EDITOR'S BIOGRAPHY

John B. Taylor is the Mary and Robert Raymond Professor of Economics at Stanford University and the George P. Shultz Senior Fellow in Economics at Stanford's Hoover Institution. He is also the director of Stanford's Introductory Economics Center. His research focuses on macroeconomics, monetary economics, and international economics. He coedited Volume 1 of the Handbook of Macroeconomics and recently wrote *Getting Off Track*, one of the first books on the financial crisis, and *First Principles: Five Keys to Restoring America's Prosperity*. He served as senior economist and member of the President's Council of Economic Advisers. From 2001 to 2005, he served as undersecretary of the US Treasury for international affairs. Taylor was awarded the Hoagland Prize and the Rhodes Prize by Stanford University for excellence in undergraduate teaching. He received the Alexander Hamilton Award and the Treasury Distinguished Service Award for his policy contributions at the US Treasury. Taylor received a BA in economics summa cum laude from Princeton and a PhD in economics from Stanford.

Harald Uhlig, born 1961, is a professor at the Department of Economics of the University of Chicago since 2007 and was chairman of that department from 2009 to 2012. Previously, he held positions at Princeton, Tilburg University and the Humboldt-Universität zu Berlin. His research interests are in quantitative macroeconomics, financial markets, and Bayesian econometrics. He served as coeditor of *Econometrica* from 2006 to 2010 and as editor of the *Journal of Political Economy* since 2012 (head editor since 2013). He is a consultant of the Bundesbank, the European Central Bank, and the Federal Reserve Bank of Chicago. He is a fellow of the Econometric Society and a recipient of the Gossen Preis of the Verein für Socialpolitik, awarded annually to an economist in the German language area whose work has gained an international reputation.

PREFACE

This *Handbook* aims to survey the state of knowledge and major advances during the past two decades in the field of macroeconomics. It covers empirical, theoretical, methodological, and policy issues, including fiscal, monetary, and regulatory policies to deal with unemployment, economic growth, and crises, taking account of research developments before, during, and after the global financial crisis of 2007–2009. It can serve as a textbook and as an introduction to frontier research.

THE STATE OF MACRO, THE FINANCIAL CRISIS, AND NEW CURRENTS

The *Handbook* displays an amazing range of new and different ideas. There are neoclassical chapters on real business cycles and there are new Keynesian chapters on monetary business cycles. There are also chapters extending well beyond traditional macro, including the macroeconomics of the family, natural experiments, environmental issues, time allocation, and the fast moving areas of the connection between financial and real factors, incomplete markets, incomplete contracts, heterogeneous agents, and recursive contracts. There are also treatments of macroprudential policies, the impact of fiscal policy at the zero lower bound on interest rates, the fiscal theory of the price level, and the political economy of bailouts and debt. And there are chapters essential for research on the latest estimation and solution techniques (in continuous and discrete time), as well as encyclopedic reviews of the key facts of economic growth and economic fluctuations both at the aggregate and individual level.

A widely debated question for macroeconomics is whether the 2007–2009 financial crisis demonstrated a failure of the field or whether there was a failure of policy to follow the advice implied by the field. The chapters in the *Handbook* written by active and experienced researchers in macroeconomics can help answer that question in ways that informal policy debates cannot, and we hope that this is an important contribution of the *Handbook*.

There is no question that the field of macroeconomics has continued to progress enormously since the advent of rational expectations, microeconomic foundations, dynamic optimization, and general equilibrium models. Using this paradigm macroeconomists—before and after the financial crisis—have been able to introduce real-world rigidities in price setting, learning, incomplete markets, and financial frictions.

Since the global financial crisis and the Great Recession, some view a lack of financial frictions in macroeconomic models as an indication of failure, and of course there is much in this new *Handbook* on financial frictions and the financial sector more generally in macro models. But the 1999 *Handbook* already included work on financial frictions as evidenced by the chapter written by Ben Bernanke, Mark Gertler, and Simon Gilchrist. And an important finding reported in the chapter in this *Handbook* by Jesper Linde, Frank Smets, and Raf Wouters is that when more financial factors are added to macro models used at central banks, they do not help that much in explaining the financial crisis.

SUMMARY

The 33 chapters of the *Handbook* are divided into five sections. Each chapter starts with a short summary written by its authors, and reading these is the best way to understand what is in the *Handbook*. This short summary of the whole book shows how the chapters are organized and fit together.

Section 1, *The Facts of Economic Growth and Economic Fluctuation*, starts off with examination of the fundamental facts upon which macroeconomic theories are built and with which they must be consistent. It covers both the long run—going back 100 years—and the short run—tracing how shocks impact and propagate over time and how changes in policy regimes or rules affect economic fluctuations. Emphasizing microeconomic underpinnings, the chapters in this section look at the time allocation by people and families, the impact of longer decisions take on debt or purchases houses, the way wage decisions affect the allocation of labor, and the historical impact of financial and fiscal crises.

Section 2 focuses *The Methodology of Macroeconomics*. It covers factor models, structural VARs, solution methods, estimation of DSGE models, recursive contracts, endogenously incomplete markets, heterogeneous agents, natural experiments, the use of "wedges" as accounting framework for business cycle models, incomplete information, coordination frictions, and comprehensive methods of comparing models and achieving robustness.

Section 3, *Financial-Real Connections*, covers bank runs, the real effects of financial crises, credit markets, booms and busts, the central role of the housing market, and quantitative models of sovereign debt crises. It also shows different ways to connect the real and the financial sector including through continuous-time methods and models of the term structure of uncertainty.

Section 4, *Models of Economic Growth and Fluctuations*, covers several approaches to modeling the economy, including neoclassical or real business cycle models and staggered wage and price models or other rigidities that can explain slow recoveries and long slums. It takes a macroeconomic perspective on environmental issues as well as family decisions.

Section 5, *Macroeconomic Policy*, contains a thorough review of models used by central banks for conducting monetary policy, the analysis of regulatory policy including liquidity requirements, the fiscal theory of the price level, fiscal multipliers, liquidity traps, currency unions, and the technical sustainability vs the political economy of government debt.

Harald Uhlig

ACKNOWLEDGMENTS

First, we would like to acknowledge the initial encouragement from Kenneth Arrow and Michael Intriligator who, as Co-Editors of the *Handbook of Economics* Series, suggested in May 2007—nearly a decade ago and before the Global Financial Crisis—the need for a new *Handbook of Macroeconomics*. We are also grateful to Scott Bentley, Elsevier Acquisition Editor, who worked closely with us to get helpful comments and reviews of our initial outline, to Michael Woodford, who succeeded Mike Intriligator as Co-Editor of the Series for his helpful suggestions on organization and coverage, and to Joslyn Chaiprasert-Paguio, Editorial Project Manager, who brought the project to completion.

We—along with all the economists and students who will benefit from this volume—owe a great deal of thanks to the 74 accomplished economists who agreed to contribute to this endeavor for the time and creativity they invested in their chapters. We thank them for attending the conferences, presenting draft chapters, and then revising the chapters under strict deadlines. We particularly thank the discussants of the draft chapters whose careful comments helped improve the chapters and the overall book itself, including Manuel Amador, Ruediger Bachmann, Bob Barsky, Michael Bauer, Luigi Bocola, Jeff Campbell, John Cochrane, Sebastian Di Tella, Thorsten Drautzberg, Jonas Fisher, Yuriy Gorodnichenko, Kinda Cheryl Hachem, Zhiguo He, John Heaton, Bart Hobijn, Robert Hodrick, Cosmin Ilut, Oscar Jorda, Amir Kermani, Peter Klenow, Charles Kolstad, Arvind Krishnamurthy, Pablo Kurlat, Thibaut Lamadon, Guido Lorenzoni, Serguei Maliar, Casey Mulligan, Stavros Panageas, Pierre Siklos, Eric Sims, Alp Simsek, Christopher Tonetti, Alessandra Voena, Carl Walsh, and Michael Weber.

