSI/t \quad \text{or} \quad 1/\lambda$$

[RSI^*] has units m K/W.

Building codes and requirements are usually discussed in terms of R-values or RSI-values, while manufacturers and marketers often quote resistivity values, R^* or RSI^*.

The total thermal resistance (R_T or RSI_T) of an assembly consisting of layers of materials perpendicular to the direction of heat flow is additive:

$$R_T = R_1 + R_2 + R_3 + \cdots \tag{3}$$

A given section of a building envelope (e.g., a wall) will likely consist of at least three materials: an inner sheathing, an insulation filled region, and an external sheathing or façade. The total thermal resistance from the interior surface to the exterior surface is the sum of the individual resistances. The design for energy conservation involves selection of materials with high thermal resistance in order to reduce heat flow across an area, A, as shown by Eq. 4. The greater the R_T or RSI_T the smaller the heat flow:

$$Q = A \cdot \Delta T/R_T \tag{4}$$

- [A] is area perpendicular to heat flow direction (ft^2 or m^2).
- [ΔT] is ($T_{hot} - T_{cold}$) in °F or K.
- [R_T or RSI_T] is total thermal resistance.
- [Q] is heat flow in Btu/h or watts.

Standardized test methods are used to determine the thermal resistance values for building materials for the purpose of labeling and design calculations. In the case of thermal insulation materials, the most commonly used apparatus is described in the test method ASTM C 518 (ASTM C 518 (2014)). Figure 1 is a photograph of two heat flow meters. The apparatus is designed to provide values for three of the four quantities in Eq. 4 (Q, A, and ΔT). A value for R can then be calculated. The apparent thermal conductivity, k_a, can be calculated from the thickness of the test material using Eq. 1. This test method provides steady-state physical property values for materials that have been conditioned to prevent water (moisture) movement in the test specimen during the test. Thermal testing of building elements is accomplished using a hotbox facility to be discussed later.

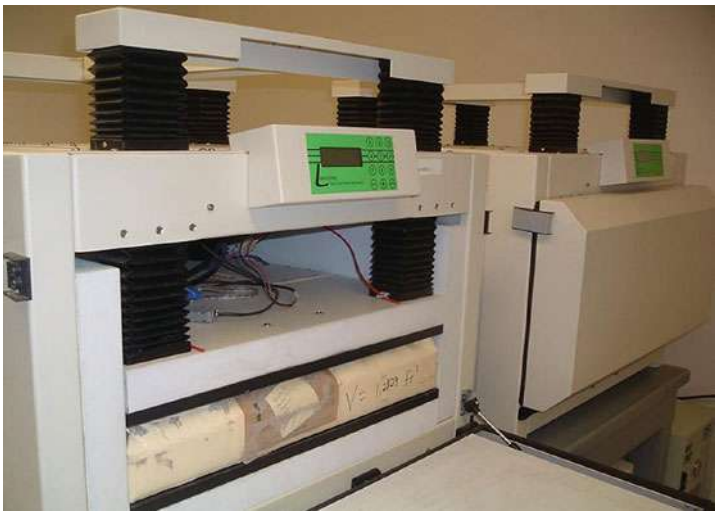

Fig. 1 Photograph of two heat flow meters (*open* and *closed*). The *brown* test specimen is between two *black* isothermal plates. The front is closed during a test

Factors That Affect Thermal Resistance

The thermal resistance of practically all materials depends on the temperature of the material. The temperature is usually characterized as the average of the warm side temperature and the cool side temperature. Thermal resistance measurements are generally made with a relatively small temperature difference such as 50°F or 28°C and an average temperature specified by labeling conventions. The average temperature is 75°F (23.9°C) in some parts of the world and as low as 50°F (10°C) in some locations. The laboratory test methods are generally capable of measuring the thermal resistance over the temperature range anticipated for buildings.

In most cases, the thermal resistance of building insulations decreases as the temperature increases (or increases as the temperature decreases) when other factors are held constant. This is easily understood for the insulations that are based on air. The thermal conductivity of air increases with temperature thus reducing the thermal resistance of the insulation in question. Equations 5a and 5b are relations between temperature and thermal conductivity of air for the limited temperature range likely to be encountered in buildings. Actual variation with temperature of the apparent thermal conductivity will differ from that of air because there are other heat flow mechanisms. Variations of the thermal resistance of insulation materials with temperature have been measured and reported (Abdou and Budaiui 2005):

$$k_{air} = 0.18 + 0.027^{*}(T(^{\circ}F) - 75)/100 \qquad (5a)$$

$$32 < T < 176^{\circ}F$$

k_a with units Btu in./ft^2 h °F

$$\lambda_{air} = 0.026 + 0.0070^{*}(T(^{\circ}C) - 24)/100 \quad (5b)$$

$$0 < T < 80^{\circ}C$$

λ_a with units W/m K.

An important observation about air-based insulations follows from approximate values given by Eq. 5. The maximum possible R-value at a given temperature that can be achieved by an air-based thermal insulation can be calculated from the thermal conductivity of air. The maximum occurs when there is no convection present, and all radiation has been eliminated. The heat transfer by conduction is all that is left. The solid components of the insulation will have thermal conductivities greater than air meaning that k_{air} is a lower bound on k_a. Equation 1 gives $R_{max} = 5.56$ for 1-in. thickness at 75°F and $RSI_{max} = 0.96$ for 25-mm thickness at 24°C. Practical air-based insulation invariable has R-values less than the maximum value because radiation is not completely blocked, and there is a conductive contribution from the solid material in the insulation.

The thermal resistances of cellular plastic insulations containing a gas other than air or a gas mixture with thermal conductivity less than that of air also decrease with increase in temperature as long as the composition of the gas trapped in the cells does not change. In some cases, it is possible to have temperatures low enough to condense the low thermal conductivity gas components in a closed-cell foam thus changing the cell-gas composition. Generally, this means that the fraction of gas that is low thermal conductivity decreases and the overall thermal conductivity increases. If this phenomena occurs, then the thermal resistance decreases as the temperature decreases. As a result of the aging phenomena, the performance of closed-cell cellular plastic insulation is evaluated in terms of an average value over a long period of time such as 15 years. This is called the long-term thermal resistance (LTTR). There are consensus laboratory methods for determining LTTR (ASTM C 1303 2014).

Air movement through porous or fibrous insulations like fiberglass, rock wool, or cellulose changes the heat flow rates in or out of a building. The heat content of air depends on its temperature. Cold air entering a building must be heated to the interior set point temperature. Conversely, warm air entering the building is cooled to the interior set point temperature. In both cases, there is an expenditure of energy to maintain the temperature in the conditioned space. In addition, the movement of air through the insulation changes the temperature profile in the insulation which in term changes the rate of heat flow through the insulation. The movement of air through insulated regions can also carry water vapor into the building thus adding another item of cost, for example, the removal of excess water by condensation and heating or cooling the water vapor transported by air. These factors provide motivation for construction that reduces air infiltration to as low a level as health considerations permit.

The thermal resistance of compressible insulations like fiberglass, rock wool, polyester, or cellulose depends on the density (mass per unit volume) of the material as installed in the building envelope. Insulation manufacturers specify the thickness and

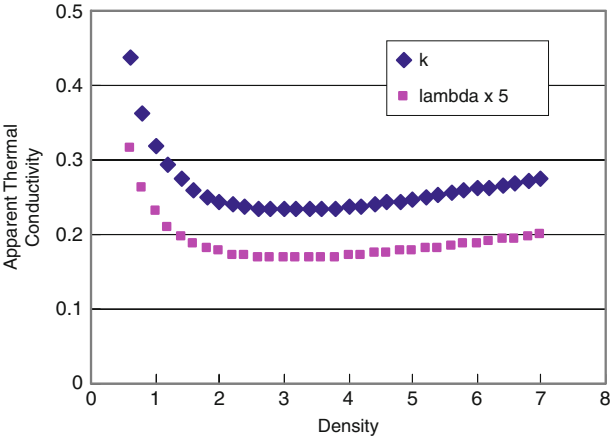

Fig. 2 Apparent thermal conductivity as a function of density (lb_m/ft^3). The curve labeled k has units Btu in/ft^2 h °F, while the curve labeled lambda × 5 has units W/m K. Multiply the density in the figure by 16.02 to obtain density with units kg/m^3

density (or weight per unit area) of their product that is required to achieve a specific R or RSI. If the specified thickness and weight of material are not achieved, then the R or RSI will likely be different from the target value. Each insulation type has a characteristic curve like that shown in Fig. 2. The curve in Fig. 2 shows data for an example material with constant composition and fiber diameter at a constant temperature (Siegel and Howell 1971). As the density of the insulation changes, the three heat transfer contributions (conduction, convection, and radiation) change, and the overall rate of heat transfer changes. When the density of the insulation is low, the curve indicates that the apparent thermal conductivity will decrease as density increases (thermal resistance will increase), while the high-density state shows increasing apparent thermal conductivity with increasing density (decreasing thermal resistance). Every thermal insulation product has its own characteristic curve. Thermal insulations are labeled and sold with a thickness at which the advertised R will be achieved. The thermal resistance will be different if compressed to thicknesses other than that on the label because as the thickness changes, the density changes (Robinson and Powell 1957).

Figures 3 and 4 show R-values for a 1-in. thickness of insulation and RSI-values for 25-mm thickness of insulation for the material illustrated in Fig. 2. The important point here is the significant change in the insulation performance per unit thickness as the density (amount of material per unit volume) is changed.

Reflective Insulations

Enclosed air spaces with low emittance surfaces provide resistance to heat flow by reducing or nearly eliminating radiative transfer across the air space. This is readily shown by the following equation for the net radiation, Q_{rad}, between large parallel planes with emittances ε_1 and ε_2 (Siegel and Howell 1971):

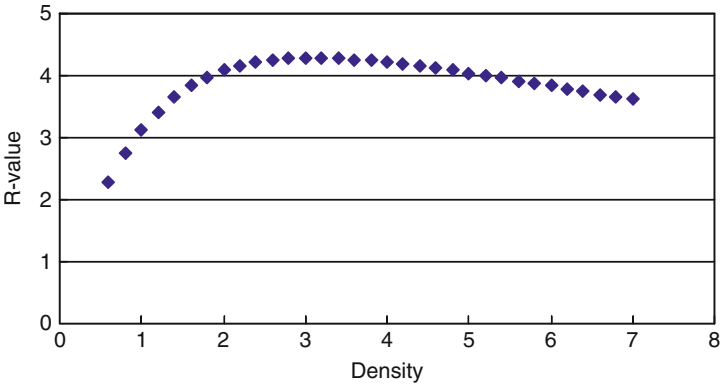

Fig. 3 R-value for a 1 in. of insulation at the indicated density units: R-value (ft^2 h °F/Btu) density (lb_m/ft^3)

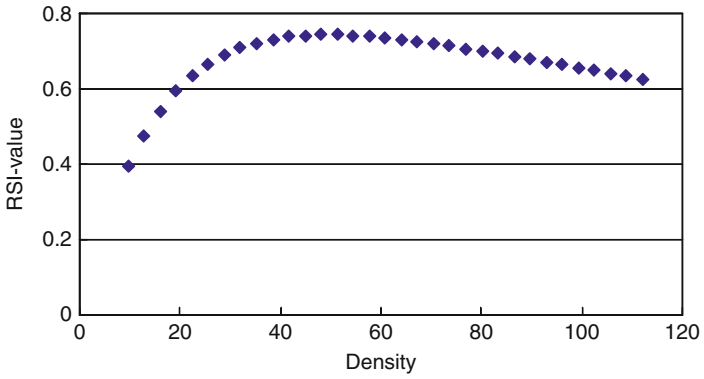

Fig. 4 R-value for 25 mm of insulation at the indicated density units: RSI-value (m^2 K/W) density (kg/m^3)

$$Q_{rad} = E\{A \cdot \sigma \cdot (T_{hot}^4 - T_{cold}^4)\} \tag{6}$$

- Q_{rad} is net radiation from the hot surface to the cold surface (Btu/h or watts).
- A is the area perpendicular to the heat flow (ft^2 or m^2).
- T_{hot} and T_{cold} are absolute temperatures (R or K).
- σ is the Stefan-Boltzmann constant 0.1712×10^{-8} (Btu/h ft^2 °R^4) or 5.669×10^{-8} (W/m^2 K^4).

$$E = (1/\epsilon_1 + 1/\epsilon_2 - 1)^{-1} \tag{7}$$

The heat transfer by radiation is directly proportional to the effective emittance (E), a quantity that varies from 0 (a perfect reflector) to 1 (a perfect absorber or block body). A large number of building materials (wood, masonry, and common

Table 4 Examples of effective emittance values

Surface	ϵ_1	E with ($\epsilon_2 = 0.9$)	E with ($\epsilon_2 = \varepsilon_1$)
Aluminum foil	0.03	0.030	0.015
Metallized film	0.05	0.050	0.026
Coating	0.25	0.243	0.143
Wood	0.90	0.818	0.818

Table 5 Maximum radiation exchange and reductions

T_{hot} °F (°C)	T_{cold} °F (°C)	Q with E = 0.9 (kW)	Q with E = 0.05 (kW)	Reduction (kW)
70 (21.1)	65 (18.3)	1.54	0.09	1.45
100 (37.8)	90 (32.2)	3.59	0.20	3.39
100 (37.8)	85 (29.4)	5.31	0.30	5.01

nonmetallic paints) have emittances near 0.9. A few emittance values (ε) are listed in Table 4 along with calculated values for E. The first column contains E with one surface having a low emittance, while the other surface is wood or a common building material. The second column contains E for low emittance surfaces on both sides of the reflective air space.

The bracketed term in Eq. 6 provides the maximum net radiation between the two surfaces for a given area and specific temperatures. Table 5 contains a few examples of the radiation term between two wood or two masonry surfaces and the reduction that can be achieved by changing one surface to emittance 0.05.

The results in Table 5 are for an area of 100 ft^2 (9.3 m^2) and the indicated temperatures.

The total heat flow across a reflective air space can be approximated by Eq. 8 where the term h_c represents heat transport by convention and conduction (Robinson and Powell 1957). The term h_c is determined from an experimental measurement of total heat flow with a subsequent subtraction of the radiative term. The term h_c can be determined from published equations and hotbox data (Robinson and Powell 1957; Desjarlais and Yarbrough 1991). Since h_c includes convection, the values depend on the heat flow direction. The standard ISO 6946 also provides a method for determining h_c (ISO 6946 (2005)):

$$\begin{aligned} Q_{total}/A &= (h_{rad} + h_c) \cdot \Delta T \\ h_{rad} &= 4 \cdot E \cdot \sigma \cdot T_m^3 \\ T_m &= (T_{hot} + T_{cold})/2 \\ \Delta T &= (T_{hot} - T_{cold}) \end{aligned} \tag{8}$$

Table 6 contains some examples of enclosed reflective air space thermal resistances for a single enclosed air space with E = 0.03. The *ASHRAE Handbook of Fundamentals* contains reflective air space thermal resistances for various conditions (ASHRAE (2009)).

Table 6 Single reflective air space thermal resistance values at $T_m = 77\ °F\ (25\ °C)$

Thickness in. (mm)	ΔT °F (°C)	Thermal resistance ft² h °F/Btu (m² K/W)		
		Down	Horizontal	Up
0.47 (12)	18 (10)	2.38 (0.42)	2.33 (0.41)	1.87 (0.33)
0.94 (24)	18 (10)	4.43 (0.78)	3.41 (0.60)	2.04 (0.36)
1.50 (38)	18 (10)	5.85 (1.03)	3.24 (0.57)	2.16 (0.38)
0.47 (12)	27 (15)	2.38 (0.42)	2.38 (0.42)	1.70 (0.30)

Envelope R-Values

Heat flow across a section of the building envelope depends on the temperatures of the regions on both sides on the element and the thermal resistances between the regions. The situation is best discussed for a wall section that does not include doors or windows. The resistance between the regions includes layers of different building materials and in many cases materials positioned in the direction of heat flow (thermal bridges). Heat flow calculations are commonly based on U-values (overall heat transfer coefficient) that take into account all of the materials between the bounding regions and surface film resistances:

$$Q = U \cdot A \cdot \Delta T \tag{9}$$

- U, Btu/ft² h °F or (W/m² K)
- A, ft², or (m²)
- ΔT, °F, or (K or °C)
- Q, Btu/h, or (W)

In order to avoid the complication of wind and the difference between the temperature of the outside air and the temperature of sunlit wall, the outside surface of the wall will be taken as region 1, and the inside air temperature will be taken as region 2. The U in this case will include an inside air film resistance (R_{film}), an interior sheathing material resistance (R_1), the resistance of the wall structure (R_s), the exterior sheathing (R_2), and final exterior wall material (R_3). For this case, U is given by Eq. 10:

$$U = 1/(R_{film} + R_1 + R_s + R_2 + R_3) \tag{10}$$

$$R_T = 1/U \tag{11}$$

R_s is the complication in the equation for U since in many cases, the region is not a homogeneous layer of material. If the wall is a layer of material like concrete, brick, or solid wood, then the denominator in Eq. 10 is a sum of resistances. If the wall is a wood frame or timber wall type of structure, then there are parallel paths (commonly two) for heat to move across this region. One path is through the insulated region, while the second path is through the frame or timber region. Equation 12 is often

used to calculate a value for R_{cav} where f_c is the fraction of the wall area that bounds cavity and f_w is the fraction that bounds the wood framing ($f_c + f_w = 1$). The f values depend on the design of the framing. For example, nominal 2 × 4-in. wood framing placed 16 in. on center with double top plates and a single bottom plate has $f_w = 0.14$ for a ceiling to floor distance of 8 ft. The corresponding value for f_c is 0.87. This means that only 86% of the wall area is insulated by installing material in the cavity formed by wood framing members:

$$f_w = (14.5 \cdot 91.5)/(16.0 \cdot 96) = 0.86$$

If R_w 4.2 ft^2 h °F/Btu is taken as the resistance for the wood in the direction of heat flow and R_c 15 ft^2 h °F/Btu is taken for the resistance of the insulation, then the value for R_s from Eq. 1 is 11.03. If R_c is 11, then R_s is 8.97:

$$R_s = 1/(f_w/R_w + f_c/R_c) \tag{12}$$

Specification of values such as $R_{film} = 0.68$, $R_1 = 0.5$, $R_2 = 0.45$, and $R_3 = 0.2$ permits an evaluation of U for R_c 15. The R_T describes the overall resistance of the structure between the inside air and the exterior surface. If an exterior air film is included, then it can be added to the result for R_T:

$$U = 1/(0.68 + 0.5 + 11.24 + 0.5 + 0.45 + 0.2) = 0.0737$$
$$R_T = 13.57$$

This example is intended to show several factors to consider. The total thermal resistance of the wall is not equal to the thermal resistance of the cavity insulation even though it includes several additional resistance factors. The total resistance of the wall depends on the design (e.g., spacing) of the structure and the materials used to build the structure. If metal is substituted for wood, then the resistance R_w drops to near zero, and thermal resistance in the path through the metal structure has to be added. A few examples of steel wall resistances taken from an American Iron and Steel Institute publication (American Iron and Steel Institute 1995) are shown in Table 7. The data for R 11, R 13, and R 15 cavity insulations are for 3.625-in. steel framing that is 24 in. on center, while R 19 is for 6.0-in. framing that is 24 in. on

Table 7 R_{tot} for steel stud walls

R cavity	R sheathing	R_{total}
ft^2 h °F/Btu (m^2 K/W)		
11 (1.937)	1.0 (0.176)	7.0 (1.23)
13 (2.289)	1.0 (0.176)	7.3 (1.29)
15 (2.642)	1.0 (0.176)	7.6 (1.34)
19 (3.346)	1.0 (0.176)	8.0 (1.41)
11 (1.937)	5.0 (0.881)	13.0 (2.29)
13 (2.289)	5.0 (0.881)	13.6 (2.40)
15 (2.642)	5.0 (0.881)	14.3 (2.52)
19 (3.346)	5.0 (0.881)	15.0 (2.64)

Fig. 5 An open hotbox (Photo courtesy of the BTRIC, Oak Ridge National Laboratory, USA)

center. R sheathing refers to continuous insulation placed perpendicular to the direction of heat flow. This is R_2 in Eq. 10.

The U-values for building assemblies can be measured using a hotbox facility that can be used to test relatively large test specimens, 9 by 16 f. (2.7 by 4.88 m), for example. The total heat flow at steady state from a warm region to a cold region is determined from a measurement of heat input to maintain the temperature of the warm region ASTM C 1363 (2014). A hotbox measurement includes heat transfer by all mechanisms. Figure 5 is a photograph of a rotatable hotbox used for building assemblies. The outline of a test specimen can be seen between the two sections of the hotbox. The two sections are closed to perform a test.

Concrete masonry walls and concrete block walls represent a somewhat different type of situation in that the R_s is representing a layer of material. Solid concrete walls built using "standard" weight concrete (density of 100–125 lb/ft^3) have thermal resistance values of approximately 0.1 ft^2 h °F/Btu per inch of thickness. An 8-in.-thick wall using this material has an R of about 0.8 ft^2 h °F/Btu. Masonry blocks with interval cells (air filled) have slightly high R-values (range 1.5–2.0) that depend on the density of the concrete used to produce the blocks. Insulation can be added to cells to make modest increase in the resistance of the blocks. Application of the parallel path idea introduced above shows that a concrete block with insulation core region has a maximum R of about 3 ft^2 h °F/Btu that is achieved as the resistance of the core material becomes very large. This situation is remedied in part by adding layers of insulation usually on the interior side of the wall. When this is done, the concrete or block wall resistance becomes R_2 in Eq. 10, and the interior insulation system becomes R_s.

In many cases, the performance of massive walls is improved by the dynamics of absorbing and discharging heat as the outside temperature changes. This is called "the mass effect." The mass effect is sometimes described by a factor called the "dynamic benefit for massive walls (DBMS)." The DBMS is a multiplier that describes the thermal performance in terms of a "dynamic R" (Kosny et al. 2001):

$$\text{Dynamic } R = \text{Conventional R} \cdot \text{DBMS} \tag{13}$$

DBMS values range from 1 to perhaps 4. The DBMS depends on the temperature variation in a given location and the mass, specific heat, density, and thermal conductivity of the construction material in question. The determination of a DBMS value generally requires computer simulations of the structure to determine the factor DBMS that will result in equal performances of the massive wall and a conventional wall with specified thermal resistance. For the present discussion, it is sufficient to note that massive walls can demonstrate thermal performance that is much better than anticipated from the relatively modest conventional R.

Attic or roof cavity insulation receives a lot of attention since the roof surface can become very hot due to solar radiation and very cold due to radiation to the night sky. Attic spaces or roof cavities are often ventilated to remove moisture from the occupied part of the building and remove some heat. The attic space insulation is commonly located on the attic floor directly above the conditioned space. In some applications, the insulation is placed directly below the roof deck. This latter application is sometimes combined with a non-ventilated attic strategy.

Attic floor insulation is commonly viewed as a continuous layer of material of uniform thickness. A small correction can be applied to account for the presence of structural members buried in the insulation (ceiling joists), but this is a minor factor in modern times with insulation thicknesses that are much greater than the height of the ceiling joist. The depth of attic floor insulation is dictated in part by economic factors since there is often sufficient space for large thicknesses of insulation. This is in contrast with walls with fixed amount of space for insulation. Attic thermal resistance recommendations and requirements vary around the world with current recommendations as high as R 60 ft^2 h °F/Btu (RSI 10.6 m^2 K/W) rated at 75°F or 24°C. A wide variety of insulations in the form of batts (or blankets) or loose-fill insulation that is pneumatically installed or poured is used. The important considerations in choosing attic insulation type and R-value include mechanical stability of the insulation, moisture absorption/desorption, and fire performance.

Mechanical stability is important since the thermal resistance depends on thickness as shown by Eq. 1. If the insulation loses thickness, then its thermal resistance will be reduced. In the case of loose-fill insulations, this phenomena is called "settling." As an insulation settles, its density increases, and the apparent thermal conductivity changes.

An analysis of data for most of the common types of insulation shows that settling or thickness reduction results in R-value reduction. Some insulation products, cellulose, for example, are labeled to account for settling after the material is installed. Some insulations contain binders or adhesives to reduce settling after the

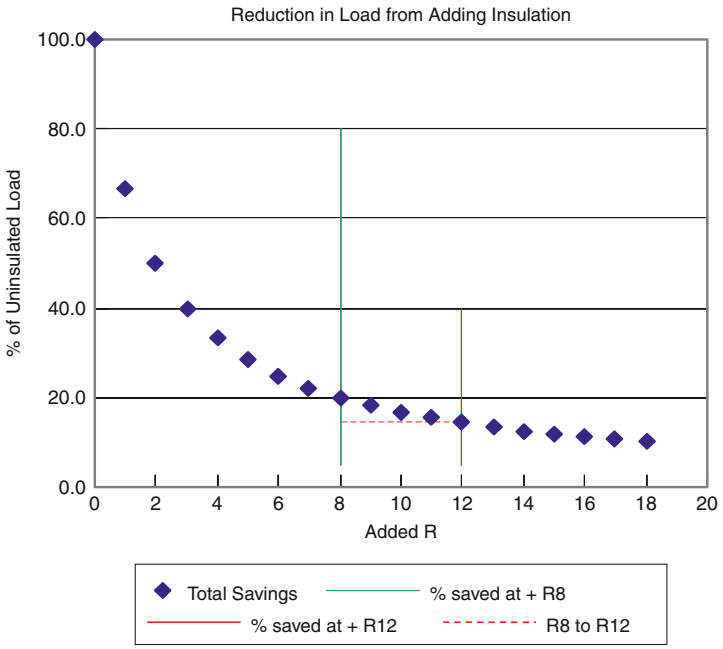

Fig. 6 Example of diminishing return

insulation is installed. Stabilized cellulose is an example of this type of insulation (ASTM C 1497 (2010)).

A builder or designer should be aware of the settling phenomena and examine the care with which the insulation manufacturer deals with this issue. The resistance of attic insulation to ignition or spread of fire is important because the attic region operates at elevated temperatures in the summer, often contains electrical wiring, and sometimes contains hot surfaces such as lights, flues, or chimneys.

Some types of insulation, for example, cellulose, cellular plastic, plastic fiber, wool, and wood fiber, can be ignited and will burn. These insulations are often treated with fire-retardant chemicals to reduce smoldering tendency and limit the spread of fire on the surface. Care must be taken to keep material that can ignite and burn away from potentially hot surfaces. The condition of electrical wiring can also be a safety issue especially if the wiring becomes buried in a material that will ignite and burn. An understanding of the fire-retardant chemicals being used, their long-term stability, and the manufacturer testing and quality control is important and difficult. At a minimum, the user of the insulation should verify that the product undergoes regular verification of its fire resistance and that permanence of the fire-retardant chemicals has been established.

A combination of Eqs. 6 and 11 introduces an interesting and overlooked concept about insulation: a diminishing return. Consider, for example, the heat flux (Q/A) through a region when the temperature difference (ΔT) is specified. The heat flux is inversely proportional to R as shown in Fig. 6.

Table 8 Anticipated savings from increased attic insulation

R total	R added	Heat flux reduction (%)	Base heat flux (%)
2	0	0.0	100.0
10	8	80.0	20.0
14	12	85.7	14.3
15	13	86.7	13.3
20	18	90.0	10.0
25	23	92.0	8.0
30	28	93.3	6.7
35	33	94.3	5.7
60	58	96.7	3.3

The diamonds in Fig. 6 represent the percent of heat flux calculated for a ceiling with added R-value to an uninsulated ceiling assigned the value R 2. Adding R 8 to the ceiling to provide a total R of 10 reduces the ceiling heat flux to 20 % of the uninsulated value. Adding R 12 reduces the ceiling heat flux to 15 % of the uninsulated value. Table 8 extends the added R-value to R 60 showing the rapidly declining savings to be expected. The same type of calculation would apply to other parts of the building envelope.

Below floor insulation is used when there is space below the floor or when the building is positioned on a slab. Slab insulation is often limited to the perimeter region with insulation installed either on the interior or exterior side of the foundation perpendicular to the heat flow direction. The amount of thermal resistance recommended for perimeter application is generally in the range R 5–R 10 (RSI 0.9–1.8).

There are several strategies for insulating floors above the ground (with crawl space). One technique involves installing fiberglass batt insulation between the floor joists. A water vapor retarder is usually installed below the insulation to keep water vapor from condensing on the bottom of the flooring. Reflective insulations are also used in below-floor applications either as single sheet materials attached to the bottom edge of the floor joists or between floor joists. Multilayer reflective insulation has also been used in the application.

Hybrid Systems

Different types of insulations are being combined to economically enhance overall performance. Combinations of spray polyurethane insulation and fiberglass or reflective insulation are examples of this type of system. When installed in a wall cavity, the spray foam can provide an airtight seal and a level of thermal resistance that depends on the thickness of the foam. The wall cavity is then filled with a mass insulation such as fiberglass or provided with a reflective insulation. In either case, the thermal resistance of the cavity is the sum of the thermal resistance of the foam and the thermal resistance of the insulation used to fill the cavity. The benefits of such a system are enhanced thermal resistance and a barrier to air infiltration.

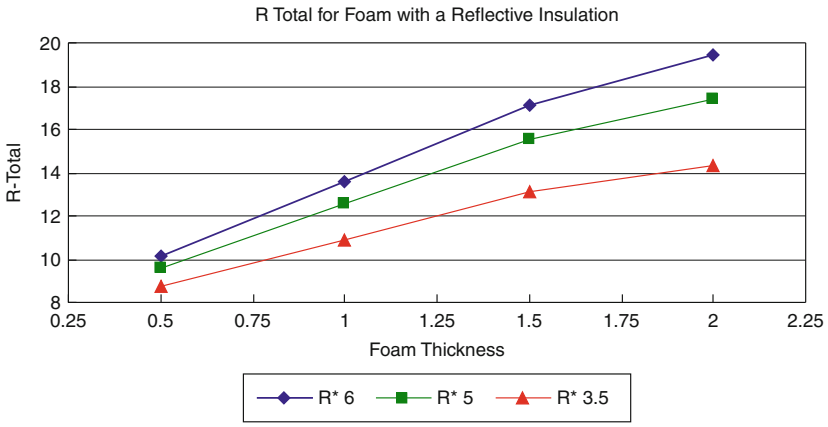

Fig. 7 Total R for a hybrid insulation system combining cellular foam and a reflective insulation

Figure 7 shows calculated values for a wall element containing a layer of spray polyurethane foam and a reflective insulation assembly with R = 6.8−7.8 (RSI = 1.2−1.4). The curves in Fig. 7 are for foams with thermal resistivities, R^*, from 3.5 ft^2 h °F/Btu (open cell) to 6 ft^2 h °F/Btu (closed cell). The total space for the hybrid system is 5.5 in. (140 mm).

Summary

This chapter has outlined some of the fundamental considerations related to building insulation. Important properties have been identified and factors that affect performance have been discussed. The selection of thermal protection for the building envelope must include consideration of moisture transport and a requirement that air infiltration be addressed. In many cases, this means that materials in addition to thermal insulation will be required. Air barrier materials and water vapor retarders are examples. In some cases, thermal insulation serves dual purposes such as being an air barrier and a thermal insulation.

Future Directions

Future developments in the area of building insulation will no doubt find increased use of super-insulations such as vacuum panels, aerogel insulation, and gas-filled panels.

Conventional insulations will be improved by adding components to block radiation (opacifiers). Phase-change material will be added to conventional insulation to provide for improved dynamic performance. The rate of advance in these areas is tied to cost of the materials, cost of energy, and availability of energy.

Advanced technologies that proved materials or systems that provide thermal resistance that changes with conditions will lead to new levels of energy conservation and contribute to construction of "zero energy buildings." Variable resistance insulations can be used to take maximum use of incoming solar energy.

Abstract

The efficient use of energy is important to restrain the emission of greenhouse effect gases. Thermal energy storage and heat transport technology enable to utilize the renewable energy and the waste heat which are generally unstable, maldistributed, and thin. They also enable to operate energy devices at a highly efficient condition. This chapter introduces some basic research and development activities of thermal energy storage and heat transport, especially latent heat utilization. First, the following fundamental knowledge of thermal energy storage is explained: (1) the functions of thermal energy storage, (2) the classification of storage methods, (3) the characteristics of thermal energy storage materials especially phase change materials (PCMs), and (4) the constitutions of thermal energy storage devices. Other characteristics and challenges of latent heat thermal energy storage (LHTES) which utilize supercooling phenomenon are also explained. Second, several examples of the practical use of LHTES including the utilization of snow and ice are discussed. In the same way, several characteristics and examples of the practical use of the heat transport using latent heat are also explained. Furthermore, recent developments on the following research subjects are introduced: (1) thermal energy storage for hot water supply using the supercooling phenomenon of sugar alcohol, (2) heat storage for space heating using the supercooling of hydrate, (3) the improvement of thermal characteristics of paraffin wax as a PCM, (4) a steam accumulator using sugar alcohol, (5) pipeless heat transport using sugar alcohol or hydrate, and (6) heat transport method using the microencapsulated PCM slurry.

Introduction

Global warming and depletion of fossil fuels are two major problems that are caused by large-scale energy consumption. To resolve these problems, the current practice of focusing on inexpensive energy use should be reconsidered, and the focus should be shifted to efficient energy use that does not adversely affect the environment. From the heat usage point of view, there are many heat demands within a temperature range of 0–200 °C. Although the heat demands can be basically provided by waste heat and renewable energy such as solar heat, most of them are directly provided by combustion of fossil fuels (Fig. 1). Such waste heat and solar heat are usually unstable and dispersing thinly.

By using thermal energy storage, such thin heat can be stored temporarily, so that the instability of heat supply can be smoothed. Thus thermal energy storage is the essential technology for utilizing such unstable or thin renewable heat. Thermal energy storage has another important feature which enables to generate and use energy efficiently because thermal energy storage can store energy during slack demand times (e.g., at night) and provide energy during high demand times (e.g., during the day). To meet a given peak demand, energy storage permits smaller power plants to be built, and it also permits them to be continually run at peak operating efficiency.

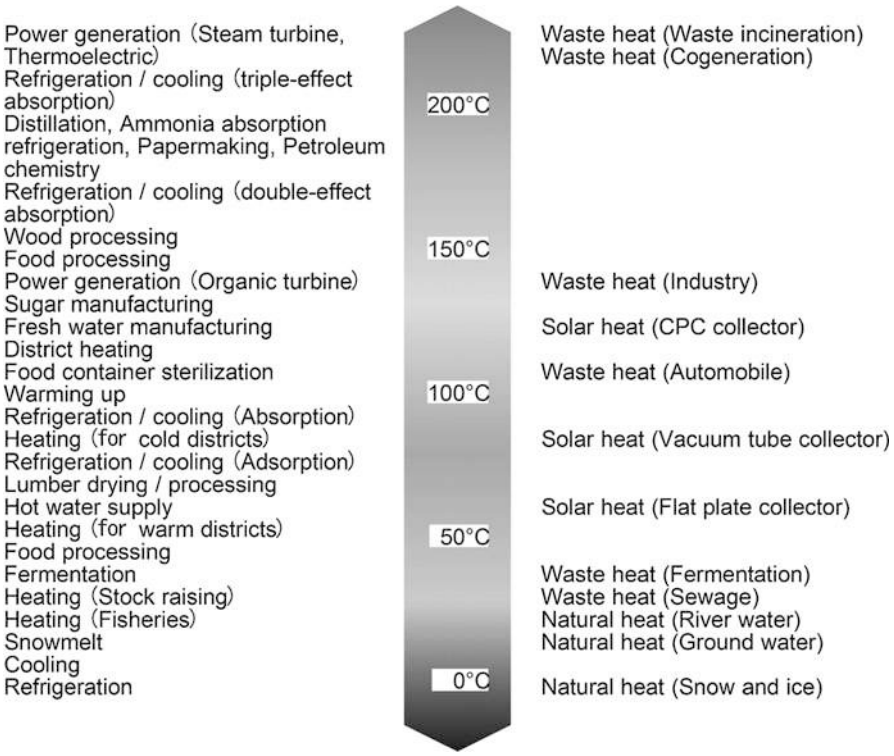

Fig. 1 Heat demands and heat sources by renewable energy and waste heat from 0 °C to 200 °C

By using heat transport, various heat sources can be connected and various heat demands which are located far from the heat sources can be fulfilled. The heat transport technology also enables to use a variety of heat sources such as a boiler, waste heat, and solar heat. Therefore, heat transport is the key technology to realize the thermal network among heat sources and heat demands, which can minimize the capacity of each heat source.

This chapter describes fundamental technology and the recent research trend of thermal energy storage and its application to heat transport.

Fundamentals of Thermal Energy Storage

Solar System and Thermal Energy Storage

The quantity and quality of heat supply from natural energy generally change with time. It is only during the daytime that solar energy can be acquired. Particularly, direct solar radiation is provided only at the time of fine weather. Heat demand in the commercial sector and residential sector, on the other hand, is apt to concentrate in

the morning and evening rather than in the daytime. Therefore, to improve the utility value of solar energy and magnify the application field of the energy, the technologies to collect and store solar heat in the daytime and to supply the stored heat during the high demand times become important.

Figures 2 and 3 show general components of solar systems with the thermal energy storage which can temporarily store the heat from solar collectors and can supply the stored heat on demand. Three thermal processes, (1) charging, (2) keeping, and (3) discharging, are necessary for thermal energy storage. The simplest constitution of a thermal energy storage method is that an object of heating is contacted to a thermal energy storage body or is included in the body as shown in Fig. 2a.

In Fig. 2, all the above thermal processes (1–3) are done passively. For example, there are houses and buildings which adopt this thermal energy storage method to use solar heat. The system using this method is called a passive solar system. If the system is designed such that the solar heat goes to the structure of a building through a transparent thermal insulation as shown in Fig. 2b and such that the time taken for thermal conduction from the structure to the indoor wall is about half a day, this storage method can automatically supply solar heat for space heating in the

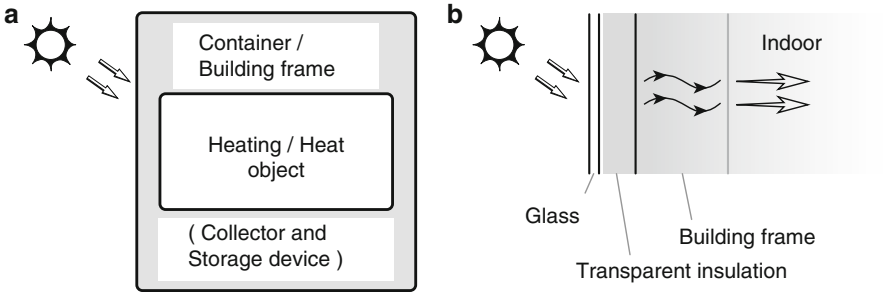

Fig. 2 (**a**) Component of passive thermal energy storage device and (**b**) application to heating by wall heat storage

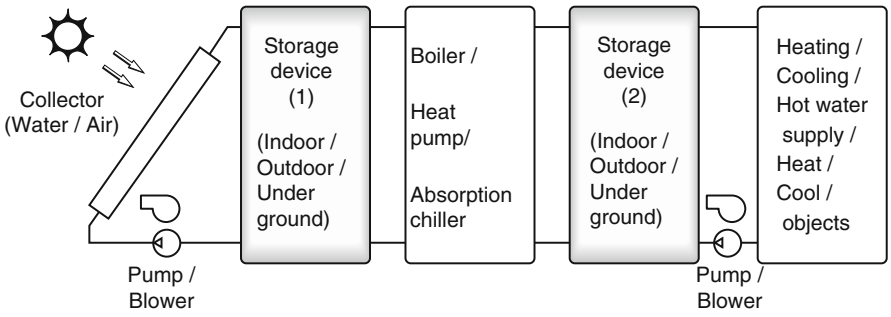

Fig. 3 Configuration of an active solar system

nighttime. Although the passive thermal energy storage is simple in constitution, it is difficult to control the above processes (1–3) depending on the condition. Therefore, the thermal optimization of the system is important in designing such passive systems.