The two conferences at Stanford and Chicago where authors presented draft chapters and received this critical commentary were essential to the completion of the *Handbook of Macroeconomics*. We thank the Hoover Institution at Stanford University and the Becker-Friedman Institute at the University of Chicago for the financial and logistical support that made these conferences possible. We also wish to thank Marie-Christine Slakey for managing the overall manuscript and communications with authors from the very beginning of the project.

Abstract

Why are people in the richest countries of the world so much richer today than 100 years ago? And why are some countries so much richer than others? Questions such as these define the field of economic growth. This paper documents the facts that underlie these questions. How much richer are we today than 100 years ago, and how large are the income gaps between countries? The purpose of the paper is to provide an encyclopedia of the fundamental facts of economic growth upon which our theories are built, gathering them together in one place and updating them with the latest available data.

Keywords

Economic growth, Development, Long-run growth, Productivity

> *"[T]he errors which arise from the absence of facts are far more numerous and more durable than those which result from unsound reasoning respecting true data."—Charles Babbage, quoted in (Rosenberg, 1994, p. 27).*
>
> *"[I]t is quite wrong to try founding a theory on observable magnitudes alone… It is the theory which decides what we can observe."—Albert Einstein, quoted in (Heisenberg, 1971, p. 63).*

Why are people in the United States, Germany, and Japan so much richer today than 100 or 1000 years ago? Why are people in France and the Netherlands today so much richer than people in Haiti and Kenya? Questions like these are at the heart of the study of economic growth.

Economics seeks to answer these questions by building quantitative models—models that can be compared with empirical data. That is, we'd like our models to tell us not only that one country will be richer than another, but by how much. Or to explain not only that we should be richer today than a century ago, but that the growth rate should be 2% per year rather than 10%. Growth economics has only partially achieved these goals, but a critical input into our analysis is knowing where the goalposts lie—that is, knowing the facts of economic growth.

The purpose of this paper is to lay out as many of these facts as possible. Kaldor (1961) was content with documenting a few key stylized facts that basic growth theory should hope to explain. Jones and Romer (2010) updated his list to reflect what we've learned over the last 50 years. The approach here is different. Rather than highlighting a handful of stylized facts, we draw on the last 30 years of the renaissance of growth economics to lay out what is known empirically about the subject. These facts are updated with the latest data and gathered together in a single place—potentially useful to newcomers to the field as well as to experts. The result, I hope, is a fascinating tour of the growth literature from the perspective of the basic data.

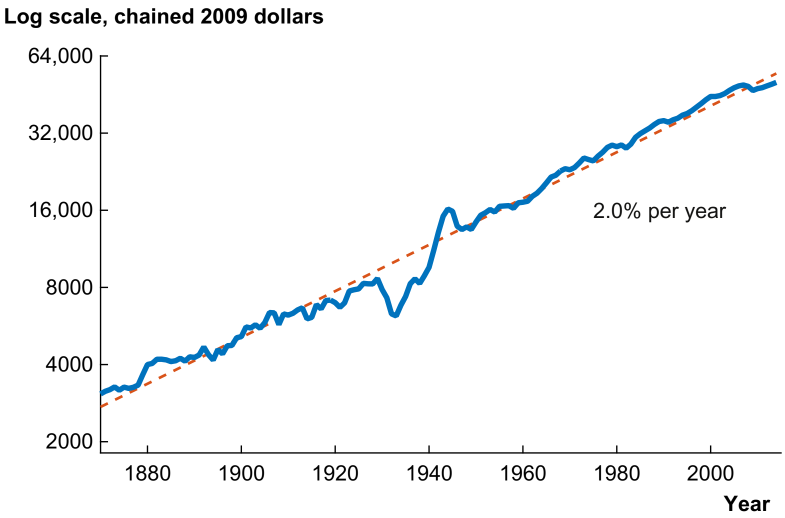

Fig. 1 GDP per person in the United States. Source: *Data for 1929–2014 are from the U.S. Bureau of Economic Analysis, NIPA table 7.1. Data before 1929 are spliced from Maddison, A. 2008. Statistics on world population, GDP and per capita GDP, 1-2006 AD. Downloaded on December 4, 2008 from http://www.ggdc.net/maddison/.*

The paper is divided broadly into two parts. First, I present the facts related to the growth of the "frontier" over time: what are the growth patterns exhibited by the richest countries in the world? Second, I focus on the spread of economic growth throughout the world. To what extent are countries behind the frontier catching up, falling behind, or staying in place? And what characteristics do countries in these various groups share?

1. GROWTH AT THE FRONTIER

We begin by discussing economic growth at the "frontier." By this I mean growth among the richest set of countries in any given time period. For much of the last century, the United States has served as a stand in for the frontier, and we will follow this tradition.

1.1 Modern Economic Growth

Fig. 1 shows one of the key stylized facts of frontier growth: For nearly 150 years, GDP per person in the US economy has grown at a remarkably steady average rate of around 2% per year. Starting at around $3,000 in 1870, per capita GDP rose to more than $50,000 by 2014, a nearly 17-fold increase.

Beyond the large, sustained growth in living standards, several other features of this graph stand out. One is the significant decline in income associated with the Great

Table 1 The stability of US Growth

Period	Growth Rate	Period	Growth Rate
1870–2007	2.03	1973–1995	1.82
1870–1929	1.76	1995–2007	2.13
1929–2007	2.23		
1900–1950	2.06	1995–2001	2.55
1950–2007	2.16	2001–2007	1.72
1950–1973	2.50		
1973–2007	1.93		

Note: Annualized growth rates for the data shown in Fig. 1.

Depression. However, to me this decline stands out most for how anomalous it is. Many of the other recessions barely make an impression on the eye: over long periods of time, economic growth swamps economic fluctuations. Moreover, despite the singular severity of the Great Depression—GDP per person fell by nearly 20% in just 4 years—it is equally remarkable that the Great Depression was *temporary*. By 1939, the economy is already passing its previous peak and the macroeconomic story a decade later is once again one of sustained, almost relentless, economic growth.

The stability of US growth also merits some discussion. With the aid of the trend line in Fig. 1, one can see that growth was slightly slower pre-1929 than post. Table 1 makes this point more precisely. Between 1870 and 1929, growth averaged 1.76%, vs 2.23% between 1929 and 2007 (using "peak to peak" dates to avoid business cycle problems). Alternatively, between 1900 and 1950, growth averaged 2.06% vs 2.16% since 1950. Before one is too quick to conclude that growth rates are increasing; however, notice that the period since 1950 shows a more mixed pattern, with rapid growth between 1950 and 1973, slower growth between 1973 and 1995, and then rapid growth during the late 1990s that gives way to slower growth more recently.

The interesting "trees" that one sees in Table 1 serves to support the main point one gets from looking at the "forest" in Fig. 1: steady, sustained exponential growth for the last 150 years is a key characteristic of the frontier. All modern theories of economic growth—for example, Solow (1956), Lucas (1988), Romer (1990), and Aghion and Howitt (1992)—are designed with this fact in mind.

The sustained growth in Fig. 1 also naturally raises the question of whether such growth can and will continue for the next century. On the one hand, this fact more than any other helps justify the focus of many growth models on the balanced growth path, a situation in which all economic variables grow at constant exponential rates forever. And the logic of the balanced growth path suggests that the growth can continue indefinitely. On the other hand, as we will see, there are reasons from other facts and theories to question this logic.