Figure 3 shows the example of an active solar system which carries out the above three thermal processes actively. Each device shown in Fig. 3 is appropriately selected depending on the objective of the system. For example, a solar domestic hot water system corresponds to the simplest composition of the system shown in Fig. 3. The domestic hot water system consists of a solar collector and a water tank for thermal energy storage, both of which are installed on a roof. Cold water which flows into the collector is heated by solar heat in the daytime, which causes natural convection of the water and circulates the water between the collector and the tank. Thereby the water temperature in the tank gradually rises to a high temperature for hot water supply after sunset.

Water is the most convenient medium to transport heat among the components shown in Fig. 3. In the system which deals with the lower temperature than the freezing point of water, nonfreezing fluid is usually used as a heat transfer medium. On the other hand, in the system which deals with the higher temperature than a room temperature, an organic compound or chloride is often used for a heat transfer medium. In the system in which heat transfer medium is not water, a heat exchanger is often used in the storage device to heat the water. Air is sometimes used for the heat transfer medium in the solar collector because air can directly be used for space heating or for heating.

The thermal energy storage device (1) in Fig. 3 can regulate the fluctuation of heat supply. When the output from the thermal energy storage device (1) is short in temperature or quantity for heat demand, boilers, heat pumps, or absorption chillers are used as an auxiliary heat source. The thermal energy storage device (2) in Fig. 3 can regulate the fluctuation of heat demand. If the quantities of heat supply and heat demand can be patternized, either thermal energy storage device (1) or (2) is omitted by designing the system matching the fluctuation of the quantities. Optimization of operating temperature and equipment capacity based on the thermal performance of each component is necessary for designing the system with thermal energy storage.

Functions of Thermal Energy Storage

The effects of thermal energy storage are classified into three functions as shown in Fig. 4, that is to say, phase regulation between heat supply and heat demand (Fig. 4a), an amplification of heat supply (Fig. 4b), and smoothing of heat supply (Fig. 4c). For example, the function of phase regulation is utilized when solar heat gained in the daytime is used to supply hot water in the nighttime. The amplification function of heat supply is utilized when solar heat gradually gained through a year is used for heating in winter concentratedly. The smoothing function of heat supply is utilized when solar heat gained under an unstable weather condition is used for solar thermal power generation at constant output.

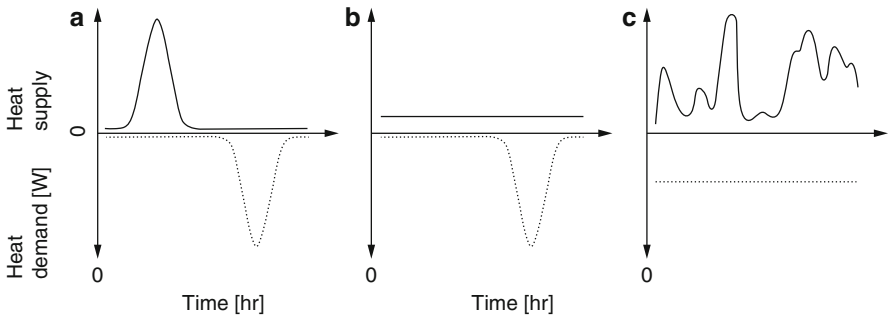

Fig. 4 Functions of thermal energy storage. (**a**) Phase regulation, (**b**) amplification, (**c**) smoothing

In many practical uses, these three functions should be properly selected and combined to fit applications. For example, the passive thermal energy storage device in Fig. 2 uses two functions: the phase regulation shown in Fig. 4a and the smoothing shown in Fig. 4c. The active thermal energy storage system in Fig. 3 uses all the three functions: the phase regulation, the amplification, and the smoothing shown in Fig. 4.

Classification of Thermal Energy Storage Methods

A material absorbs or discharges heat when the kinetic energy or the potential energy of the atoms or the molecules in the material changes by temperature change or phase transition. Besides, a material absorbs or discharges heat when the condition of the atomic bond or the molecular bond changes by chemical reaction. Thermal energy can be temporarily stored by using these phenomena as necessary. Table 1 shows the example of thermal energy storage methods classified by physical and chemical phenomena which are used to store heat.

Thermal energy storage methods using the physical change of a material are classified into the following three methods: (1) The thermal energy storage method which uses the absorption and discharge effects of heat caused by the temperature change of materials is called sensible heat thermal energy storage (SHTES). The SHTES is applied to hot water bags or electric water heaters with water tanks. (2) The thermal energy storage method which uses the absorption and discharge effects of heat caused by the phase transition of materials is called latent heat thermal energy storage (LHTES). The LHTES is applied to ice pillows or ice storage air conditioners. (3) The thermal energy storage method which uses the adsorption and desorption heats of material is called adsorption thermal energy storage. The adsorption storage is applied to air conditioners or chillers. The particular classification of SHTES and LHTES in Table 1 is mentioned later.

Thermal energy storage methods using the chemical change of a material are classified into the following three methods: (1) The thermal energy storage method which uses the endothermic and exothermic reactions of materials is called chemical

Table 1 Thermal energy storage methods

Use of physical change of materials	
Sensible heat thermal energy storage (SHTES)	Conventional SHTES (e.g., hot water storage)
	Soil thermal energy storage/underground thermal energy storage
	Aquifer thermal energy storage
	Solar pond
Latent heat thermal energy storage (LHTES)	Conventional LHTES (e.g., ice storage)
	Supercooled thermal energy storage
Adsorption thermal energy storage	
Use of chemical change of materials	
Chemical thermal energy storage (CTES)	Conventional CTES (e.g., reversible reaction between calcium hydroxide and calcium oxide)
	Metal hydride thermal energy storage
	Concentration difference thermal energy storage

thermal energy storage (CTES). Because repeatability becomes premise as for the functions of thermal energy storage, it is necessary for the reaction of CTES to be reversible. As subspecies of the CTES, there are (2) metal hydride thermal energy storage and (3) concentration difference thermal energy storage using heat of dilution.

Thermal Energy Storage Materials

Any substance can be used as thermal energy storage material in theory. The effectiveness as thermal energy storage materials depends on thermophysical properties like specific heat, transition point, and heat of transition. However, practicable materials are limited by chemical properties like deliquescence, efflorescence, corrosiveness, noxiousness, heat resistance, and economy.

Table 2 shows heat capacities per 1 L of several familiar materials used as heat storage materials (The Japan Society of Mechanical Engineers (JSME) 2009). In a room temperature, water is the best material for SHTES system in point of cost, safety, and thermal energy storage density. At a high temperature over several hundred degrees Celsius, rocks and bricks are effective as materials for SHTES system, too.

Table 3 shows melting points and heats of fusion per 1 L around the melting points of several familiar materials (Hirano 2002). Water is also the most suitable phase change material (PCM) for LHTES systems which is operated near 0 °C. Ice storage systems are good examples of LHTES systems and are widely spread today. Paraffin is one of usable PCMs. The heat of fusion per unit volume of paraffin is small because both density and heat of fusion per unit mass are small. Besides, inflammability of low-melting-point paraffin is high. However, paraffin has low noxiousness, and the influence of supercooling (mentioned later) before freezing is small. Therefore, paraffin is used as a comparatively cheap PCM.

Table 2 Heat capacities of ordinary materials per 1 L

Material	Heat capacity (J/K)
Water	4170[a]
Mild steel	3720[b]
Loam (water content 37 %)	3440[a]
Basalt	2670[c]
Sand and clay (water content 22 %)	2350[a]
Limestone concrete	2160[a]
Chamotte brick	2000[a]
Asphalt	1950[a]
Cedar (water content 48 %)	540[b]

[a]At 20 °C
[b]At 27 °C
[c]At 127 °C

Table 3 Heat of fusion of ordinary materials per 1 L

Material	Melting point (°C)	Heat of fusion (kJ/L)
Water	0	306
Polyethylene glycol #400	8	97
Sodium sulfate decahydrate	32	334
Disodium hydrogen phosphate dodecahydrate	36	384
Sodium acetate trihydrate	58	356
Paraffin wax	42 ∼ 70[a]	120 ∼ 190[a]
Polyethylene glycol # 6,000	57	201
D-Threitol	87	328
Erythritol	118	416
Mannitol	167	422
Tin	232	422
Aluminum	660	940

[a]Depending on the number of carbon atoms in a molecule

Hydrate is also one of the useful PCMs. Noxiousness of most hydrate is low. However, supercooling and segregation (mentioned later) become a problem when the hydrate is used as a PCM. Sugar alcohol is one of the safe and promising PCMs. However, the supercooling and cost of sugar alcohol may be problematic. Thus the further utilization of hydrate or sugar alcohol is expected in the future LHTES systems because the thermal energy storage densities of hydrate and sugar alcohol are larger than that of paraffin.

Thermal Energy Storage Devices

In the thermal energy storage device shown in Fig. 3, suitable mechanisms are necessary to control the three processes: (1) charging, (2) keeping, and (3) discharging. For the control of the processes, most thermal energy storage

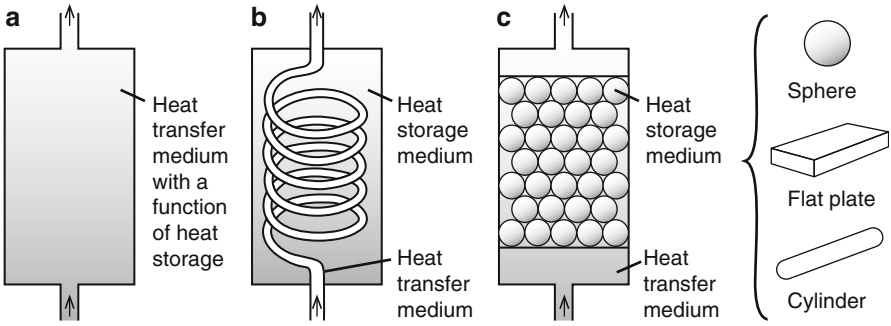

Fig. 5 Typical configuration of thermal energy storage device. (**a**) Combined use of heat transfer medium and heat storage material, (**b**) separation by pipe, (**c**) separation by capsule

devices take either constitution shown in Fig. 5. When the storage space for a heat transfer medium is installed in the middle of piping shown in Fig. 5a, the abovementioned thermal processes (1–3) can be carried out simply by injecting and extracting the heat transfer medium if necessary. For example, water as a heat transfer medium also functions as a heat storage medium in a solar domestic hot water system. The thermal energy storage is given only by sensible heat when the phase of the heat transfer medium does not change within the temperature range of operation. On the other hand, when hydrates, inclusion compounds, or clathrate compounds of hydrocarbon or fluorocarbon, or fluids like the ice slurry are used as the heat transfer media, latent heat is also available to use along with sensible heat.

In the thermal energy storage tank shown in Fig. 5a, the heat transfer medium is easily mixed if the agitating behavior by the inflow motion of the heat transfer medium is strong. In this case, the storage tank is called a mixed tank. The mixed-type heat storage tank provides a high performance in the smoothing function of Fig. 4c. However, the available energy easily decreases in the mixed tank because the temperature difference is easily lost by the agitating behavior. On the other hand, if the mixing behavior by the inflow motion of the heat transfer medium is small, the thermal stratification due to density variations is easily formed in the heat storage tank. In this case, the storage tank is called a stratified tank. The heat storage tank of thermally stratified type can easily maintain available energy in the tank. To promote the formation of plug flow in the stratified tank, a diffuser or a manifold is often used.

For example, the thermal energy storage device for a solar system is considered. The efficiency of a solar collector which is installed in the upstream side of the thermal energy storage device becomes higher as the temperature difference between the solar collector and the ambient air becomes smaller. The efficiency of the thermal appliances such as a heat pump installed in the downstream side of the thermal energy storage device becomes higher as the output temperature of the storage device becomes higher. Therefore, the thermal energy storage device of thermally stratified type is more profitable in efficiency of the solar system than the mixed-type device (Duffie and Beckman 1991).

One practicable idea for solar energy systems is the use of a pond as the thermal energy storage tank and a solar collector. The pond for this purpose is called a solar pond. The heat transfer medium flows into the solar pond and flows out from the pond with gained solar heat to supply heat. A wide pond is advantageous to collect solar heat. However, the gained solar heat is usually going to be dissipated and lost easily from the surface of the pond to the ambient air because of natural convection in the pond. On this account, an inverse thermal stratification is applied to reduce the heat dissipation. Sodium chloride, polymer compound, porous structure, or honeycomb structure is added to the pond to form the inverted temperature profile in the direction of depth such that the temperature in the lower layer is higher than that in the upper layer. Salt lakes are just available to use as the solar ponds.

In cold districts, it is necessary for antifreezing fluids to be used as the heat transfer medium to prevent freezing. When the antifreezing fluid can be just used for not only the heat transfer medium but also the heat storage medium, thermal energy storage devices shown in Fig. 5a can be applied. On the other hand, the thermal energy storage device shown in Fig. 5b, c is used when the heat storage medium is different from the heat transfer medium. The materials listed in Tables 2 and 3 can be used as the heat storage materials for the system shown in Fig. 5b, c. In the constitution shown in Fig. 5b, c, the heat exchange rate between the heat transfer medium and the heat storage medium is one of the most significant factors to determine the thermal time constant of the device. It is effective to broaden the contact area between both media for improving the heat exchange rate. It is also convenient to handle the heat storage medium when the medium is divided into small pieces. Therefore, the heat storage media are usually filled into the plural small capsules shown in Fig. 5c whose shape is spherical, cylindrical, or flat.

There are several methods which use the underground soil and rocks as the heat storage medium. The method which is called soil thermal energy storage or underground thermal energy storage uses the antifreezing fluid and the soil as the heat transfer medium and the heat storage medium shown in Fig. 5b, respectively. The method which is called aquifer thermal energy storage uses the underground water for the heat transfer medium and uses underground rocks and sands for the heat storage medium as in Fig. 5c. Above both methods using the earth are effective for a large quantity and long-term thermal energy storage. When the storage period is longer than a season, the method is particularly called seasonal thermal energy storage. For example, the surplus solar heat gained in the summer can be effectively utilized in the winter by the seasonal thermal energy storage.

Characterization of Thermal Energy Storage

In a thermal energy storage system, quantity of stored sensible heat, Q_s (J); quantity of stored latent heat, Q_l (J); and quantity of stored heat of reaction, Q_r (J), are given in the next equations, respectively:

$$Q_s = m\int c(T)dT \tag{1}$$

$$Q_s \approx mc\Delta T = \rho V c\Delta T \tag{2}$$

$$Q_l = m\Delta_f H M_f \tag{3}$$

$$Q_r = n\Delta_r H R_f \tag{4}$$

where $c(T)$ is the specific heat at temperature T(J/g/K); M_f, melting fraction (defined by [melted mass]/[total mass]); m, mass (g); n, number of moles (mol); R_f, reacting fraction (defined by [reacted mass]/[total mass]); T, temperature (K); V, volume (m^3); $\Delta_f H$, heat of fusion (J/g); $\Delta_r H$, heat of reaction (J/mol); ΔT, temperature change (K); and ρ, density (g/m^3).

If the temperature dependence of specific heat of the thermal energy storage material is small or if the temperature change of the material during the storage processes is small, Eq. 1 can be approximated by Eq. 2. The quantity of stored heat in the SHTES system is governed only by Eq. 1. Storage process with the LHTES system is usually accompanied by temperature change before and after the phase transition. Therefore, the quantity of stored heat in the LHTES system is usually governed by Eqs. 1 and 3. Storage process with the CTES system is usually accompanied by temperature change or by temperature change and phase transition before and after the reaction. Therefore, the quantity of stored heat in the CTES system is usually governed by Eqs. 1 and 4 or Eqs. 1, 3, and 4.

The efficiency of thermal storage, η, and the efficiency of a heat storage tank, η_t, defined by the following equations are used for typical indexes to characterize the performance of a thermal energy storage device:

$$\eta = Q_{out}/Q_{in} \tag{5}$$

$$\eta_t = Q_{out}/Q_{th} \tag{6}$$

where Q_{out} is the output thermal energy (J); Q_{in}, input thermal energy (J); and Q_{th}, theoretical storage capacity of thermal energy (J).

The efficiency of available energy, exergy, based on the environmental temperature is also important to evaluate the performance of the storage devices with which the charging and the discharging processes occur in a specific small temperature range such as the LHTES system.

Each thermal energy storage method is characterized in Table 4. The thermal energy storage density is defined by the quantity of heat which can be stored in a unit mass or in a unit volume of the storage material. The SHTES has a lot of embodiments and is technically mature. The LHTES has some technical issues in repeatability, stability, or profitability except an ice storage system, one of the LHTES systems. Thus, the technology of the LHTES is in the middle of development. Although the CTES has the highest functionality, there are many pending issues including the material compatibility.

Table 4 General merits and demerits of three methods of thermal energy storage

Rating item	SHTES	LHTES	CTES
Storage density	X	Δ	O
Stability of output temperature	X	O	O
Repetition stability	O	Δ	X
Responsibility	O	Δ	Δ
Safety	Δ	Δ	Δ
Initial cost	O	Δ	X

SHTES sensible heat thermal energy storage, *LHTES* latent heat thermal energy storage, *CTES* chemical thermal energy storage

The thermal energy storage density of the LHTES device is larger than that of the SHTES device. Therefore, LHTES is more advantageous than SHTES for the applications where the size of heat storage systems must be minimized, for example, in urban areas. The temperature of the heat storage medium during the charging and discharging processes of sensible heat varies with time. On the other hand, the temperature of the heat storage medium during the charging and discharging processes of latent heat is maintained at the transition point. This is the reason that LHTES is more advantageous than SHTES in point of the storage efficiency of available energy. In addition, the repeatability of the storage processes of LHTES is comparatively stable. Thus, further application of LHTES is expected. From the following section, thermal energy storage and heat transport which use latent heat of PCMs will be explained in detail.

Phase Change Thermal Energy Storage

General Feature of Phase Change Materials

It is well experienced routinely that ice absorbs large heat of fusion and cools surrounding substances during melting process. In this case, water functions as a PCM. Many candidates of PCMs were listed up in various kinds of literature especially in 1970s when we experienced two oil crises. Among those candidates, however, many of them were substances with toxicity, noxiousness, corrosiveness, irritation, oxidizability, combustibility, or inflammability. Thus the number of available materials for PCMs has been decreasing as regulations for the use of chemical substances have been strengthened.

As typical examples of PCMs, paraffin, hydrate, and sugar alcohol are recently attracting attention. Major physical properties of water (Hirano 2002), *n*-eicosane (Kosaka et al. 1980), disodium hydrogen phosphate dodecahydrate (DHD) (Hirano et al. 2001), and erythritol (Kakiuchi 2008) are given in Table 5. Compared with water in Table 5, the following points are given as the characteristics of the three materials: paraffin, hydrate, and sugar alcohol. Hydrate and sugar alcohol are profitable to densification of thermal energy storage because densities are larger

Table 5 Comparison of physical properties of water, *n*-eicosane, DHD, and erythritol

Property	(Phase)	Water	*n*-eicosane	DHD	Erythritol
Density (kg/m^3)	(Solid)	917[a]	830	1520[c]	1480[e]
	(Liquid)	999.84[a]	780	1447[d]	1300[f]
Specific heat (kJ/kg·K)	(Solid)	2.101[b]	1.9	2.00[c]	1.38[e]
	(Liquid)	4.2174[a]	2.3	3.45[d]	2.77[f]
Thermal conductivity (W/m·K)	(Solid)	2.09[a]	0.34	1.02[c]	0.73[e]
	(Liquid)	0.565[a]	0.15	0.61[d]	0.33[f]
Melting point (°C)		0	36.4	35.54	119
Heat of fusion	(kJ/kg)	333.6	247	265.6	330
	(kJ/L (liquid))	333.5	193	384.3	429

[e]20 °C
[f]140 °C

than that of water. On the other hand, paraffin is disadvantageous for densification of thermal energy storage because the density is small. It is effective to use not only latent heat but also sensible heat of hydrate for thermal energy storage because the specific heat of hydrate is as large as that of water. The utilization effect of sensible heat of paraffin and sugar alcohol is not large compared with water due to the same reason. Hydrate and sugar alcohol are disadvantageous in the heat exchange during the phase change process because thermal conductivities of them are about a half of that of water. Paraffin is more disadvantageous in the heat exchange during the phase change process because the thermal conductivity of paraffin is only about a quarter of that of water.

The selection of the suitable material for PCMs depends on the place where the heat storage device is used as well. For a mobile heat storage system, not only the volume of the heat storage medium but also the weight becomes an important factor. For a stationary heat storage system, on the other hand, the volume of the heat storage medium is overwhelmingly more important than the weight of the medium. Figure 6 shows the relationships between the melting points and heats of fusion per unit volume for several candidates of PCMs whose melting points exist between 0 °C and 200 °C. The unit volume of each material except water is based on the volume in the liquid phase at around the melting point because the maximum quantity of the material filled in a capsule is limited by the volume in the liquid phase. The unit volume of water is based on the volume in the solid phase at around the melting point because the volume of water decreases after melting. In comparison with the heat of fusion of water which is used for an ice storage air-conditioning system, the heats of fusion of hydrate and sugar alcohol are large, and the heats of fusion of paraffin and other organic substances are small.

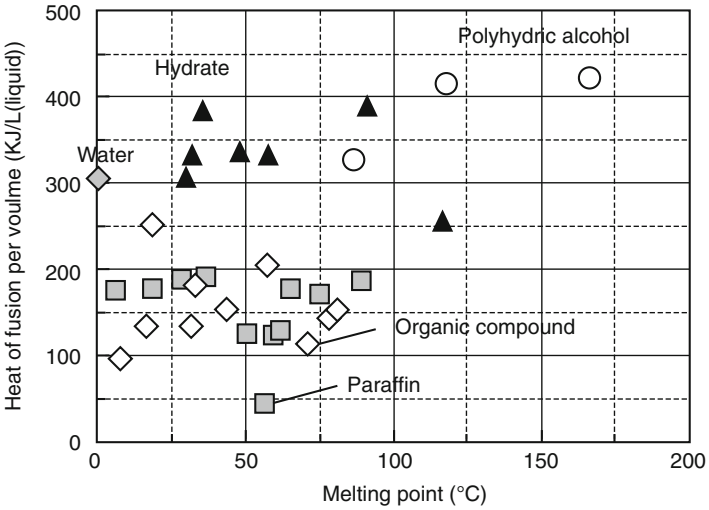

Fig. 6 Example of heats of fusion per unit volume of some promising PCMs in the liquid phase

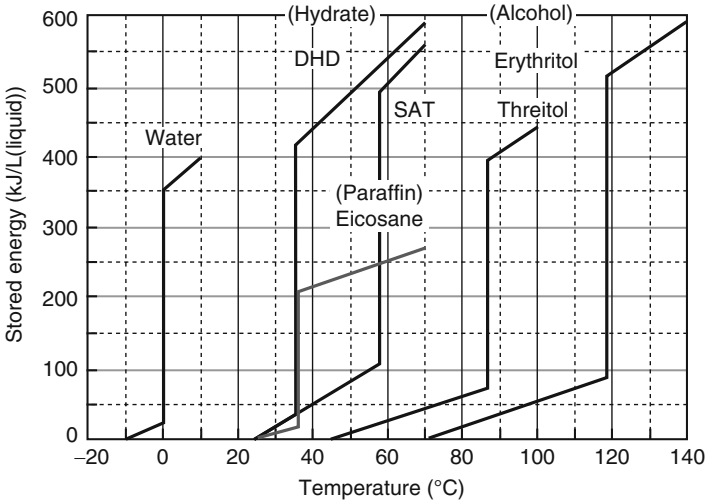

Fig. 7 Temperature dependence of the thermal energy which can be stored per unit volume

Thermal Energy Storage Density

It is extremely rare for practical LHTES systems to use only latent heat. The LHTES systems usually use not only latent heat but also sensible heat in the proper operating temperature range including the transition point of the heat storage medium. Figure 7 expresses the variations of the thermal energy which can be stored in each proper

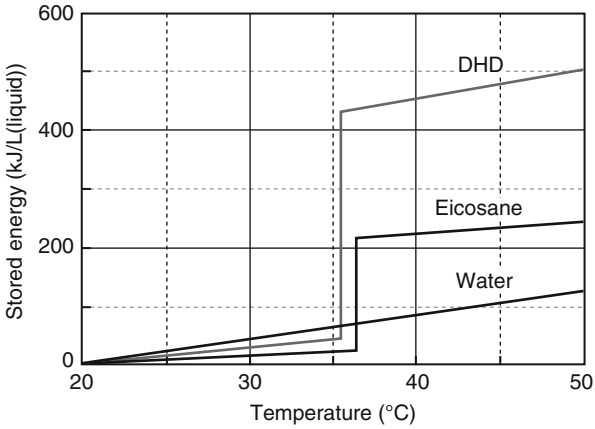

Fig. 8 Comparison of the thermal energy which can be stored per unit volume in the temperature range from 20 °C to 50 °C

temperature range about *n*-eicosane, disodium hydrogen phosphate dodecahydrate (DHD), sodium acetate trihydrate (SAT), threitol, and erythritol as typical examples of paraffin, hydrate, and sugar alcohol. Hydrate can store large energy because both specific heat and heat of fusion are large; thus it is effective to use hydrate with a wide temperature range. On the other hand, both specific heat and heat of fusion of paraffin are small. Thus the superiority of LHTES with paraffin over the SHTES with water becomes lower as the operating temperature range of paraffin becomes wider.

For example, Fig. 8 gives the variations of the thermal energy which can be stored per unit volume of water, *n*-eicosane, and DHD when the materials are heated from 20 °C to 50 °C. The thermal energy which can be stored with *n*-eicosane by the temperature rise of 30 °C is about twice as much as that with water. By the way, when the temperature rise from 35.9 °C to 36.9 °C is considered, the thermal energy which can be stored with water by this temperature rise is 4.2 kJ/L. On the other hand, the thermal energy which can be stored with *n*-eicosane by the same temperature rise, 1 °C, as that of water is evaluated at 195 kJ/L including heat of fusion. In this temperature change, 1 °C, the thermal energy which can be stored with *n*-eicosane is 46 times larger than that with water. That is to say, the superiority of the thermal energy storage density of LHTES against SHTES deteriorates when the range of the operating temperature of LHTES system becomes wide.

Variations of the thermal exergy (available energy) which can be stored per unit volume of the PCMs are shown in Fig. 9 when 20 °C is assumed to be the standard environmental temperature. Sugar alcohol can store larger exergy than hydrate and paraffin because the melting point is high. In other words, the quality of the thermal energy which can be stored with sugar alcohol is high. Thus, LHTES with sugar alcohol has high added value for space heating or hot water supply. To use PCMs shown in Fig. 6 effectively, it is important to make better use of the merits of each PCM and to make up for the demerits of it. Besides, the development of new materials located in the upper part of the graph in Fig. 6 is eagerly awaited in future.

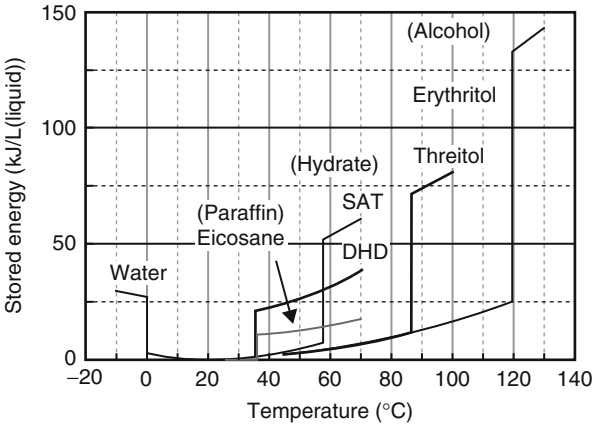

Fig. 9 Temperature dependence of the thermal energy which can be stored per unit volume

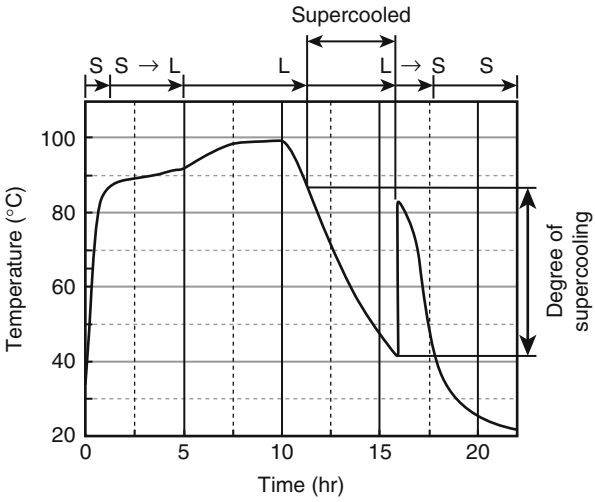

Fig. 10 Example of the temperature variation of D-threitol during melting and solidification processes. The letters "S" and "L" are mean solid phase and liquid phase, respectively

Supercooling and Segregation

A material changes its phase from solid to liquid (fusion) or vice versa (solidification) ideally at the melting point. Practically, however, the temperature gap between fusion and solidification processes occurs. For example, Fig. 10 shows the temperature variation of D-threitol during melting and solidification processes. In Fig. 10, a heating operation increases the temperature of the threitol in the solid phase. The threitol starts to melt at the melting point, 87 °C. After the threitol completely melted, the melt is cooled to the room temperature. By the cooling operation, the temperature of the threitol falls to the melting point. However, the solidification process does not start at the melting point. The melt is continuously cooled to the lower temperature than the melting point, in the liquid phase called a supercooled state.

Supercooling phenomenon is caused by not the delay of thermal conduction in the melt, but the difference in free energy between a liquid phase and a solid phase. To generate a crystal nucleus in the melt, it is necessary for the radius of the molecular cluster in the melt to exceed the critical size which is determined from the relationship between the volume-free energy and the surface-free energy. Therefore, the supercooled state is maintained in the metastable state unless the melt is cooled to the spontaneous nucleation temperature, about 41 °C in Fig. 10. The difference between the spontaneous nucleation temperature and the melting point is equivalent to the maximum degree of supercooling of the material. The maximum degree of supercooling depends not only on the intensive properties, such as the melting point, but also on extensive properties, such as the mass of the material filled into a container.

Once the solidification starts by the generation of a crystal nucleus, the temperature of the threitol recovers to the melting point as is shown in Fig. 10. After that, the threitol continues releasing heat of solidification till solidification is completed. The supercooling phenomenon is easily observed in hydrate and sugar alcohol.

There are two aspects to the supercooling phenomenon that the supercooling of a PCM is favorable for LHTES or unfavorable for it. When the heat of solidification of a PCM is kept in the supercooled state at the lower temperature than the melting point, the heat loss from the PCM to the ambient air can be reduced. In this case, the supercooling becomes a favorable phenomenon for LHTES. On the other hand, even when the heat of solidification of a PCM is demanded, the latent heat is not obtained due to the supercooling unless the temperature of the PCM falls to the spontaneous nucleation temperature below the melting point. In this case, the supercooling becomes an unfavorable phenomenon for LHTES. Most research on LHTES has been conducted from the latter viewpoint. Thus, great efforts of research and development of PCMs have been focused on the prevention technology against supercooling.

The research on the prevention technology against supercooling became in earnest from the research by Telkes in 1940s. Telkes discovered that the sodium tetraborate decahydrate was effective as a nucleating agent for sodium sulfate decahydrate (Telkes 1954). The nucleation cannot be promoted easily even if the additive for nucleation is kept in the solid phase. It is considered that the effect of the nucleating agent and the factor of the induction of nucleation are different among base materials, so that it is necessary to discover the agents by a trial-and-error method. Discovery of nucleating agent by Telkes attracted next research, and from 1950s to 1980s, several nucleating agents were discovered, and several physical nucleation methods were invented. However, there are many PCMs whose proper nucleating agents are not found yet.

Segregation in hydrate is another challenging phenomenon as well as the supercooling. In the melt of the hydrate, the hydrate of the lower order which crystallized in advance by peritectic reaction is going to precipitate in the melt due to density variations. The hydration reaction of the higher order does not completely proceed if the hydrate of the lower order precipitates before it takes in more water molecules and becomes the original hydrate of the higher order. Segregation causes

the substantial decrease in heat of fusion and the functional deterioration as a PCM. Therefore, proper inhibitors for segregation or stabilizers such as thickeners and polymers for liquid adsorption have been developed. However, the optimization of the proportion of the segregation inhibitors to a PCM is necessary because the inhibitors cause decrease in the storage density of thermal energy.

The maximum degrees of supercooling of paraffin and some other organic substances are smaller than those of hydrate and sugar alcohol. Besides, the segregation does not occur in paraffin and any other organic substances. Those advantages are two of the reasons why paraffin and other organic substances are often used as PCM at around a room temperature.

Research and Development Situation

Looking back upon the progress, the two oil crises in the 1970s accelerated research and development on thermal energy storage methods in the industrial world and the academic world. From the second half of the 1970s to the first half of the 1980s, various kinds of materials and their application methods were searched for throughout the world and put in order. Besides, most of theoretical or experimental analyses concerning melting or solidification processes of PCMs or performances of the thermal energy storage with PCMs were conducted in this epoch. After that, the number of the research and development on thermal energy storage temporarily decreased. Recently, however, the number is a little increasing by a cognitive surge to the global warming issue represented by the Kyoto Protocol. Many of the articles related to phase change thermal energy storage were reported from 1980 to 1990, and many books and literature summarizing the reports were published after that.

However, physical properties of PCMs including mixtures are not fully known even though the names of the materials are well known. Besides, it is not rare that physical properties of PCMs listed in handbooks and literature include gross errors or the transmitted errors by using references which made mistakes of numerical mentions when the properties are quoted from original references (Hirano et al. 2001). The LHTES systems are generally used in the broad temperature range from the lower temperature than the melting point of a PCM to the upper temperature. Therefore, the temperature and pressure dependences of the physical properties of PCMs are important to the effectual design of the system. However, such detailed data are available only for several PCMs.

The technology of LHTES at the lower temperature than the room temperature has advanced by the research for more than 10 years after the oil crises. For example, an ice storage air-conditioning system has been downsized, improved in efficiency, and widespread. The research on LHTES by natural snow and ice was advanced as snow-utilization and snow-persistence technologies, and demonstration tests came into operation. Food storage and transport are suitable for use of snow and ice because the added values of the food storage and transport are higher than that of space cooling. The food transport at a low temperature with ice has been used

Table 6 Features of commercial encapsulated PCMs

Melting point (°C)	Heat of fusion (kJ/kg)	Principal component

conventionally as methods to retain the freshness. As food culture became rich, the uses of natural snow and ice came to attract attention not only for simple freshness retainment but also for increase and retainment in flavor. The lower the storage temperature of food is, the longer the preservation term is. However, the storage at the optimal temperature around the freezing point of water is good for the point of increase and retainment in flavor. The proper storage temperature, humidity, and period are actually different among food. For example, from the room temperature to the ice point, the flavor of rice becomes much superior as the storage temperature becomes lower. However, it is reported that the additional improvement of flavor of rice is small even if the storage temperature is kept at the lower temperature than the ice point (Hirano 2006).

The PCMs are often filled in containers of proper size such as in Fig. 5c and the containers are tightly sealed. The subdivision of the PCMs to the containers accelerates the heat exchange rate between the PCMs and the heat transfer medium and stabilizes the characteristic of phase change. In addition, the subdivision to the containers improves handling ability and prevents the PCMs from contamination. The manufacturing technology of encapsulated PCMs of which the containers are mainly made of polyolefin resin was developed in the 1980s. The heat-resistant temperature of polyolefin resin for the containers is about 70–100 °C. As a result, the spread of ice storage systems and floor heating systems with LHTES advanced.

Examples of the physical properties of the commercial encapsulated PCMs are listed in Table 6 (Mitsubishi Chemical Engineering 1999; Phase Change Products 2009). In the heat storage systems which use heat transfer media, convective heat transfer is dominant over the heat exchange between the PCMs and the heat transfer media. Thus spherical or cylindrical containers are often used in encapsulating PCMs to increase the contact area between the PCMs and the media. For example, the shapes of most PCM capsules on the market for hot water supply systems and for

space cooling and heating systems are spherical or cylindrical. The melting points of the PCMs in the spherical or cylindrical capsules are set to various temperatures which are shown in Table 6, in response to the purposes of uses.

In the heat storage systems which do not use heat transfer media, thermal conduction is dominant over the heat exchange between the PCMs and the cooling or heating objects. Thus, tabular containers are often used in encapsulating PCMs to increase the contact area between the PCMs and the objects. For example, the shapes of most PCM capsules on the market for floor heating systems are tabular. The materials of the container are selected from a soft film or a hard resin depending on applications. Several types of encapsulated PCMs which use sodium sulfate decahydrate (melting point is 32 °C) or sodium acetate trihydrate (adjusted melting point is 43 °C) are put on the market for floor heating systems (Hirano 2009a). Besides on the market, there are tabular encapsulated PCMs which use sodium sulfate decahydrate (adjusted melting point is 23 °C) for the heat capacity of passive solar systems. For equipment of the blackout indemnification of communication repeating facilities, tabular encapsulated PCMs of which the melting points are 36 °C are put on the market. For leveling the temperature of battery, there are resin-packaged PCMs of which the melting points are 29 °C.

As unique examples of the use of PCMs, there are warm keeping trays which use PCMs for maintaining the temperature of food. The melting points of the PCMs in the trays are set to various temperatures in response to the purposes. For maintaining the temperature of the hot water of baths, warm keeping packs are put on the market. These warm keeping packs are also usable as hot water bottles. Furthermore, there are flexible warm keeping mats for pets. Both warm keeping packs and mats use the organic compounds such as polyethylene glycol whose melting point is between 40 °C and 60 °C.

Phase Change Heat Transport

Transport Methods

Steam discharges large heat of condensation when it changes to liquid water. Therefore, steam has been used for long as a heat transport medium using the phase change between gas and liquid. However, to use the phase change between gas and liquid at around the room temperature, the decompression of the heat transport system or the use of the medium with a low boiling point is necessary. Besides, in using the phase change between gas and liquid, there is a problem of the thermal energy transport density defined by the quantity of heat which can be transported in a unit mass or in a unit volume of the transport material.

For instance, Table 7 gives the physical properties of ice, liquid water, and steam, respectively (Hirano 2002; International association for the properties of water and steam (IAPWS) 1998). The transporting power for gas is smaller than that for liquid, and the heat of condensation per unit mass is larger than the heat of solidification. However, the heat of condensation per unit volume is smaller than the heat of

Table 7 Comparison of physical properties of ice, liquid water, and steam

Property	Ice	Liquid water		Steam
Density (kg/m^3)	917[a]	999.84[a]	958.4[c]	0.5981[c]
Specific heat (kJ/kg·K)	2.101[b]	4.2174[a]	4.217[c]	2.077[c]
Thermal conductivity (W/m·K)	2.09[a]	0.565[a]	0.679[c]	0.0250[c]

Heat of phase transition (kJ/kg)	333.6	–	–	2256
Heat of phase transition (kJ/L(liquid))	333.5	–	–	1.349

[a]0.0 °C
[b] −2.2 °C
[c]100 °C

solidification because the density in the gas phase is small. Thus heat transport using the phase change between solid and liquid has been researched and developed as a promising method at around the room temperature.

The heat transport methods with fusion and solidification are as follows: (1) a method to freeze the heat transfer medium partially and flow the slurry in piping, (2) a method to suspend fine grains of PCMs in the heat transfer medium and flow the emulsion in piping, (3) a method to suspend encapsulated PCMs with micro-dimensions in the heat transfer medium and flow the suspension in piping, (4) a method to fill up storage tanks with PCMs and carry the tanks by freight trains, freighters, or automobiles between heat source equipment and heat demand equipment. As for the transport density of thermal energy, the same argument as LHTES basically stands up. That is to say, the transport density depends on the content of PCMs in the base fluids, heat of fusion of PCMs, and so on.

The spread of phase change heat transport has not been advanced because of the same economical efficiency as phase change thermal energy storage. The clogging in the piping by the solidification or the aggregation of the PCMs is one of the serious issues in phase change heat transport. Therefore, suitable mechanism for preventing the clogging is necessary. Besides, the durability of the microcapsule shell generally deteriorates in a hot water, so that the improvement of heat resistance of the shell is required in the future.

Research and Development Situation

Around the 1990s, research and development of heat transport technologies by a hydrate slurry and a microcapsule slurry were conducted as the applications of phase change thermal energy storage technology at a low temperature, and part of the technologies was put to practical use. For example, a transport technology of latent heat at a low temperature with a tetra-*n*-butylammonium bromide (TBAB) aqueous solution (heat of fusion is 193–206 kJ/kg) was put to practical use (New Air Conditioning System Division 2009). The crystal deposition temperature of a TBAB aqueous solution is adjustable in the range from 0 °C to 12 °C by the concentration of the aqueous solution. When the crystal deposition temperature of

the hydrate slurry is higher than 0 °C, the coefficient of performance of chillers for generating the hydrate slurry becomes larger than that for generating the ice slurry, which reduces the consumption of electric power for generating the hydrate slurry holding the same latent heat as the ice slurry.

The viscosity of the hydrate slurry is larger than that of water. On the other hand, the thermal energy transport density of the hydrate slurry is larger than that of water, which can reduce the flow rate of the heat transport medium for air-conditioning. Since the reduction of the flow rate reduces the pressure drop in piping, the consumption of electric power for transporting the slurry is less than that for water. Therefore, the reduction of the transportation power of a heat transport medium and the improvement of the operation efficiency of a refrigerating machine are concurrently achieved if high-density heat transport is taken at 7 °C where the efficiency of cooling operation of the air in rooms is high.

The application of subsumption compounds except TBAB to the heat transport is also examined. Besides, the research of freezing control technology by synthetic polymers is conducted as research to improve the latent heat transport (Inada 2006). The substitution effect of natural antifreezing protein (AFP) was found in cheap heavy chemicals like polyvinyl alcohol.

Examples of Recent Technical Development

Thermal Energy Storage System for Hot Water Supply

In the temperature range for a hot water supply, paraffin waxes, organic compounds, and sugar alcohol shown in Fig. 6 are considered to be comparatively safe PCMs. In respect to the storage density of thermal energy and thermal conductivity, however, paraffin waxes and organic compounds are inferior as PCMs. Besides, there are no proper hydrates which are safe, have reproducibility in repetition of phase change, and have the melting point in the temperature range for a hot water supply. Therefore, sugar alcohol attracts much attention in the 2000s, and the proper methods for using the material have been studied (Kakiuchi 2008). The attractive points of sugar alcohol are its safeness used as medicines and food and its proper melting point for hot water supply. On the other hand, it was difficult to use sugar alcohol effectively as a PCM because the maximum degree of supercooling of sugar alcohol is large.

For example, in Fig. 10, the solidification of D-threitol whose melting point is 87 °C cannot be triggered unless the threitol is once cooled to around 40 °C because the spontaneous nucleation temperature is about 40 °C. That is to say, the heat of solidification of the threitol cannot be immediately extracted at the melting point. If the heat for cooling the threitol to the spontaneous nucleation temperature cannot be used, about 40 % of the heat stored in the threitol will be lost for the nucleation process. On the other hand, the heat of solidification can be saved in the supercooled state at a low temperature for a long term if the release time of the supercooled state is controlled actively. Besides, if the heat for cooling the threitol to the spontaneous

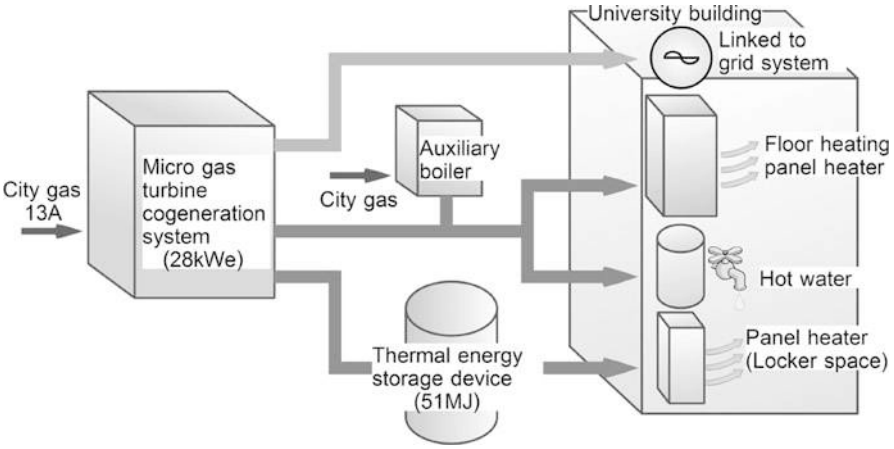

Fig. 11 Cogeneration system with hot water supply and space heating by thermal energy storage

nucleation temperature can be used effectively, the stored heat can be discharged twice in separate hours before and after the storage period in the supercooled state.

As an example of the applications of the LHTES using supercooling, a cogeneration system with the LHTES of D-threitol is shown in Fig. 11 (Hirano 2009b; Hirano and Takeuchi 2009). The system was installed in a building of the university located in Sapporo, Japan. The heat engine of the system is a micro gas turbine (MGT). The shaft power of the MGT drives a generator (27 kW). The exhaust gas of the MGT heats water for hot water supply with heat exchangers. Thus the cogeneration system can simultaneously supply both electricity and heat to the building. In the daytime, the hot water is partially supplied to the LHTES unit to store the surplus heat from the MGT. During the nighttime when the MGT is not operated, the LHTES unit can supply hot water in response to the demand of space heating.

In this system, the supercooled thermal energy storage unit with dual tanks illustrated in Fig. 12 enables the use of the threitol for thermal energy storage. The threitol is filled into thin and long cylindrical copper capsules. The capacity of each capsule is 912 mL. The storage tank is 166 L in capacity and is filled up with 96 capsules. The heat of fusion of the encapsulated threitol is 28 MJ in total. The storage tank is partitioned into two sections by thermal insulation. The PCM capsules exist in both sides of the partition. The upper large section, 152 L in capacity, is used for thermal energy storage. The lower small section, 1.6 L, is used for initiating nucleation in the supercooled threitol. The trigger for nucleation is the circulating water in the piping of the system at the room temperature. Circulation of the water through the nucleation section for only 5 min cools the bottom of each PCM capsule, which initiates nucleation in the supercooled threitol.

Figure 13 shows the variations of the thermal output and the outlet temperature of the circulating water from the storage unit during a daily storage cycle. As the charging process, the threitol is heated for 12 h by the exhaust heat from the MGT.

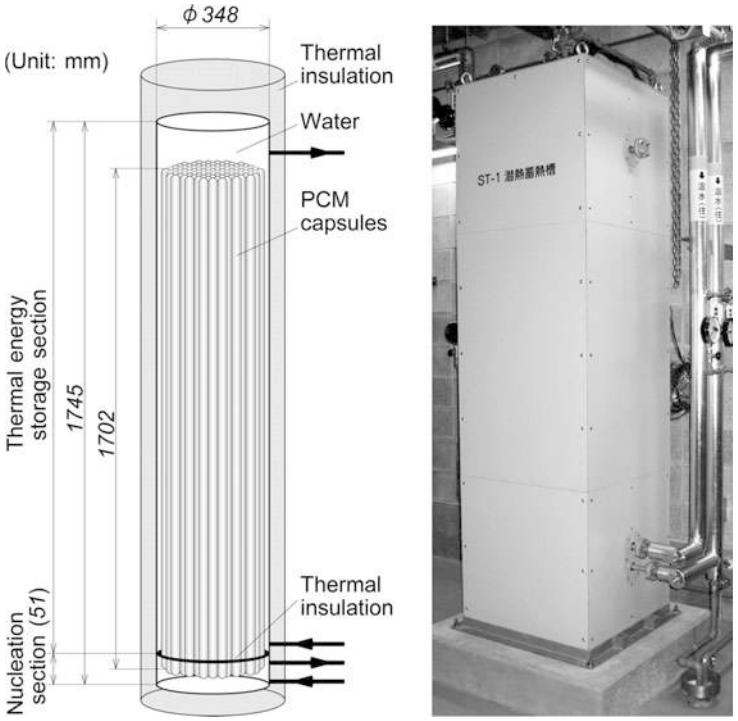

Fig. 12 Supercooled thermal energy storage unit

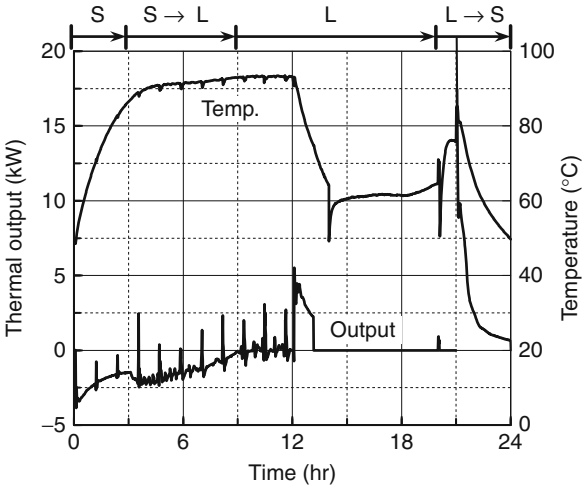
Fig. 13 Thermal output and the outlet temperature of the circulating water from the storage unit during a daily storage cycle



After the threitol completely melted, part of the sensible heat is discharged from the storage unit as the first thermal output, which makes the threitol supercooled. As the keeping process, the heat of solidification of the threitol is completely kept for about 8 h in the nighttime. After the supercooled storage, the threitol is intentionally nucleated to discharge the remained latent heat and sensible heat from the storage unit as the second thermal output. The two thermal outputs from the storage unit are used for space heating after and before the operation of the MGT. The heat for cooling the threitol in the nucleation section to the spontaneous nucleation temperature was equivalent to only the 1 % of the heat which is retained with the storage unit just after the charging process. Furthermore, the cooling heat for the nucleation operation can be used to preheat the circulating water in the piping effectively. By these processes, the 91 % of heat retained with the storage unit just after the charging process can be effectively used for space heating in the evening and early in the morning.

Heat Storage System for Heating

There are floor heating systems using solar heat gained in the daytime of fine weather day. The gained solar heat is partially stored in a thermal energy storage device or underfloor slab. The stored solar heat is emitted indoors gradually, and floor heating continues from night to the early morning of the following day. However, the additional heat is sometimes necessary for heating in the next morning because of the shortage of the available stored heat by the conventional thermal energy storage device. The reason for the shortage is that the stored heat by the conventional LHTES or SHTES is always dissipated into the ambient air regardless of a demand. The active use of the supercooling phenomenon in addition to the conventional systems enables the thermal energy storage device to store solar heat, midnight power, and so on effectively for half a day, or beyond cloudy days, a weekend, or a season. In the operating temperature range from 30 °C to 60 °C, the hydrate is superior as a PCM for space heating in point of the storage density of thermal energy as is shown in Fig. 6.

Thus the research on the floor heating system as illustrated in Fig. 14 has been conducted (Hirano et al. 2010). The PCM is disodium hydrogen phosphate dodecahydrate (cf. Table 5). The DHD is filled into thin and long cylindrical capsules made of polypropylene. The capacity of the capsule is 1,810 mL. Fifty-six capsules are horizontally embedded in the floor between subfloor joints. The heat of fusion of the encapsulated DHD is 25 MJ in total. By the supercooled storage of the hydrate, the system can effectively radiate the stored heat twice. For example, part of the sensible heat of the DHD in the liquid phase can be discharged in the evening, which makes the DHD supercooled. After the supercooled storage in the nighttime, the DHD is intentionally nucleated on the following morning and can discharge the remained latent heat and sensible heat.

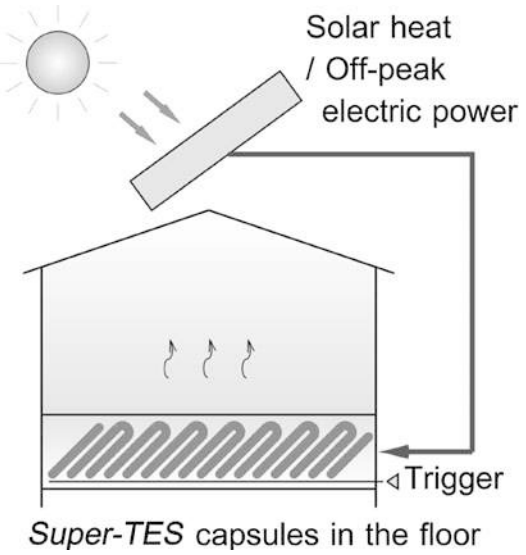


Fig. 14 Floor heating system with supercooled thermal energy storage

One of the most interesting applications of this storage method is the system which can store solar heat for cloudy or rainy days. If the storage system in the floor is divided into several sets and each set can be operated individually on demand, the stored solar heat can be partially discharged depending on more heat demands than twice. For example, after the supercooled storage in the nighttime, only a half of the sets is intentionally nucleated on the following morning, and the half of the stored latent heat is discharged and remained sensible heat as the second thermal output if it is cloudy or rainy. Then the remaining latent heat can be discharged from the remaining half of the sets as the third thermal output on the next morning of the cloudy or rainy day.

Furthermore, research on the seasonal LHTES using the supercooling phenomenon has been conducted. For example, the performance of a long-term LHTES unit using DHD as a PCM was experimentally investigated (Hirano and Saitoh 2007). The storage tank used in the experiment is partitioned into two sections by thermal insulation as is already shown in Fig. 12. The PCM capsules exist in both sides of the partition. The capacity of the storage tank is 53 L in total and the tank holds 31 capsules of DHD. The heat of fusion of the encapsulated DHD is 9.1 MJ in total. The result of the experiments shows that the storage unit can control the nucleation of the DHD after the supercooled storage for 203 days. From the result of the storage operation between 22 °C and 66 °C, the sensible heat of the unit was released to the room and lost. However, the latent heat is kept in the supercooled DHD, and the 49 % of the initial stored heat could be discharged by the nucleation operation after half a year.

Paraffin is chemically stable and is comparatively cheap. Therefore, the development of application of paraffin to PCMs at around room temperature is still continuing. The thermal conductivity of paraffin, especially in the solid phase, is small as

shown in Table 5, which deteriorates the heat exchange with the heat transfer medium. In addition, the separation of the solid phase of paraffin from the wall surface of the container easily occurs with thermal contraction during solidification. Therefore, the heat exchange of paraffin in the solid phase with the heat transfer medium often becomes rate-determining process of the storage device. On this account, research to promote heat transfer by mixing carbon fibers in paraffin or impregnating paraffin into a porous metal has been conducted. Besides, the application of paraffin to the warm keeping containers to transport corneas, joints, and skin for grafting has been studied as the application to high-value-added objects (Hirano 2009a).

Steam Accumulator

Steam accumulators are often used in the facilities that the consumption of thermal energy is large and the consumption of steam varies with time intensely. The steam accumulator is the device which stores the steam generated by a boiler as pressurized water and smooths the temporally variable steam supply to manufacturing processes. The heat dissipation from the conventional steam accumulator to the ambient air tends to be large because the surface area of the accumulator is large. Besides, depending on thermal load, a steep output variation is sometimes demanded to the steam accumulator every several minutes. The heat of solidification per unit volume is larger than the heat of condensation as is mentioned in section "Transport Methods." Therefore, the steam accumulator can be downsized if the phase change between solid and liquid is applied to. The downsizing by the solid–liquid phase change reduces the surface area of the accumulator, which reduces the heat dissipation from the accumulator to the ambient air by around 50 % at the maximum.

Thus, the steam accumulator which uses one type of sugar alcohol, mannitol (cf. Table 3), as a PCM is proposed (Hoshi and Saitoh 2001). The mannitol is filled into long and thin capsules made of copper. The storage tank is 190 L in capacity and is filled up with 190 capsules. Heat of fusion of the encapsulated mannitol is 23 MJ in total. To use mannitol as a PCM, there occurs a problem regarding supercooling in the discharging process because the maximum degree of supercooling of the pure mannitol amounts to about 50 °C. Therefore, the method to restrain the maximum degree of supercooling to about 15 °C by adding calcium sulfate as a nucleating agent has been adopted. The steam accumulator generated 200–250 kg/m^3 of steam at the flow rate of 30–40 kg/h. Besides, the combined system of the steam accumulator of mannitol with solar collectors and a disk turbine of the organic Rankine cycle is proposed (Saitoh 2008).

Pipeless Heat Transport

Many factories and incineration plants, which are potential heat sources, are usually located far from office areas and residential areas where the heat is consumed. It is

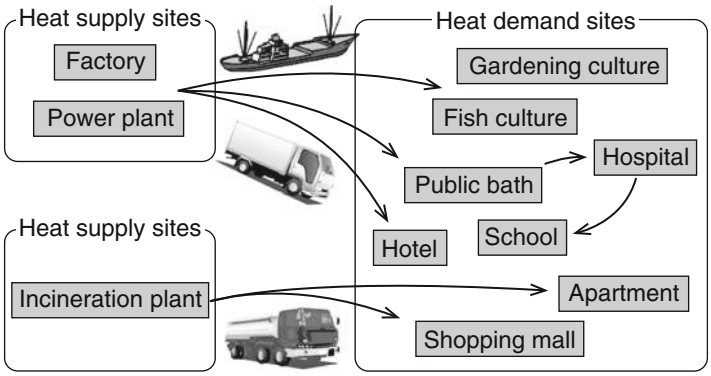

Fig. 15 Pipeless heat transport

important to transport heat efficiently for using the exhaust heat from the factories effectively. Thus the transport methods using PCMs from the heat supply site to the heat demand site by car, freight train, or ship as shown in Fig. 15 have been investigated.

For example, truck transportation systems using erythritol (cf. Table 3) or sodium acetate trihydrate (cf. Table 3) as PCMs were proposed and tested in several fields (Aoki 2007; Kawai et al. 2006). In the field tests, the PCMs filled into stainless steel tanks are melted and solidified by the heat exchange of direct contact with heat transfer oil. The proper capacity of the storage tank for the truck transport depends on the road condition and the traffic regulation. For example, the proper capacity of the storage tank for transportation in Japan is estimated to be 5–20 m^3.

The results of the field tests show that the charging process of thermal energy to the storage tank was completed in a heat supply site in about 2 h. The discharging process was completed in a heat demand site in about 4 h. The distance of conveyance that truck transportation is advantageous on energy is evaluated to be less than about 20 km. The most serious assignment at present is how to improve the investment effect. The promotion of the heat exchange rate between the PCMs and the heat transfer medium can improve the capacity utilization and cost-effectiveness.

Microcapsule Slurry Heat Transport

Building materials, fibers of clothes, and heat transfer media are just available for heat storage media for SHTES. However, the thermal energy storage densities of those materials are smaller than those of PCMs. Thus several methods to improve the thermal energy storage densities of those materials have been studied. One of the methods is mixing those base materials with the fine grains of PCMs which are insoluble to the base materials. Encapsulated paraffin or polyethylene glycol is often

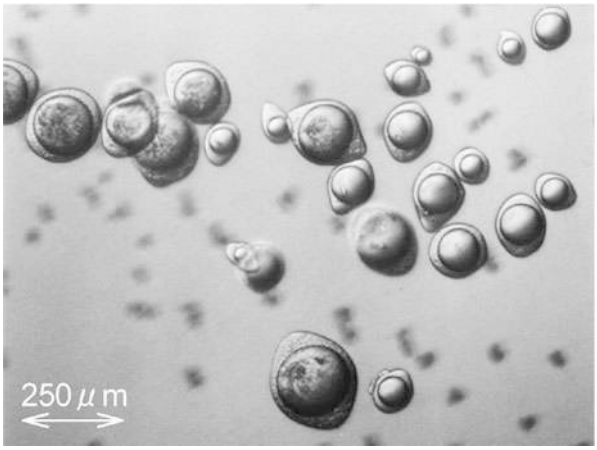

Fig. 16 Microencapsulated PCM particles produced by coacervation method (gelatin wall) (Photography by Takeuchi H et al.)

used as fine grains of PCMs. The diameters of the PCM capsules are usually on the order of micrometer. Gelatin, melamine resin, or urea resin is used for the shell of microcapsules. The PCMs can be mixed into various kinds of base materials by encapsulating the PCMs in a micro-size. Besides, the capsulation makes it easy to handle the PCMs and widens the surface area for heat transfer. The microencapsulated PCMs are applied to high-density heat transport by the slurry mixed with heat transfer media. Besides, the PCMs are applied to the passive thermal energy storage as thermal mass and to warm keeping sheets.

In the 1990s, several researches of slurry heat transport for space cooling were conducted. Figure 16 shows the microencapsulated PCMs that *n*-octadecane is coated with gelatin (Takeuchi et al. 1998). The addition of the particle dispersion agent prevents the aggregation among the PCM capsules, which is important to maintain the performance of the PCM slurry. It is necessary to raise the concentration of the microcapsules for increasing the thermal energy storage density of the slurry. When the concentration of the microcapsules in the slurry increases, the flow velocity range for laminar flow expands because the apparent viscosity of the slurry increases. Then there is the optimal flow velocity of the PCM slurry that the pressure loss for circulating the slurry becomes smaller than that for the pure heat transfer medium. When the PCM slurry is circulated at such optimal flow rate, the consumption of electric power by pumps can be reduced.

The results of the endurance test of the PCM capsules and the heat exchange test of the PCM slurry are shown in Figs. 17 and 18, respectively. If the capsule diameter is smaller than dozens of micrometers, the damage of the capsule by the transportation pumps is prevented (Fig. 17). Besides, if the particle concentration in the slurry increases, the overall coefficient of heat transfer of the slurry decreases (Fig. 18). Decrease in coefficient of heat transfer reduces the heat dissipation from piping to the ambient air. Therefore, the microencapsulated PCM slurry becomes effective for long-distance heat transport.

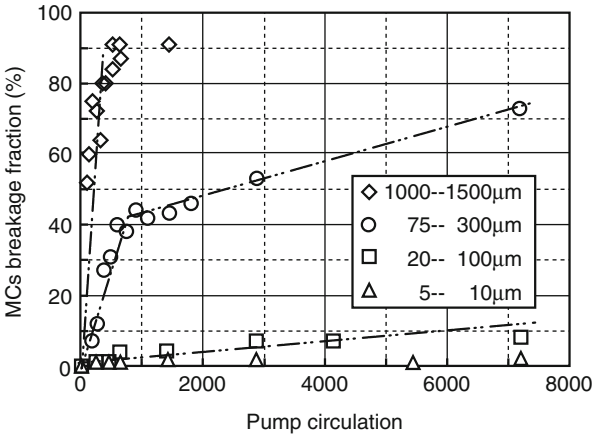

Fig. 17 Breakage fraction of the microcapsules by thermal cycles

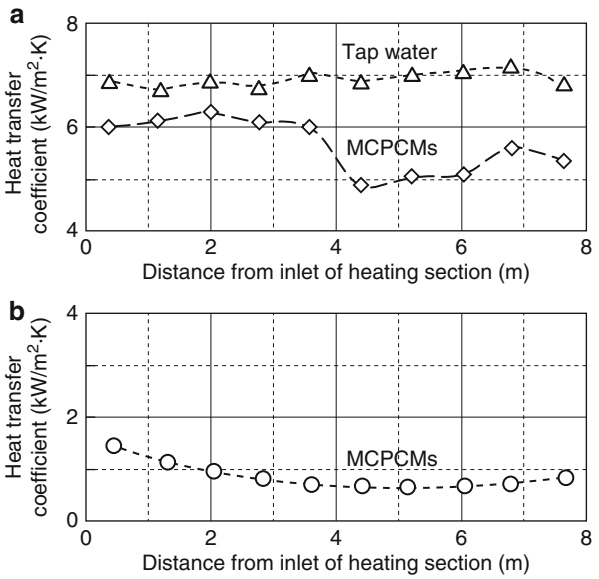

Fig. 18 Heat transfer coefficients of the microcapsule PCM slurry for the cases of (**a**) turbulent flow (particle size, 5 μm; particles concentration, 15 vol.%; Reynolds number = 12,000; flow velocity = 1.33 m/s) and (**b**) laminar flow (particle size, 5 μm; particle concentration, 25 vol.%; Reynolds number = 1,900; flow velocity = 1.22 m/s)

Future Directions

Thermal energy storage and heat transport enable to promote the utilization of waste heat and renewable energy which are unstable, maldistributed, and thin in general. In addition, high densities of thermal energy storage and heat transport enable to reduce heat loss during heat storage and transportation. However, except water or rock, the introduction of high-density thermal energy storage and heat transport is not advanced in point of cost-effectiveness.

The issue of the material cost can be improved by modification of manufacturing methods and mass productions. For example, although threitol has been produced by a synthetic process conventionally, a fermentation method to produce D body was recently discovered (Ueda and Yasuda 2004), which leads the manufacturing cost of D-threitol to the same level as erythritol. The issue of the overall cost of the system can be improved by using technology like the supercooled thermal energy storage which raises added value.

The 1970s and 1980s, when characteristics of various kinds of materials and applications for thermal energy storage were investigated, can be considered as the first golden age of research and development of thermal energy storage and heat transport. In the near future, the creation and application of novel PCMs which are designed by computational chemistry and synthetic process will be required as well as the revolution of the manufacturing methods which use microorganisms, and developments of high-value-added utilization technology.

Abstract

Smart grid holds a great promise for a cleaner, more efficient power; healthier air; and lower greenhouse gas emissions. A smart grid vastly improves energy efficiency and is already revolutionizing our energy future. A smart power grid delivers electricity from suppliers to consumers using digital technology with two-way communication to control appliances at consumers' homes to save energy, reduce cost, and increase reliability and transparency. A smart grid includes an intelligent monitoring system that keeps track of all electricity flowing in the system. It also incorporates the capability of integrating renewable electricity, such as solar and wind, at the consumer end. For houses equipped with solar panels and/or wind turbines, the goal is for them to consume no more energy than they produce and to produce net zero carbon emissions. The future with smart grid may look like a lot of distributed "green" generation at the consumer end replacing the conventional generation and thus easing its way to more sustainable future energy needs.

This chapter will start with an introduction that provides an overview of conventional power grid and its evolution to smart grid. It will then discuss the worldwide applications of the smart grid and its technologies in sections "Worldwide Applications of Smart Grids" and "Smart Grid Technologies," respectively. Renewable energy (RE) is considered as a universal remedy for solving current climate change or global warming threats. Section "Renewable Energy Resources in the Grid: Challenges and Opportunities" will discuss a number of potential challenges and opportunities in integrating RE with the existing grid.

One way to decrease the electrical load is a concept called demand response (DR). DR programs give consumers the ability to voluntarily reduce electricity usage at specific times of the day (such as peak hours) during high electricity prices or during emergencies (such as preventing a blackout). The benefit of DR is not only in the economic cost savings but also in the environmental costs. The DR programs and their benefits derived from the smart grid will be discussed in section "Demand Response for Smart Grid."

With the smart grid's promises of a more reliable, robust electric delivery system comes the virtual representation of that system used to make operational decisions. The source of the basic data for this virtual representation is the geographical information system (GIS). The importance of GIS interface with the smart grid will be highlighted in section "Geographical Information System Interface with Smart Grid."

Communication networks play a crucial role in facilitating smart grid functionality as being able to adapt to load and demand changes, intelligently manage bidirectional

data flow, and crucially enhance system reliability, robustness, security, and sustainability. In section "Smart Grid Networking and Communication Technologies," the role of the communications network in smart grid operation will be described together with its main functionalities. The increase of data transfer through the grid communications network raises many concerns regarding the network security and privacy. These aspects will be tackled in more detail in section "Security and Privacy."

Given the environment of the smart grid, the amount of data handling will increase tremendously. Conventional data storage and management will encounter great difficulties. Section "Cloud Computing for the Smart Grid" will explore the use of cloud computing to tackle this problem.

Control systems are required across broad geographical and industry scales in real time – from devices to power system wide, from fuel sources to consumers, from utility pricing to demand response, etc. Section "Advances and Challenges in the Development of Smart Grids" will deal with the advances and challenges in the development of the smart grid. Of course, the transition from conventional to smart grid should weigh the costs and benefits related to implementation. These are discussed in section "Smart Grid Economics."

Many countries are greatly interested to shift from conventional grid to smart grid. In the last section "Future Directions: Road Map to "Mature" Smart Grids," a model is discussed that can provide guidance and a road map to establish a fully functioning "mature" smart grid.

Introduction

Producing electricity from fossil fuels is one of the major factors of atmosphere pollution, which results in global warming. For example, approximately 40 % of total US GHG emissions are produced from electric utilities (Jung and Yeung 2011). Oil- and coal-fired power plants are the most widespread means for bulk generation and are responsible for GHG emissions.

To reduce this effect, the world has started shifting toward producing electricity from renewable sources of energy, such as solar, wind, and geothermal energy systems. After more than a decade of various campaigns, the world leaders are now close to an agreement on actions to save the environment and to reduce causes of climate change. "World leaders agreed that climate change is a defining issue of our time and that bold action is needed today to reduce emissions and build resilience and that they would lead this effort" (United Nations 2014). Therefore, renewable energy sources are growing fast. However, without the appropriate enabling technologies linking them to the grid, their potential will not be fully realized (Department of Energy 2008). Smart grid provides such enabling technologies.

The power networks around the globe are evolving from conventional grids to smart grids. In the conventional model, the power is generated in power stations and flows in an interconnected transmission network to a distribution system. The power flow in the distribution system has a one-way direction from power substations toward loads.

In contrast to the conventional grid, the distribution system in a smart grid provides a two-way power flow between customers and utilities. Customers have the option of generating electricity using renewable energy systems and exporting energy to the grid at times that they select. Meters become smart by having the capability of measuring quantities of interest in both directions of power flow and by having the feature of a two-way communication between the customers and the power utilities. Storage devices will be available to store the excess of produced energy and release to the network when needed. As a whole, then, the system becomes more efficient and reliable and provides a better configuration to absorb high penetration of renewable energy sources compared with the conventional grids.

Smart grid is a result of utilizing the communication and control technology in the power grid to give customers flexibility in controlling the way that they consume electricity and to give utilities more control on the power flow. The development of smart grid is not directly caused by the expansion of renewable energy sources, but connecting these sources to the grid is one of the driving forces in the development of smart grids.

A smart grid may have different meanings in different applications. One definition is given as follows (SRA 2035 2012):

> A smart grid is an electricity network that can intelligently integrate the actions of all users connected to it—generators, consumers and those that do both—in order to efficiently deliver sustainable, economic and secure electricity supplies.

Smart grid deployment must include information and communications technology, regulatory framework, standardization usage, commercial considerations, environmental impact, societal requirements, and governmental laws.

> Smart grids incorporate information and communications technology into every aspect of electricity generation, delivery and consumption in order to minimize environmental impact, enhance markets, improve reliability and service, and reduce costs and improve efficiency (International Renewable Energy Agency (IRENA) 2013).

By reducing system energy losses and controlling loads on the power network, a smart grid reduces the need for electricity generation and, therefore, reduces greenhouse emissions that otherwise would be produced.

Smart grid can facilitate economical downstream GHG reduction opportunities by boosting energy efficiency (in both grid efficiency and end-use conservation), as well as enabling greater integration of renewables (in both utility-scale projects and distributed generation). Furthermore, smart grid infrastructure can help to enable widespread transport electrification that not only can dramatically reduce GHG and other emissions but can also serve to enhance energy security by making less dependence on fossil fuels.

The smart grid is an encouraging advancement for developed and developing countries because it inaugurates a new era of power system management and will help the governments to attain their targets in the energy sector. In the framework of climate change, the transition to smart grid is an imperative to reduce greenhouse gas emissions and requires a clear diagnosis of the abovementioned considerations.

Worldwide Applications of Smart Grids

Each nation has slightly different goals in pursuing smart grid technologies and programs and a slightly different definition of what constitutes a smart grid (Schneider Electric 2012). For the USA, smart grid is the national economic stimulus and grid modernization. For Europe, however, the focus is on greenhouse gas reduction and energy system improvement. Meanwhile, South Korea and Japan focus on green growth through the use of information technology and the introduction of renewable energies and related technologies, respectively.

Smart grid infrastructure, including grid automation upgrades as well as smart metering, is expected to represent a huge market opportunity and will attract $200 billion in worldwide investment between 2008 and 2015 (Bouvier and Strubel 2010). In fact, for 2010, the US and the Chinese governments have decided to invest more than $7.1 billion and $7.3 billion, respectively, in the development of smart grid technologies (BuddeComm 2010). Meanwhile, the annual investment in Europe is estimated to be approximately five billion euros. The EU's blueprint for financing its Strategic Energy Technology Plan estimates that the cost of upgrading interconnections and building new super grid connections to supply Europe securely would cost over 200 billion euros by 2050 (BuddeComm 2010). Similarly, Australia has allocated approximately AU$100 million for a National Energy Efficiency Initiative to develop an innovative smart grid energy network. The project combines broadband with intelligent grid technology and smart meters in homes and will enable greater energy efficiency and better integration of renewable energy sources, such as solar and wind power. For Africa, smart grid technology is expected to help address its chronic power shortage in a market growing at around 10 % per annum (Power 2010).

Smart Grid Technologies

It is believed that the transmission network is already considerably smart even in the conventional grids. However, distribution networks of the conventional grids are far from being smart! Smart grid technologies can add intelligence to these networks. However, "at the residential level, smart grid must be simple, 'set-it-and-forget-it' technology, enabling consumers to easily adjust their own energy use" (Department of Energy 2008).

Many types of technologies can be utilized in a smart grid. While some of them are more specific to smart grid, other technologies may be commonly used in both conventional and smart grids. Smart grid technologies should generally facilitate communication, information management, and control of the grid.

Smart grid technologies can be put into four functional categories (Department of Energy 2008):

- ***Information collectors:*** To make a grid smart, data should be collected from many system locations using various types of sensors. These sensors generally measure performance-related characteristics of electricity system components.

An example is a meter, called smart meter, which continually measures the power imported or exported by any customer. These meters are connected to the network by an advanced metering infrastructure (AMI), which refers to two-way electricity meters and the communications and data processing equipment required to collect smart meter data and deliver it to the grid operator (King 2005).

- Another example is a set of sensors that track temperature, vibration, and other characteristics of a transformer. Other sensors may also be used to collect information, such as meters that measure electricity characteristics (voltage, current, etc.) of a distribution line.
- ***Information assemblers, displayers, and assessors***: This category includes devices that accept information and display and/or analyze it.
- ***Information-based controllers***: These devices control the behavior of other devices to achieve some goals based on the information received. Examples of these goals are reduction of energy consumption at peak-demand times, demand-side management, voltage regulation, improvement of power quality, increase of reliability and efficiency, etc.
- ***Energy/power resources***: Included in this category are technologies that can contribute to the generation of electricity, storage of electrical energy, or reduction of demand.

Renewable Energy Resources in the Grid: Challenges and Opportunities

Renewable Energy Challenges

The increased penetration level of renewable energy-based generation facilities in the electricity grid brings up many issues and uncertainties, which are related mainly to economic efficiency, energy security, and owner financial issues. A brief description of each of these issues is given below.

Economic Efficiency

Economic efficiency means maximizing the net value of the benefits gained from the available resources (Au and Au 1983). In the renewable energy-based generation facility context, it means efficient and optimum deployment of these units. Market structure, operation, and pricing determine whether these units are integrated efficiently or not (IEA 2002). Market structure has a major influence on the efficient penetration of renewable energy-based generation units to the system. The liberalization of the wholesale market is not enough when the distribution level is still a monopoly. This monopoly could hinder the penetration of renewable energy units by imposing standby tariffs and high prices for ancillary services. To overcome this problem, the regulator should ensure nondiscriminatory access of these units to the grid once technical issues are resolved. For efficient market operation, liberalization of the retail market would provide customers the option to locally generate their own electricity when electricity prices are high.

The participation of renewable energy-based generation facilities in electricity markets involves difficulties because the wholesale markets were originally designed for large central generation plants. Policy intervention is necessary to enable small renewable energy units to actively participate in the market. For example, facility owners must use the expensive spot market to cover for any discrepancy between expected needs and actual demand/generation, if the owner decides to participate in the market.

The liberalization of electricity markets evolved in price fluctuation. Higher prices of electricity during peak periods and lower prices during off-peak periods favor new generation units' deployment during peak hours. In many places, electricity prices are not sensitive to location, and electricity markets have a uniform market price. In such a case, the true value of renewable energy-based generation facilities is underestimated. Units' location plays an important role in reducing transmission and distribution (T&D) losses, relieving distribution network congestion, deferring or avoiding T&D infrastructure upgrades and reinforcement, and providing ancillary services. The restructuring of electricity prices is crucial for the true value of these units to be realized. Using locational marginal prices, as in standard market design, will enable efficient investment decisions (Bhattacharya et al. 2001).