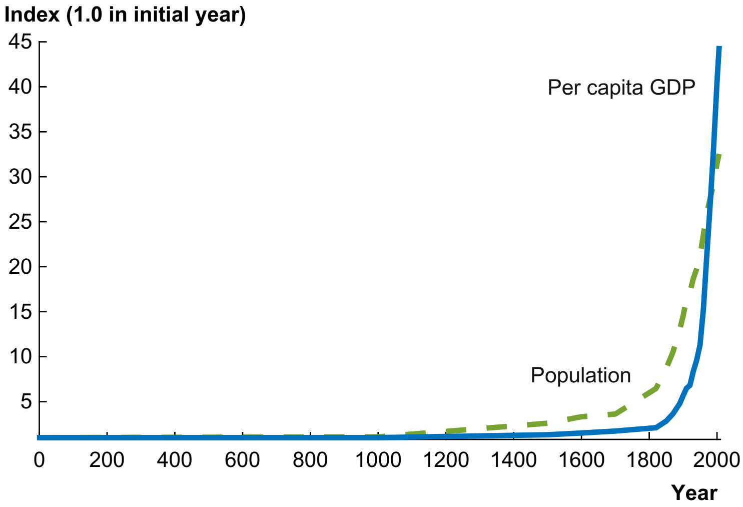

Fig. 2 Economic growth over the very long run. Source: *Data are from Maddison, A. 2008. Statistics on world population, GDP and per capita GDP, 1-2006 AD. Downloaded on December 4, 2008 from http://www.ggdc.net/maddison/ for the "West," ie, Western Europe plus the United States. A similar pattern holds using the "world" numbers from Maddison.*

1.2 Growth Over the Very Long Run

While the future of frontier growth is surely hard to know, the stability of frontier growth suggested by Fig. 1 is most certainly misleading as a guide to growth further back in history. Fig. 2 shows that sustained exponential growth in living standards is an incredibly recent phenomenon. For thousands and thousands of years, life was, in the evocative language of Thomas Hobbes, "nasty, brutish, and short." Only in the last two centuries has this changed, but in this relatively brief time, the change has been dramatic.[a]

Between the year 1 C.E. and the year 1820, living standards in the "West" (measured with data from Western Europe and the United States) essentially doubled, from around $600 per person to around $1200 per person, as shown in Table 2. Over the next 200 years; however, GDP per person rose by more than a factor of twenty, reaching $26,000.

The era of modern economic growth is in fact even more special than this. Evidence suggests that living standards were comparatively stagnant for thousands and thousands of years before. For example, for much of prehistory, humans lived as simple hunters and gatherers, not far above subsistence. From this perspective—say for the last 200,000 years

[a] Papers that played a key role in documenting and elaborating upon this fact include Maddison (1979), Kremer (1993), Maddison (1995), Diamond (1997), Pritchett (1997), and Clark (2001). This list neglects a long, important literature in economic history; see Clark (2014) for a more complete list of references.

Table 2 The Acceleration of world growth

Year	GDP per person	Growth rate	Population (millions)	Growth rate
1	590	–	19	–
1000	420	−0.03	21	0.01
1500	780	0.12	50	0.17
1820	1240	0.15	125	0.28
1900	3350	1.24	280	1.01
2006	26,200	1.94	627	0.76

Note: Growth rates are average annual growth rates in percent, and GDP per person is measured in real 1990 dollars.
Source: Data are from Maddison, A. 2008. Statistics on world population, GDP and per capita GDP, 1-2006 AD. Downloaded on December 4, 2008 from http://www.ggdc.net/maddison/ for the "West," ie, Western Europe plus the United States

or more—the era of modern growth is spectacularly brief. It is the economic equivalent of Carl Sagan's famous "pale blue dot" image of the earth viewed from the outer edge of the solar system.

Table 2 reveals several other interesting facts. First and foremost, over the very long run, economic growth at the frontier has accelerated—that is, the rates of economic growth are themselves increasing over time. Romer (1986) emphasized this fact for living standards as part of his early motivation for endogenous growth models. Kremer (1993) highlighted the acceleration in population growth rates, dating as far back as a million years ago, and his evidence serves as a very useful reminder. Between 1 million B.C.E. and 10,000 B.C.E., the average population growth rate in Kremer's data was 0.00035% per year. Yet despite this tiny growth rate, world population increased by a factor of 32, from around 125,000 people to 4 million. As an interesting comparison, that's similar to the proportionate increase in the population in Western Europe and the United States during the past 2000 years, shown in Table 2.

Various growth models have been developed to explain the transition from stagnant living standards for thousands of years to the modern era of economic growth. A key ingredient in nearly all of these models is Malthusian diminishing returns. In particular, there is assumed to be a fixed supply of land which is a necessary input in production.[b] Adding more people to the land reduces the marginal product of labor (holding technology constant) and therefore reduces living standards. Combined with some subsistence level of consumption below which people cannot survive, this ties the size of the population to the level of technology in the economy: a better technology can support a larger population.

[b] I have used this assumption in my models as well, but I have to admit that an alternative reading of history justifies the exact opposite assumption: up until very recently, land was completely elastic—whenever we needed more, we spread out and found greener pastures.

Various models then combine the Malthusian channel with different mechanisms for generating growth. Lee (1988), Kremer (1993), and Jones (2001) emphasize the positive feedback loop between "people produce ideas" as in the Romer model of growth with the Malthusian "ideas produce people" channel. Provided the increasing returns associated with ideas is sufficiently strong to counter the Malthusian diminishing returns, this mechanism can give rise to dynamics like those shown in Fig. 2. Lucas (2002) emphasizes the role of human capital accumulation, while Hansen and Prescott (2002) focus on a neoclassical model that features a structural transformation from agriculture to manufacturing. Oded Galor, with his coauthors, has been one of the most significant contributors, labeling this literature "unified growth theory." See Galor and Weil (2000) and Galor (2005).

2. SOURCES OF FRONTIER GROWTH

The next collection of facts related to economic growth are best presented in the context of the famous growth accounting decomposition developed by Solow (1957) and others. This exercise studies the sources of growth in the economy through the lens of a single aggregate production function. It is well known that the conditions for an aggregate production function to exist in an environment with a rich underlying microstructure are very stringent. The point is not that anyone believes those conditions hold. Instead, one often wishes to look at the data "through the lens of" some growth model that is much simpler than the world that generates the observed data. A long list of famous papers supports the claim that this is a productive approach to gaining knowledge, Solow (1957) itself being an obvious example.

While not necessary, it is convenient to explain this accounting using a Cobb–Douglas specification. More specifically, suppose final output Y_t is produced using stocks of physical capital K_t and human capital H_t:

$$Y_t = \underbrace{A_t M_t}_{\text{TFP}} K_t^{\alpha} H_t^{1-\alpha} \tag{1}$$

where α is between zero and one, A_t denotes the economy's stock of knowledge, and M_t is anything else that influences total factor productivity (the letter "M" is reminiscent of the "measure of our ignorance" label applied to the residual by Abramovitz (1956) and also is suggestive of "misallocation," as will be discussed in more detail later). The next subsection provides a general overview of growth accounting for the United States based on this equation, and then the remainder of this section looks more closely at each individual term in Eq. (1).

2.1 Growth Accounting

It is traditional to perform the growth accounting exercise with a production function like (1). However, that approach creates some confusion in that some of the accumulation of physical capital is caused by growth in total factor productivity (eg, as in a standard Solow model). If one wishes to credit such growth to total factor productivity, it is helpful to do the accounting in a slightly different way.[c] In particular, divide both sides of the production function by Y_t^{α} and solve for Y_t to get

$$Y_t = \left(\frac{K_t}{Y_t}\right)^{\frac{\alpha}{1-\alpha}} H_t Z_t \tag{2}$$

where $Z_t \equiv (A_t M_t)^{\frac{1}{1-\alpha}}$ is total factor productivity measured in labor-augmenting units. Finally, dividing both sides by the aggregate amount of time worked, L_t, gives

$$\frac{Y_t}{L_t} = \left(\frac{K_t}{Y_t}\right)^{\frac{\alpha}{1-\alpha}} \frac{H_t}{L_t} \cdot Z_t \tag{3}$$

In this form, growth in output per hour Y_t/L_t comes from growth in the capital-output ratio K_t/Y_t, growth in human capital per hour H_t/L_t, and growth in labor-augmenting TFP, Z_t. This can be seen explicitly by taking logs and differencing Eq. (3). Also, notice that in a neoclassical growth model, the capital-output ratio is proportional to the investment rate in the long-run and does not depend on total factor productivity. Hence the contributions from productivity and capital deepening are separated in this version, in a way that they were not in Eq. (1).