Energy Security

The large penetration of renewable energy-based generation facilities in the system can affect energy security. This effect can appear in two forms: primary fuel diversification and power system reliability. Renewable energy technologies help in diversifying the primary fuel of electrical energy from depending on fossil fuels as a primary source of energy. The main reliability concern for renewable energy technologies in this context is the fact that these units are nondispatchable because of natural or operational intermittency. In such cases, these units might not be able to respond to demand variations, and this condition in turn reduces the system's ability to provide reserve power when necessary (IEA 2002).

Owner Financial Issues

Renewable energy-based generation facilities have higher capital cost per kW of installed capacity than conventional central power plants. In many cases, governmental incentives and subsidies are necessary to facilitate the integration of some renewable-based technologies.

Utilities may require the owner of renewable energy-based generation facilities to pay for studies and sometimes system upgrades to ensure the reliability, safety, and power quality of the system. When not regulated, distribution companies might impose high standby charges. According to the theory of economic efficiency, the power producer should pay for all the costs for upgrading the distribution system. Therefore, owners of renewable generation facilities should pay for the cost incurred by the distribution system operator. These costs could be very high if the system needs to be reinforced. By contrast, large central plants do not pay for transmission system upgrades and reinforcements. Thus, a fair solution is for owners of renewable

generation facilities to pay a connection fee and for the rest of the cost to be covered by customers as part of the operating cost (IEA 2002).

Renewable Energy Potential Benefits

Utilities can benefit from using renewable generation facilities in their planning process. Owners and customers can use renewable generation facilities to reduce their cost of energy. Additionally, the integration of renewable generation facilities can benefit all other members of society.

Utility Applications

Deferred or Avoided T&D Expansion

Renewable generation facilities are becoming a viable choice in power delivery system planning (El-Khattam 2004). Utilities can avoid expensive network expansion and other network reinforcements by encouraging the installation of renewable generation facilities at selected locations. These facilities have the potential to relieve transmission congestion and reduce power losses in both T&D networks. Since T&D system costs represent a considerable share of the total price of electricity, these facilities could save up to 30 % of electricity costs on average (IEA 2002). Moreover, extending the network to remote areas is economically not practical. Utilities could gain substantial savings by using locally generated power. The costs of network capacity expansion projects would otherwise be reflected in the price of electricity paid by consumers. Utility planning tools could be used to assess potential utility value to be gained by using renewable generation facilities instead of relying completely on conventional capacity expansion (El-Khattam 2004).

Reduced System Losses

Power losses (I^2R) are proportional to the resistance, "R," of the power path and the loading, "I," of the line. Unlike central plants, small renewable generation facilities are located near consumers; therefore, the resistance in the current path is much lower than that between central plants and electricity consumers. Moreover, renewable generation facilities will reduce the loading of transmission lines and relieve heavily loaded lines, leading to more reduction in power loss. Numerous studies demonstrated that loss reduction depends on renewable generation facility penetration, technology, dispersion, location, and reactive power control (Albadi et al. 2013; Quezada et al. 2006). The value of this benefit can be substantial in some cases where system losses are high. Although loss reduction calculations can be done using power flow calculations, a lot of data are required, and the results are valid only for certain loading profiles. Nevertheless, with certain loading levels, especially with light loads, the renewable generation facilities might result in increasing the energy losses compared with situations for which these facilities are not used.

Voltage Support to Electricity Grid

Similar to other types of distributed generation (DG) units, renewable generation facilities can be used to support the distribution system voltage profile through the injection of reactive power. This in turn improves power quality for nearby customers and reduces losses in distribution systems. Losses are reduced when reactive power is locally provided; consequently, this minimizes the reactive component of the current flowing in the system. The benefit of this application is not substantial because other cheaper means for voltage support could be available, such as switched capacitors. Moreover, voltage support is characterized as a localized problem (Ackermann et al. 2001).

Customer Applications

Lower Cost of Electricity

The T&D cost of electricity represents 30 % of the total price on average. Customers with on-site generation might find that the cost of installing and operating on-site generation is less than the cost of buying electricity from the grid. The difference between the two costs represents the value of this benefit to the customer. This value is case sensitive and depends on electricity price, load profile, renewable generation facility capital cost, and operation and maintenance costs. Studies have reported that the benefits of this application mainly drive most customers in considering deployment of DG units in general (Ackermann et al. 2001). They are obviously the main drivers for most customers in market environments where the cost of electricity from the public grid is higher than the cost of energy from locally available renewable generation facilities.

Consumer Electricity Price Protection

Renewable generation facilities can minimize the risks associated with electricity price volatility when price spikes appear because of congestion, generation shortage, and market power (Albadi and El-Saadany 2008). Moreover, the owner will have the flexibility of switching between renewable generation facilities and utility generation if real-time pricing (RTP) is used. The size of this benefit depends on price volatility and customer risk preferences (Ackermann et al. 2001).

Enhanced Demand Response and Elasticity

Without on-site generation, most customers do not have the means to react to changes in electricity price and its volatile fluctuations. Yet on-site generation appeals to customers with its desirable flexibility. Customers with installed on-site generation units will certainly consider generating their own electricity instead of buying from the grid when electricity prices are higher than that for their own generation. This situation will appear as a demand response and elasticity in electricity markets, ultimately reducing electricity prices and price volatility for the benefit of all consumers (Albadi and El-Saadany 2008). Given the intermittency nature of most renewable energy resources, having storage is essential to realize this benefit. The value of this benefit will increase as on-site generation penetration levels

increase, up to a certain level – beyond which the value starts decreasing. Although this benefit is very difficult to quantify, it can be estimated using market simulation tools (Albadi and El-Saadany 2008).

Improved Reliability and Power Quality

For customers concerned with both the reliability and quality of main grid power, using on-site renewable generation facilities is an attractive solution. Reliability in this context can be expressed as the expected duration of an outage over a period, while the power quality is expressed by the frequency of occurrence and duration of voltage sags. The value of this application depends on the frequency, duration, and timing of interruptions and voltage sags. Obviously, this condition differs from one class of customers to another and sometimes even within the same class (C. E. Commission 2004). The value of higher reliability and power quality is the main motivation for installing on-site generation facilities in places, such as hospitals, high-rise buildings, and process industries, with sensitive loads. The value of this application is characterized by avoiding the costs incurred in case of interruption (Gumerman et al. 2003). This value is customer dependent, and it can reach very high levels in some industries. Given the intermittency nature of most renewable energy resources, having storage is essential to improve reliability and power quality.

Consumer Control

Renewable generation facilities offer a useful alternative to customers seeking independence from utility power, generally individualistic consumers who want to be in charge of everything in their daily life, including supplying electricity requirements. Another group of candidates are consumers who want to obtain their electricity needs from a certain source, such as from environmentally friendly units (Gumerman et al. 2003).

Other Benefits

Improving Grid Security

Using local renewable generation facilities to supply part of the electricity demand will reduce grid dependence on large central plants and the transmission system, which could be forced out of the system or become inoperative because of vandalism or natural events. This use will in turn reduce the impact of critical system component failures. Although this benefit is spread to the whole of society and could be substantial, it is very difficult to quantify. As an example of this benefit, the International Energy Agency (IEA) reported that the availability of standby generation helped in reducing blackout risks during California's electricity crisis of 2001 (IEA 2002). Furthermore, diversifying the fuel source is advantageous to system security.

Effects on Land Use

Some renewable generation facilities have smaller footprints, that is, they require less space compared with central plants. For example, with rooftop photovoltaic

systems and wind turbines installed in farming areas, the utilization of the roof and the land is minimal. Moreover, the installation of renewable generation facilities does not need, or at least reduces, T&D infrastructure space requirements compared with central plants. A property located in an urban area is obviously worth more than one that is remotely located away from the grid. With the deployment of renewable generation facilities in rural areas, the price difference is decreased, and customers have more flexibility in deciding about the location of their projects. However, estimating the value of DG land use effects is very difficult (Gumerman et al. 2003).

Reducing Opposition to Central Power Plants and Transmission Lines

Many individuals and groups oppose building new power plants and transmission line projects for a variety of reasons, including environmental and property value concerns, among others. They can exert a tremendous force to stop new central plants and transmission lines. It is expected that renewable generation facilities will not be faced with such strong opposition. The value of this benefit is complex and difficult to estimate. One method of estimating this value is by comparing property value before and after the project (Gumerman et al. 2003).

Reducing Emissions

Emissions, such as NO_x and CO_2, are by-products of electricity generation. Renewable generation technologies do not produce emissions when converting renewable energy to electricity. This benefit affects all of society but is difficult to evaluate. Owners of renewable generation facilities receive incentives for reducing the health risks associated with emissions (Gumerman et al. 2003).

Supporting Renewable Portfolio Standards Goals

Renewable portfolio standards (RPSs) are legislations that mandate utilities to generate a minimum percentage of the electricity through use of renewable energy sources. Having renewable generation facilities in the system makes RPS achievable. The value of allowing a utility to meet RPS is presented by renewable energy credits and incentives to renewable facilities owners.

Demand Response for Smart Grid

Demand response (DR) can be defined as the changes in electricity usage by end-use customers from their normal consumption patterns in response to changes in the price of electricity over time. DR may include incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized. DR actions include all intentional electricity consumption pattern modifications by end-use customers that are intended to alter the timing, level of instantaneous demand, or total electricity consumption (Albadi and El-Saadany 2008).

Table 1 Customer response actions

Target	Action examples	Cost
Reducing demand during peak periods	Changing thermostat settings temporarily	Temporary loss of comfort
Shifting demand from peak to off-peak periods	Shifting some household activities, rescheduling industrial activities	Residential customer: no cost Industrial customer: rescheduling cost
Reducing demand during peak and/or off-peak demand	Using on-site generation, using more energy-efficient appliances	Installation cost and/or fuel cost

Table 2 Classification DR of programs

Program types	1. Price based (market led or economic based)	2. Incentive based (system led, emergency based, stability based)	
		A. Classical DSM	B. Market based
Program examples	Time-of-use (TOU) rate Critical peak pricing (CPP) Extreme day pricing (EDP) Extreme day CPP (ED-CPP) Real-time pricing (RTP)	Direct load control Interruptible/ curtailable load	Emergency DR Demand bidding Capacity market Ancillary service market

A customer response can be achieved by three general actions (Valero et al. 2007). Each of these actions involves cost and measures taken by the customer, as described in Table 1.

DR Programs

DR can be achieved through different programs: price based and incentive based. Incentive-based programs are classified into two types (Albadi and El-Saadany 2008): classical demand-side management (DSM) and market-based programs, as shown in Table 2.

In classical incentive-based programs, participating customers receive participation payments, usually as a bill credit or discount rate, for their participation in the programs. In market-based programs, participants are rewarded with money for their performance, depending on the amount of load reduction during critical conditions. The price-based programs are based on dynamic pricing rates in which electricity tariffs are not flat; the rates fluctuate following the real-time cost of electricity. Many economists claim that RTP programs are the most direct and efficient DR programs suitable for competitive electricity markets and should be the focus of policy makers (Albadi and El-Saadany 2008; Bloustein 2005).

DR Benefits and Cost

DR benefits fall under four main categories: participant, market wide, reliability, and market performance benefits (Albadi and El-Saadany 2008), as shown in Table 3.

Table 3 DR benefits

Category	Participant	Market wide	System reliability	Market performance	Environmental benefits
Benefit examples	Incentive payments Bill savings	Reduce electricity prices Avoid/ defer capacity costs	Reduce outages Diversify system operator resources	Reduce market power Reduce price volatility Offer more options to customers	Better land utilization Air and water quality improvement Reduction of natural resources depletion

Table 4 DR benefits

Burden owner	Participant		Program owner/operator	
Cost category	Initial	Operation	Initial	Operation
Cost examples	Enabling technology Response plan/ strategy On-site generation Capital expenditure (CAPEX)	Inconvenience Lost business Rescheduling On-site generation Operation expenditure (OPEX)	Advanced metering infrastructure (AMI) Customer education campaign	Marketing campaign Incentive payments Administration Program evaluation

Participants in classical DSM incentive-based programs are entitled to receive incentive payments for their participation, whereas market-based customers will receive payments based on their performance. The DR benefits extend to other nonparticipating customers through an overall electricity price reduction because of more efficient utilization of the available infrastructure and avoided or deferred infrastructure enforcements and upgrades. DR programs allow customers to participate in reducing forced outages and their consequences. Customer participation provides the system operator more resources to maintain system reliability (US Department of Energy 2006; International Energy Agency 2003).

Another benefit of DR programs is the improvement of electricity market performance. Participants have more choices in the market even when retail competition is not available. With the market-based programs and dynamic pricing programs, consumers can manage their consumption, and therefore, they have an impact on the market through reducing market power and price volatility. The indirect benefits of DR programs to the environment include better land utilization as a result of avoided/deferred new electricity infrastructure, better air and water quality as a result of efficient use of resources, and extended lifetime of natural resources.

A classification of DR program costs is shown in Table 4. Both DR program operator/owner and participants incur initial costs before the implementation of

the program and operational costs during the program (Albadi and El-Saadany 2008).

The program participant's initial costs include the installation of enabling technologies, such as smart thermostats, peak load controls, energy management systems, and on-site generation units. In addition, a response plan/strategy that will be implemented in case of an event should be established before the enrolment. Depending on the response plan, operation cost varies (US Department of Energy 2006). Some cost components are more difficult to quantify than others. For example, it is difficult to quantify the reduction of comfort that may result if a customer decides to reset the thermostat (International Energy Agency 2003). Other event-relevant costs are easier to quantify, for instance, lost business or rescheduling of industrial processes or activities. Fuel and maintenance costs need to be considered if a participant decides to use a backup on-site generation unit.

The program owner/operator initial costs include building an AMI that covers both metering and communication sides depending on the type of DR program (s) under consideration. For example, advanced metering systems to measure, store, and transmit energy usage at required intervals is a prerequisite to the implementation of RTP programs. Another important element before commissioning DR programs is customer education. Operation costs that might be incurred by the DR program owner/operator are administration and management costs in addition to incentive payments in the case of incentive-based programs. The continuous marketing for commissioned program and the continuous evaluation of the program are important components of the program operation costs and are essential for the success of the program.

Geographical Information System Interface with Smart Grid

The implementation of the smart grid passes through multiple phases that require strategy of deployment and include numerous challenges. A challenge associated with the technology is finding a way to make efficient use of the large amounts of data collected by the meters. In this regard, geographical information system (GIS) technology will play a key role in the automation strategy in that it will provide the initial infrastructure data that will fuel the automated analytics. In addition, the results of analytics on the intelligent grid are best presented in a geographic dimension. The smart grid is also a heavy investment that necessitates a financial risk analysis. Much like electronic banking, the smart grid is not the sum total of its components but how those components work together.

Role of GIS in the Smart Grid

A smart grid requires real-time analytic engines able to analyze the network, determine the current state and condition of the system, predict what may happen, and develop a plan. These engines receive data from the electric power operators and

outside parties, such as weather services, through an AMI. AMI is a combination of smart meters, data management, communications network, and applications specific to metering and plays a key role in smart grid technology, and many electric power operators began smart grid implementation with AMI (Schneider Electric 2012).

Although AMI was considered for a long time as the masterpiece technology of the smart grid, electric power operators now see the distribution management system (DMS) as one of the most key components of an effective smart grid strategy. The DMS is driven by a network model, which must reflect precisely the following forms of data:

- Network asset information
- Real-time data
- Time series data
- Transactional data

An enterprise GIS database is the key in managing the network model in terms of data integrity and quality. Enterprise GIS is also the most dynamic system feeding the DMS, through managing and securing the workflow for update of asset information. GIS can provide an accurate and up-to-date network model that can be easily served to all smart grid information systems, including supervisory control and data acquisition (SCADA), outage management system, and DMS (Schneider Electric 2012).

Challenges of GIS Data Quality

The quality of GIS database is a serious challenge for the performances expected from DMS functionality. A network model handled with inaccurate or stale GIS data leads to ineffective results. The frequent causes of data errors are mainly related to import and conversion of data from CAD systems, with a lack of network integrity rules to GIS. Errors such as transformer/customer connectivity and voltage mismatches are recurrent and can be linked to poor data management workflow when graphic work design (GWD) is accomplished with a non-GIS platform. This kind of data error requires an incessant data correction and leads to a long backlog and a network model that is certainly not quite accurate (Schneider Electric 2012).

Nowadays, the distribution network is dynamic and in perpetual changing, with demand from customers for more electric power, seasonal variability of load and power demand, and occurrences of outages. For this reason, the GWD process by which the electric power operators sustain and upgrade their infrastructure is involved in daily work, and their network model must be built in a manner that can be quickly and accurately updated (Flynn 2007).

The design of the GWD is highly complex and contains multidimensional workflows. It requires simultaneous design and collaboration. Thus, the enterprise of the complex GWD workflows is very critical because multiple designs might implicate a shared asset like pole or fuse. The GWD process is also characterized by

its long transaction and partial posting because some designs might take years to achieve and other portions take a week.

GIS-based GWD is the optimal solution to avoid a long backlog and errors in the core data of the network model. Most significantly, the GIS-based GWD process is built with central asset and network repository, for fast and accurate design and timely network model update. In other words, workflow designers do not need to develop their own designs or to redigitize existent designs in GIS and to import designs from CAD systems. GIS-based GWD is much more productive than any other systems in terms of design optimization and is also a confirmed solution for preserving network model date accuracy (Bouvier and Strubel 2010).

Smart Grid Networking and Communication Technologies

The expected amount of data generated by different subsystems within the smart grid is quite huge. These data include smart meter readings, diagnostic sensor measurements, control information, real-time pricing (RTP), etc. As a result, networking is an essential ingredient in the smart grid vision to transfer this huge amount of data between various devices, applications, and subsystems. Although there is no networking standard that emerged as the de facto standard for smart grid, there are few essential requirements for any such standard, including supporting quality of service (QoS), reliability, high availability, and wide coverage and ensuring security and privacy (Fang et al. 2012). It is unlikely that there will be a single networking technology used in the smart grid. It is more realistic to expect several networking technologies used in various parts of the grid that should be integrated in a broader communication framework. At this point, one may wonder why not use the existing supervisory control and data acquisition (SCADA) system for data transfer. Unfortunately, the current SCADA cannot support the new requirements for smart grid. In particular, existing SCADA systems do not sufficiently support the real-time requirement (Galli et al. 2011), which is essential for dynamic control and optimization of the power system. For example, in the current SCADA systems, sensors report measurements asynchronously (Galli et al. 2011). Designing an efficient communication infrastructure for smart grid will require taking into consideration many new challenges, including the following (Yu et al. 2011):

- Huge amount of data that will be generated by the various smart devices in the smart grid.
- High variability of traffic during the day because of the changes in the volume of data generated based on the dynamics of the grid (e.g., switching order of equipment based on RTP).
- Interoperability between the various technologies that will be used in the different parts of the smart grid (generation, transmission, distribution, control, etc.).
- Different QoS requirements are needed for different data flow. For example, control commands will have stringent time-delay requirements compared with the monthly utility bill data.

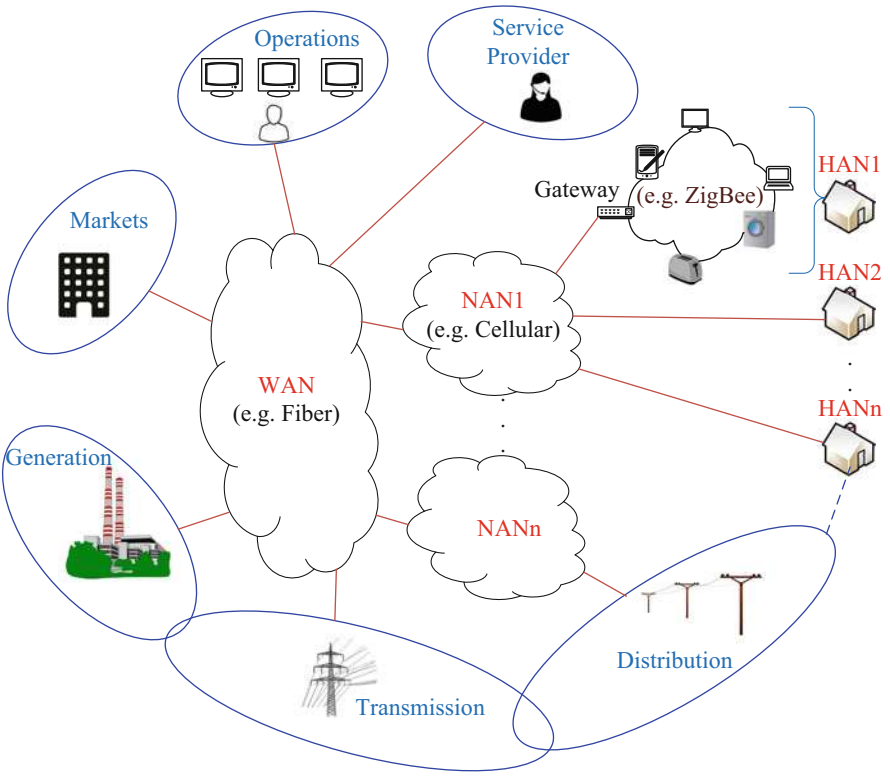

Fig. 1 Smart grid network architecture

- The need to secure the data transmitted to protect the critical grid infrastructure from attacks that could disrupt the normal operation of the grid.

Network Architecture

The large number of devices and subsystems that need to communicate with each other in the smart grid will require hierarchical networking architecture to facilitate the manageability and scalability of the overall communications infrastructure. One level of networking will be done at the home level where various smart appliances are connected together to form a home area network (HAN), as shown in Fig. 1. Through the HAN, a controller can orchestrate the operation of other appliances (e.g., turn on/off) in accordance with the dynamics of the smart grid (e.g., prices). Communication outside the home (e.g., from meter to power provider) will be done through a gateway that is connected to a neighborhood area network (NAN). NANs will be connecting multiple HANs and subsystems that exist within a neighborhood. A NAN may be used to aggregate data from various sources to reduce the load on the network core. These NANs will be connected to the rest of the smart grid domain

(generation, transmission, etc.) through a wide-area network (WAN). Given the huge volume of traffic that the WAN needs to handle, it is vital that high-speed networking technologies should be utilized in constructing the WANs.

Networking Technologies

This section briefly reviews the networking technologies that can be utilized in the smart grid. These technologies can be classified into two: wired and wireless.

Wired Networking Technologies

Power-Line Communication

In power-line communication (PLC), the same lines used to transfer power are utilized to carry the data. This is very attractive because the infrastructure is already widely available, which means that the investment required to utilize it for communication purposes is minimal. On the downside, the PLC environment is very harsh because of time- and frequency-varying signal attenuation, various types of noises injected by loads, and dependence on location, network topology, and loads connected (Biglieri 2003). Characterizing these various impairments is essential to create a reliable communication system. However, such a task is very challenging because of the dynamic nature of loads connection/disconnection to the grid (Sutterlin and Downey 1999). Moreover, although PLC had been used for Internet access and home networking, the many incompatible standards hinder its wide deployment (Galli et al. 2011). Some of the main PLC issues that need to be resolved are the type of communication modulation scheme, scheme that nodes should use to access the power line to send their data (i.e., medium access control [MAC]), and routing the data to the final destination. Galli et al. (2011) advocated that PLC is one suitable networking technology for future smart grid that can support various applications over all voltage levels (LV, MV, HV), such as remote fault detection, remote control, and vehicle-to-grid communication.

Digital Subscriber Line

Digital subscriber line (DSL) is a high-speed access technology that utilizes the same wires as the conventional phone system to provide network access. The basic idea is to use the spectrum above the range used by the phone system. DSL is an umbrella term that is used to represent a family of standards (the most popular being the asymmetric DSL). The achievable data rate depends on the variant of DSL and the cable length and condition. It can range from 256 kbps up to 1 Gbps in the new G. fast standard (Timmers et al. 2013). Considering its widespread use, it may be used by utility companies to collect smart grid data (e.g., meter reading). In fact, some companies have already utilized this option in their smart grid projects (see, e.g., Gungor et al. 2011).

Optical Networking

Optical fiber has an extremely large bandwidth that makes it an attractive choice in providing high data communication rates compared with copper-based media. The capacity of fiber exceeds 100 Tbit/s (Essiambre et al. 2013). Another advantage of optical fiber is that it has a good immunity characteristic to interference caused by electrometric signals. Thus, it is a good candidate for a communication media for a high-voltage environment (Gungor and Lambert 2006). Optical networking solution is also attractive for the core of the network to carry the huge amount of data between the various subsystems (e.g., SONET/SDH). The biggest hurdle in using optical fiber is the high initial deployment cost. To overcome this, existing public optical fiber infrastructure may be utilized at the beginning, and then private optical fiber should be gradually deployed to serve the needs of the smart grid network. As in the DSL case, optical fibers may be utilized to transmit data from customers to utility companies in areas where fibers are used as a broadband access technology (e.g., passive optical network (Banerjee et al. 2005)).

Wireless Networking Technologies

WiFi

WiFi is a wireless technology based on the IEEE802.11 standard, which specifies the lower two layers of OSI model (MAC and physical) for implementing wireless network. The IEEE802.11 has various specifications that utilize different frequency ranges (2.4 GHz, 5 GHz, 60 GHz) and provide data rates that vary from 1 Mbps in the legacy IEEE802.11 to approximately 7 Gbps in the IEEE802.11ad (Cordeiro et al. 2010), which is promoted under the name Wireless Gigabit Alliance. The range varies and can reach up to 70 m indoor and 250 m outdoor although it may be extended by various techniques (e.g., increase antenna power). Compared with other short-range wireless technology, WiFi consumes more power, which is a concern for power-limited mobile devices. Using WiFi is a viable in-home network because of its wide use to create WLAN in homes.

ZigBee

ZigBee is a standard developed by the ZigBee Alliance (http://zigbee.org) that is based on the IEEE802.15.4 standard. The focus of the IEEE802.15.4 is on the physical and MAC layers for low-rate, low-power personal area networks, whereas ZigBee focuses on the higher layer of the networking stack (Ergen 2004). The goal of ZigBee is to provide standards that address the needs for automation and control for low-power and low-rate application. The smart energy profile of ZigBee is an application profile that is developed for communicating energy-related information, such as pricing and consumption (Bilgin and Gungor 2012). The ZigBee is one of the technologies that the US National Institute for Standards and Technology (NIST) has identified for customer-premise smart grid technology. Research suggests that ZigBee is suitable for low-rate and low-voltage environments that do not require high reliability and tight deadlines (Bilgin and Gungor 2012). The main disadvantages of using ZigBee are low bit rate and interference that may occur with other

networking technologies that share the same license-free spectrum, particularly WiFi within the 2.4 GHz industrial, scientific, and medical (ISM) band (Yi et al. 2011).

Z-Wave

Z-Wave is an automation, control, and status monitoring technology. This technology is based on ITU-T G.9959 for its MAC and physical layer specification. Its main focus is on interoperability between devices utilizing this technology (http://www.z-wavealliance.org/). Like ZigBee, it targets low-rate and low-power applications, and it operates in the sub-1 GHz band, which makes it immune to interference from WiFi and other wireless technologies that operate in the 2.4 GHz band. A large number of products support this technology. Thus, it is a strong contender for the home networking arena.

DASH7

DASH7 is a low-power and low-rate wireless technology based on the ISO 18000-7 standard for radio frequency identification for devices operating in the 433 MHz bands. The nominal coverage range of this technology is 250 m (Norair 2009). This wide range makes it a good alternative to ZigBee, and hence, this reduces the number of devices and delay (Usman and Shami 2013). For example, one master DASH7 device may be sufficient to coordinate with all other devices in a home environment. The main method of communication used in this technology is a command-response model that sends small chunks of data abruptly (Norair 2009).

Cellular Communication

One of the main advantages of cellular communication technologies is that the infrastructure already exists in most places. This situation enables rapid deployment of smart grid solutions that are based on cellular networks. The option is viable for linking different smart grid entities that are located over a wide geographic area. Many companies from around the globe are utilizing the existing cellular network infrastructure for collecting the data from the smart meters (Gungor et al. 2011). The only concern regarding this communication option is the possible degradation in performance during peak usage hours by ordinary cellular service users, which may affect mission-critical smart grid applications.

Satellite Communication

Given its extensive coverage, satellite communication may be an attractive solution for remote areas where no other communications infrastructure exists. From an economical point of view, the installation cost of other technologies may cost more than using satellite communication. For example, satellite communication had been used for monitoring and controlling remote substations (Gungor and Lambert 2006). On the downside, satellite communication suffers from long round-trip delays compared with other terrestrial networking technologies. Moreover, weather conditions have a pronounced effect on the performance of satellite links.

Networking Research Challenges

- Integration between the smart grid system and Internet of Things (IoT) objects to achieve the goals of the smart grid. In IoT, objects are envisioned to communicate and cooperate with each other to create some smart service. For example, the IoT objects can cooperate between themselves in future smart homes to reduce the power consumption when needed by the smart grid and without dependence on a central controller to coordinate the process. Another example is to use the IoT sensors to monitor a power transmission line to prevent or recover from disasters (e.g., Liu et al. 2011).
- Reliable simulation of the smart grid. Simulation is one of the important tools used to analyze the performance of the systems. Given that the smart grid involves interaction between cyber and physical systems, a reliable approach to simulate such cyber-physical systems is essential to advance the field. Although some researchers had tackled this problem by combining well-known simulators for the different domains (e.g., ns2 for simulating networks) encompassed by the smart grid (e.g., Lin et al. 2011), it is unclear if this is the best and most optimum approach to handle the smart grid simulation. This issue needs further investigations to assess the reliability of the simulation results obtained by such an approach. Emphasis should also be given to optimization of the simulation environment to handle the large number of devices, the huge amount of data these devices generate, and the dynamic interactions between the various physical and cyber systems.
- Optimization/coexistence of different wireless technologies that operate over the same frequency band. With the expected huge growth of number of devices that will be connected to the Internet wirelessly, considerable interference is expected to happen between these devices that may impair the network connectivity and hence may have undesirable effects on the overall operation of the smart grid. Analyzing these effects and proposing optimal coexisting schemes will be crucial.

Security and Privacy

Security

The use of networking technologies will inevitably require security to ensure the continuous operation of the smart grid. Given that the smart grid is a large and complex system that encompasses many networking technologies, new unforeseeable security risks are likely to emerge that are not part of the current network security solutions. Hence, a new and fresh approach is necessary to handle them. For example, an attacker that successfully compromises a control center may be able to interrupt service or cause blackout in severe cases. Ideally, the smart grid should be able to withstand all sorts of attacks targeting it. However, in practice, guarding against all attacks is not feasible. Hence, the system should be designed to achieve important security goals that provide assurance that the system can deal

safely with the attack targeting these specific security goals. Desirable security goals include the following (Dzung et al. 2005):

Confidentiality: This goal refers to ensuring that the data are not disclosed except to authorized personnel. For example, meter readings and management messages should be kept confidential to protect the private data of consumers from being viewed by unauthorized entities (Yan et al. 2011).

Integrity: This objective refers to protecting the data from modification by unauthorized entities.

Availability: The aim here is to ensure that only authorized entities have a timely and reliable access to the services or resources. This is one of the most essential requirements to ensure that power is delivered to the consumers without interruption.

Authentication: This goal deals with verifying entity claim about its identity. This is a crucial security goal since most of the other services depend on knowing the entity involved. For example, proper authentication is essential to determine if a person is authorized to issue control commands that may affect the overall operation of the grid.

Authorization (access control): This security objective deals with granting access to services to authorized entities only. As mentioned previously, there is a strong dependence on identifying the entity correctly (i.e., authentication) to determine whether to permit or deny access to the requested resource.

Auditability: This refers to the ability to reconstruct the events and behavior of the system over a previous period. Achieving this goal helps in analyzing attacks and learning the causes and weaknesses that led to compromising the system.

Nonrepudiability: This goal refers to the ability to provide an evidence, which withstands the scrutinizing of a trusted third party, of which entity initiated a certain action even if that entity is not cooperating. This is very useful to resolve accountability and liability disputes.

Third-party protection: This goal prevents any damage that may happen to a third party because of any compromise to the IT system. Since the grid consists of many systems interconnected to one another, compromising one system may cause damage to another, which may have undesirable consequences, from loss of reputation to legal liability for the caused damage.

Attacks

Once the attacker manages to compromise a system by exploiting some weakness, he may execute many forms of attacks, including the following (Mo et al. 2012):

Denial of service (DoS): This form of attack targets the availability of the system and aims to deny the authorized personnel from accessing the system services in a timely fashion. Such attack, if successful, could easily disrupt the overall operation of the smart grid by denying the authorized personnel the timely access to critical information or control equipment to react to contingency.

Data modification/injection: In this attack, the malicious intruder attempts to modify data exchange between different entities or falsely inject fake data. For example, the attacker can alter smart meter data to cheat the utility companies by modifying the consumption readings to low values. It is even possible that an attacker can modify the readings of several power meters so that such modification is not detectable by state-estimation mechanisms employed by utility companies to detect bad data (Giani et al. 2011). Another example that may cause DoS attack is to inject lower (or negative) prices that will lead to a spike in consumption and possible blackout.

Eavesdropping: This form of attack aims to capture the network traffic to obtain sensitive information, such as power usage, pricing, and commands to subsystems, thus violating the confidentiality requirement.

Malware spreading: The attacker can spread a malware through the smart grid network, which enables him to retrieve sensitive information and/or control devices.

Countermeasures

Cryptography and key management: Cryptography will be an essential ingredient to accomplish many of the goals for the smart grids. Many cryptographic protocols require a shared secret (known as key) for bootstrapping the scheme. The keys could be the same in both communicating devices (i.e., symmetric key cryptography), or the keys could be different although they are related (i.e., public key cryptography). However, although the keys are related in public key cryptography, obtaining one key from the other is computationally infeasible. Symmetric key schemes are usually faster than the public key cryptography systems, but their disadvantage is the key distribution problem. For proper security, the symmetric key cryptography requires each pair of devices to have a shared key. Consequently, developing an efficient scheme to distribute the shared key between the different communicating pairs is a challenging task considering the huge number of devices that exist in the smart grid. Therefore, applying the current scheme may not be feasible in all parts of the grid, and hence, new lightweight cryptographic protection schemes will be necessary (e.g., Fouda et al. 2011). Moreover, managing the huge number of keys and related tasks, such as updating and revoking the key, is not a trivial task (see Smith 2012).

Secure architecture: The overall design of the smart grid network should be resilient to attacks. The design considerations include (Mo et al. 2012) choosing a resilient network topology, securing routing protocols, and securing forwarding.

System and device security: This area deals with preventing an attacker from exploiting vulnerabilities that exist in software that enable the attacker to commit malicious attacks, such as privilege escalation, bypassing authentication, and installing malicious code. One promising approach to verify the authenticity of the code and detect the presence of malware is a technique called code attestation. This technique enables an external entity to obtain the signature of the software running in the system and hence detect the presence of malware if the signature is altered (Mo et al. 2012).

Intrusion detection: The goal here is to detect attacks and possibly attempt to handle them safely. Usually, intrusion detection works by detecting anomaly in the network operation. However, a traditional scheme may need modification to accommodate attacks that are unique to the smart grid. For example, a selfish renewable power source may stop providing power to the grid, which may sabotage the overall operation of the grid. Detecting such selfish sources is unique to the smart grid (Li et al. 2012).

Privacy

Privacy may be defined broadly as keeping one's own information to oneself. According to the US cyber security working group (The Smart Grid Interoperability Panel and Cyber Security Working Group 2010), four dimensions of privacy should be considered in the context of the smart grid. These dimensions are as follows:

- Privacyof personal information: This includes any information related to the individual (e.g., civil identification number, occupation, etc.).
- Privacy of the person: This is related to the person's own body (e.g., medical devices used by the person).
- Privacy of personal behavior: This is related to the person's activities (e.g., sleeping, watching TV, etc.).
- Privacy of personal communication: This is related to protecting the individual's communication from unwarranted surveillance.

Obviously, the privacy concerns exist even in the old grid although at a lower scale. For example, the monthly consumption can be used to infer the occupancy status of the house during the month. In the future smart grid, the larger amount of data collected at shorter time intervals, the larger the concern on infringement on the personal privacy. The following examples illustrate the sort of personal information that may be gleaned from data pertaining to the smart grid (The Smart Grid Interoperability Panel and Cyber Security Working Group 2010):

- The activities within the person's dwelling can be constructed by comparing the electrical profile of various appliances with the observed consumption pattern reported by the smart meter of the individual. In addition, the pattern of use and the number of individuals present in the dwelling may be deduced.
- The data about plug-in electric vehicle (PEV), such as charging time and location, can be used to construct travel pattern and location of the owner.
- The use of live energy data can be used to conduct real-time surveillance to determine things, such as the presence inside the dwelling, sleeping/waking hours of owner, or where they are inside the dwelling.
- The health pattern and risk can be determined by monitoring, through appliance profiling, the frequency of meals, the cooking method (e.g., microwave or oven), time in front of TV, time using treadmills, etc.

The personal information that can be learned from data collected by the smart grid is attractive to many parties, including the following:

- Law enforcement to perform surveillance on suspected criminals
- Criminals and other unauthorized users to determine house appliances and the best time for burglary
- Appliance manufacturers to determine usage pattern and efficiency
- Marketing companies to perform targeted marketing

Hence, safeguarding and protecting this information is an essential requirement for privacy. The issue of privacy cannot be tackled by pure technical solution; privacy laws are necessary in this regard.

Research Challenges

- **Modeling the impact of attacks on smart grid:** Given the cyber-physical nature of the smart grid, an attack that is not considered a serious threat in the purely cyber system may be devastating in the smart grid. Real-time control may be disrupted by introducing a small amount of delay that may not be an issue in other less time-sensitive applications. Therefore, modeling and characterizing the impact of different attacks on the smart grid are essential to develop a robust and secure future smart grid.
- **Cryptographic algorithms and key management:** Although a vast number of cryptographic schemes have been proposed to meet the security goal requirements in traditional network security arena, many of them may be computationally intensive to be used in the smart grid environment, and they could introduce unacceptable delays for real-time applications. Hence, adopting existing solutions for a smart grid environment or developing new lightweight cryptographic protocols will be necessary to meet the security requirements of the grid without affecting its performance. Moreover, the efficient management of the cryptographic keys (e.g., distributing, updating, revoking, etc.) required for many of the schemes is also essential considering the huge number of devices/subsystems that exist in the grid. The cryptography and key management is one of the top priority research areas identified by the US cyber security working group (The Smart Grid Interoperability Panel and Cyber Security Working Group 2010).

Cloud Computing for the Smart Grid

Cloud computing may be defined as delivering a computing solution over the Internet as opposed to building this solution in-house. For example, an application (e.g., energy-usage visualization) may be run on the infrastructure provided by the cloud computing service provider instead of running it on a dedicated server. The cloud computing paradigm provides many advantages compared with the traditional

computing paradigm where each organization runs its own data center. These advantages include the following:

- Rapid deployment of services: Organization needs to ink a contract with a cloud service provider to start deploying a new service.
- Scalability: Customer may request additional (or less) resources from the service provider if the demand for service warrants such request.
- Pay per use: Customer pays according to his or her use of computing resource as specified in the agreement with the service provider.
- Economy of scale: Many customers share the same computing resources.
- Ease of maintenance: All maintenance issues, such as troubleshooting and upgrading, are handled by the service provider.

Three main service models exist in the cloud computing arena:

- Software as a service (SaaS): The client is provided with access to software running in the cloud infrastructure of the provider.
- Platform as a service (PaaS): The client is provided with a platform for application development (typically, it includes operating system, programming language development platform, database, and web server).
- Infrastructure as a service (IaaS): The client is given access to hardware (typically virtual).

The cloud computing paradigm can contribute to the advancement of the future smart grid by providing services essential to the operation of the grid, such as the following (Markovic et al. 2013):

- Processing and storing the large amount of data generated by the grid (e.g., meter and sensor readings)
- Running smart grid applications, such as AMI
- Functioning as a virtual power plant by acting as a flexible consumer that can adjust its consumption based on the computing power

Advances and Challenges in the Development of Smart Grids

The smart grid development and implementation in many countries is underway and growing rapidly. The theoretical and technological advancements move this development forward.

> Advances in distributed sensing, modeling, and control may contribute toward the development of an effective, intelligent, distributed control of power system networks. Assets optimization, novel control algorithms, control/coordination of energy storage, advanced power electronics, cyber security, policies, and technologies play important roles in the smart grid of the future (Massoud Amin 2011).

Nevertheless, challenges exist in the technological field. A power grid, particularly in its smart grid configuration, is a complex dynamic system. One of the challenges for developing a smart grid is using systems science, controls, and applied mathematics to perform the following (Massoud Amin 2011):

- Modeling
- Robust control
- Further expansion of the theory underpinnings of complex interactive systems
- Dynamic interaction in interdependent layered networks
- Disturbance propagation in networks
- Forecasting and handling uncertainty and risk

Some obstacles hinder smart grid implementation. Key barriers appear to be policy related, social, or regulatory, rather than technical. These obstacles are summarized by Giordano et al. (2013) as follows:

- Lack of interoperability and standards
- Regulatory barriers: uncertainty over roles and responsibilities in new smart grid applications and uncertainty over sharing of costs and benefits and consequently over new business models
- Consumer resistance to participating in trials

The range of regulatory arrangements might present significant barriers to the replicability of project results in different countries.

Smart Grid Economics

Smart grid is generally characterized by high investment costs and low operating costs. However, the benefits are many, and some are hard to monetize. Some of the challenges that are recognized in the cost-benefit evaluation of smart grid projects are as follows (Jackson 2011):

- The streams of smart grid costs and benefits are characterized by uncertainty caused by a variety of technologies, software, programs, and operational practices that influence over a sufficiently long planning horizon.
- Smart grid benefits are systemic in nature and are only realized once the entire system is in place and market players have taken up their roles.
- The uncertainty of consumer participation and response is another challenge the utility companies face in deciding the economics of the smart grid. The active participation of customers in hourly load contribution is an essential factor in determining the benefits of many smart grid solutions.

The GridWise Alliance (a consortium of public and private stakeholders that include utilities, IT companies, equipment vendors, new technology providers, and

academic institutions) recommended (Nibler and Masiello 2009) that smart grid project costs should consist of the following:

- Retrofits to transmission apparatus with smart grid capabilities, such as flexible AC transmission technologies, high-efficiency technologies (e.g., low-loss or superconducting technologies), high-speed switchgear, new voltage transient suppression technologies, etc.
- Transmission monitoring, control, and optimization, including sensors, communications, and computer systems and software
- Distribution monitoring, control, and optimization, including sensors, communications, and computer systems and software
- Smart grid technologies focused on renewable facilitation, such as inverters capable of providing voltage var support, governor response, and power system stabilization to protection/automation systems, feeder and station protection and automation systems developed for high local renewable penetration, etc.
- Advanced metering including advanced meters, communications infrastructure, and computer systems and software capable of providing a variety of functionalities, including RTP, remote connect/disconnect, integration of electric vehicles and HANs at some level, power quality sensing and communications, etc.
- Communications infrastructure to support the smart grid, including distribution automation and advanced metering
- Microgrids capable of high reliability/resiliency and islanded operation
- Integration of distribution automation, feeder automation, AMI, and microgrid technologies
- Technologies to assist in the efficient integration of plug-in hybrid vehicles
- Consumer integration into energy markets and grid operations
- IT, communications, and field automation projects concentrated on achieving compliance with cyber security standards

The most elaborate work performed for the estimation and calculation of the benefits of the smart grid is by the Electric Power Research Institute (EPRI) of the USA. The EPRI methodology (EPRI Report 2010, 2012, 2013) provides a framework for evaluating the economic, environmental, reliability, safety, and security benefits from the perspective of the different stakeholder groups (utilities, customers, and society). The methodology developed a systematic way of defining and estimating the benefits of the smart grid. The first EPRI report (2010) outlined an initial approach to quantify and monetize the 22 benefits of the smart grid. These benefits included optimized generation operation; deferred generation, transmission, and distribution capacity; reduced ancillary service cost; reduced congestion cost; reduced equipment failure; reduced maintenance cost; reduced meter reading cost; reduced electricity theft; reduced emissions; and reduced wide-scale blackouts, among others. A list of benefits with a small description of each is presented below. A complete guide to the calculation of benefits can be found in EPRI Report (2010, 2012, 2013) and European Commission JRC Report (2012):

1. *Optimized generation operation*: Better forecasting and monitoring of load and grid performance coupled with ancillary services that may come from stationary electricity storage and/or PEV would enable grid operators to dispatch a more efficient mix of generation to reduce cost. The optimized generation operation benefit is likely to be estimated rather than calculated.
2. *Deferred generation capacity investments*: Reduction in system peak demand by end-use customers in response to changes in electricity prices could lead to reduction/deferral of generation capacity. The benefit could be monetized as follows:

$$\begin{aligned}\text{Value}\,(\$) = \quad & \text{Annual capital carrying charge of new generation}\,(\$/\text{year}) \\ & \times \text{Time deferred}\,(\text{years})\end{aligned}$$

3. *Reduced ancillary service cost*: Ancillary services are services required to ensure that electricity can be transmitted reliably, efficiently, and securely. These services include regulation and operating reserves, maintenance of power frequency, and the cost-based services of scheduling, system control and dispatch, voltage control, and black start. Ancillary services could be reduced if generators follow load more closely. The benefit of these services is hard to assess as their requirements vary significantly from year to year and are market based.
4. *Reduced congestion cost*: Transmission congestion occurs when scheduled market transactions (generator and load) result in power flow over a transmission line that exceeds the power-carrying capability of the line. When congestion occurs in a competitive market, there is a risk of price hike from utilities that control transmission services. The reduced congestion cost benefit can be realized through DR and making use of DG.
5. *Deferred transmission capacity investment*: Reducing the overloads on transmission lines results in better asset management and reduction in the potential needs for upgrades. This can be achieved by the use of DR and customer energy resources, such as DG, energy storage, and PEV. The benefit could be monetized as follows:

$$\begin{aligned}\text{Value}\,(\$) = \quad & \text{Annual capital carrying charge of upgrade}\,(\$/\text{year}) \\ & \times \text{Time deferred}\,(\text{years})\end{aligned}$$

6. *Deferred distribution capacity investment*: Similar to transmission lines, closer monitoring and load management on distribution feeders could potentially postpone the need for upgrades or defer the capacity additions.
7. *Reduced equipment failure*: Reducing mechanical stresses on central generating equipment and T&D apparatus increases service life and reduces the probability of premature failure. The reduced equipment failure can be realized through four functions: fault current limiting, dynamic capability rating, diagnosis and notification of equipment condition, and enhanced fault protection.

8. *Reduced distribution equipment maintenance cost*: Online diagnosis and notification of equipment condition could eliminate or reduce the need to send the maintenance staff in the field to check the equipment condition.
9. *Reduced distribution operation costs*: Automatic feeder switching and automatic voltage and reactive power control through capacitors' switching eliminate the need for field crew required to carry out switching. The avoided cost benefit can be calculated by the difference of distribution operations cost before and after the implementation of the smart grid.
10. *Reduced meter reading costs*: Real-time load measurement and management would eliminate the need of meter readers and hence the cost related to sending them to read the meter manually.
11. *Reduced electricity theft*: Smart meters can detect any meter tampering. Moreover, any event of electricity theft can be detected by the real-time load measurement and management system.
12. *Reduced electricity losses*: Automatic voltage regulation and reactive power control, real-time load measurement and management, and real-time transfer functions of the smart grid help manage peak feeder loads, locate electricity production closer to load, and ensure that the voltage remains within the standard limits while minimizing the reactive power provided. These measures reduce the peak load and improve the power factor, thus reducing the T&D line losses for a given load served.
13. *Reduced electricity cost*: Customer electricity use optimization function could help alter customer usage patterns (DR with price signals or direct load control) or help reduce the cost of electricity during peak times by using DG or customer storage (plug-in vehicles or stationary electricity storage).
14. *Reduced sustained outages*: A sustained outage is one that lasts more than 5 min excluding major outages and blackouts (European Commission JRC Report 2012). Adaptive protection, automated feeder switching, automated islanding and reconnection, enhanced fault protection, and other functions of the smart grid together with DG and storage could reduce the likelihood of outage and allow the system to be reconfigured in time to help restore the service to as many customers as possible. The benefit to consumers is based on the value of service provided by the utility.
15. *Reduced major outages*: The following functions help in the reduction of major outages: wide-area monitoring, visualization, and control; automated islanding and reconnection; real-time load measurement and management; and real-time load transfer. These functions can isolate portions of the system that include DG that could help in serving the isolated customers until the service is fully restored.
16. *Reduced restoration cost*: The cost of restoring the service may include the cost related to line crew labor, material equipment, and support services, such as logistics, call centers, media relations, and other professional staff time. The reduced restoration cost benefit could be realized through the following functions: adaptive protection, automated feeder switching, diagnosis and notification of equipment condition, and enhanced fault protection.

17. *Reduced momentary outages*: A momentary outage is classified that lasts less than 5 min (European Commission JRC Report 2012). The reduced momentary outage benefit could be realized through enhanced fault protection and stationary electricity storage. The value of this benefit is based on the value of service metrics that are typically determined by customer class (residential, commercial, industrial) and may vary geographically.
18. *Reduced sags and swells*: A voltage sag is a short-duration reduction in voltage that can occur because of short circuit, overload, or starting of electrical motor, whereas voltage swell, which is a momentary increase in voltage, happens when a heavy load turns off in a power system. The frequency and severity of voltage fluctuations can be reduced by locating high-impedance faults more quickly and precisely. The reduced sags and swells benefit could be realized through enhanced fault protection and stationary electricity storage.
19. *Reduced CO_2 emissions*: This benefit is achieved through several functions and enabled energy resources in the smart grid, such as power flow control, automated feeder switching, automated voltage and reactive power control, real-time load measurement and management, customer electricity, customer electricity use optimization, DG, stationary electricity storage, and plug-in vehicles. An example of its benefit could come from reduced vehicle rolls for operation and maintenance and meter reading; fewer T&D line losses; reduction in peak demand and use of central generation, which is mainly fossil fuel based; and use of DG, which is mainly renewable energy based.
20. *Reduced SO_x, NO_x, PM-10, and other emissions*: The reduction of SO_x, NO_x, PM-10, and other pollutants is achieved with the same functions and enabled energy resources as discussed above for CO_2 emissions. The benefit could also come from reduced truck rolls, less use of central generation, etc.
21. *Reduced oil usage*: The benefit could be realized through automated feeder switching, diagnosis and notification of equipment condition, real-time load measurement and management, and PEVs. The functions that provide this benefit eliminate or minimize the need of sending line workers or crew to the switch location to operate it. Similarly, the typical number of trips to perform maintenance per feeder would be reduced. Meanwhile, the electrical energy used by PEVs displaces the equivalent amount of gasoline. Making use of DG, which is mainly renewable energy based, would reduce the usage of fossil fuel energy.
22. *Reduced wide-scale blackouts*: The reduced wide-scale blackouts benefit is achieved through wide-area monitoring and visualization, dynamic capability rating, and enhanced fault detection functions. These functions allow the grid operator to view and monitor a better picture of the bulk power system and then allow for better coordination of resources and operations between regions, which would lower the probability of wide-area blackouts. The value of this benefit is estimated by calculating the "expected" number of blackouts that could be avoided and the cost of each event.

After identifying the types of costs and benefits involved in smart grids, it would be worthwhile to see whether these smart grids lead to financial savings over the

existing grids or not. Therefore, two case studies of developed countries, USA and Great Britain, and one case study of a developing country, Oman, are discussed (Babic 2014).

The Case of USA: In 2011 (EPRI Report 2011), the EPRI made a forecast that the cost to upgrade the US grid to "smart" status would be between $338 billion and $476 billion and would generate benefits of between $1,294 billion and $2,028 billion, for a projected benefit-to-cost ratio of between 2.8 and 6.0 to 1. However, US utility smart grid business cases typically forecast benefit-to-cost ratios of between 1.1 and 3.0 to 1. These studies are mainly based on macroeconomic analysis. In 2013 (Smart Grid Consumer Collaborative 2013), the Smart Grid Consumer Collaborative (SGCC) completed a review of available research quantifying the actual – rather than forecast – benefits and costs to help stakeholders analyze and maximize the value of various capabilities. SGCC is a consumer-focused nonprofit organization formed to promote an understanding of the benefits of modernized electrical systems among all stakeholders in the USA. The stakeholders are consumer advocates; environmental advocates; regulators; consumers; legislators; utilities; and hardware, software, and service suppliers to the utility industry, among others. This report summarizes available research in terms consumers can understand and synthesizes findings in a "per-customer" context whenever possible. SGCC presents the results of two cases: the "reference case" and the "ideal case." The reference case is made with a set of conservative assumptions and the ideal case with aggressive assumptions that one can hope to achieve. The analysis is performed assuming 13-year project life, incorporating 3 years of implementation and 10 years of operation. Based on available research and incorporating the reference and ideal case assumptions detailed in the report, the ratio of benefits to costs ranges from 1.5 to 2.6 to 1 in the reference and ideal cases, respectively. The net benefit of the estimated net present value (NPV) is approximately $247 per customer in the reference case and $713 per customer in the ideal case.

The Case of Great Britain: The study is carried out by Ernst & Young (EY) in 2012 (Ernst & Young 2012) to determine the economic benefits of smart grid deployment in British economy. This report draws on existing British and international studies and interviews conducted with relevant stakeholders and EY economic analysis, as well as some assumptions introduced, where access to more detailed information has been limited, in order to conduct the analysis. The report has two broad, major conclusions. The first is that the benefits of moving toward smart grid development in a timely fashion far outweigh the risks and appear robust across a number of different scenarios. The second is that the timely creation of a smart grid can prompt noteworthy benefits in other industries, providing an appreciable boost to growth, jobs, and exports. The analysis in this report indicates that an incremental £23 billion NPV is required between 2012 and 2050 on smart investments to upgrade the distribution network, whereas a total of £27 billion NPV is required for a complete smart grid deployment. However, this is significantly cheaper than pursuing a conventional investment strategy in grids that

cost £46 billion NPV. Therefore, the study concludes that smart grid investment strategy could deliver cost savings of as much as £19 billion NPV over conventional technology investment strategy.

The Case of Oman: This study (Malik and Bouzguenda 2013) evaluated the long-term load management benefits of the smart grid in terms of avoided cost of generation, transmission, and distribution in the Sultanate of Oman. The avoided generation cost is calculated by taking the difference between the costs of two optimal generation expansion plans of 26 years. The first plan is with the base load forecast, and the second plan is with the modified load forecast caused by load management. The T&D capacity cost is calculated indirectly using the concept of asset distribution in a power system. The savings in T&D losses and environmental benefits are also estimated. The projected benefits from the smart grid range from $2.3 to $4.2 billion, which covers the assumed cost of upgrading the grid that may be somewhere between 1.4 and 2.0 billion dollars for 560,000 households. However, both the cost and the benefit estimates are based on certain assumptions and have limitations. For example, the cost of doing load management is not included. By contrast, the benefits of the smart grid are only partially estimated; benefits such as reduced ancillary service cost, reduced congestion cost, reduced equipment failure, reduced maintenance cost, reduced meter reading cost, reduced electricity theft, self-healing, avoiding blackouts, the use of renewable energy sources, etc., are not considered.

Future Directions: Road Map to "Mature" Smart Grids

There is no doubt that there are numerous economic and environmental benefits of the smart grid, and for that reason, so many developed and developing countries are already progressing toward smart grid deployment (see, e.g., Smart Grid Consumer Collaborative 2013; Ernst & Young 2012; Malik and Bouzguenda 2013; Ontario Smart Grid Forum 2013; Fadaeenejada et al. 2014). Tracking the progress of smart grid development is a topic of intense interest around the world (Fadaeenejada et al. 2014). It is also an overwhelming task, given the effects of smart grid beyond the electricity sector into other areas of society. Recent IEA report says that smart grid deployment in EU countries is steadily growing, but available deployment data do not give a full picture (IEA 2014). The report also warns that the current rate of deployment is insufficient and recommends promoting the development metrics, national data collection, and international data coordination. To measure and monitor the progress of smart grid development, a management tool called the smart grid maturity model (SGMM) has been developed by utilities for utilities (Carnegie Mellon University 2014a).

The SGMM model provides a framework for understanding the current state of smart grid deployment and capability within an electric utility and provides a context for establishing future strategies and work plans as they pertain to smart grid implementations. It is composed of eight model domains, and each contains six defined levels of maturity, ranging from level 0 (lowest) to level 5. Domains are

Table 5 Maturity levels and their characteristics

Maturity levels	Name	Maturity characteristics
5	Pioneering	Breaking new ground, industry-leading innovation
4	Optimizing	Optimizing smart grid to benefit entire organization, may reach beyond organization, increased automation
3	Integrating	Integrating smart grid deployments across the organization, realizing measurably improved performance
2	Enabling	Investing based on clear strategy, implementing first projects to enable the smart grid (may be compartmentalized)
1	Initiating	Taking the first steps, exploring options, conducting experiments, developing smart grid vision
0	Default	Default level (status quo)

logical groupings of smart grid-related capabilities and characteristics. The eight domains of the model are as follows:

1. Strategy, Management, and Regulatory (SMR)
2. Organization and Structure (OS)
3. Grid Operations (GO)
4. Work and Asset Management (WAM)
5. Technology (TECH)
6. Customer (CUST)
7. Value Chain Integration (VCI)
8. Societal and Environmental (SE)

The six levels of maturity (see Table 5) represent defined stages of an organization's progress toward achieving its smart grid vision in terms of automation, efficiency, reliability, energy and cost savings, integration of alternative energy sources, improved customer interaction, and access to new business opportunities and markets. By assessing its current maturity level in each domain and taking steps to increase its levels as appropriate, an organization moves closer to obtaining the desired benefits of adopting and implementing smart grid technology.

As of year 2014, 142 major investor-owned utilities and small public power utilities in the USA and in 29 countries are using SGMM (Carnegie Mellon University 2014b). The model has proven to be a valuable tool for utilities to help in:

- Identifying the smart grid landscape
- Developing a shared smart grid vision and road map
- Communicating with internal and external stakeholders using a common language
- Prioritizing options and supporting decision-making
- Comparing progress over time and to the rest of the community
- Measuring progress
- Preparing for and facilitating change

Contents

Abstract

In spite of several successful alternative energy production installations in recent years, it is difficult to point to more than one or two examples of a modern industrial nation obtaining the bulk of its energy from sources other than oil, coal, and natural gas. Thus, a meaningful energy transition from conventional to renewable sources of energy is yet to be realized. It is also reasonable to assume that a full replacement of the energy currently derived from fossil fuels with energy from alternative sources is probably impossible over the short term. For example, the prospects for large-scale production of cost-effective renewable

electricity remain to be generated utilizing either the wind energy or certain forms of solar energy. These renewable energies face important limitations due to intermittency, remoteness of good resource regions, and scale potential. One of the promising approaches to overcome most of the limitations is to implement many recent advances in solar thermal electricity technology. In this section, various advanced solar thermal technologies are reviewed with an emphasis on new technologies and new approaches for rapid market implementation.

The first topic is the conventional parabolic trough collector, which is the most established technology and is under continuing development with the main focus being on the installed cost reductions with modern materials, along with heat storage. This is followed by the recently developed linear Fresnel reflector technologies. In two-axis tracking technologies, the advances in dish-Stirling systems are presented. More recently, the solar thermal electricity applications in two-axis tracking using tower technology are gaining ground, especially with multi-tower solar array technology. A novel solar chimney technology is also discussed for large-scale power generation. Non-tracking concentrating solar technologies, when used in a cogeneration system, offer low-cost electricity, albeit at lower efficiencies – an approach that seems to be most suitable in rural communities.

Introduction

Solar thermally generated electricity is a low-cost solar energy source that utilizes complex collectors to gather solar radiation in order to produce temperatures high enough to drive steam turbines to produce electric power. For example, a turbine fed from parabolic trough collectors might require steam at 750 K and reject heat into the atmosphere at 300 K, thus having an ideal thermal (Carnot) efficiency of about 60 %. Realistic overall conversion (system) efficiency of about 35 % is feasible with intelligent management of waste heat. The solar radiation can be collected by different concentrating solar power (CSP) technologies to provide high temperature heat. The solar heat is then used to operate a conventional power cycle, such as Rankine (steam engine), Brayton (gas turbine engine), or Stirling (Stirling engine) (Decher 1994). While generating power during the daytime, additional solar heat can be collected and stored, generally in a phase-change medium such as molten salt (Pilkington Solar International GmbH 2000). The stored heat can then be used during the nighttime for power generation. A simple schematic, shown in Fig. 1, describes the main elements of such a system.

The markets and applications for CSP dictate the category of the system and its components. Typically, the general categories considered by size are small ($<$100 kW), medium ($<$10 MW), and large ($>$10 MW). The CSP systems can be made of combinations of different collectors, power cycles, and, if required, thermal storage technologies. The CSP system processes heat like any conventional power plant, and, as such, the plant efficiency depends primarily upon the operating temperature. Therefore, the useful energy produced will depend on the solar-field collection and

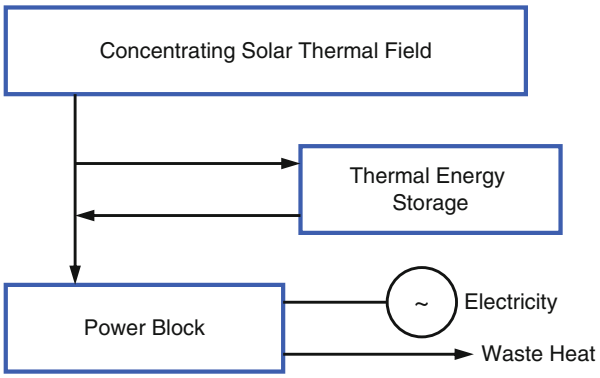

Fig. 1 Main components of a concentrating solar power (CSP) system

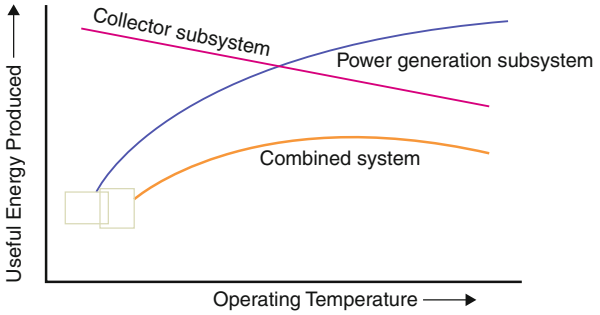

Fig. 2 CSP system efficiency variation with operating temperature

the power cycle efficiencies, as illustrated in Fig. 2. The efficiency of a solar collector field is defined as the quotient of usable thermal energy versus received solar energy. The power generation subsystem efficiency is the ratio of net power out to the heat input.

The different CSP technologies that will be explored in the following sections are parabolic trough, central tower receiver, dish-Stirling, linear Fresnel, and solar chimney. CSP technologies require sufficiently large (>5.2 kWh/m^2/day) direct normal irradiance (DNI), as opposed to PV technologies that can use diffuse, or scattered, irradiance as well (Duffie and Beckman 2006). The history of the Solar Electricity Generating Systems (SEGS) in the southwest desert of California (Jensen et al. 1989), where DNI is quite favorable for CSP, shows impressive cost reductions as shown in Fig. 3. These parabolic trough plants have been operating successfully for over three decades, thus providing valuable data. As indicated in the figure, the advanced concepts, with large-scale implementation and improved plant operation and maintenance, provide a great opportunity for further reductions in the levelized electricity cost (LEC), a topic that will be discussed later. Life cycle assessment of emissions and land surface impacts of the CSP systems suggest that they are best suited for greenhouse gas and other pollutant reductions. CSP systems are also best suited, because of the effortless capture of the waste heat, for multi-generation applications, such as the simultaneous production of electricity and water

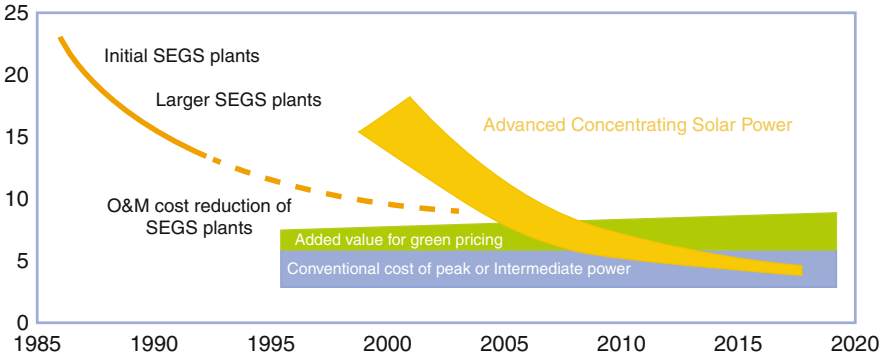

Fig. 3 Levelized electricity cost (cents/kWh) projections of CSP (Source: Solar Paces)

purification. Because of rapid developments occurring both in technology and electricity market strategies, CSP has the greatest potential of any single renewable energy area. It also has significant potential for further development and achieving low cost because of its guaranteed fuel supply (the sun).

In this chapter, a succinct review of the current technologies is given together with an assessment of their market potential. While describing some of the recent approaches in some detail, the activity around the world will also be included.

Solar Radiation

The potential for CSP implementation in any given geographic location is largely determined by the solar radiation characteristics (Duffie and Beckman 2006). The total specific radiant power per unit area, or radiant flux, that reaches a receiver surface is called irradiance and it is measured in W/m^2. When integrating the irradiance over a certain time period, it becomes solar irradiation and is measured in Wh/m^2. When this irradiation is considered over the course of a given day, it is referred to as solar insolation, which has units of $kWh/m^2/day$ ($= 3.6\ MJ/m^2/day$). However, by assigning a number of useful solar hours in a given day, then the units simplify to W/m^2. As such, the terms irradiance and insolation are typically used interchangeably. Solar radiation consists primarily of direct beam and diffuse, or scattered, components. The term "global" solar radiation simply refers to the sum of these two components. The daily variation of the different components depends upon meteorological and environmental factors (e.g., cloud cover, air pollution, and humidity) and the relative earth-sun geometry. The direct normal irradiance (DNI) is synonymous with the direct beam radiation, and it is measured by tracking the sun throughout the sky. Figure 4 shows an example of the global solar radiation that is measured on a stationary two flat plates and a plate that is tracking the sun. The measured DNI is also included, and its lower value can be attributed to the fact that it does not account for the diffuse radiation component (Molenbroek et al. 2008).

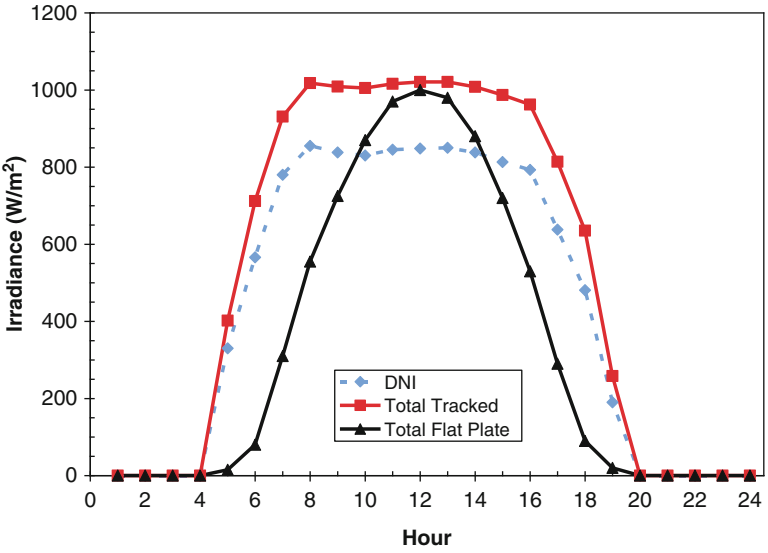

Fig. 4 Solar irradiance variation within a day measured on a flat plate positioned horizontal and tracking the sun and direct normal irradiance (DNI) (Source: Molenbroek 2008)

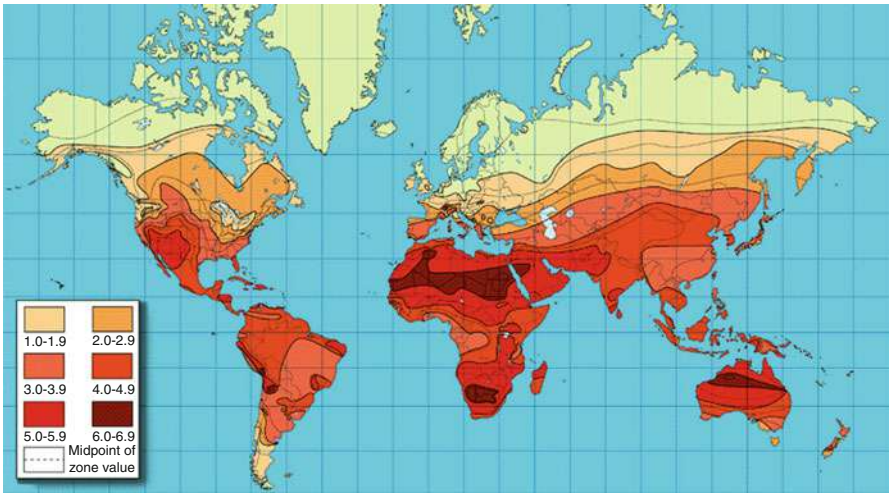

Fig. 5 The solar insolation (kWh/m^2/day) on an optimally tilted surface during the worst month of the year (Source: http://www.meteostest.ch)

In CSP applications, the DNI is important in determining the available solar energy. It is also for this reason that the collectors are designed to track the sun throughout the day. Figure 5 shows the daily solar insolation on an optimally tilted surface during the worst month of the year around the world (www.meteotest.ch;

Crete, Greece	35°N	2,293
Jodhpur, India	26°N	2,200

www.wrdc-mgo.nrel.gov). Regions represented by light and dark red colors are most suitable for CSP implementation. The annual DNI value will also greatly influence the levelized electricity cost (LEC), which will be discussed later. Typical values of DNI at different latitudes and selected locations around the world are given in Fig. 6 and Table 1. Based on the information presented here, it can be seen that desert and equatorial regions appear to provide the best resources for CSP implementation.

CSP Technologies

Parabolic Trough Technology

This technology is comprised of relatively long and narrow parabolic reflectors with a single-axis tracker to keep the sun's image in focus on a linear absorber or receiver. This technology uses reflectors curved around the rotation axis (which is typically oriented east-west) using a linear parabolic shape, which has the property of collecting nearly parallel rays from the direct solar beam in a line image. A long pipe receiver can be placed at the focus for heating of heat transfer fluid (Fig. 7). The receiver is normally a tube, which contains a heat transfer fluid or water for direct steam generation.

The two major components of the collector subsystem are the parabolic trough reflector, including its support structure, and the receiver, also referred to as the heat collector element. Important factors for the most efficient parabolic trough reflector include the stability and accuracy of the parabolic profile, optical error tolerance, method of fabrication, material availability, and strength constraints. The geometry, length of the trough, the aperture, and rim angle will dictate the amount of heat collection. Since there are a large number of collector modules in a typical plant, the cost optimization requires minimizing the material weight (steel or aluminum), the operations needed to manufacture the structure, and the assembly of the elements that compose the collector (Gee and Hale 2006). A typical modern structure using

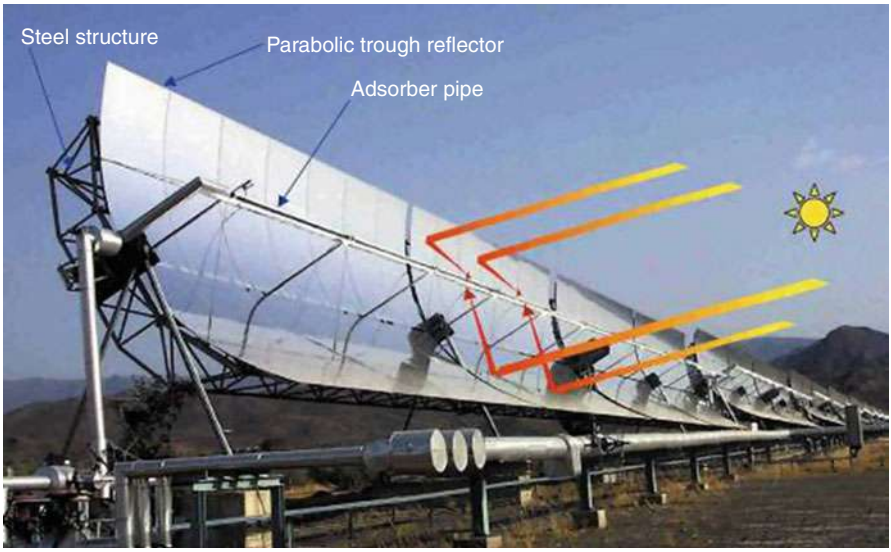

Fig. 7 A typical parabolic trough system (Source: http://www.abengoasolar.com)

Fig. 8 *Left*: parabolic trough space frame structure (Source: NREL). *Right*: lightweight trough with reflective thin film mirror (Farr and Gee 2009)

aluminum space frame technology to support the reflector is shown in Fig. 8. These are considerably lighter per unit of aperture area compared to standard steel structures.

All utility-scale parabolic trough installations to date have utilized silvered glass mirrors as reflectors (Fig. 7). These reflectors are limited in size and are typically driven by manufacturing limitations, strength, handling, shipping, and installation issues. These parabolic trough modules will have between 20 and 40 mirrors mounted to a single space frame module. The mirrors are typically 4–5 mm thick and are mounted to the structural frame with bolted connections. Alternatively, a UV-stabilized mirror film (i.e., ReflecTech™) laminated onto an aluminum substrate (Fig. 8b) provides a reflectance of about 94 % (Farr et al. 2009). The weight of the modern reflective surface is about 3.5 kg/m^2 versus 10 kg/m^2 (2.1 lbf/ft^2) for glass mirrors and allows for a lower initial cost.

The receiver must achieve high efficiency with high solar absorptance, low thermal losses, and minimum shading. The receiver typically consists of a pipe with a solar-selective coating encased in a glass tube throughout which there is a vacuum. The most commonly used thermal receiver is the SCHOTT PTR™

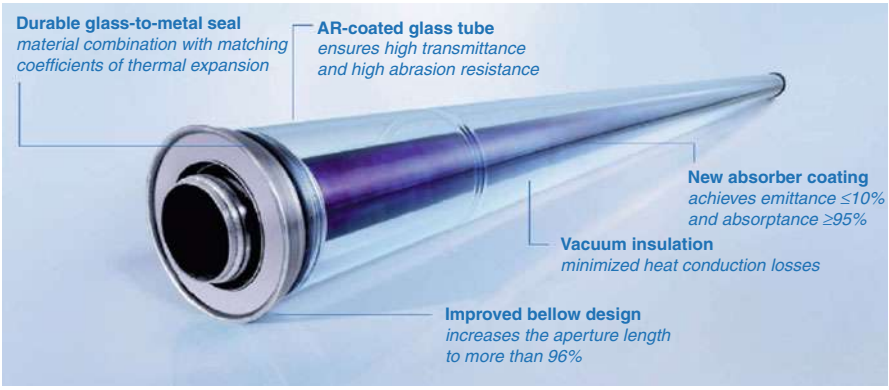

Fig. 9 Schott PTR™ 70 receiver

70 (http://www.schottsolar.com/global/products/concentrated-solar-power/schott-ptr-70-receiver/), shown in Fig. 9, which has a highly selective absorber coating on a stainless steel tube that has an outside diameter of 70 mm. The tube is enclosed in a glass cylinder with vacuum insulation to minimize the long-wave IR radiation and convection losses. The receiver tube supports are designed to minimize any receiver deflection and sunlight blockage. This particular configuration is in widespread use, but it has a number of drawbacks, which include the fact that it is difficult to maintain the vacuum seals, especially after welding, and, as has been observed, the heat transfer fluid and solar-selective coating off-gas hydrogen into the vacuum tube, thus negating the convection reducing effects of the tube.

The typical thermal conversion efficiency (net heat collected/incident solar radiation over the trough aperture area) for a parabolic trough is shown in Fig. 10 for the PT-1 concentrator (Dudley et al. 1995). The efficiency is largely affected by the collector thermal and optical losses. Since the radiation losses are proportional to the fourth power of the temperature, the efficiency decreases rapidly with increasing working fluid temperature. The nominal operating temperature of many plants (e.g., SEGS) is about 400 °C (~350 °C above ambient) operating at a thermal conversion efficiency of about 50 % at best. The trend over the last 25 years has been to make larger collectors with higher concentration ratios in order to improve the collector thermal efficiency. However, due to increased material manufacturing and installation costs of the large aperture (>6 m) troughs, the LEC still remains high for widespread implementation.