The only term we have yet to comment on is H_t/L_t, the aggregate amount of human capital divided by total hours worked. In a simple model with one type of labor, one can think of $H_t = h_t L_t$, where h_t is human capital per worker which increases because of education. In a richer setting with different types of labor that are perfect substitutes when measured in efficiency units, H_t/L_t also captures composition effects. The Bureau of Labor Statistics, from which I've obtained the accounting numbers discussed next, therefore refers to this term as "labor composition."

Table 3 contains the growth accounting decomposition for the United States since 1948, corresponding to Eq. (3). Several well-known facts emerge from this accounting. First, growth in output per hour at 2.5% is slightly faster than the growth in GDP per person that we saw earlier. One reason is that the BLS data measure growth for the private business sector, excluding the government sector (in which there is zero productivity growth more or less by assumption). Second, the capital-output ratio is relatively stable over this period, contributing almost nothing to growth. Third, labor composition (a rise in educational attainment, a shift from manufacturing to services, and the increased labor force participation of women) contributes 0.3 percentage points per year to growth. Finally, as documented by Abramovitz, Solow, and others, the "residual" of total factor

[c] Klenow and Rodriguez-Clare (1997), for example, takes this approach.

Table 3 Growth accounting for the United States

Period	Output per hour	Contributions from		
		K/Y	Labor composition	Labor-Aug. TFP
1948–2013	**2.5**	**0.1**	**0.3**	**2.0**
1948–1973	3.3	−0.2	0.3	3.2
1973–1990	1.6	0.5	0.3	0.8
1990–1995	1.6	0.2	0.7	0.7
1995–2000	3.0	0.3	0.3	2.3
2000–2007	2.7	0.2	0.3	2.2
2007–2013	1.7	0.1	0.5	1.1

Note: Average annual growth rates (in percent) for output per hour and its components for the private business sector, following Eq. (3).

productivity accounts for the bulk of growth, coming in at 2.0 percentage points, or 80% of growth since 1948.

The remainder of Table 3 shows the evolution of growth and its decomposition over various periods since 1948. We see the rapid growth and rapid TFP growth of the 1948–1973 period, followed by the well-known "productivity slowdown" from 1973 to 1995. The causes of this slowdown are much debated but not convincingly pinned down, as suggested by the fact that the entirety of the slowdown comes from the TFP residual rather than from physical or human capital; Griliches (1988) contains a discussion of the slowdown.

Remarkably, the period 1995–2007 sees a substantial recovery of growth, not quite to the rates seen in the 1950s and 1960s, but impressive nonetheless, coinciding with the dot-com boom and the rise in the importance of information technology. Byrne et al. (2013) provide a recent analysis of the importance of information technology to growth over this period and going forward. Lackluster growth in output per hour since 2007 is surely in large part attributable to the Great Recession, but the slowdown in TFP growth (which some such as Fernald, 2014 date back to 2003) is troubling.[d]

2.2 Physical Capital

The fact that the contribution of the capital-output ratio was modest in the growth accounting decomposition suggests that the capital-output ratio is relatively constant over

[d] There are a number of important applications of growth accounting in recent decades. Young (1992) and Young (1995) document the surprisingly slow total factor productivity growth in the East Asian miracle countries. Krugman (1994) puts Young's accounting in context and relates it to the surprising finding of early growth accounting exercises that the Soviet Union exhibited slow TFP growth as well. Klenow and Rodriguez-Clare (1997) conduct a growth accounting exercise using large multicountry data sets and show the general importance of TFP growth in that setting.

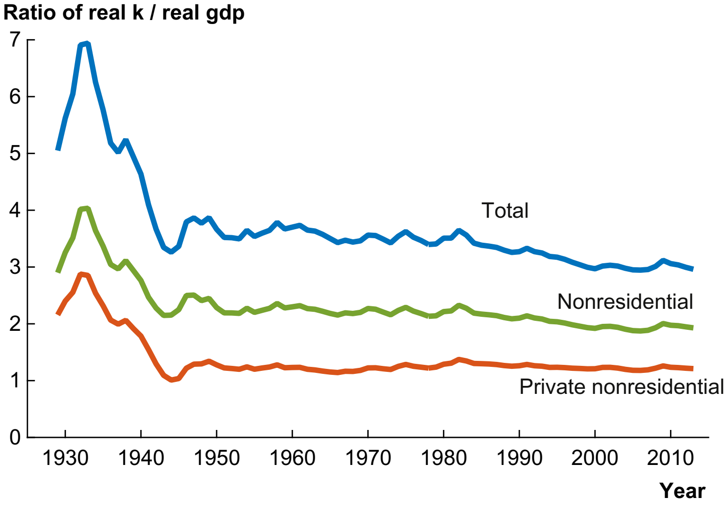

Fig. 3 The ratio of physical capital to GDP. Source: *Burea of Economic Analysis Fixed Assets tables 1.1 and 1.2. The numerator in each case is a different measure of the real stock of physical capital, while the denominator is real GDP.*

time. This suggestion is confirmed in Fig. 3. The broadest concept of physical capital (Total), including both public and private capital as well as both residential and nonresidential capital, has a ratio of 3 to real GDP. Focusing on nonresidential capital brings this ratio down to 2, and further restricting to private nonresidential capital leads a ratio of just over 1.

The capital stock is itself the cumulation of investment, adjusted for depreciation. Fig. 4 shows nominal spending on investment as a share of GDP back to 1929. The share is relatively stable for much of the period, with a notable decline during the last two decades.

In addition to cumulating investment, however, another step in going from the (nominal) investment rate series to the (real) capital-output ratio involves adjusting for relative prices. Fig. 5 shows the price of various categories of investment, relative to the GDP deflator. Two facts stand out: the relative price of equipment has fallen sharply since 1960 by more than a factor of 3 and the relative price of structures has risen since 1929 by a factor of 2 (for residential) or 3 (for nonresidential).

A fascinating observation comes from comparing the trends in the relative prices shown in Fig. 5 to the investment shares in Fig. 4: the nominal investment shares are relatively stable when compared to the huge trends in relative prices. For example, even though the relative price of equipment has fallen by more than a factor of 3 since 1960, the nominal share of GDP spent on equipment has remained steady.

The fall of equipment prices has featured prominently in parts of the growth literature; for example, see Greenwood et al. (1997) and Whelan (2003). These papers make the point that one way to reconcile the facts is with a two-sector model in which

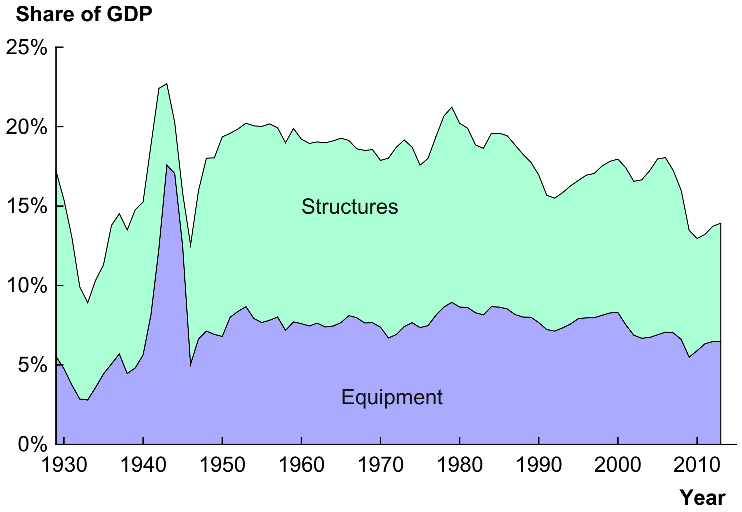

Fig. 4 Investment in physical capital (private and public), United States. Source: *National Income and Product Accounts, U.S. Bureau of Economic Analysis, table 5.2.5. Intellectual property products and inventories are excluded. Government and private investment are combined. Structures includes both residential and nonresidential investment. Ratios of nominal investment to GDP are shown.*

technological progress in the equipment sector is substantially faster that technological progress in the rest of the economy—an assumption that rings true in light of Moore's Law and the tremendous decline in the price of a semiconductors. Combining this assumption with Cobb–Douglas production functions leads to a two-sector model that