The concentrating parabolic trough systems typically produce power based on the Rankine cycle, which is the most fundamental and widely used steam-power cycle. The cycle starts with superheated steam generated by the heat collected from the parabolic trough field. The superheated vapor expands to lower pressure in a steam turbine that drives a generator to convert the work into electricity. The turbine exhaust steam is then condensed and recycled as the feed water for the superheated steam generation to begin the cycle again. The simple steam cycle thermodynamic efficiency can be as high as 35 %. Considering that the generator sets are better than

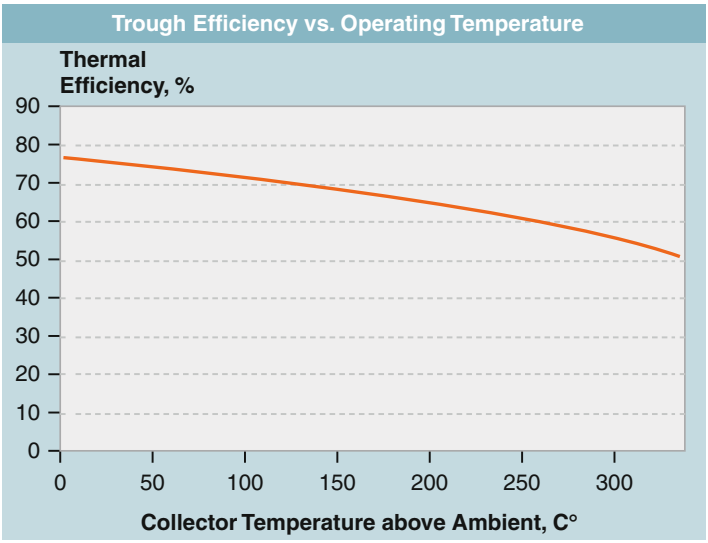

Fig. 10 The variation of the thermal efficiency of a parabolic collector with operating temperature (Dudley et al. 1995)

90 % efficient in converting the shaft power into electricity, it is expected that the cycle can produce electricity at an efficiency in excess of 30 %. As such, the total combined plant efficiency (solar to electricity) is best estimated to be about 15 %. The SEGS system experience shows that the annual solar to electric efficiency varies from 10.7 % to 14.6 %, with the higher number corresponding to the case where thermal storage is included in the plant. Although the plant efficiency appears low when compared to conventional fossil fuel-based plants, the operation and maintenance (O&M) costs are negligible due to the absence of any fuel costs, thus making the LEC largely depend on the capital costs. It is useful to think in terms of the cost/efficiency ratio to determine the viability of the CSP plant. Although much of the recent effort is on increasing the efficiency of the plant, it is more useful to find ways to reduce capital costs, thereby reducing the LEC. Hence, the following is a discussion assessing the component costs for a parabolic trough plant.

Figure 11 gives a breakdown of the investment costs associated with a typical parabolic trough plant utilizing the Rankine steam cycle (Brakmann et al. 2002). As the pie chart indicates, the majority of the initial investment cost is associated with the solar field. Much progress has been made recently with the introduction of lightweight space frame structure designs and the development of efficient highly reflective film (www.reflectechsolar.com), such as ReflecTech™ and 3M's new solar mirror film (http://solutions.3m.com). The heat transfer fluid (HTF) system moves the heat from the solar field to the power block, and it requires an HTF with the following properties: high-temperature operation with high thermal stability, good heat transfer properties, low energy transportation losses, low vapor pressure, low

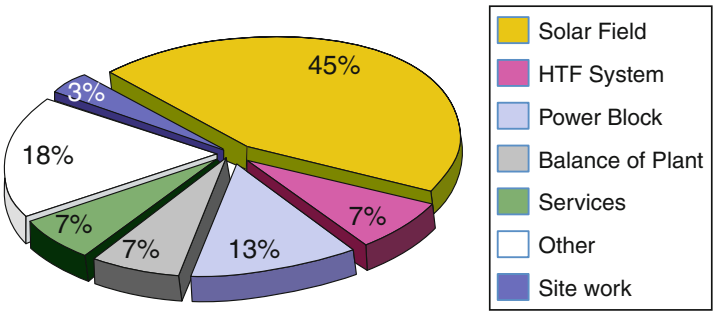

Fig. 11 Typical cost breakdown of a parabolic trough SEGS plant

freeze point, low hazard properties, good material compatibility, low hydrogen permeability of the steel pipe, and economical product and maintenance costs. As a result, synthetic organic HTFs are most suitable for the parabolic trough plants. For example, SYLTHERM™ 800, a high-temperature HTF by Dow Chemical Company, can be used in liquid form up to 400 °C and meets many of the requirements delineated above (http://www.dow.com/webapps/lit/litorder.asp?filepath=heattrans/pdfs/noreg/176-01469.pdf&pdf=true). The last of the major components is the power block, which consists of a conventional steam turbine-based system, the costs of which are well established and a number of new players from China and India have made the prices quite competitive. Any significant reduction in the cost of any of these three major components will result in a lower LEC for CSP systems.

The most recent 64 MW (nominal) installation in Nevada (Nevada Solar One), shown in Fig. 12, uses 5.77 m aperture parabolic troughs with PTR-70 receivers, resulting in a geometric concentration ratio of 26. The total solar field is 357,200 m^2 and the plant site area is 1.62 km^2. Field inlet and outlet temperatures are 300 °C and 390 °C, respectively. The solar steam turbine inlet temperature is about 371 °C at 86.1 bar. The plant uses a supplementary gas heater to provide 2 % of the total heat requirement. The plant produces about 134×10^6 kWh of electricity annually, which yields a plant capacity factor of about 0.24. Coal power plants have a capacity factor on the order of 0.74, and as such they can produce the equivalent electricity output from a 21 MW plant. The solar to electricity efficiency of the plant (Fig. 13 shows the plant schematic) is estimated, based on the annual DNI of 2,573 kWh/m^2, to be 14.6 %. The CO_2 emission reduction (as compared to a equivalent coal plant) is estimated to be about 100,000 MT/year. A typical electricity production in a day is depicted in Fig. 14, where the hourly DNI variation is also displayed. The total installed cost of the project was $266 million resulting in a nominal price of about $4.15/W. With medium temperature (250–300 °C) parabolic troughs and advanced receiver designs, it is anticipated that the installed costs may reach as low as $2.50/W, thus making the parabolic trough systems competitive with many other renewable energy solutions.

The ability to provide near-firm power through the use of thermal energy storage is gaining prominence. This characteristic differentiates CSP from PV technology, as

Fig. 12 *Left*: parabolic trough field. *Right*: power block at Nevada Solar One power plant (Source: www.acciona-na.com)

the utilities can tailor the use of CSP electricity as needed. The thermal storage can also provide more uniform output over the day and increase annual electricity generation, thereby increasing the plant capacity factor. For example, while solar energy availability peaks at noon, demand peaks in the late afternoon when the

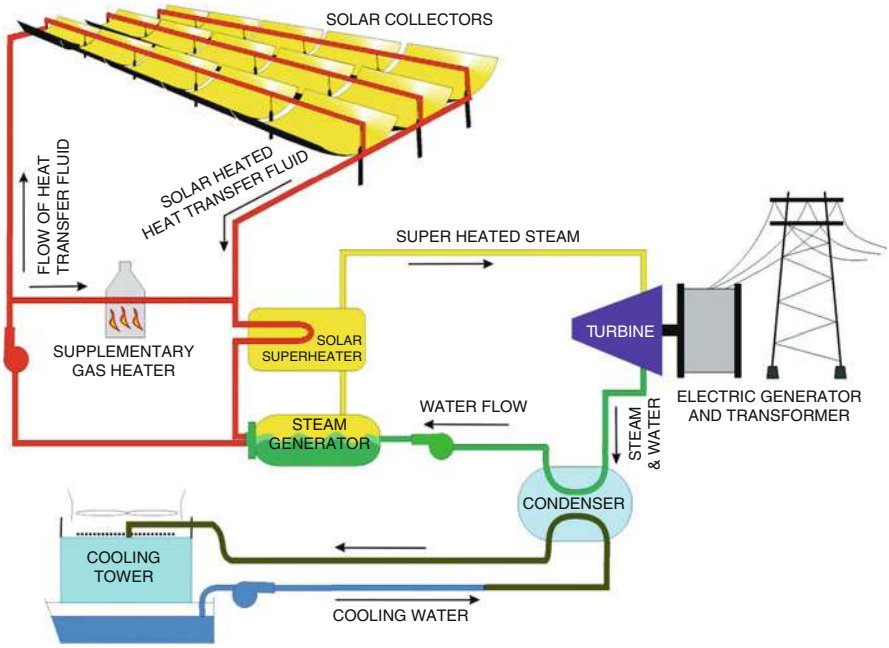

Fig. 13 Nevada Solar One plant schematic (Source: www.acciona-na.com)

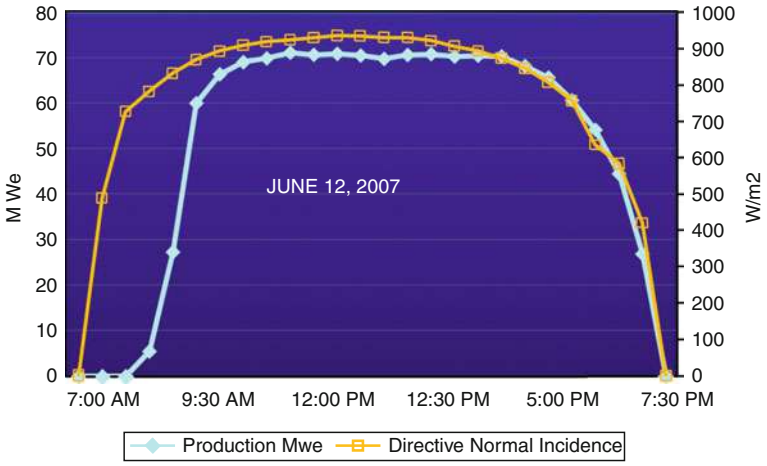

Fig. 14 Nevada Solar One electricity output and DNI for a typical summer day (Source: www.acciona-na.com)

energy from the sun is already going down. Figure 15 shows a parabolic trough plant schematic with molten salt thermal storage incorporated (Kearney and Morse 2010). A high-temperature thermal energy storage option has been developed for parabolic troughs that use molten nitrate salt as the storage medium in a two-tank system; it has

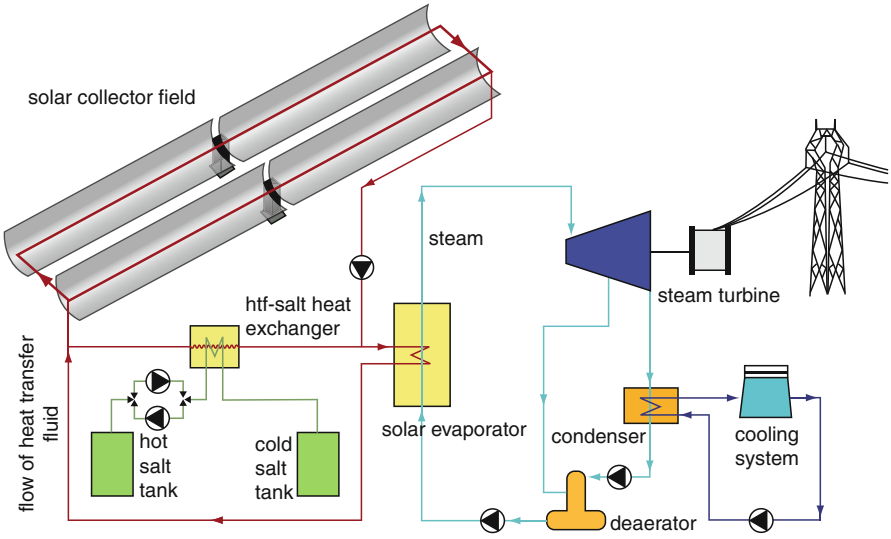

Fig. 15 A schematic of a parabolic trough plant with added thermal storage (Kearney and Morse 2010)

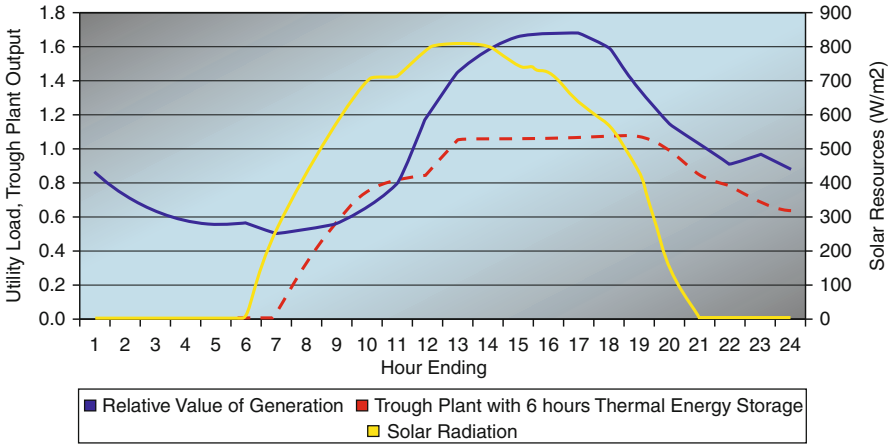

Fig. 16 The effect of storage on utility load during a typical day (Kearney and Morse 2010)

an oil-to-salt heat exchanger to transfer thermal energy from the solar field to the storage system (Laing et al. 2009). A more desirable option under development is an advanced heat transfer fluid (HTF) that is thermally stable at high temperatures, has a high thermal capacity and a low vapor pressure, and remains a liquid at ambient temperatures. The effect of storage to follow the utility system demand is clearly depicted in Fig. 16. When compared to the data shown in Fig. 14, where the

electricity supply follows closely with the sun's energy, the storage extends the availability of electricity through evening hours.

The performance of SEGS plants, the successful development of Nevada Solar One, and the progress made by industry innovations have greatly increased interest in utility-scale CSP projects in the USA and Europe. Abengoa Solar's proposed 250 MW Solana parabolic trough plant provides an example of the potential of this technology (http://www.abengoasolar.com/corp/web/en/our_projects/solana/).

Linear Fresnel Reflector Technology

Fresnel lenses are used as solar concentrators where the reflector is composed of many long row segments of flat mirrors, which concentrate beam radiation onto a fixed receiver, located at few meters height, running parallel to the mirrors axis of rotation (Fig. 17). Linear Fresnel follows the principles of parabolic trough technology but replaces the curved mirrors with long parallel lines of flat, or slightly curved, mirrors. Unlike parabolic troughs where the aperture is limited to few meters, a large aperture can be achieved by the linear Fresnel reflector at low cost. Although the original idea is quite old (Francia 1961, 1968), only recently has this concept been brought to fruition by two teams in Australia and Belgium. The concentration ratios used in this system are quite similar to those achieved using parabolic troughs (10–80). Hence, the operating temperatures are also in the same range of the parabolic trough systems, 250–400 °C. A picture of the Solarmundo prototype system (Häberle et al. 2002) erected in Liege, Belgium, is shown in Fig. 18. The collector area is 2,500 m^2 (25 m wide and 100 m long) and the absorber tube has an outer diameter of 18 cm. The prototype used a black (nonselective) absorber. However, in order to achieve satisfactory thermal performance, a highly selective absorber coating that is stable at high operation temperatures must be applied. A pilot plant, a 1 MW (peak) thermal, system similar to the prototype was built at PSA

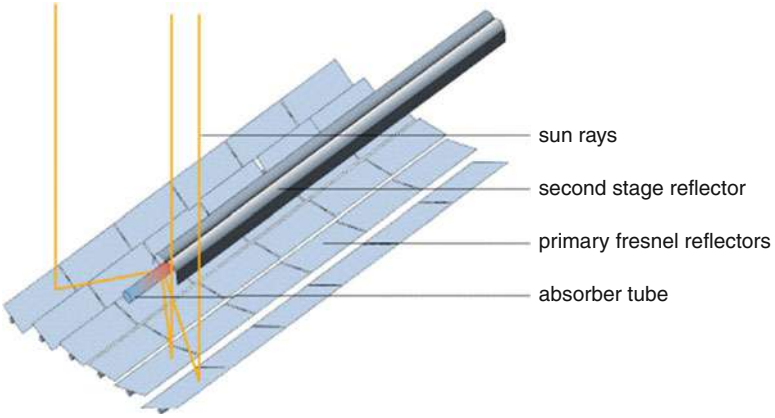

Fig. 17 The principle of a typical Fresnel collector (Haberle et al. 2002)

Fig. 18 2,500 m^2 reflected area Fresnel concentrator prototype in Belgium (Haberle et al. 2002)

in Almeria, Spain. Water flows through this absorber pipe, which is heated to temperatures of up to 450 °C. This produces steam (as in a conventional power plant), which is converted into electrical energy through the use of a steam turbine.

A 5 MW_e compact linear Fresnel reflector (CLFR) power plant was built by Ausra in California as a demonstration plant (www.ausra.com) (Fig. 19). The solar-field aperture area was 26,000 m^2, with three lines, each 385 m length with a mirror width of 2 m. The plant produces 354 °C superheated steam at 70 bar. The CLFR utilizes multiple absorbers, which is an alternate solution to the linear Fresnel reflector (LFR) where only one linear absorber on a single linear tower is used. This prohibits any option of the direction of orientation of a given reflector. Therefore, if the linear absorbers are close enough, individual reflectors will have the option of directing reflected solar radiation to at least two absorbers. This additional factor gives potential for more densely packed arrays, since patterns of alternative reflector inclination can be set up such that closely packed reflectors can be positioned without shading and blocking.

The main advantages of linear Fresnel are its lower investment and operational costs. Firstly, the flat mirrors are cheaper and easier to produce than parabolic curved reflectors and so are readily available from manufacturers worldwide. The structure also has a low profile, with mirrors just 1 or 2 m aboveground. This means the plant

Fig. 19 The Ausra 5 MW Kimberlina solar thermal demonstration plant (Source: http://www.ausra.com)

can operate in strong winds and it can use a lightweight, simple collector structure. Although the technology offers a simpler and more cost-effective solution, it has not been tested long enough to determine its viability as an alternative to parabolic trough technologies.

Dish-Stirling Technology

Dish-Stirling systems are relatively small units that track the sun and focus solar energy onto a cavity receiver at the focal point of the reflector, where it is absorbed and transferred to a heat engine/generator. The ideal concentrator shape is a paraboloid of revolution (Fig. 20, left). Some concentrators approximate this shape with multiple spherically shaped mirrors supported with a truss structure (Fig. 20, right). An engine based on the Stirling cycle is most commonly used in this application due to its use of an external heat supply that is indifferent to how the heat is generated (Saad 1997). Hence, it is an ideal candidate to convert solar heat into mechanical energy. The high-efficiency conversion process involves a closed cycle engine using an internal working fluid (usually hydrogen or helium) that is recycled through the engine. The working fluid is heated and pressurized by the solar receiver, which in turn powers the Stirling engine. Stirling engines have decades of recorded operating history. For over 20 years, the Stirling Energy System (www.stirlingenergy.com) dish-Stirling system has held the world's efficiency record for converting solar energy into electricity with a record of 31.25 % efficiency. Their size typically ranges from 1 to 25 kW with a dish that is 5–15 m in diameter. Because of their

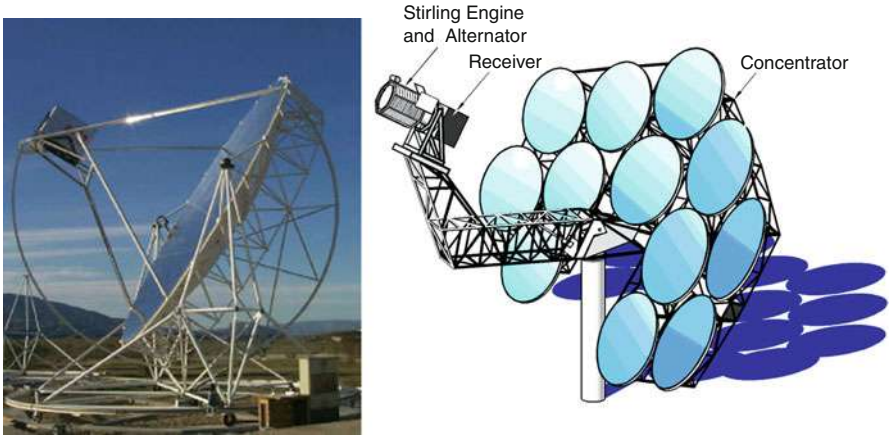

Fig. 20 *Left*: Euro Dish (Source: http://www.sbp.de). *Right*: SAIC-Sandia dish (Source: http://www.energylan.sandia.gov/)

size, they are particularly well suited for decentralized applications, such as remote stand-alone power systems.

One of the most advanced dual-axis tracking parabolic dish-Stirling systems is manufactured by Stirling Energy Systems (SES), and it produces 25 kW_e peak power (at 1,000 W/m^2 DNI) (www.stirlingenergy.com). This unique design uses a radial solar concentrator dish structure that supports an array of curved glass mirror facets as shown in Fig. 21. The dish has a diameter of about 11.6 m (glass surface area ≈90 m^2), which results in a concentration ratio of about 7,500. The heat input from the sun is focused onto solar receiver tubes (at a focal length of 7.45 m) that contain hydrogen gas. The solar receiver is an external heat exchanger that absorbs the incoming solar thermal energy. This heats and pressurizes the gas in the heat exchanger tubing, which in turn powers the Stirling engine at a typical operating temperature of about 800 °C. A generator that is connected to the engine then provides the electrical output. Waste heat from the engine is transferred to the ambient air via a radiator system similar to those used in automobiles. The gas is cooled by a radiator system and is continually recycled within the engine during the power cycle. The solar energy to electricity peak conversion efficiency is reported as 31.25 %. A much smaller 3 kW_e advanced parabolic dish-Stirling system is manufactured by Infinia (Fig. 21). The single free-piston Stirling engine uses helium in a hermetically sealed system, thereby avoiding maintenance issues generally associated with moving parts. The solar to electric peak efficiency is reported to be around 24 %.

Dish-Stirling systems are quite flexible in terms of size and scale of deployment. Owing to their modular design, they are capable of both small-scale distributed power output and large-scale, utility-scale projects. Although dish-Stirling systems have been tested and proven for over two decades with no appreciable loss in the key performance criteria, there were no utility-scale plants in operation until very recently. Within the past year, 60 SES SunCatcher™ systems were installed as part

Fig. 21 *Left*: SES Sun Catcher™ (Source: http://www.stirlingenergy.com/). *Right*: Power Dish™ by Infinia (Source: http://www.infiniacorp.com)

of the Maricopa Solar demonstration plant in Arizona (Fig. 22). The plant is currently operational and it is capable of producing 1.5 MW_e. Two other plants in California, totaling over 1.4 GW are slated to begin construction soon using thousands of the SES systems. A similar 1 MW system is under construction in Villarrobledo, Spain, using the Infinia 3 kW units (www.infiniacorp.com). The successful installation and operation of these dish-Stirling systems in a scale beyond a handful of units will demonstrate their technical viability for the large-, utility-scale plants. Unlike steam cycles, this technology uses no water in the power conversion process, a key benefit compared to other CSP plants.

Current installed cost for the dish-Stirling systems at demonstration scale, with few units (mostly built in semiautomated manufacturing facilities), is about $6,000/kW. This cost is approximately distributed with 40 % in the concentrator and controls, 33 % in the power conversion unit, and the remaining 27 % of the costs in the balance of plant and installation of the system. Mass production techniques, such as those employed at the automotive scale, will provide great cost benefits to these systems. With the economies of scale in their favor and because of higher solar to electricity efficiency (25–30 %), the dish-Stirling systems will become competitive with the photovoltaic and parabolic trough systems. However, unlike the parabolic trough systems, the 20-year life cycle costs of these systems are yet to be determined.

Power Tower Technology

The solar central receiver power tower is a concept that has been under study both in the USA and Spain over the last three decades. This technique utilizes a central

Fig. 22 *Left*: 1.5 MW Maricopa Solar installation (Source: http://www.srpnet.com/maricopasolar). *Right*: 1 MW solar installation in Villarrobledo, Spain (Source: http://www.infiniacorp.com)

power tower that is surrounded by a large array of two-axis tracking mirrors – termed heliostats – that reflect direct solar radiation onto a fixed receiver located on the top of the tower. The typical concentration ratio for this approach is in excess of 400. Within the receiver, a fluid transfers the absorbed solar heat to the power block where it is used to generate steam for a Rankine cycle steam engine/generator. Until recently, the largest demonstration plant employing this technology was the 11.7 MW_e "Solar One" plant in Barstow, California (Fig. 23), that was constructed and operated in the 1980s. Solar One operated at a nominal temperature of 510 °C and it had a peak solar to electric efficiency of about 8.7 %. In the 1990s, Solar One was converted to "Solar Two" through the addition of additional heliostats and a two-tank molten salt storage system to improve the capacity factor of the system (www1.eere.energy.gov/library/pdfs/28751.pdf).

Two important components of the power tower technology are the heliostats and the receiver. Heliostats are the most important cost element of the power tower plant, and they typically contribute to about 50 % of the total plant cost. Consequently, much attention has been paid to reduce the cost of heliostats to improve the economic viability of the plant. The most commonly used design is the two-axis sun-tracking pedestal-mounted system as shown in Fig. 24. A heliostat consists of a

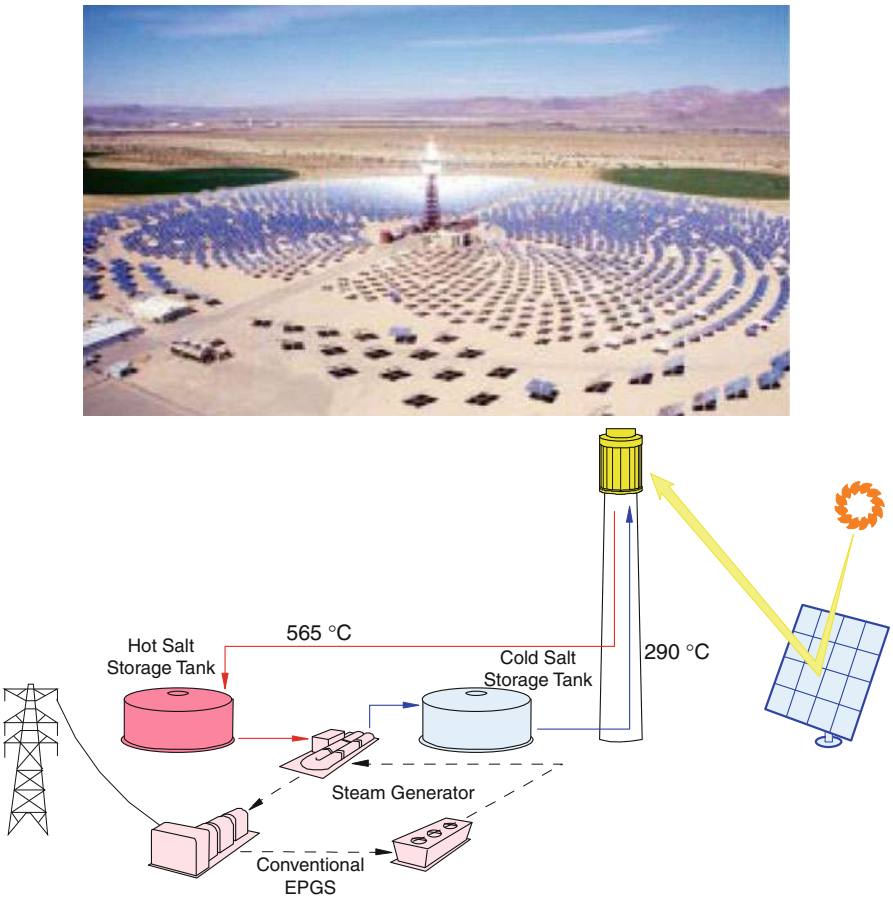

Fig. 23 *Left*: Solar One/Two central solar tower receiver plant. *Right*: schematic of the plant's major components (Source: USDOE)

large mirror with the motorized mechanisms to actuate it, such that it reflects sunlight onto a given target throughout the day. A heliostat array is a collection of heliostats that focus sunlight continuously on a central receiver. A 148 m^2 ATS glass/metal heliostat has successfully operated for over 20 years at the National Solar Thermal Test Facility in Albuquerque, USA, without much degradation of the beam quality. It has also survived high winds in excess of 40 m/s. Depending upon the production rates, the installed price of the ATS heliostat was estimated to be between $126 and 164 per square meter (Kolb et al. 2007). With increasing installations, the estimated installation price will be around $90/$m^2$. The Sandia study also suggests that large heliostats are more cost efficient than small ones on a cost per square meter basis (Kolb et al. 2007).

A relatively new facility that began operation in 2006 is the PS10 solar power tower in Spain (10 MW Solar Thermal Power Plant for Southern Spain 2006). The

Fig. 24 Typical advanced heliostat field (Source: Plataforma Solar de Almeria – PSA, Spain)

main goal of the PS10 project was to design, construct, and operate a power tower on a commercial basis and produce electricity in a grid-connected mode. This 11 MW_e facility generates about 23,000 MWh of grid-connected electricity annually at an estimated solar to electricity efficiency of about 15 %. However, it should be noted that the plant also uses natural gas for 12–15 % of its electricity production. The solar radiation is concentrated through the use of 624 reflective heliostats, each of which has a 121 m^2 curved reflective surface, arranged in 35 circular rows, as shown in Fig. 25. As a result, the total reflective surface is 75,216 m^2. The heliostats concentrate the solar radiation to a cavity receiver that is located at the top of a 115 m high tower. The cavity receiver is basically a forced circulation radiant boiler designed to use the thermal energy supplied by the concentrated solar radiation flux to produce more than 100,000 kg/h of saturated steam at 40 bar and 250 °C. The saturated steam is then sent to the turbine where it expands to produce mechanical work and electricity. For cloudy transient periods, the plant has a saturated water thermal storage system with a thermal capacity of 20 MWh, which is equivalent to an effective operational capacity of 50 min at 50 % turbine workload. This is a relatively short storage time, partially because the tower uses water rather than molten salt for heat storage. The water is held in thermally clad tanks and reaches temperatures of 250–255 °C (instead of around 600 °C for systems using salt).

The investment cost of the PS10 plant was about 35 million euros, thus resulting in an installed cost of about 3,000 euros per kW_e. Of this cost, the heliostat cost was reported to be about 140 euros/m^2. From this experience, it appears that about 30 % of the total installed cost of a solar power tower goes toward the heliostat expense.

A second-generation plant, referred to as PS20, has twice the PS10 output (20 MW), with 1,255 two-axis sun-tracking heliostats. The receiver is located on top of a 165 m tower, and it utilizes the same technology as that of PS10 for electricity generation. The new plant features include control and operational systems enhancements, an improved thermal energy storage system, and a higher efficiency receiver.

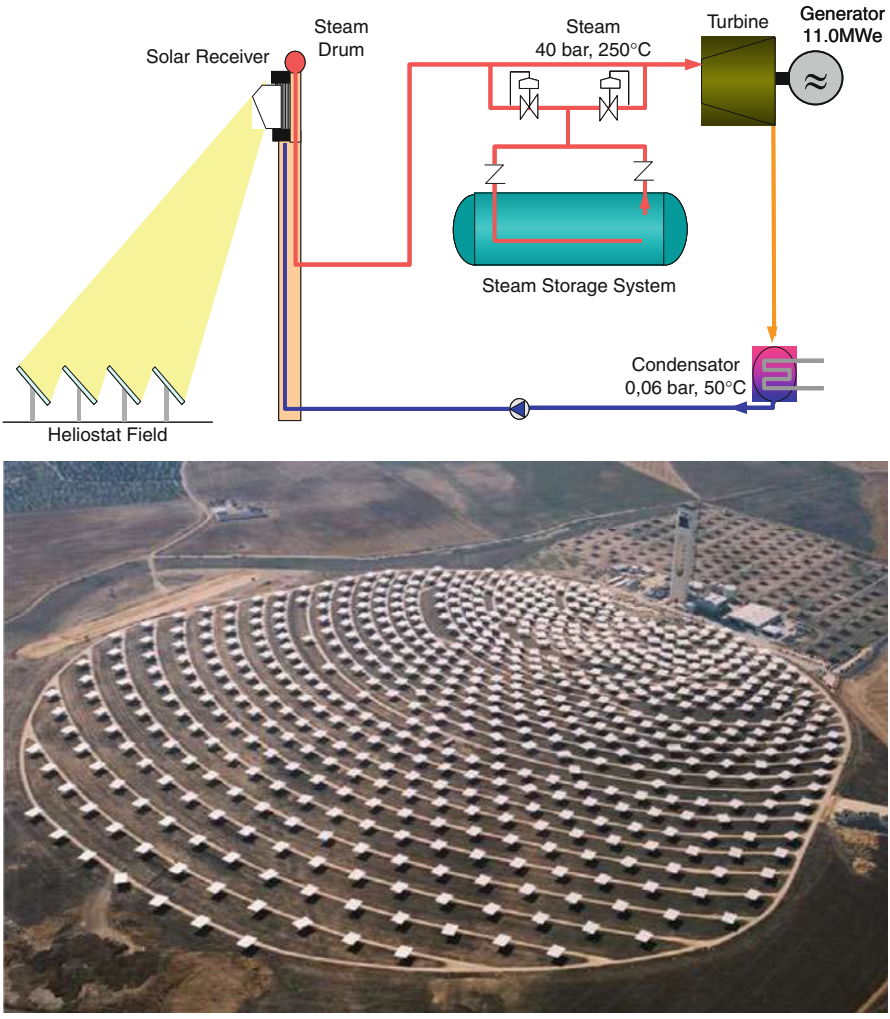

Fig. 25 PS10 11 MW central receiver tower project in southern Spain. *Left*: plant schematic. *Right*: the PS10 plant aerial picture (Source: Abengoa Solar)

A utility-scale 400 MW solar tower power project, referred to as the "Ivanpah Solar Power Complex," is being built in California by a consortium led by Bright Source Energy, and it is operational in 2013 (www.brightsourceenergy.com). The heliostats in this project will consist of smaller flat mirrors, termed the LPT 550, each having a reflecting area of 14.4 m^2. Fifty thousand of these LPT 550 heliostats will be required for every 100 MW of installed capacity. The receiver is a traditional high-efficiency boiler positioned on top of the tower. The boiler tubes in the receiver are coated with a solar-selective material that maximizes energy absorbance, and there are sections within the receiver for steam generation, superheating, and reheating.

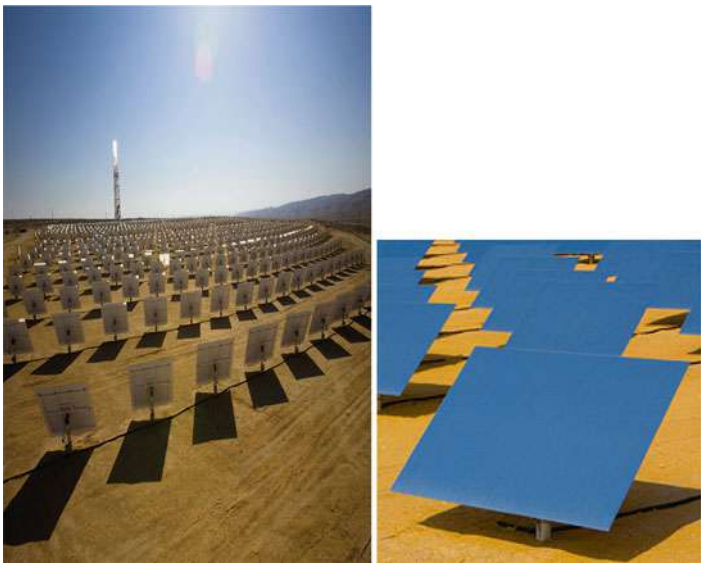

Fig. 26 The LPT 550 central receiver tower demonstration plant in Israel's Negev desert. *Left*: heliostat field with central tower. *Right*: 7.22 m^2 heliostat (Source: Brightsource Energy)

This results in the generation of superheated steam at 550 °C and 160 bars (unlike the saturated steam that is produced in the PS10 and PS20). The power block consists of a conventional Siemens steam turbine generator with a reheat cycle and auxiliary functions of heat rejection, water treatment, water disposal, and grid interconnection capabilities. The technology demonstration plant, as shown in Fig. 26, has 1,641 heliostats (reflecting area ~12,000 m^2) with each measuring 2.25 × 3.21 m (7.22 m^2). The tower height was 75 m (60 m tower plus 15 m receiver), and the thermal energy collected by the receiver was between 4.5 and 6 MW_{th}. Because of the higher operating temperature, the solar to electrical efficiency of these plants is expected to be about 20 %. Although there is not yet any experience with utility-scale plant installations, it appears that the installation cost of these plants may be in the range of \$3,000/kW_e.

In an attempt to bring down the installed cost of the solar power plant technology, eSolar, a California company introduced a modular/distributed tower design with a 1 m^2 reflected area heliostat (www.esolar.com). These much smaller heliostats, with fully automated two-axis sun tacking system, are easy to assemble and install in large numbers. Each central tower unit is capable of producing 2.5 MW_e through the use of 12,000 mirrors that reflect the radiation onto a 47 m high tower. The thermal receiver in the tower has external evaporator panels for producing superheated steam at 440 °C and 60 bar. Figure 27 shows a technology demonstration plant with two-tower system that nominally produces 5 MW_e of electricity. Since the performance details of the plant are not disclosed in any public domain, it is difficult to assess the solar to electric efficiency and the installed plant cost. In principle, the

Fig. 27 5 MW twin central receiver tower facility with 1 m^2 heliostats in California (Source: eSolar)

smaller heliostats are easy to manufacture, install, and maintain. However, the solar energy collection may involve significant losses due to spillage reaching the thermal receiver. Hence, it is important to study the pilot plant performance characteristics before a utility-scale plant design is considered.

Solar Chimney Power Plant Technology

A solar chimney power plant has a high chimney (tower) that is surrounded by a large collector roof made of either glass or resistive plastic supported on a framework (Fig. 28) (von Backstrom et al. 2008). Toward its center, the roof curves upward to join the chimney, thus creating a funnel. Solar radiation (direct and diffuse) strikes the collector and transmits part of its energy that heats up the ground and the air underneath the collector roof. At the ground surface, part of the transmitted energy is absorbed and the rest is reflected back to the roof, where it is subsequently reflected to the ground. The multiple reflections result in a higher fraction of energy absorbed by the ground. The warm ground surface heats the adjacent air through natural convection. The buoyant air follows the upward incline of the roof until it reaches the chimney, thereby drawing in more air at the collector perimeter. The natural and forced convection set up between the ground and the collector flows at high speed through the chimney and drives wind generators at its bottom. As the air flows from the collector perimeter toward the chimney, its temperature increases, while the velocity remains constant due to the increasing collector height at the center as shown in the schematic (Fig. 28). The pressure difference between the outside cold air and the hot air inside the chimney causes the air to flow through the turbine. The ground under the collector roof behaves as a storage medium and can even heat up

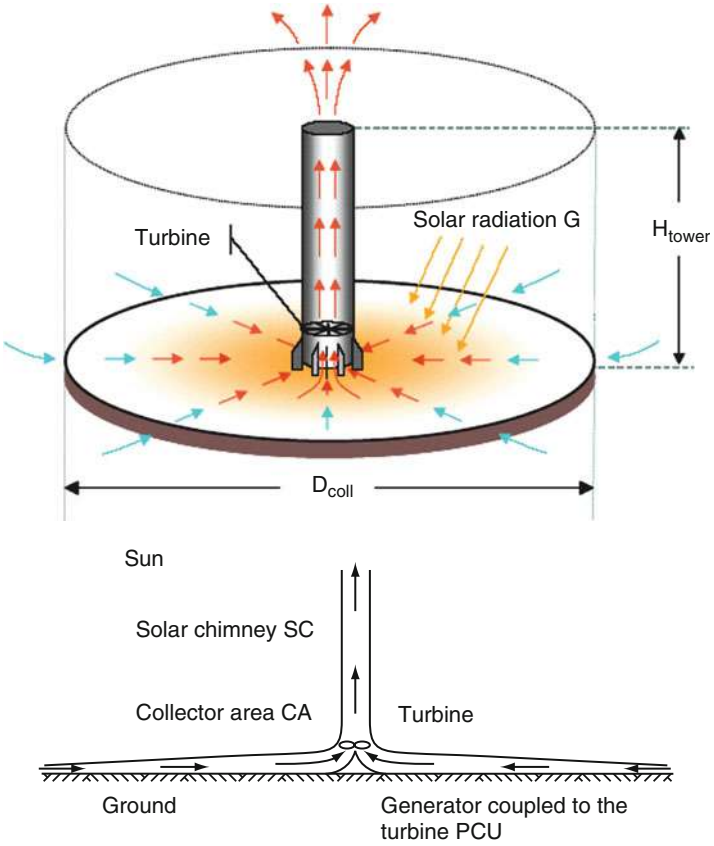

Fig. 28 *Left*: an artist rendering of a 5 MW solar chimney plant (Source: http://www.sbp.de). *Right*: a schematic indicating the main components of the plant (von Backstrom et al. 2008)

the air for a significant time after sunset. The efficiency of the solar chimney power plant is below 2 % and depends mainly on the height of the tower. As a result, these power plants can only be constructed on land that is very cheap or free. Such areas are usually situated in desert regions. However, this approach is not without other uses, as the outer area under the collector roof can also be utilized as a greenhouse for agricultural purposes.