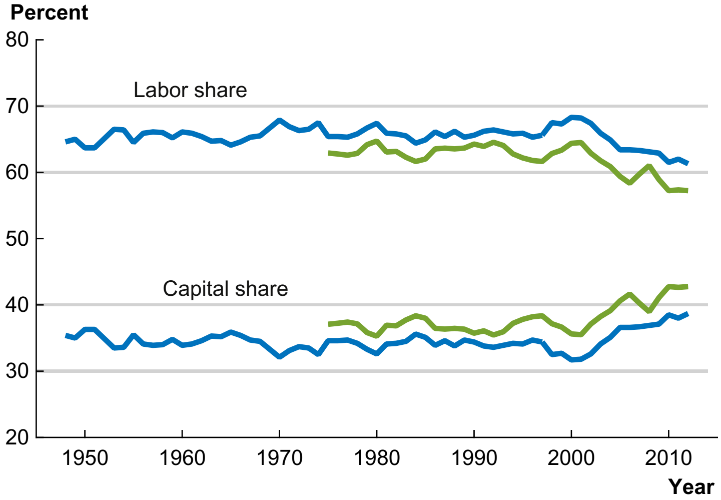

Fig. 6 Capital and labor shares of factor payments, United States. Source: *The series starting in 1975 are from Karabarbounis, L., Neiman, B. 2014. The global decline of the labor share. Q. J. Econ. 129 (1), 61–103. http://ideas.repec.org/a/oup/qjecon/v129y2014i1p61-103.html and measure the factor shares for the corporate sector, which the authors argue is helpful in eliminating issues related to self-employment. The series starting in 1948 is from the Bureau of Labor Statistics* Multifactor Productivity Trends, *August 21, 2014, for the private business sector. The factor shares add to 100%.*

is broadly consistent with the facts we've laid out. A key assumption in this approach is that better computers are equivalent to having more of the old computers, so that technological change is, at least partially, capital (equipment) augmenting. The Cobb–Douglas assumption ensures that this nonlabor augmenting technological change can coexist with a balanced growth path and delivers a stable nominal investment rate.[e]

2.3 Factor Shares

One of the original Kaldor (1961) stylized facts of growth was the stability of the shares of GDP paid to capital and labor. Fig. 6 shows these shares using two different data sets, but the patterns are quite similar. First, between 1948 and 2000, the factor shares were indeed quite stable. Second, since 2000 or so, there has been a marked decline in the labor share and a corresponding rise in the capital share. According to the data from the Bureau of Labor Statistics, the capital share rose from an average value of 34.2% between 1948 and 2000 to a value of 38.7% by 2012. Or in terms of the complement, the labor share declined from an average value of 65.8% to 61.3%.

[e] This discussion is related to the famous Uzawa theorem about the restrictions on technical change required to obtain balanced growth; see Schlicht (2006) and Jones and Scrimgeour (2008).

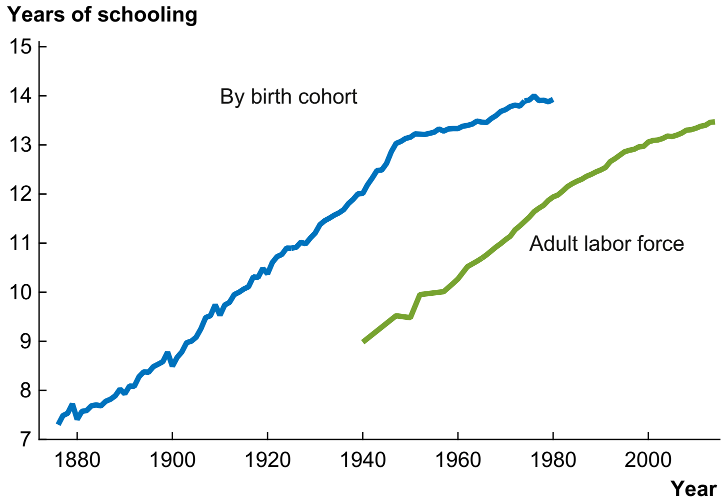

Fig. 7 Educational attainment, United States. Source: *The* blue (dark gray *in the print version) line shows educational attainment by birth cohort from Goldin, C., Katz, L.F. 2007. The* green (gray *in the print version) line shows average educational attainment for the labor force aged 25 and over from the Current Population Survey.*

It is hard to know what to make of the recent movements in factor shares. Is this a temporary phenomenon, perhaps amplified by the Great Recession? Or are some more deeper structural factors at work? Karabarbounis and Neiman (2014) document that the fact extends to many countries around the world and perhaps on average starts even before 2000. Other papers seek to explain the recent trend by studying depreciation, housing, and/or intellectual property and include Elsby et al. (2013), Bridgman (2014), Koh et al. (2015), and Rognlie (2015).

A closely-related fact is the pattern of factor shares exhibited across industries within an economy and across countries. Jones (2003) noted the presence of large trends, both positive and negative, in the 35 industry (2-digit) breakdown of data in the United States from Dale Jorgenson. Gollin (2002) suggests that factor shares are uncorrelated with GDP per person across a large number of countries.

2.4 Human Capital

The other major neoclassical input in production is human capital. Fig. 7 shows a time series for one of the key forms of human capital in the economy, education. More specifically, the graph shows educational attainment by birth cohort, starting with the cohort born in 1875.

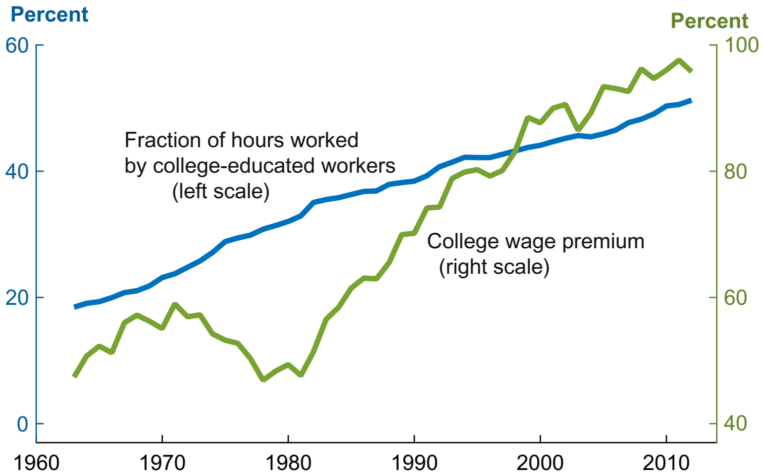

Fig. 8 The supply of college graduates and the college wage premium, 1963–2012. *Note:* The supply of US college graduates, measured by their share of total hours worked, has risen from below 20% to more than 50% by 2012. The US college wage premium is calculated as the average excess amount earned by college graduates relative to nongraduates, controlling for experience and gender composition within each educational group. Source: *Autor, D.H. 2014. Skills, education, and the rise of earnings inequality among the "other 99 percent". Science 344 (6186), 843–851, fig. 3.*

Two facts emerge. First, for 75 years, educational attainment rose steadily, at a rate of slightly less than 1 year per decade. For example, the cohort born in 1880 got just over 7 years of education, while the cohort born in 1950 received 13 years of education on average. As shown in the second (green) line in the figure, this translated into steadily rising educational attainment in the adult labor force. Between 1940 and 1980, for example, educational attainment rose from 9 years to 12 years, or about 3/4 of a year per decade. With a Mincerian return to education of 7%, this corresponds to a contribution of about 0.5 percentage points per year to growth in output per worker.