A 200 m high solar chimney demonstration plant based was constructed in Manzanares, Spain (http://www.youtube.com/watch?v=XCGVTYtJEFk). The peak power output of this demonstration plant was 50 kW, and it operated for over 8 years without any significant degradation in performance. However, as with other CSP plants, the minimum economical size of the solar chimney power plant is in the several MW range. Although no pilot plant has been built to demonstrate the viability of this technology in the MW range, computer simulations suggest its promise as a low-cost solar thermal technology. Figure 29 shows the results from

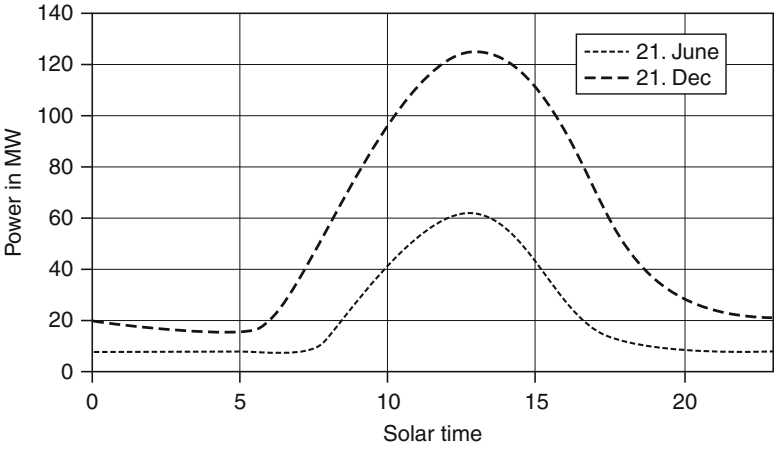

Fig. 29 Simulated results of electrical power output of solar chimney power plant during summer and winter (von Backstrom et al. 2008)

a simulation of a large-scale solar chimney power plant with a 5,000 m collector diameter (~20 km^2 area) and a chimney height of 1,000 m and inside diameter 210 m (von Backstrom et al. 2008). With the vast expanse of unpopulated land in Australia, it may be possible to economically erect a solar chimney plant of this size.

Nonimaging Concentrator Technology

All of the concentrating technologies discussed thus far require some type of active solar tracking in order to account for the change in the elevation of the sun on any given day and throughout the year. Nonimaging concentrators, such as the compound parabolic concentrator (CPC), allow for the use of a non-tracking stationary concentrator that can account for the daily and annual excursion in solar elevation (Meinel and Meinel 1976). Figure 30 illustrates how the light rays in a commercial CPC collector are concentrated when the source is directly overhead (left), such as solar noon on the equinox, and when it is at the acceptance angle of the CPC design (right), such as would be observed during the solstice.

The stationary benefit of the CPC comes at the expense of a concentration ratio of 2 for the design. This is an order of magnitude lower than what can be achieved through the use of a parabolic trough, but it is twice that of a typical flat-plate collector. As such, the CPC design is capable of producing sensible heat at temperatures well in excess of 120 °C, thus making it a good candidate for use with an absorption refrigeration system. It can also be paired with a low-temperature power cycle, such as an organic Rankine cycle, to generate electricity. The resulting system would be fairly inefficient when compared to a dish-Stirling system, but it would have a cost-to-efficiency ratio that would make it attractive for use in rural areas.

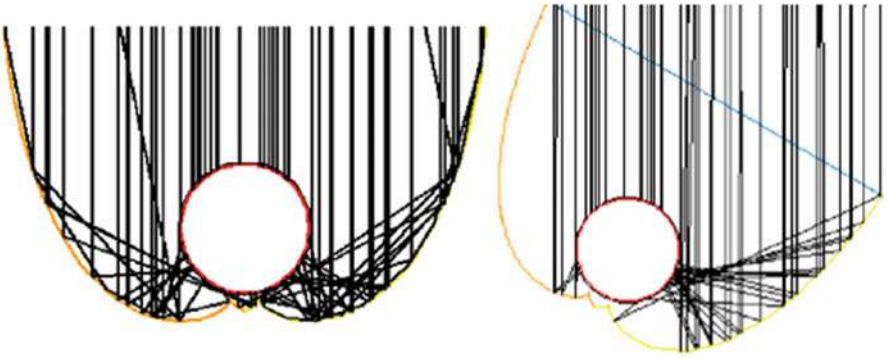

Fig. 30 Ray tracing diagrams for the Winston Series CPC. *Left* – incoming light rays directly overhead. *Right* – incoming light rays at the acceptance angle of the design (Source: www.soalrgenix.com)

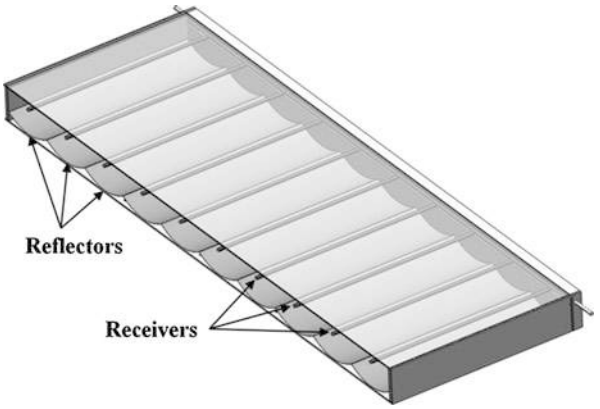

Fig. 31 Cutaway of multiple parabolic trough flat-plate collector

Industrial process heat from solar energy is becoming important in many industries such as pharmaceutical and textile, etc. In this context, the goal is to create a solar collector that can produce thermal energy in the medium temperature range (100–150 °C). To achieve this goal, a collector is designed to emulate features of existing flat-plate and CPC collectors while utilizing parabolic trough collector (PTC) geometry (Pandolfini et al. 2013).

The Multiple Parabolic Reflector Flat Panel Collector (MPFC) applies aspects of a stationary panel with the reflector geometry of a PTC. Multiple parabolic reflectors are arranged in an array within the envelope of the panel (Fig. 31). A tubular receiver is associated with each reflector, collecting the reflected light. The receivers are able to transverse within the panel independently from the reflectors. This allows for collection of concentrated light while the entire panel remains stationary.

The main feature of the MPFC is its moving receiver (which differs from conventional stationary reflector designs). Movement of the receiver is along a

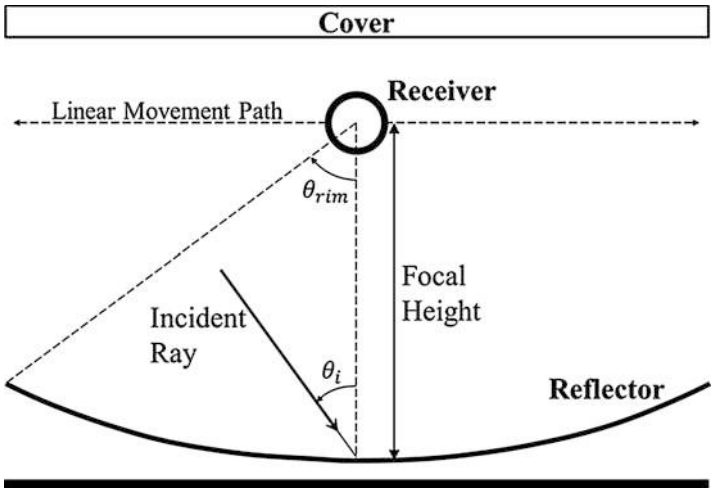

Fig. 32 A schematic of a single section of the MPFC

constant height, located through the focal point of the reflector. A motor controls the movement of the receiver assembly. The motor moves a rack-and-pinion system that in turn moves the receiver array. Position of the receiver must be accurate because it determines the optical gain of the receiver. The placement of the receiver causes some loss of solar energy that is determined by the incident angle of the sun on the reflector, θ_i. However, the reflector and the receiver designs are both optimized to collect solar energy over the course of a year.

Analysis of this new design is based on two parameters that affect the amount of light collected: concentration ratio, C, and rim angle, θ_{rim} (Fig. 32). The concentration ratio is defined as the ratio of the collector aperture area to the receiver's surface area. The rim angle defines the angle swept around the focal point, from the surface normal to the edge of the parabolic reflector.

Ray tracing is used to determine an optimal rim angle. The amount of light accepted by the receiver at concentration ratio of 6 is found greatest for $50 < \theta_{rim} < 60°$. Figure 33 shows the receiver placed at the focal height f. The receiver is allowed to be positioned at any horizontal position at this height. The ideal placement for the receiver is where the edge of the receiver is tangent to the caustic surface with the center of the receiver within the caustic envelope. The relative position of the receiver will change as θ_i changes, seen in Fig. 33.

The MPFC being stationary as the sun moves across the sky enables the receiver to accept varying amounts of radiation with minimal tracking except the receiver tubes move with respect to a parabolic reflector. The simplicity of the MPFC design makes it a cost-viable alternative to other collector types for producing heat at medium temperatures. For example, the levelized cost of energy (LCOE) is estimated at $\$0.006/kWh_{th}$ at a collection temperature of about 125 °C over its lifetime of about 20 years.

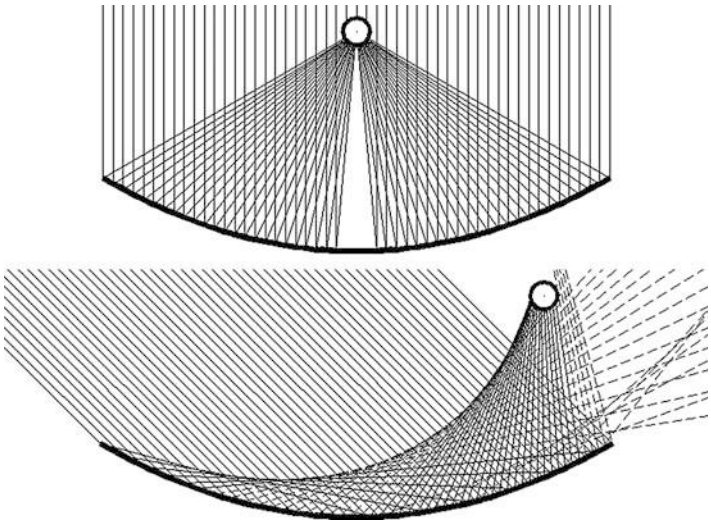

Fig. 33 Reflected rays at $\theta_i = 0^\circ$ (*top*), $\theta_i = 45^\circ$ (*bottom*)

Concentrating Solar Power (Thermal) Systems Economics

The concentrating solar power (CSP) for electricity generation technologies examined in the previous sections is the most dominant and has the greatest potential for commercialization. Current projects are targeted so that they meet specific needs at an economic benefit. Once success is achieved, the price points will come down, and good economics will drive the CSP projects. The following discussion is included here to indicate that CSP is becoming more economically attractive. Component manufacturers, utilities, and regulators are making decisions now that will determine the scale, structure, and performance of the CSP industry. Since each country's approaches to the renewable electricity industry are different, only the observations that are more common globally are included here. When considering the economic viability of CSP, often the levelized electricity cost (LEC) is calculated and compared among different technologies. Therefore, in the following, a general method is given for determining LEC.

The LEC is dependent on many variables related to the site, technology chosen, and the plant financing. The LEC is defined as (Pitz-Paal et al. 2005)

$$\text{LEC} = \frac{CRF \times K_I + K_{OM} + K_F}{E}$$

where

$$\text{CRF} = \frac{k_d(1+k_d)^n}{(1+k_d)^n - 1} + k_i$$

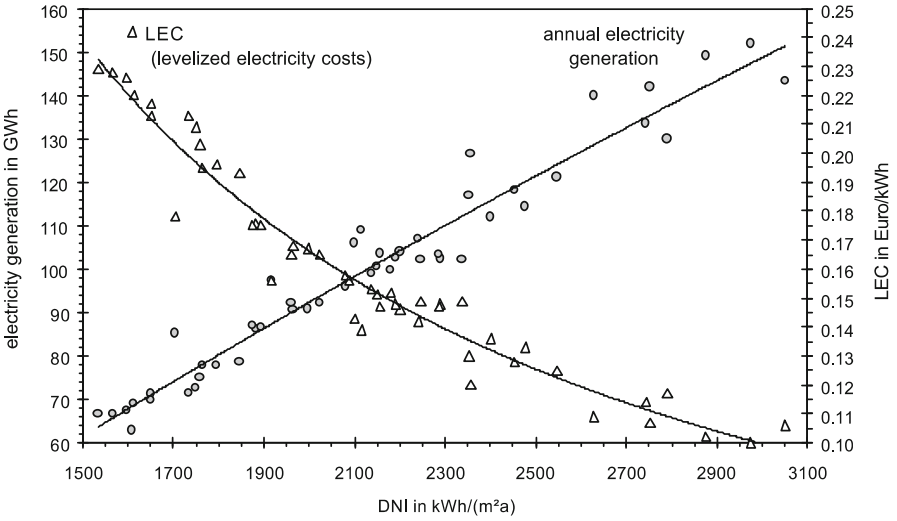

Fig. 34 The variation of annual electricity generation and LEC for a 50 MW_e parabolic trough plant with a 375,000 m^2 solar field for fifty chosen sites (Quaschning et al. 2001)

CRF is capital recovery factor, K_I total investment of the plant, K_{OM} annual operation and maintenance costs, K_F annual fuel costs (any fossil fuel, such as natural gas), E annual net electricity revenue, k_d debt interest rate, n depreciation period in years (~30), and k_i annual insurance rate (~1 %).

The many factors that determine the LEC vary greatly due to government subsidies, tax incentives, and annual net electricity production. One of the key parameters in the above formula is the determination of the annual electricity generation, which depends largely on the available DNI at the plant location. For example, Fig. 34 shows the impact of the annual DNI on the annual power generation and the LEC of a 50 MW_e parabolic trough SEGS type power plant with a 375,000 m^2 solar field. The economic parameters (e.g., discount rate of 6.5 %, solar-field costs of 200 euro/m^2, power block costs of 1,000 euro/kW, and O&M costs of 3.7 million euro per annum) have been kept constant (Quaschning et al. 2001). Although some of the financial data may be outdated, the intent here is simply to show that the annual electricity generation is approximately proportional to the DNI. This suggests that a careful analysis needs to be carried out for the determination of an economically optimized project site that not only depends on the solar irradiance (DNI) but on many other influencing parameters.

The present evaluation estimates (Fig. 35) from a number of sources that the LEC for CSP systems, shown here as cost of electricity (COE), will be around \$0.15–0.20/kWh, assuming a load demand between 9:00 am and 11:00 pm. However, the absolute cost data on many of the CSP systems considered here, and those planned for commercial deployment around the world, is largely unavailable so these numbers must be considered with some caution. Cost reductions

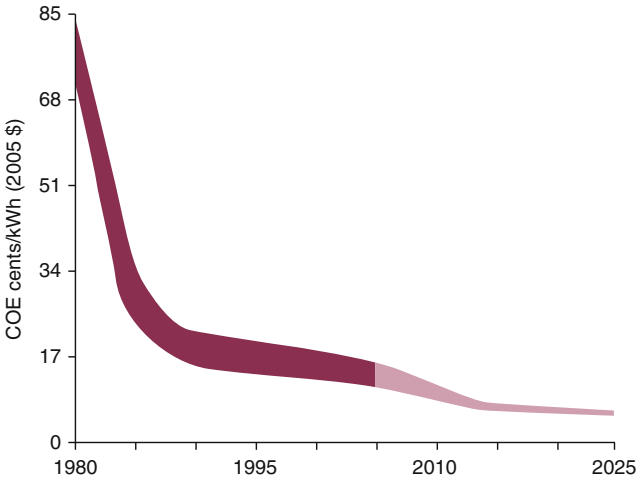

Fig. 35 The variation of the LEC for concentrating solar thermal power (Source: National Renewable Energy Laboratory, USA)

due to technological improvements, such as the implementation of thermal storage, and large-scale deployment are estimated to be around 10–30 % for parabolic trough systems, 20–35 % for central receiver systems, and 20–40 % for dish-Stirling systems (Quaschning et al. 2001). Given the rapid deployment of CSP systems, it is suggested that within the next 5 years, the LEC will be $0.10–0.15/kWh. With the additional benefit of carbon credits, CSP technology is poised to become the dominant solar electricity generating plant development in places where there is good DNI.

Summary and Conclusions

Concentrating solar thermal power (CSP) is a proven technology, which has significant potential for further development and achieving low cost. The history of the Solar Electricity Generating Systems (SEGS) in California demonstrates impressive cost reductions achieved up to now, with electricity costs ranging today between $0.10 and $0.15/kWh. Advanced technologies, mass production, economies of scale, and improved operation will allow for a reduction in the cost of solar-produced electricity to a competitive level within the next 5–10 years. Hybrid solar-and-fuel plants, at favorable sites, making use of special schemes of finance, can already deliver competitively priced electricity today. With over two decades of experience, parabolic trough technology is mature enough that its investment cost estimates can be made with confidence. Given the rapid growth contemplated within the immediate future (mostly in the southwest USA) and medium temperature CSP systems (250–300 °C), it is very likely that the LEC price target of $0.10/kWh may well be met within the next 3 years using the parabolic trough technology. When the

parabolic trough technology is combined with biomass gasification in a hybrid system, the overall plant efficiency will be substantially increased, thus resulting in a relatively low LEC. This is an approach that is ideally suited for regions of moderate DNI (5.2–5.5 kWh/m^2/day) and for distributed power applications (1–5 MW power plants). A greater opportunity lies in the thousands of niche markets that are primed for smaller-scale (1–10 MW) parabolic trough projects at a lower cost.

The central receiver tower (CRT) systems are being pursued aggressively by a number of companies with approaches that mostly differ in the heliostat size. The distributed approach with multiple towers appears to gain prominence because of their lower installation costs. Both parabolic trough and central tower systems benefit from heat storage, especially when the power demand is during off-peak solar hours. The CRT systems are best suited in areas of good annual solar insolation (>2,000 kWh/m^2/year) and utility-scale plant sizes (>50 MW). Because of the steam cycle used in the power block, the water availability can be an issue, especially in desert regions. The problem can be overcome by the use of an air-cooling system, which will have the adverse effect of reducing the overall plant efficiency.

The recent advances made in dish-Stirling systems in improving their solar to electric efficiency in the range of 30 % make them attractive for utility-scale power plant implementation. Because of their small unit electricity output (<25 kW), they are most attractive for distributed applications, especially when hermetically sealed Stirling engines are used as this may result in much lower operation and maintenance costs.

In summary, CSP is poised to become a significant player in the renewable electricity generation in countries where a significant solar energy resource is available, such as those near desert and equatorial regions.

Abstract

Historically, the growth and prosperity of human civilization have mainly been propelled by fossil energy (coal and petroleum) usage. Decades of tested and proven technologies have led to a continuous increase in demand for fossil-based fuels. As a result, we are now finding ourselves at the threshold of a critical tipping point where environmental consequences and global climate can be irreversibly affected and hence cannot be ignored. More than ever before, our unending and rapidly growing need for energy has necessitated urgent action on efforts to examine alternative forms of energy sources that are eco-friendly, sustainable, and economical.

There are several alternatives to fossil-based fuels. These include biomass, solar, wind, geothermal, and nuclear options as prominent and possible sources. All these options can assist us with reducing our dependence on fossil fuels. Solar energy, being one of them, has the unique potential to meet a broad gamut of current global energy demand. These include domestic applications such as solar-assisted cooking, space, heating, as well as industrial processes such as drying. Solar energy utilization in several key areas such as electricity generation (photovoltaics), clean fuel production (hydrogen), environmental remediation (photocatalytic degradation of pollutants), and reduction of greenhouse gases (CO_2 conversion to value-added chemicals) is also of great interest. A key challenge that must be addressed to boost commercialization of solar energy technologies, and common to these applications, is material properties and solar energy utilization efficiency. To realize large-scale and efficient solar energy utilization, application-based materials with a unique combination of properties have to be developed. The material has to absorb visible light and be cost competitive, composed of earth-abundant elements, and nontoxic, all at the same time.

This chapter consists of ten sections. The first introduction section consists of a detailed discussion on the importance of energy in human activity, the effects of fossil fuels on climate and human lifestyle, and materials that meet many of the above criteria. The second section provides a short and critical comparison of solar energy with other alternatives. The third section provides a quick review of the basic concepts of solar energy. The commonly employed toolkits used in the characterization of materials for solar energy conversion are discussed in section "Toolkit for Characterization of Photoactive Materials (PMs).". Some of these tools can be used to evaluate specific optical, electronic, and catalytic properties of materials. Section five discusses the main categories of materials that are either commercialized or under development. The challenges to developing new materials for solar energy conversion are addressed in section "Materials for Solar Energy Utilization". Section "Integrating Tested Concepts of Solar Energy Utilization to Produce Fuels in an Effective Way" outlines some of the main strategies to test the promising materials before a large-scale commercialization attempt is initiated. Section "Commercial Ventures" profiles companies and institutions that are engaged in efforts to evaluate, improve, and commercialize solar energy technologies. This segment provides information about the product from a few representative companies around the world and their niche in the commercial market. Section "Future Work" provides a general outlook into the trend in solar energy utilization, commercialization, and its future. Finally, section "Conclusion" provides the authors' concluding perspective about the solar energy as a pathway for reducing our dependence on fossil fuels. At the conclusion of this chapter, we have also provided over 100 references that are highly recommended for further in-depth study into various aspects of solar energy.

Introduction

Importance of Energy in Human History

Energy has been one of the basic requirements for human activity and has played a pivotal role in human history. Research has been undertaken that correlates the increased availability of energy within a society to its citizens to an increase in the standard of living conditions. The nineteenth century saw the ushering of a technology revolution, a period in time that contributed to a significant improvement in the quality of human life while witnessing an increasing demand for energy in order to maintain these improved standard living conditions. Fossil fuels were critical to the industrial revolution that accompanied technological development during this era. The latter twentieth century saw a rapid increase in the demand for various other forms of energy in different parts of the world. Moreover, it is anticipated that this voracious demand for energy will only increase in the foreseeable future as many more countries of the world strive to improve quality of life for their citizenry (Hultman 2007; Weiss et al. 2009; Rotmans and Swart 1990).

Table 1 2003 US energy consumption

Source	Amount	QBtu	Percent
Coal	1.08×10^9 t	22.6	23.0
Natural gas	21.8×10^{12} ft^3	22.5	22.9
Petroleum	6.72×10^9 bbl	39.1	39.8
Nuclear	757×10^9 kWh	7.97	8.1
Renewable	578×10^9 kWh	6.15	6.3
Total		98.3	100

Present Sources of Large-Scale Energy

The US Department of Energy's 2003 Annual Energy Report divides US energy usage into four main categories with a percentage of the total US 98.3 QBtu/year usage: residential usage (21.23 %), commercial (17.55 %), industrial (32.52 %), and transportation (26.86 %). This same report then proceeds to break down the 2003 US energy consumption which is shown in Table 1.

As is evident from Table 1, fossil fuels (coal, petroleum, and natural gas) make up 85.7 % of the US energy consumption, making them the first and by far the predominantly used sources (Danielsen 1978). The reason for a predominantly fossil-fuel-based economy is that (1) the technologies and infrastructure using fossil-based fuels have been well developed over several decades and (2) the comparatively lower cost of fossil fuels in relation to other types of energy sources.

The next highest US energy consumption after the fossil fuel is nuclear energy. Nuclear energy has been extensively exploited as an energy source in several developed countries as an alternate to fossil fuels and is a promising eco-friendly energy source for large-scale applications (Lenzen 2008; Germogenova 2002). However, nuclear energy has a high capital cost, vulnerability to man-made disruption, and the potential to be used for destructive purposes. Furthermore, a tremendous challenge lies in changing negative public perception about nuclear technology, stemming from perceived danger due to prior unfortunate nuclear-related incidents in Chernobyl, USSR, and Three Mile Island, USA. It is to be noted that the trend in the United States' energy consumption has been reflected in several developed countries as well.

Issues with Large-Scale Usage of Fossil Fuels

In spite of the availability of several energy sources for large-scale usage, fossil fuels have been one of the most cost competitive, easily accessible, widely available, and therefore a more attractive option. It continues to be the primary form of cheap energy source in many countries with wide-ranging economic portfolios. However, with the continued use of fossil fuels coupled with a demand, their detrimental impact on climate and environment has forced us to reexamine the viability of relying further on this form of energy as mankind's primary resource for the future. Speculated major concerns are climate change, health hazards, and potential for

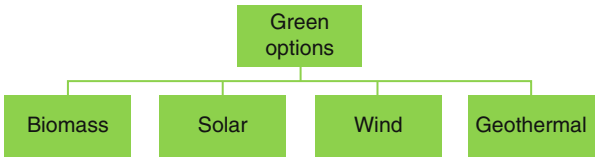
Table 2 Issues with continued reliance on fossil fuels as a primary resource for mankind's energy needs

Problem areas for fossil fuels	Specifics	Description
Climate change issues	Global warming	Emission of greenhouse gases such as CO_2 traps solar heat which raises atmospheric temperature
	Sea level rise	Rise in sea levels due to global warming can lead to flooding of low-lying areas
	Alternation of weather pattern resulting from temperature change	Draughts, floods, hurricanes, and tornados can critically impair local/regional economic activities such as agriculture and even lead to displacement of the population
Health hazard	Tailpipe/stack emissions	SO_x, NO_x, and particulates in emissions can reduce air quality by promoting smog formation which may lead to health hazards such as lung cancer
Economic risks	Unsteady supply of increasingly finite resources	Increasing demand for finite resources can lead to spiraling prices (price fluctuations) that can hurt or even stunt economic growth
Others	Geopolitical instability	Extreme reliance on very few sources where political situation can become unfavorable
	Man-made disruption	Disruption of stable supply of energy due to activities such as terrorism
	Land destruction	Environmental impact on local animal and plant life

economic chaos. The details of some leading concerns regarding continued dependence on fossil fuel as a primary resource are listed in Table 2.

Need for an Alternate Energy Focus

A closer look at other alternatives to meet mankind's demand for energy is urgently needed. The reasons cited in Table 2 highlight the need for a serious reexamination of mankind's approach to identifying, researching, and implementing possible options of energy resources. The key criteria for choosing an alternative energy form are: (a) sustainability, (b) eco-friendliness, (c) availability, (d) cost (capital and operating), (e) political will to change status quo by modifying governmental public policies, (f) population support, (g) technological reliability, and (h) safety aspects. It has to be first understood that no single form of energy can offset fossil-fuel usage completely and continue to meet the rising demands globally. It is also perhaps a smart decision to avoid focusing on just one form of alternate energy, but explore a diversified energy portfolio. It is generally agreed that an energy portfolio containing a mix of various forms of non-fossil-based alternative ranked using the above criteria should be tailored based on region- or country-specific needs.



Scheme 1 Green energy options that have potential to meet global energy needs

Options Available to Us

There are several non-fossil-fuel-based alternatives that have been examined as possible energy sources (Tester et al. 2005). The United States and Europe are leading the effort in examining the induction of non-fossil alternatives into mainstream energy sector. However, there is still a long way to go in this direction. For example, current US consumption of renewable energy forms – wind, biomass, geothermal, and solar – is 6.3 %, a very small fraction of the total 98.3 QBtu of energy used by the United States. Some of the pros and cons of these green alternatives are discussed next.

Wind Energy

Wind power is broadly defined as the conversion of wind energy into a useful form of energy-utilizing machinery such as sailing vessels, windmills, and wind turbines (Scheme 1). Wind energy shows promise as a replacement for fossil fuels as an energy source; theoretical estimates indicate that global output from wind can be the equivalent of ~5,800 quads of energy per year (AWEA 2010) (1 quad = 172 million barrels of oil =425 million tons of coal). Moreover, wind power has certain advantages over other renewable forms of energy such as solar energy, for the wind can blow day and night, sunny or cloudy, and often is strongest during dark, overcast winter storms when energy is needed for heating and getting solar energy is not possible.

However, wind power also has its limitations. Many devices that convert wind energy need specific wind velocities to work efficiently, and as a result, these specific wind velocities are often location specific, limiting the areas in which wind energy conversion devices can be used. Furthermore, contentious issues such as potential harm to endangered birds due to the rotating blades, noise concerns, health concerns, and the effects on aesthetics of the landscape due to the presence of several hundred windmills in a farm need to be resolved. Countries such as the United States (Knoll and Klink 2009) and England (Price et al. 1996) are seriously considering or have projects underway to harvest wind energy. The data from such case study locations should be carefully examined and appropriate changes have to be made to address the aforementioned concerns to exploit wind energy on a larger scale.

Biomass Energy

Biomass is a renewable energy source because the energy it contains comes from the sun. Plants capture the sun's energy via the process of photosynthesis. Photosynthesis converts carbon dioxide from the air and water from the ground into

carbohydrates, complex compounds composed of carbon, hydrogen, and oxygen. Later when these carbohydrates are combusted, fermented, or gasified for energy utilization, they turn back into carbon dioxide and water and release the sun's energy that they contain. Through this cyclic process, biomass functions as a sort of natural and potentially infinite battery for storing solar energy. Depending on the biomass source and method used for releasing the captured energy, biomass energy can have the potential to supply 79 QBtu of energy (this is 80 % of the US energy consumption). However, in order to reach this output, the current 350×10^6 acres of land being harvested in the United States would have to be used solely for biomass production. This leads to the main disadvantage of biomass – the land needed to produce the biomass often leads to competition with land for food, destruction of forests, and with some biomass technologies, such as ethanol, food crops are used directly (Sanderson 2007). However, biomass from solid maniple waste and new research investigating biomass produced from nontraditional sources such as coffee waste or algae-based biofuel production possibly positively influence technological and commercial advances within this field (Oliveira et al. 2008; Kondamudi et al. 2008).

Geothermal Power

Geothermal power utilizes the continuous flow of heat energy from the hot interior of the earth to its surface, by means of space heating and the generation of electricity. Unlike fossil fuels, biomass, wind, and solar, geothermal has the capacity to sustain itself in a continuous closed-loop system using heat from the earth's crust.

Moreover, the world's geothermal energy reserve is recorded at 10^8 QBtu, a million times the total yearly US energy consumption. Unfortunately, current geothermal energy is limited by locations where natural reserves occur and the heat energy can be tapped in a commercially viable manner; however, there are new technologies being researched, such as the Normal Geothermal Gradient and Hot Dry Rock technologies, which would expand geothermal usage tremendously.

Solar Power

It is to be noted that solar energy can be considered as the indirect source for wind (solar-driven temperature changes cause wind movement) and biomass (chlorophyll pigments absorbing sunlight to grow plants/biomass). However, we do not focus on that aspect often when we talk about solar power. Solar power harnesses the radiant light and heat given off by the sun and is unquestionably the most universally available and least utilized form of renewable energy resource. It is estimated that the earth receives 162,000 TW of energy from the sun (Ginley et al. 2008). If one assumes that earth has a land mass of approximately 20 %, the fraction of energy reaching land is ~32,400 TW, a fraction of the world's yearly energy consumption! If it is possible to build systems that can harness this solar energy, it could solve mankind's energy problems. However, the biggest challenge is the development of materials that can economically and efficiently convert solar energy into useful forms at a commercially viable efficiency. This chapter focuses on solar energy

and some of the factors that are pivotal to using solar energy as a resource for meeting global energy needs.

For further details on these topical areas, the readers are referred to four chapters on biomass and one chapter on wind energy in this text.

Solar Energy

The following sections assume that the reader already has a fundamental knowledge of solar energy. For a review of these concepts, there are numerous publications in circulation that cover these fundamentals in greater detail.

What Is Solar Energy?

Solar radiation consists of light of different wavelengths (energy). The energy associated with each wavelength can be estimated using the equation $E = h\frac{c}{\lambda}$, where E = energy (eV), h = Planck's constant (6.6×10^{-34} J s), λ = wavelength of light (nm), and c = velocity of light (3×10^{8} m/s). As the wavelength of light increases, the energy associated with that wavelength decreases. Solar energy received at the surface of the earth also depends on the location (zenith angle) and effects of atmospheric interference (pollution or turbidity). In general, the irradiance at the surface reduces toward the poles and increases with atmospheric pollution. The solar spectrum can be divided into several regions. These include far-UV (<200 nm), UV (200–400 nm), visible (400–700 nm), infrared (700–1,400 nm), and far-infrared (>1,400 nm). The distribution of energy associated with sunlight can be identified to different regions and may be approximated as UV <5 %, visible ~40–50 %, and the rest being infrared. The heat associated with the solar energy can be attributed to the infrared part of the solar spectrum. Photoactive materials involved in solar energy conversion respond to the irradiation by absorbing solar energy and undergoing electronic and/or chemical transformations. The primary step is a process of generating oppositely charged species called excitons or electrons and holes (Bahnemann 2004; Mills et al. 1993). A secondary process may involve production of electricity (flow of electrons) or initiation of chemical reactions that result in product(s) that have energy applications.

Advantages/Disadvantages of Solar Energy

Just as the other forms of energy resources have advantages and limitations, solar energy has its own set of benefits as well as drawbacks. These points are compared in Table 3.

Table 3 Advantages and disadvantages of solar energy

Advantages	Disadvantages
1. Universally available, infinite energy source, and free. Complementary technologies ensure continuous availability	Large area required to produce sizeable power (may not be possible to harvest solar energy in densely populated areas)
2. Clean eco-friendly, very low maintenance, supports local economy "*green jobs*," and does not contribute to global warming	Some materials used currently in solar energy conversion can be expensive and toxic and may require carefully planned disposal protocols
3. Sustainable and free of geopolitical instabilities. No security issues	Weather patterns can be a source of unpredictable interference
4. Political support and incentives to switch to solar energy systems are favored in many countries	Public awareness about incentives (rebates) and education is still low and needs a significant boost
5. Solar energy usages range from food processing (solar cookers) to large-scale electricity generation	Solar conversion efficiencies in most applications are low. Efficiency improvement via materials development is a key challenge

Applications of Solar Energy

Traditionally, the most common forms of solar energy usage have been harvesting the heat associated with the solar radiation, which is later utilized in applications such as cooking, space heating, and drying. Many of these applications have undergone technical refinement over time leading to cost competitive, efficient, and wide-scale usage. A brief discussion on some of these applications is presented in section "Principles of Solar Energy Utilization." Figure 1 shows the breadth of applications that employ various aspects of solar power. Since the 1900s, efforts to use solar energy for energy generation involved focusing on the direct production of electricity, liquid, and gaseous fuels utilizing solar energy. Of particular interest, and also a great challenge, is using solar energy to sequester CO_2 for producing value-added products such as fuels and control its emissions into the environment at the same time. The objective is to address two of mankind's fundamental challenges: provide sustainable energy and reduce impact on climate. Due to the criticality of these challenges, CO_2 control using solar energy is an emerging area of research.

From an environmental perspective, the applications of solar energy in waste treatment cannot be ignored. Photocatalytic degradation of a wide variety of gas-phase and liquid-phase pollutants assists in keeping the atmosphere and water bodies clean. This process involves the destruction of potentially toxic materials through a series of steps into relatively benign intermediates and later into CO_2 and water. Depending on the nature of the pollutant(s), the application of solar energy for environmental protection can therefore be a simple and cost-effective method to treat recalcitrant materials. A limited discussion of this aspect of solar energy utilization is provided later (sections "CO_2 Conversion," "Example 1: Integrated Organic Waste Treatment and Fuel Cell System," and "Example 3: Bioprocesses to Convert Waste to Energy Using Algae").

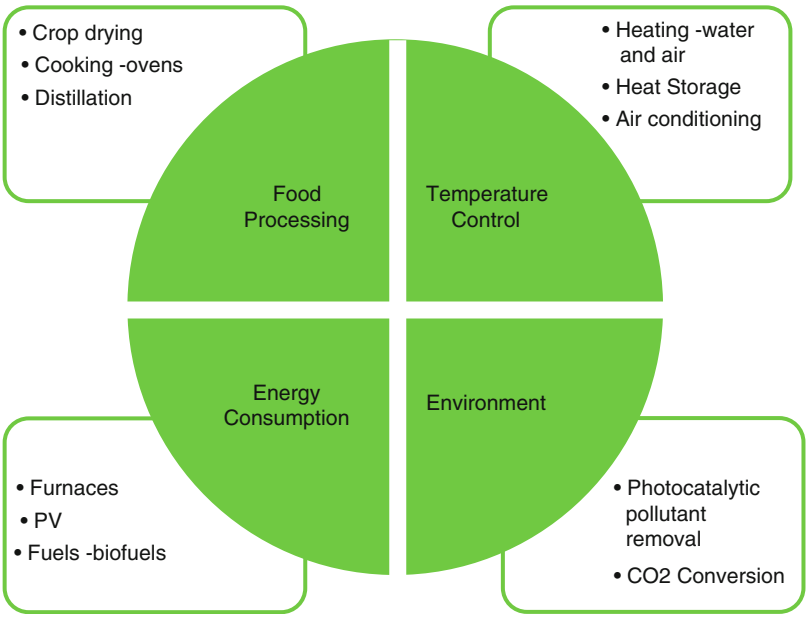


Fig. 1 Solar energy can be utilized in a wide range of applications from processing of agricultural precuts to energy generation to environmental remediation

Principles of Solar Energy Utilization

This section discusses the principles of solar energy utilization in commonly used applications such as water purification, residential heating, food processing, biofuel production, photovoltaics, water splitting, and CO_2 conversion to hydrocarbons.