The other fact that stands out prominently, however, is the leveling-off of educational attainment. For cohorts born after 1950, educational attainment rose more slowly than before, and for the latest cohorts, educational attainment has essentially flattened out. Over time, one expects this to translate into a slowdown in the increase of educational attainment for the labor force as a whole, and some of this can perhaps be seen in the last decade of the graph.

Fig. 8 shows another collection of stylized facts related to human capital made famous by Katz and Murphy (1992). The blue line in the graph shows the fraction of hours worked in the US economy accounted for by college-educated workers. This fraction rose from less than 20% in 1963 to more than 50% by 2012. The figure also shows the college wage premium, that is the excess amount earned by college graduates over nongraduates after controlling for experience and gender. This wage premium averaged around 50% between 1963 and the early 1980s but then rose sharply through 2012 to peak at nearly 100%. Thus, even though the supply of college graduates was growing rapidly, the wage premium for college graduates was increasing sharply as well.

Katz and Murphy (1992) provide an elegant way to understand the dynamics of the college wage premium. Letting "coll" and "hs" denote two kinds of labor ("college graduates" and "high school graduates"), the human capital aggregate that enters production is given by a CES specification:

$$H = ((A_{coll}L_{coll})^{\rho} + (A_{hs}L_{hs})^{\rho})^{1/\rho} \tag{4}$$

An increase in the supply of college graduates lowers their marginal product, while an increase in the technology parameter A_{coll} raises their marginal product. Katz and Murphy (1992) show that with an elasticity of substitution of around 1.4, a constant growth rate of A_{coll}/A_{hs}, which Katz and Murphy call "skill-biased technical change," together with the observed movements in L_{coll}/L_{hs} can explain the time series for the college wage premium.

Human capital includes more than just education, of course. Workers continue to accumulate skills on the job. This human capital shows up as higher wages for workers, but separating this into a quantity of human capital and a price per unit of human capital requires work. One simple approach is to assume each year of work experience leads to a constant increase in human capital, and this approach is commonly pursued in growth accounting. Examples of richer efforts to measure human capital in a growth setting include Lucas (2009), Erosa et al. (2010), Lucas and Moll (2014), and Manuelli and Seshadri (2014).

2.5 Ideas

Our next set of facts relate to the economy's stock of knowledge or ideas, the A in the production function that we began with back in Eq. (1). It has long been recognized that the "idea production function" is hard to measure. Where do ideas come from? Part of the difficulty is that the answer is surely multidimensional. Ideas are themselves very heterogeneous, some clearly arise through intentional research, but others seem to arrive by chance out of seemingly nowhere. Confronted with these difficulties, Solow (1956) modeled technological change as purely exogenous, but this surely goes too far. The more people there are searching for new ideas, the more likely it is that discoveries will be made. This is true if the searching is intentional, as in research, but even if it is a byproduct of the production process itself as in models of learning by doing. The production of new ideas plays a fundamental role in the modern understanding of growth; see Romer (1990), Grossman and Helpman (1991), and Aghion and Howitt (1992).[f]

[f] Various perspectives on the idea production function are presented by Mokyr (1990), Griliches (1994), Weitzman (1998), and Fernald and Jones (2014).

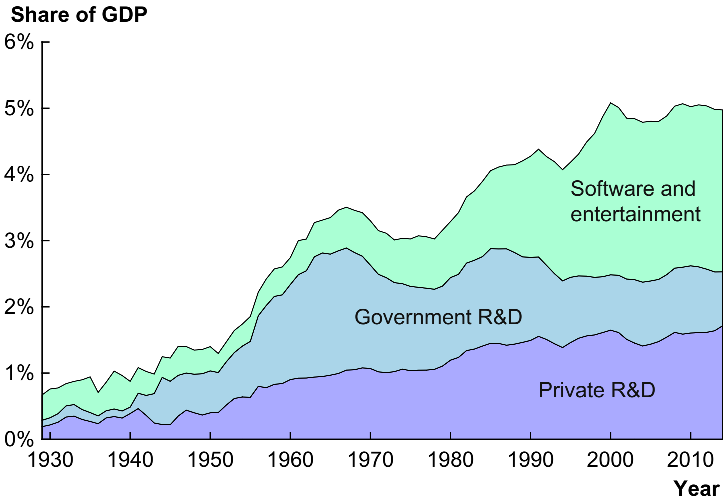

Fig. 9 Research and development spending, United States. Source: *National Income and Product Accounts, U.S. Bureau of Economic Analysis via FRED database. "Software and entertainment" combines both private and public spending. "Entertainment" includes movies, TV shows, books, and music.*

With this in mind, Fig. 9 shows spending on research and development, as a share of GDP, for the United States. These data can now be obtained directly from the National Income and Product Accounts, thanks to the latest revisions by the Bureau of Economic Analysis. The broadest measure of investment in ideas recorded by the NIPA is investment in "intellectual property products." This category includes traditional research and development, spending on computer software, and finally spending on "entertainment," which itself includes movies, TV shows, books, and music.

Several facts stand out in Fig. 9. First, total spending on investment in intellectual property products has risen from less than 1% of GDP in 1929 to nearly 5% of GDP in recent years. This overall increase reflects a large rise in private research and development and a large rise in software and entertainment investment, especially during the last 25 years. Finally, government spending on research and development has been shrinking as a share of GDP since peaking in the 1960s with the space program.

Fig. 10 provides an alternative perspective on R&D in two dimensions. First, it focuses on employment rather than dollars spent, and second it brings in an international perspective. The figure shows the number of researchers in the economy as a share of the population.[g]

[g] According to the OECD's Frascati Manual 2002, p. 93, researchers are defined as "professionals engaged in the conception or creation of new knowledge, products, processes, methods and systems and also in the management of the projects concerned."

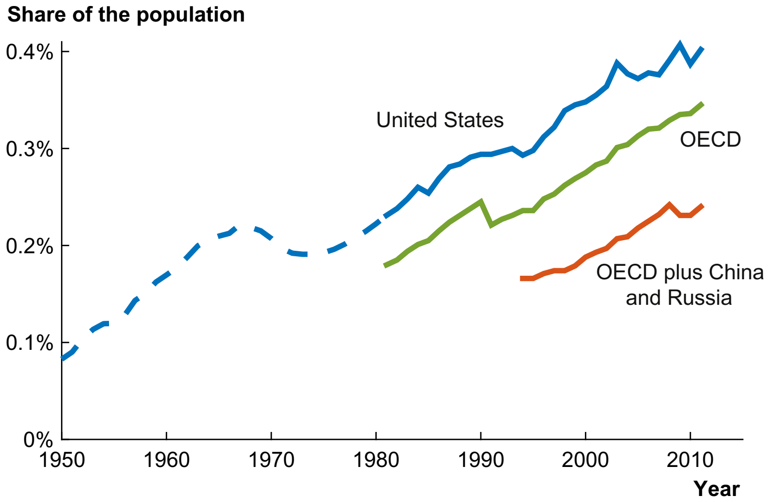

Fig. 10 Research employment share. Source: *Data for 1981–2001 are from OECD Main Science and Technology Indicators, http://stats.oecd.org/Index.aspx?DataSetCode=MSTI_PUB. Data prior to 1981 for the United States are spliced from Jones, C.I. 2002. Sources of U.S. economic growth in a world of ideas. Am. Econ. Rev. 92 (1), 220–239, which uses the NSF's definition of "scientists and engineers engaged in R&D."*

Each of the three measures in the figure tells the same story: the fraction of the population engaged in R&D has been rising in recent decades. This is true within the United States, within the OECD, and even if we incorporate China and Russia as well.

It is important to appreciate a significant limitation of the R&D data shown so far. In particular, these data only capture a small part of what an economist would call research. For example, around 70% of measured R&D occurs in the manufacturing industry. In 2012, only 18 million workers (out of US employment that exceeds 130 million) were employed by firms that conducted any official R&D.[h] According to their corporate filings, Walmart and Goldman-Sachs report doing zero R&D.