Space and Water Heating

Space heating is often used in residential and commercial areas (Bezdek et al. 1979; Sakai et al. 1976; Kulkarni et al. 2007; Kalogirou 2009; García-Valladares et al. 2008; Han et al. 2010). The process involves utilizing heat from the sun in order to provide comfortable living conditions in an eco-friendly manner. Space heating involves careful planning of the design of structures based on the orientation of the sun. The differences in the densities of warm and cold air are exploited to cause an artificially induced circulation in a confined space. The roof can be slanting or flat and made of partially transparent glass, permitting natural illumination. The principle design of one form of a well-designed space heating system, including the general steps involved, is schematically illustrated in Fig. 2a. A slight variation of this concept can also be used in heating water. A typical setup may include off-the-

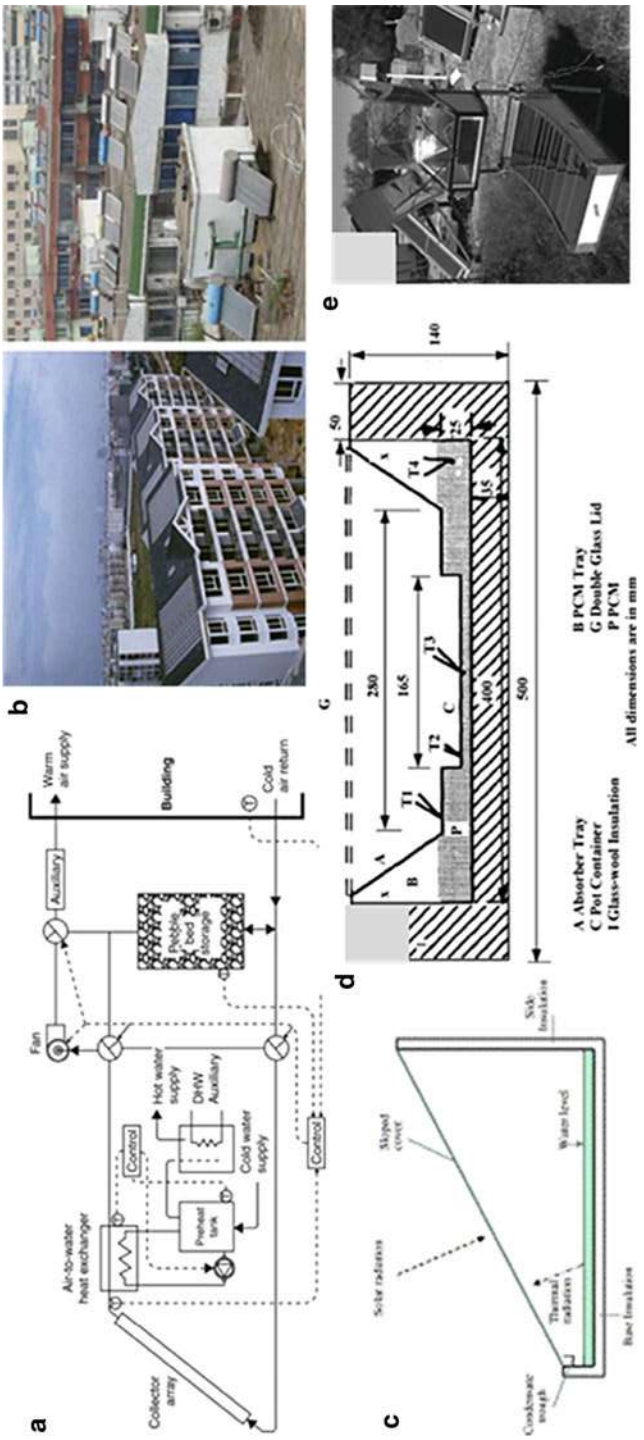

Fig. 2 The use of solar energy in several applications has been studied extensively. Here are some examples where solar energy is utilized in (**a**) large-scale and (**b**) small-scale portable water heater, (**c**) solar still, and (**d**, **e**) solar cooker. Refer to section "Principles of Solar Energy Utilization" for details (Reprinted with permission from Elsevier)

shelf metallic heat-conducting tubes that carry water through a blackened enclosure exposed on one side to solar radiation. This produces water fit for domestic use. Figure 2b shows the pictures of solar water heating apparatus on the roofs of buildings in China. Benefits of employing such eco-friendly approaches may include significant cost savings in utility bills, reduced illumination costs, reduced dependence on fossil-based fuels, and protected earth's climate by minimization of carbon footprint.

Water Purification Using Solar Stills

Solar stills (or solar distillation) are used for producing portable water from impure and/or scarce water resources (Kaushal and Varun 2010; Tiwari et al. 1996, 2003; Khalifa and Hamood 2009). A solar still can be used in places with little or no infrastructure such as deserts, regions with mines that have potential ground water contamination, in areas that have frequent disruptions in utilities (power and water supply), and as an emergency survival kit. The principle of operation of a solar still is shown in Fig. 2c. Heat energy from the sun facilitates evaporation followed by condensation of water. The still consists of a lower darkened region with a transparent cover (glass or polymer) placed at an inclination that allows solar radiation to pass through. The bottom of the still often houses the impure water and can be maintained dark if needed to maximize absorption of heat from the sun. The source of this water can be groundwater, industrial effluents, agricultural runoffs, wastes from poultry/diary, or other sources. The absorbed heat is transferred to the water which evaporates and then condenses on the inner side of the cover. The condensate trickles down along the slope of the cover and collects in a separate reservoir, providing water fit for consumption. Since water has to be boiled to kill microorganisms such as bacteria, a solar still may not be able to do this effectively as boiling is not always achieved at the still operating temperatures. One can fabricate a crude still using materials such as transparent plastic, a water-resistant darkened polystyrene sheet, and stones.

Food Processing

Solar energy can be used in cooking, drying of organic matter, and in the elimination of pests that threaten crops (Sharma et al. 2009a, b; Tiwari et al. 1994; Harmim et al. 2008). Solar cookers are the simplest form of food processing equipment. The concept is similar to a solar still or solar water heater. Incident as well as reflected sunlight is absorbed by a dark vessel that contains the food material that has to be cooked. A simple solar cooker can be made of a wooden box, with a glass wool liner and aluminum reflector sheets. A schematic representation of a solar cooker is shown in Fig. 2d. Figure 2e shows a photograph of a household solar cooker. Solar cookers can be especially effective in countries along the equator since they receive significant amounts of solar radiation for a better part of the day peaking right around the

midday periods. Therefore, solar radiation can be easily used to cook a midday lunch in a reasonable time. Larger area solar dryers consist of wooden boxes with ventilation holes in the sides. These holes assist in air circulation. Dry air carries the moisture generated from the organic matter outside. The top of the box is covered with glass or flexible polymeric materials at a latitude-based angle to allow maximum sunlight. These boxes can be used to dry organic matter: fruits, vegetables, or fish.

Solar-Assisted Biofuel Production

Fuels obtained from a biological source such as an organic matter (plants and waste matter) are called biofuels: (Hou and Zheng 2009; Vorayos et al. 2006; De Falco et al. 2009) vegetable oil (biodiesel), bioalcohols (ethanol), and biogas (methane) are common examples (Hou and Zheng 2009; Vorayos et al. 2006; De Falco et al. 2009; Peterson and Hustrulid 1998). The principles involved in the production of these biofuels vary vastly depending on the type of approach used for the biofuel production. However, common to all these processes is the (1) cyclic nature of CO_2 from the sunlight being utilized by a plant to the utilization of this stored energy and (2) the requirement that a catalyst drives this reaction. Figure 3 illustrates the different types of catalyst-driven reactions. Among the four pathways shown in Fig. 3, pathways I and II are benefited due to solar energy usage in the left side. Solar energy is absorbed by catalysts such as chlorophyll to form chemical energy in vegetables and plants. This in turn can be converted using appropriate catalysts to biodiesel and/or ethanol. The carbon cycle for an energy crop produced from the rape plant is shown in Fig. 4a. Solar energy is utilized in pathways III and IV to drive products in the right side. Path III utilizes microorganisms such as algae which drive the photoconversion of CO_2 to value-added fuels. In pathway IV, redox chemistry at the photocatalyst surface is central to the conversion of CO_2 to value-added chemicals. The development of biofuels using solar energy is very promising, and this approach to solar energy conversion can be a major player in the energy mix for the future.

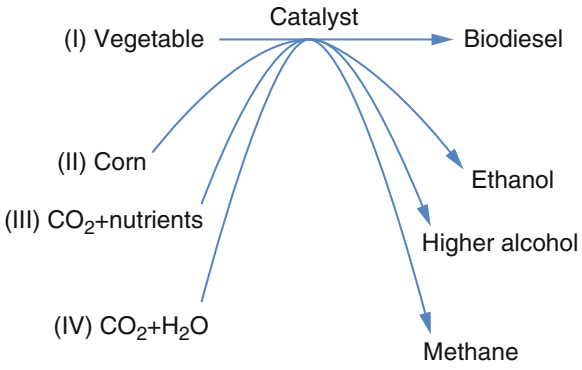

Fig. 3 The production of biofuels can be carried out using different raw materials in the presence of a catalyst

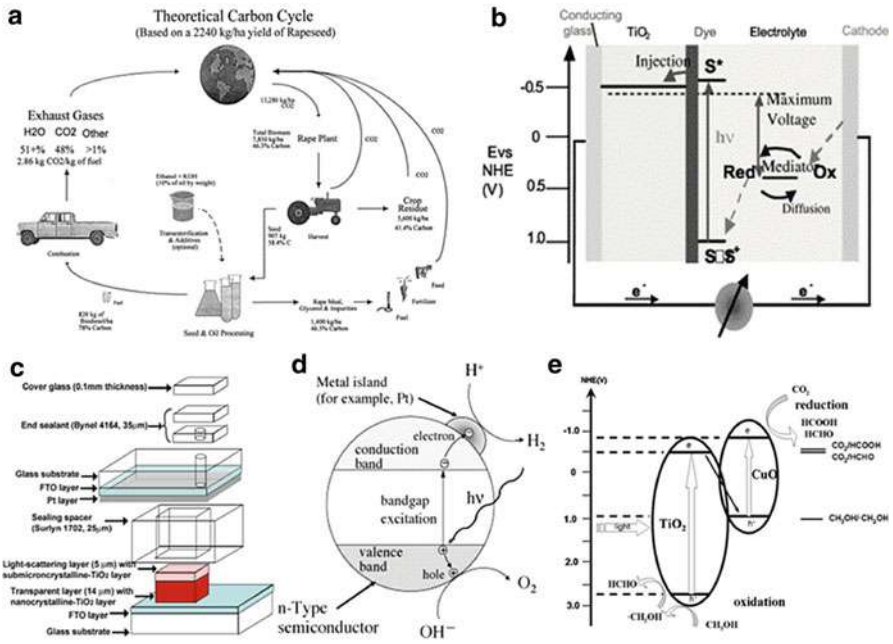

Fig. 4 (**a**) Schematic of the steps involved in biofuel cycle, (**b**) the process of solar energy conversion to electricity using a PV device, (**c**) the exploded view of a dye-sensitized solar cell, (**d**) mechanism of redox processes in a photocatalyst, and (**e**) CO_2 photocatalytic reduction using solar energy over a semiconductor oxide photocatalyst (Reprinted with permission from Elsevier)

Solar Photovoltaics (PV)

A photovoltaic device converts solar energy to electricity through two main steps: the energy from the solar radiation is absorbed by the photoactive material(s) to produce excited electrons, and these electrons then tunnel through the material to the external circuit to generate a photocurrent (Bube 1990; Server 2010; Takeda et al. 2009; Landi et al. 2005; Ito et al. 2008). Figure 4b shows the operating principle of a solar cell based on a combination of an inorganic material called titanium dioxide (TiO_2) and a visible light-absorbing dye. Figure 4c shows the parts of a dye-sensitized solar cell. In this system, electron–hole pairs are generated due to the light absorbed by the dye, and it tunnels though an underlying TiO_2 layer to a collecting conducting glass substrate. An electrolyte is present between the anode (conducting glass) and the cathode of a PV device. The role of the electrolyte is to function as a redox couple and facilitate replenishing of the charges at the photoanode. Composite systems are often used to (1) improve light absorbance, (2) promote charge separation, and (3) increase the overall performance efficiency of the solar cell. Tandem cells, inorganic composite-based solar cells, and dye-sensitized solar cells are some examples of popular photovoltaic devices. An ideal solar cell is one which is able to absorb most of the solar radiation (usable parts

of the solar radiation are ultraviolet, visible, and infrared) and generate electricity with a high level of solar-to-electric power conversion efficiency (η). Investments in the area of solar photovoltaics have been growing at an incredible rate in the last decade (REN21-Secretariat 2010). Improvement in technology, low material and processing costs, and political incentives have been identified as the major factors contributing to solar PV growth in developed as well as developing countries.

Photocatalytic Oxidative (Water Splitting) and Reductive (CO_2 → Fuel) Reactions

Solar energy can be used to drive different types of chemical reactions yielding many value-added products (Kudo and Miseki 2009; Aroutiounian et al. 2005; Matsuoka et al. 2007; Teramura et al. 2010; Anpo et al. 1995; Qin et al. 2011). Water splitting, CO_2 control, and environmental remediation are popular examples of such solar-driven reactions. The principle behind these different reactions is essentially the same. In a photocatalyst surface, both oxidative (electron liberating) and reductive (electron gaining) reactions can occur simultaneously as shown in Fig. 4d. In either type, the photocatalyst driving the reaction has to straddle the reaction of interest if it were to be performed without the application of an external electric field or bias. In photooxidative reactions such as water splitting and environmental remediation using oxidation, hole or hydroxyl radicals generated at the valence band of the semiconductor are often the main participating agents. Photocatalytic water splitting involves the hydrogen formation at the cathode and oxygen formation at the anode. Reduction reactions are performed by the electrons at the conduction band. Examples of reductive reactions include CO_2 reduction to hydrocarbons such as methane, methanol, or methyl formate (Fig. 4e) and reductive precipitation of toxic heavy metals such as mercury and cadmium from waste streams. For a detailed discussion on the mechanistic aspects of the redox reactions on a photocatalyst surface, readers are referred to a few representative reviews in the literature (Bahnemann 2004; Mills et al. 1993; Hoffmann et al. 1995; Linsebigler et al. 1995; Fujishima et al. 2000; Gogate and Pandit 2004; Mor et al. 2006; Rajeshwar et al. 2001).

Toolkit for Characterization of Photoactive Materials (PMs)

Photoactive materials or PMs for solar-to-energy conversion can be simple (consisting of one element or compound) or complex (consisting of several materials in the form of a composite). Often, synthesis procedures for complex PMs employ preformed materials as building blocks. To improve the performance of the PMs, one has to examine surface, optical, electronic, and catalytic properties of the material (s) as they start to take the desired shape or form. There are several tools that can be employed to evaluate material properties at various stages of synthesis. Some of these stages include formation, phase transformation, growth, photoactivity before and after integration with other materials, and performance after the entire device has

Table 4 Optical, surface, and electrochemical measurements that can be performed to determine the properties of photoactive materials

Category	Instrument	Purpose
Optical	Spectrometer	UV–vis absorption
	FT IR	Interaction with other materials (composite formation), synthesis progress
Surface	SEM, TEM, HRTEM	Surface morphology (shape, size, aspect ratio), crystallinity, size distribution
	BET	Surface area
	TGA-DSC	Thermal stability, phase transition properties
	XRD	Crystallinity, compound formation
	AFM	Surface properties (morphology, roughness) of films
Electronic	V_{OC}, I/t, V/t, I/V	Photoelectrochemical properties (of interest in, e.g., PV, photoelectrocatalytic water splitting), Mott–Schottky, band edges
	Incident photon to current efficiency	Effectiveness of materials to convert solar to electric energy

been fabricated. Table 4 is a list of some common tools used to evaluate material performance. A detailed description of some of these tools is also provided below. (Note: For brevity, only commonly used tools representing each of the three categories below are discussed.)

FT IR Fourier transform infrared spectrometer, *SEM* scanning electron microscope, *HR(TEM)* high-resolution (transmission electron microscope), *TGA-DSC* thermogravimetric analyzer-differential scanning calorimeter, *XRD* X-ray diffraction, *AFM* atomic force microscope, V_{oc} open circuit potential, *I/t* current–time, *V/t* voltage–time, *I/V* current–voltage

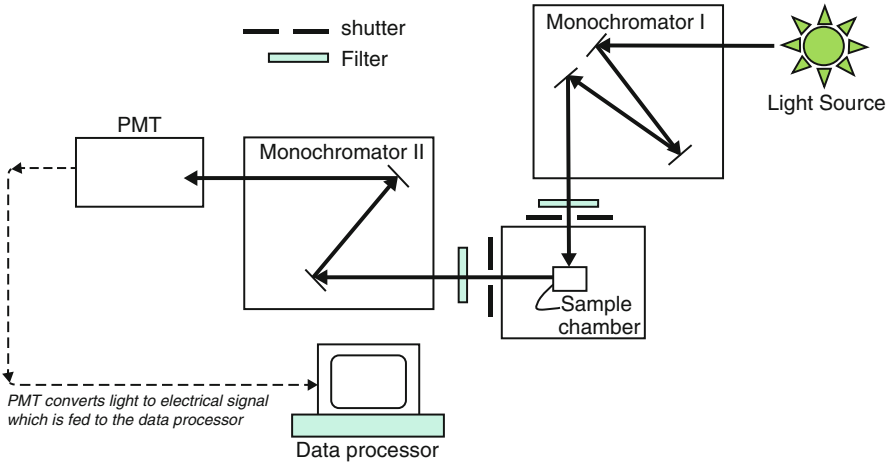
Photoelectrochemical Measurements

PMs produce charge carriers such as electrons and holes on photoillumination. These charge carriers are the basis of any activity involving the PMs. A knowledge of electron–hole transport in photoelectrochemical systems is critical to designing nanostructured materials (especially composites) with high efficiency. Factors that may contribute to altering this efficiency of charge generation are the composition of the nanostructure, film thickness (if it is a film), light intensity, electrolyte, and its concentration. An essential requirement in a photoactive system is the need to maximize the separation between the photogenerated charges. Careful consideration of other aspects such as mode of illumination (front and back faces for films), which depends on the film thickness, decides the extent of light conversion. Photoelectrochemical techniques provide the necessary means for the evaluation of a nanostructured photoactive composite to maximize light energy conversion and its application in energy production. In the case of films, the commonly used setup

for the electrochemical measurements involves a light source (solar simulator), appropriate filters to control light intensity and wavelength, and a cell consisting of three electrodes. The PM to be analyzed is deposited as a film on a conducting medium and is called the working electrode. It is flanked with a reference and counter-electrode. The activity of the PM can be determined in the presence of white light and/or light of different wavelengths. Electrochemical measurements typically involve the estimation of the open circuit potential (V_{oc}), current–voltage characteristics (cyclic voltammetry), and the estimation of efficiency. These measurements can provide information on the effectiveness of the photoelectrode to perform solar-to-electric power conversion, water splitting, or fuel production (CO_2 to value-added chemical). Efficiency is calculated in the form of incident photon to current conversion efficiency (IPCE). IPCE and other optical tools can provide information about what material is contributing to photoactivity and which region of the solar spectrum is effectively utilized. Further details of these types of analysis and the features of the plots obtained in these measurements are discussed in an earlier work (Subramanian 2007).

Spectroscopy

Spectroscopy chiefly involves absorption and fluorescence measurements (Lakowicz 2006; Workman 1998). Most of the materials participating in solar-assisted energy production can include metals, semiconductors, insulators, polymers, organic dyes, and composites of materials from these groups. These materials can exhibit absorption to varying degrees and in different regions of the light spectrum. Absorption spectroscopy is therefore an invaluable tool to probe the optical properties of the photoactive material. In the nanometer size, materials demonstrate interesting optical properties. For example, noble metals exhibit unique properties due to the development of plasmon band. Semiconductors exhibit size-dependent optoelectronic properties called quantization effect. While most of the materials exhibit absorbance, a few materials demonstrate fluorescence. Fluorescence involves energy liberated by a photoactive system when charge/energy exchange between a material and surroundings leads to the material transitioning to a steady base (unexcited state). If a material is fluorescent, conventionally both fluorescence and absorption spectroscopy is used. The layout of a fluorescence measurement system is shown in Scheme 2. Typically, the material absorbs light of a higher energy, and the emission from the material, usually of lower energy, is probed at an angle of 90° to the incident beam. Complementary usage of fluorescence and absorption for probing interactions in composites (such as TiO_2–Au) is generally applied for photoactive materials and enables a deeper understanding of the interactions in the composite. Charge transfer processes, ground and excited state interactions' bonding, and complexations between interacting molecules are some of the aspects studied using these optical techniques.



Scheme 2 Simplified layout of a general spectrofluorometer

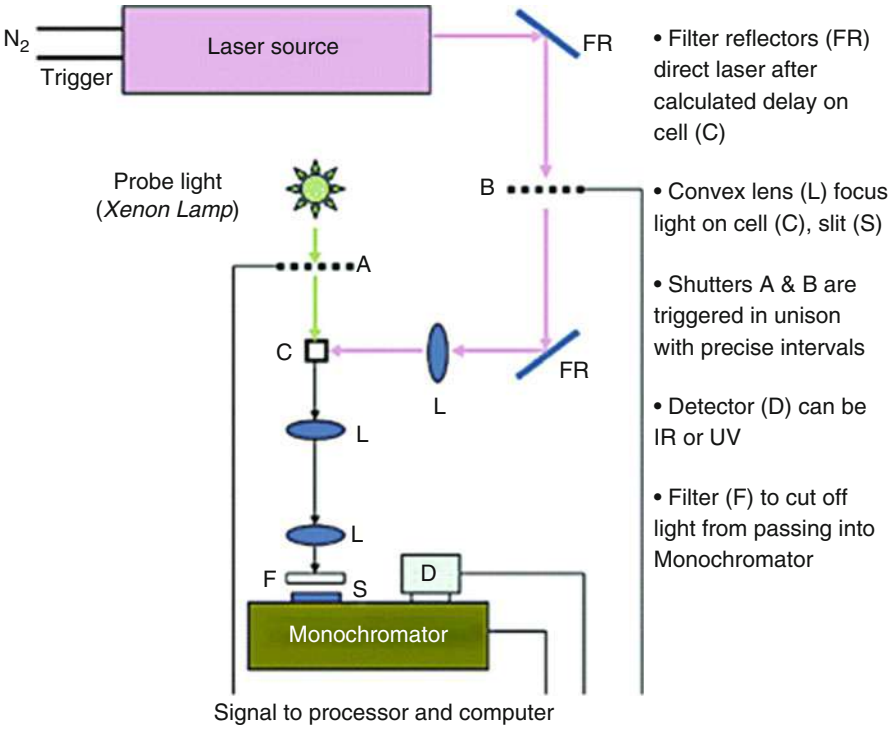
Transient Studies

Several composites can display interactions in the sub-second time domain. These interactions usually take place by charge and energy transfer and could be in the order of micro-, nano-, pico-, and femtosecond time domains. A flash photolysis study which is primarily carried out to elucidate this mechanism involves an elaborate setup consisting of an array of optics (lens, filters, photomultipliers, and monochromators) and a light source. While the source is a laser beam of known wavelength which initiates the materials in the composite to excited state, a probe beam (usually from a xenon lamp) is used to investigate the changes due to the incident monochromatic light. Scheme 3 shows a typical laser flash photolysis setup. Transient study plots are designated as difference absorption spectra (Kamat et al. 2002; Bahnemann et al. 1997) and help one to shed light on the dynamics occurring in the sub-second timescales. Pulse radiolysis (for steady state one can use γ-radiolysis) is employed to observe the effect of highly reactive species such as hydroxyl radicals and aqueous electrons on a composite system. Bombardment of water with high-energy ionizing radiation produces reductive and oxidizing species as shown below.

$$H_2O \rightarrow e_{aq}^{-} H^{\bullet}, H^{\bullet}, H_2, H_2O_2, H_3O^{+}, OH^{-}$$

Reactivity of a certain radical with the semiconductor–metal composite can be observed by selectively scavenging out other radicals from the system using different agents.

The above section provides an overview of different techniques that can be used to determine the photoelectrochemical properties of materials. Several of these techniques can be performed by a reasonably well-trained student. These techniques can be used as a screening step to determine the use of a material for a certain application.



Scheme 3 Schematic of the laser flash photolysis setup for probing charge transport dynamics in the sub-second timescale using a nitrogen excitation laser (337 nm)

Materials for Solar Energy Utilization

Photoactive compounds or composites have to pass a set of very stringent criteria to qualify as a material for solar energy utilization. This section discusses some of these criteria. A brief overview of the methods that can be used for the synthesis of photoactive materials and device fabrication is discussed. This is followed by a summary of the state of various popular photoactive materials and their limitations. The materials used in PV, water splitting, and CO_2 conversion applications are discussed in detail toward the end of this section.

What Is the Holy Grail in Photocatalysis?

The properties that one has to look for in materials for photocatalytic applications include: solar response, availability, toxicity, processability, compatibility, stability, cost, and recyclability. Specific details of these aspects are listed below:

- Response to wide range of wavelengths in solar radiation (ability to effectively utilize maximum parts of the solar spectrum).
- Availability (large supply of materials).
- Process ability (amenable to large processing techniques and preferably cost-effective).
- Absence of any toxic effects (preference is minimally environmental and/or health hazard).
- Compatibility (flexibility to couple with other materials with the intent to improve optical, electronic, and/or catalytic properties).
- Stability (providing consistent performance without significant deterioration over time).
- Cost competitive (this is directly related to availability).

These are the major criteria that a material must fulfill to be considered as a promising candidate in photocatalysis.

It is not possible to rank all known materials based on all these aspects. In this work, the authors have therefore focused on a select few materials based on applications and which meet several of the aforementioned selection criteria.

Review of Synthesis Procedures for Photocatalysts

There are several methods that can be used for the synthesis of materials for solar energy conversion. These include wet chemical methods (such as sol–gel and reverse micelle techniques) and chamber-based methods (such as chemical vapor deposition and atomic layer deposition). Wet chemical methods usually involve using precursors of the materials that form the photoactive material, agents that participate in the transformation of the precursor to the desired final product (this may include complexing agents, stabilizers, and initiators). Detailed description of the merits of different wet chemical methods can be found in reviews by several authors (Best and Dunstan 2009; Wang et al. 2009; Cui et al. 2008; Strobel et al. 2006) including one from the authors' group (Kar et al. 2008). Chamber-based methods can be expensive initially due to higher capital cost and the need for possible sophisticated materials handling. In contrast to the wet chain methods, they do not require several agents and can oftentimes lead to a product that is much purer. Anodization and layer-by-layer self-assembly (or successive ionic layer adsorption and reaction – SILAR) process are often used to prepare composite particles using preformed materials as building blocks. They are rather simple, generic protocols customizable to the synthesis of different materials. Oftentimes these methods are used to prepare the anode and/or the cathode of a solar energy harvesting device separately, and then a different method has to be used to integrate these elements to form the device (PV or photoelectrochemical (PEC) cell).

System Integration

The fabricated materials have to be integrated to form a device prior to its application in solar energy conversion. A film-based PEC device is often used in water splitting reactions. A PEC system consists of an anode, cathode, and an electrolyte. The electrolyte is often the source of the fuel (e.g., aqueous solution of an alcohol produces hydrogen by splitting water in the electrolyte). A slurry-based PEC system does not have a clear separation of the anode and cathode since the catalyst acts as a center where both redox activities occur simultaneously, whereas a dye-sensitized solar cell device consists of an anode, cathode, and electrolyte that are clearly separate from one another. On the other hand, a slurry system has no distinct anode–cathode; the particles itself act as PEC, as referred to in Bard's concept (Bard 1979).

Previous Attempts in Materials Development

A list of different materials that can be used as a photocatalyst is provided in section "Materials for Photovoltaics, Water Splitting, and CO_2 Reduction." Titanium dioxide (TiO_2) has been the most popular and extensively studied photocatalyst for its ability to harvest solar energy, and hence it is first discussed here (Zach et al. 2006). It demonstrates good stability over a wide pH range, compatibility with other materials, environmental friendliness, and low cost. Its applications include solar energy conversion (photovoltaics) (Gratzel 1991, 2001) and hydrogen production (by photocatalytic water splitting) (Aroutiounian et al. 2005). However, TiO_2 has some significant limitations. For example, TiO_2, by itself, has high charge recombination rates compared to its combination with other materials such as dyes or semiconductors. TiO_2 alone has very limited light-harvesting ability (it only absorbs UV light) (Ni et al. 2007). Several reviews have discussed the photoactivity of TiO_2 and its composites for different applications (Rajeshwar et al. 2001; Kalyanasundaram and Gratzel 1997; Cheng et al. 2005; Cozzoli et al. 2004; Robel et al. 2006; Frank et al. 2004). The photoactivity of TiO_2 can be significantly improved by dye sensitization (Kalyanasundaram and Gratzel 1997), altering its composition (such as doping) (Cheng et al. 2005; Choi et al. 1994) and/or combining TiO_2 with other materials (Rajeshwar et al. 2001; Cozzoli et al. 2004; Robel et al. 2006). These efforts have been reasonably successful in improving the performance of TiO_2 composites. With respect to photovoltaic applications, the efficiency of light absorbance and improvement in charge separation of TiO_2-based nanocomposites still remain low ($\sim$10–12 %). The limitations of TiO_2-based materials can be attributed to the absence of flexibility for altering the inherent photoactivity of TiO_2 itself (because there is just one cation site (Ti) available for manipulation of electronic properties). In this context, a photoactive material, whose inherent electronic properties can be altered with greater flexibility, is needed.

Silicon-based solar cells are probably the most reliable, with proven high efficiencies ($\eta = 10$–20 %) based on the nature of crystallite size and manufacturing methods (Perezalbuerne and Tyan 1980; Kurtz et al. 2007; Schropp 2004; Kazmerski 2006). However, silicon for high-efficiency applications is becoming increasingly expensive. Complex processing routines also drive manufacturing costs high. Chalcogenide films made of various combinations of Cu, In, Ga, As, Cd, Se, and Te can be tuned to absorb significant visible light and show near optimal photovoltaic performance ($\eta \sim 20$ %) (Goetzberger et al. 2003) but pose toxicity concerns to environment and can require expensive reagents, and processing cost is high (Bube 1990; Dhere et al. 2005). Multijunction devices can produce very high efficiencies (>35 %) (Baur et al. 2007), but one of the issues is the transparency required to activate underlying layers. Photoactive polymers with fullerenes as the electron transport agent are significantly simple to process compared to Si-based devices but are limited in their stability during long-term operations (Cravino 2007; Liang et al. 2008).

Materials for Photovoltaics, Water Splitting, and CO_2 Reduction

The following section provides a list of materials for photovoltaic, water splitting, and CO_2 reduction applications. The selection of materials is based on meeting one or more of the following criteria: cost effectiveness, eco-friendly, and ease of synthesis.

Photovoltaics

Solar cells can be distinguished on the basis of their overall *solar-to-electric* conversion efficiency into several categories. Several reviews have discussed different aspects of PV (Bube 1990; Gratzel 2005; Thomas et al. 1999; Green 2007; Guenes and Sariciftci 2008; Catchpole et al. 2001). Table 5 provides a comparison of the different technologies available today and how these technologies rank with respect to each other. Many of the materials identified here either have been commercialized or offer promise for commercialization due to aspects such as cost competitiveness or eco-friendliness or ease of process ability. In general, all solar cell technologies known today are designed for niche applications and come with advantages and disadvantages. Therefore, the choice of a solar cell technology is usually made based on the type of application and the length of time the cell is expected to be in service. A summary of the advantages and disadvantages of the different types of cells is provided in the following sections. *(Chemical formulas are shown in the table for brevity. Readers are referred to citations for details.)*

Water Splitting

Water splitting can be performed in the presence or absence of sacrificial agents. Based on the approach employed, several reviews have discussed the materials (Kudo and Miseki 2009; Aroutiounian et al. 2005; Best and Dunstan 2009;

Table 5 Materials for photovoltaic applications

Material	Reason	Refs.
CdTe	Low-cost preparation technique, high conductivity, appropriate band gap, recycling methods developed	Oktik (1988), Bosio et al. (2006), Miles et al. (2005)
$CuInSe_2$	Low-cost, non-vacuum preparation technique	Oktik (1988), Kaelin et al. (2004), Eberspacher et al. (2001)
TiO_2	Continuous non-vacuum process by simple printing techniques	Kay and Gratzel (1996)
	Combination rapid thermal process and layer-by-layer spin coating preparation	Tao et al. (2010)
	TiO_2 nanotube array in ionic liquid electrolyte cell	Kuang et al. (2008)
	TiO_2 nanorod assembly	Wei et al. (2006)
a-Si	Low-cost encapsulation method	Kondo et al. (1997)
$CuInS_2$	Low-cost vapor deposition preparation	Hou and Choy (2005)
	Low-cost, non-vacuum preparation technique with solution coating and reduction-sulfurication technique	Todorov et al. (2006)
	Synthesized hollow nanospheres from common inorganic metal salts using surfactant-assisted chemical route	Zhang et al. (2008)
Thin crystalline silicon	Thin-film reduced cost	Catchpole et al. (2001), Shah et al. (2006)
ZnO/Al_2O_3	Cheaper hybrid PV cells	Damonte et al. (2010)
$CuGaInSe_2$	High-efficiency, low-cost thin film	Miles et al. (2005)
Nafion	Charge transport material to be used with ZnO or CdTe	Feng et al. (2009)
$ZnPc/C_{60}$	Organic PV cell, low-cost, experiment with rubrene doping	Taima et al. (2009)
PbSe	Lower-cost, high-efficiency semiconductor material	Hanrath et al. (2009)
Carbon nanotube (w/TiO_2)	Alternative to platinum as a counter-electrode in DSSCs	Muduli et al. (2009), Lee et al. (2009)
P3HT/PCBM	BJH cell that is lightweight, flexible, low-cost production	Honda et al. (2009)
	Preparation by low-cost quick-drying technique, improved efficiency over other techniques	Ouyang and Xia (2009)
FeS_2	P3HT nanowires and $PC_{61}BM$ or $PC_{71}CM$	Xin et al. (2010)
	Lower cost due to abundance and production than silicon and $>$ or $=$ efficiency	Wadia et al. (2009)
FeS and FeS_2	Nanosheet films from reaction of iron foil and sulfur powder, for photocathodes in tandem solar cell with TiO_2 as photoanode	Hu et al. (2008)

Wang et al. 2009; Rajeshwar 2007; Woodhouse and Parkinson 2009). The following segments list some of the popular materials that have been used successfully for water splitting. Properties of the materials are listed in column 2. Oxides, oxide composites, and non-oxides are common materials for driving water splitting reactions. Other materials such as perovskites, sillenites, and pyrochlores are also promising families of compounds that demonstrate water splitting. However, these materials may be difficult to synthesize, and more research has to be performed to determine the applicability of such materials for water splitting reactions (Table 6).

CO_2 Conversion

Due to global environmental concern, the research in utilization of solar energy for CO_2 conversion and/or control is gaining momentum. Several articles (Hinogami et al. 1998; Koci et al. 2009; Li et al. 2008; Wang et al. 2010; Tseng et al. 2004; Wu et al. 2005) have addressed this topic, and readers are directed to these articles for further information. Table 7 lists some of the articles that demonstrate the application of a few leading and representative materials for CO_2 conversion.

Challenges and Limitations to Materials

Mathematical models that consider thermodynamic limits and the near impossibility to convert solar energy to other forms of energy without generating entropy pins the maximum attainable theoretical efficiency of conversion of solar energy at 85 % (Wurfel 2002). Specific to photovoltaics, silicon (Si) solar cells (both single and polycrystalline) have been by far the most studied devices with the greatest market penetration and demonstrate the highest efficiencies (10–25 % for wafers, 4–20 % for modules) (Green 2007; Miles et al. 2007). However, increasing demand for Si, material processing, and device manufacturing costs have led to the opportunity for other non-Si-based technologies to enter the commercial market (Green 2007; Guenes and Sariciftci 2008). Thin-film processing technologies that use amorphous silicon (a-Si) is less expensive if single junction solar cells are of interest. However, single junction a-Si solar cells have low efficiencies (3–4 %), and employing amorphous thin films in a multijunction type cell (e.g., using a-Si and a-Si_xGe_{1-x}) can improve efficiencies up to 6–8 % (Green 2007) and make them commercially viable (Guha and Yang 2006) but again increases cost. Comparative efficiencies of silicon-based and non-silicon-based solar cells are discussed at length in literature (Goetzberger et al. 2003).

Alternate to Si cells are compound semiconductor solar cells; GaAs, InGaP, and copper indium gallium selenides (CIGS) are popular examples that have tremendous commercial potential but are presently limited by processing cost and hence used only in niche areas such as space applications (Bosi and Pelosi 2007). Using these in a multijunction format to boost efficiencies to the order of 6–8 % and possibly reducing processing cost could bring the technology for terrestrial use (application in on-demand and on-site power generation) (Bosi and Pelosi 2007). Alternate concepts on how to overcome efficiency limitations using tandem cells, intermediate band gap

Table 6 Materials for photocatalytic water splitting to produce hydrogen

Material	Properties	Refs.
a-Si	Relatively high conversion efficiency, no catalyst degradation, low-cost hydrogen production	Rocheleau et al. (1998)
	Inexpensive, efficient, and renewable hydrogen source	Kelly and Gibson (2006)
TiO_2	Surface engineering to increase active sites for reaction	Nowotny et al. (2006)
	Carbon-doped TiO_2 increases efficiency of water splitting	Park et al. (2006)
	Nano-size photocatalyst, low-cost, environmentally friendly	Ni et al. (2007)
	Nanostructured photocatalyst to reduce material cost	Hu et al. (2010)
	Nanotube and nanowire arrays for improved efficiency	Shankar et al. (2009)
	Carbon modified n-type TiO_2 photoelectrodes to increase conversion efficiency	(Shaban and Khan 2008)
	Efficient photocatalyst prepared by environmentally friendly microwave-assisted hydrothermal process	Somasundaram et al. (2007)
Si/TiO_2	Si doping improves efficiency, low-cost solar-to-chemical conversion	Takabayashi et al. (2004)
Fe_2O_3	Require smaller overpotential to oxidize water, single solar cell power, lower production costs	Nowotny et al. (2006)
	Ag-Fe_2O_3 nanocomposite photocatalyst as efficient, low-cost PEC	Jang et al. (2009a)
	Doping to improve efficiency	Jang et al. (2009b)
	Thin layer of Fe_2O_3 using nanostructured host scaffold of WO_3	Sivula et al. (2009)
ZnO	Low-cost oxide semiconductor	Aroutiounian et al. (2005)
$SrTiO_3$	Low-cost oxide semiconductor	Aroutiounian et al. (2005)
WO_3	Fe^{3+}/Fe^{2+} redox over WO_3, efficient photocatalyst, low-cost option	Miseki et al. (2010)
	Nanoporous WO_3 for improved efficiency	Guo et al. (2007)
$CuInS_2$	High H_2 evolution in presence Na_2S/Na_2SO_3 as sacrificial electron donors under visible light radiation	Zheng et al. (2009)
Cu_2O	Cheaper synthesis than similar photocatalyst	Ma et al. (2008)