So far, we have considered the input side of the idea production function. We now turn to the output side. Unfortunately, the output of ideas is even harder to measure than the inputs. One of the more commonly-used measures is patents, and this measure is shown in Fig. 11.

On first glance, it appears that patents, like many other variables reviewed in this essay, have grown exponentially. Indeed, at least since 1980 one sees a very dramatic rise in the number of patents granted in the United States, both in total and to US inventors. The difference between these two lines—foreign patenting in the United States—is also interesting, and one testament to the global nature of ideas is that 56% of patents granted by the US patent office in 2013 were to foreigners.

[h] These numbers are from Wolfe (2014).

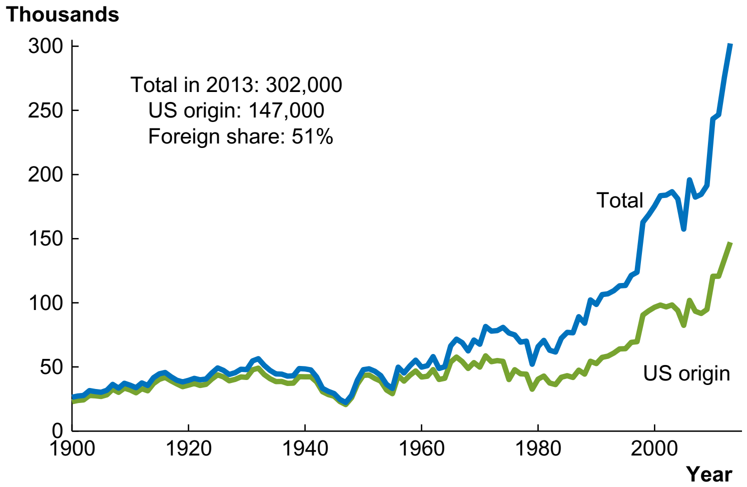

Fig. 11 Patents granted by the US Patent and Trademark Office. Source: *http://www.uspto.gov/web/offices/ac/ido/oeip/taf/h_counts.htm*.

A closer look at Fig. 11, though, reveals something equally interesting: the number of patents granted to US inventors in 1915, 1950, and 1985 was approximately the same. Put another way, during the first 85 years of the 20th century, the number of patents granted to US residents appears to be stationary, in sharp contrast to the dramatic increase since 1985 or so. Part of the increase since the 1980s is due to changes in patent policy, including extending patent protection to software and business models and changes in the judicial appeals process for patent cases (Jaffe and Lerner, 2006).

Griliches (1994) combined these two basic facts related to ideas (rapid growth in the inputs, stable production of patents) to generate a key implication: the productivity of research at producing patents fell sharply for most of the 20th century. Kortum (1997) developed a growth model designed to match these facts in which he emphasized that patents can be thought of as *proportional* improvements in productivity. If each patent raises GDP by a constant percent, then a constant flow of new patents can generate a constant rate of economic growth. The problem with this approach (or perhaps the problem with the patent data) is that it breaks down after 1980 or so. Since 1980, the number of patents has risen by more than a factor of four, while growth rates are more or less stable. The bottom line is that the idea production function remains something of a black box perhaps precisely because we do not have great measures of ideas or the inputs used to produce them.[i]

[i] Examples of progress include Caballero and Jaffe (1993), Acemoglu et al. (2013), L. (2013), and Akcigit et al. (2014b).

2.6 Misallocation

The organizing principle for this section of the paper is the production function given back in Eq. (1). In specifying that production function, I broke total factor productivity into two pieces: the stock of ideas, A, and everything else, which I labeled "M" either for the "measure of our ignorance" or for "misallocation." It is this latter interpretation that I wish to take up now.

One of the great insights of the growth literature in the last 15 years is that misallocation at the micro level can show up as a reduction in total factor productivity at a more aggregated level. This insight appears in various places, including Banerjee and Duflo (2005), Chari et al. (2007), Restuccia and Rogerson (2008) and Hsieh and Klenow (2009).

The essence of the insight is quite straightforward: when resources are allocated optimally, the economy will operate on its production possibilities frontier. When resources are misallocated, the economy will operate inside this frontier. But that is just another way of saying that TFP will be lower: a given quantity of inputs will produce less output.

As we explain in detail in the second part of this paper (in Section 4.7), there is a large literature on misallocation and development—this is our best candidate answer to the question of why are some countries so much richer than others. There is much less discussion of the extent to which misallocation is related to frontier growth, the subject at hand.

While it is clear conceptually that even the country or countries at the frontier of growth can suffer from misallocation and that changes in misallocation can contribute to growth, there has been little work quantifying this channel. Indeed, my own working hypothesis for many years was that this effect was likely small in the United States during the last 50 years. I now believe this is wrong.

Hsieh et al. (2013) highlight a striking fact that illustrates this point: in 1960, 94% of doctors and lawyers were white men; by 2008, this fraction was just 62%. Given that innate talent for these and other highly-skilled professions is unlikely to differ across groups, the occupational distribution in 1960 suggests that a large number of innately talented African Americans and white women were not working in the occupations dictated by comparative advantage. The paper quantifies the macroeconomic consequences of the remarkable convergence in the occupational distribution between 1960 and 2008 and finds that 15–20% of growth in aggregate output per worker is explained by the improved allocation of talent. In other words, declines in misallocation may explain a significant part of US economic growth during the last 50 years.

Examples to drive home these statistics are also striking. Sandra Day O'Connor—future Supreme Court Justice—graduated third in her class from Stanford Law School in 1952. But the only private sector job she could get upon graduation was as a legal secretary (Biskupic, 2006). Closer to our own profession, David Blackwell, of contraction mapping fame, was the first African American inducted into the National Academy of Sciences and the first tenured at U.C. Berkeley. Yet despite getting his Ph.D. at age 22 and obtaining a postdoc at the Institute for Advanced Studies in 1941, he was not permitted to attend lectures at Princeton and was denied employment at U.C. Berkeley for racial reasons. He worked at Howard University until 1954, when he was finally hired as a full professor in the newly-created statistics department at Berkeley.[j]

Another potential source of misallocation is related to the economics of ideas. It has long been suggested that knowledge spillovers are quite significant, both within and across countries. To the extent that these spillovers are increasingly internalized or addressed by policy—or to the extent that the opposite is true—the changing misallocation of knowledge resources may be impacting economic growth.[k]

As one final example, Hsieh and Moretti (2014) suggest that spatial misallocation within the United States may be significant. Why is it that Sand Hill Road in Palo Alto has Manhattan rents without the skyscrapers? Hsieh and Moretti argue that land use policies prevent the efficient spatial matching of people to land and to each other. They estimate that places like Silicon Valley and New York City would be four to eight times more populous in the efficient allocation.

Quantifying these and other types of misallocation affecting frontier growth is a fruitful direction for future research.

2.7 Explaining the Facts of Frontier Growth

While this essay is primarily about the facts of economic growth, it is helpful to step back and comment briefly on how multiple facts have been incorporated into our models of growth.

The basic neoclassical growth framework of Solow (1956) and Ramsey (1928) / Cass (1965) / Koopmans (1965) has long served as a benchmark organizing framework for understanding the facts of growth. The nonrivalry of ideas, emphasized by Romer (1990), helps us understand how sustained exponential growth occurs endogenously. I review this contribution and some of the extensive research it sparked in Jones (2005).[l]

The decline in the relative price of equipment and the rise in the college wage premium are looked at together in Krusell et al. (2000). That paper considers a setting in which equipment capital is complementary to skilled labor, so that the (technologically driven) decline in the price of equipment is the force of skill-biased technological change. That paper uses a general CES structure. One of the potential issues in that paper was that it could lead to movements in the labor share. But perhaps we are starting to see those in the data.

[j] See http://en.wikipedia.org/wiki/David_Blackwell. I'm grateful to Ed Prescott for this example.

[k] For evidence on knowledge spillovers, see Griliches (1992), Coe and Helpman (1995), Jones and Williams (1998), Klenow and Rodriguez-Clare (2005), and Bloom et al. (2013).

[l] Romer's insights are expanded upon in various directions. Aghion and Howitt (1992) and Grossman and Helpman (1991) emphasize the important role of creative destruction. Jones (1995), Kortum (1997), and Segerstrom (1998) clarify the way in which nonrivalry interacts with population growth to explain sustained growth in living standards.

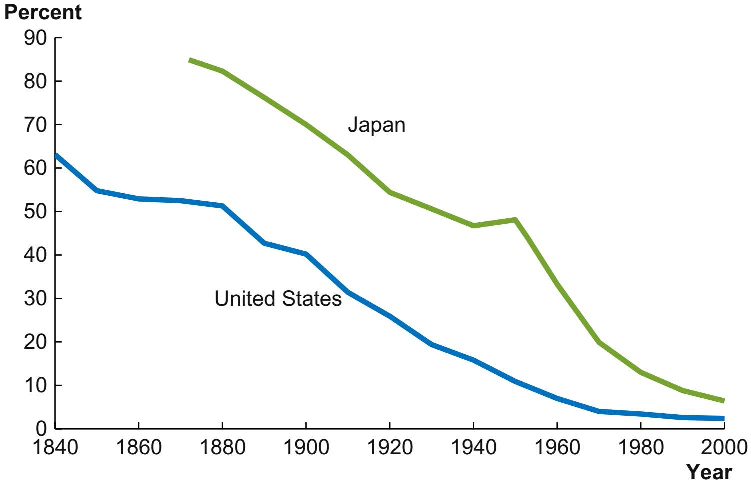

Fig. 12 Employment in agriculture as a share of total employment. Source: *Herrendorf, B., Rogerson, R., Valentinyi, A. 2014, Growth and structural transformation, In: Handbook of Economic Growth, vol. 2, Elsevier, pp. 855–941, http://ideas.repec.org/h/eee/grochp/2-855.html.*

The presence of trends in educational attainment and research investment opens up interesting opportunities for future research. Why are educational attainment and the share of labor devoted to research rising over time? What are the implications of these trends for future growth? Restuccia and Vandenbroucke (2013) suggest that skill-biased technological change is itself responsible for driving the rise in educational attainment. Acemoglu (1998) examines the further interactions when the direction of technological change is itself endogenous. Jones (2002) considers the implication of the trends in education and research intensity for future growth, suggesting that these trends have substantially raised growth during the last 50 years above the economy's long-run growth rate.

3. FRONTIER GROWTH: BEYOND GDP

The next collection of facts related to frontier growth look beyond the aggregate of GDP. These facts are related to structural change (the decline of agriculture and the rise of services, especially health), changes in leisure and fertility, rising inequality, and falling commodity prices.

3.1 Structural Change

Fig. 12 shows one of the most dramatic structural changes affecting frontier economies over the last 200 years and beyond: the decline of agriculture. In 1840, about two out of every three workers in the US economy worked in agriculture. By 2000, this share had fallen to just 2.4%. Similar changes can be seen in value-added in agriculture as a share of GDP as well as in other countries. For example, the chart also shows agriculture's share of employment in Japan, declining from 85% around 1870.[m]

The structural transformation has several other dimensions and connections in the growth literature. For example, the decline in agriculture is first associated with a rise in manufacturing, which is ultimately replaced by a rise in services, including health and education; more on this below.

Another form of structural transformation that has seen renewed interest is the possibility that machines (capital) may substitute for labor. Autor et al. (2003) look at detailed occupational classifications to study the impact of computerization on labor demand. They emphasize a polarization, with computerization being particularly substitutable for routine cognitive tasks that can be broken into specific rules but complementary to nonroutine, cognitive tasks. That is, computers substitute for bank tellers and low-level secretaries, while increasing the demand for computer programmers and leaving untouched manual jobs like janitorial work. Brynjolfsson and McAfee (2012) highlight broader ramifications of artificial intelligence, whereby computers might start driving cars, reading medical tests, and combing through troves of legal documents. That is, even many tasks thought to be cognitive and not easily routinized may be subject to computerization. What impact will such changes have on the labor market?

The answer to this question is obviously complicated and the subject of ongoing research.[n] One useful reference point is the enormous transformation that occurred as the agricultural share of the US labor force went from 2/3 to only 2%, largely because of mechanization and technological change. There is no doubt that this had a transformative affect on the labor market, but by and large this transformation was overwhelmingly beneficial. That's not to say that it must be that way in the future, but the example is surely worth bearing in mind.

3.2 The Rise of Health

A different structural transformation has been predominant during the last 50 years: the rise of health spending as a share of GDP. Fig. 13 shows this fact for the United States and for several other OECD countries. In the United States, the health share more than tripled since 1960, rising from 5% in 1960 to 17% in recent years. Large trends are

[m] The literature on structural transformation and economic growth is surveyed by Herrendorf et al. (2014). More recent contributions include Boppart (2014) and Comin et al. (2015), who emphasize demand systems with heterogeneous income effects.

[n] For some examples, see Acemoglu (1998), Zeira (1998), Caselli (1999), Hemous and Olsen (2014).

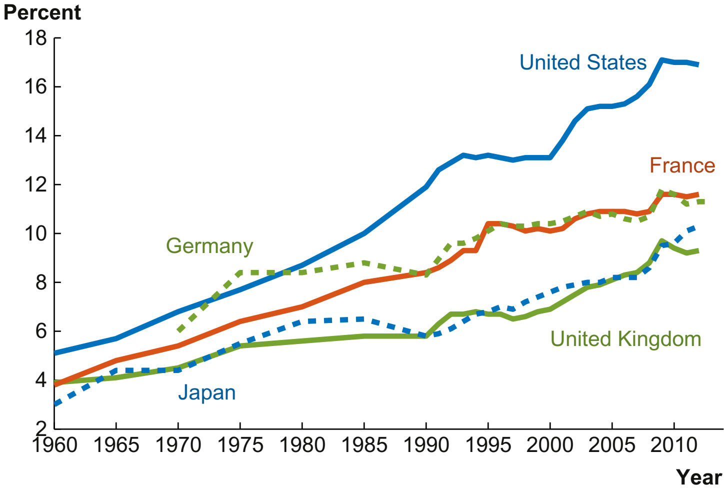

Fig. 13 Health spending as a share of GDP. Source: *OECD Health Statistics, 2014.*

present in other countries as well, with the share in France, for example, rising from under 4% to nearly 12%.

Hall and Jones (2007) propose that the widespread rise in the prominence of health care is a byproduct of economic growth. With standard preferences, the marginal utility of consumption declines rapidly. This is most easily seen for CRRA preferences in which the intertemporal elasticity of substitution is below one, in which case flow utility is bounded. As we get richer and richer, the marginal utility of consumption on any given day declines rapidly; what people really need are more days of life to enjoy their high level of consumption. Hence there is an income effect tilting spending toward life-saving categories.

One of the few time series related to economic growth that does not grow exponentially is life expectancy, where the increases tend to be arithmetic rather than exponential. Fig. 14 shows life expectancy at birth and at age 65 in the United States. Life expectancy at birth increased rapidly in the first half of the 20th century, thanks to improvements in public health and large declines in infant mortality. Since 1950, the rate of improvement has been more modest, around 1.8 years per decade. The figure also shows that the rise in life expectancy occurs at old ages. Life expectancy conditional on reaching age 65 has risen by just under 1 year per decade since 1950.[o] Interestingly,

[o] Nordhaus (2003) and Murphy and Topel (2006) discuss the rise in life expectancy and the economic returns to reducing mortality in more detail. Oeppen and Vaupel (2002) suggest that "record life expectancy" (ie, the maximum life expectancy across countries) has grown linearly at 2.5 years per decade for more than 150 years.

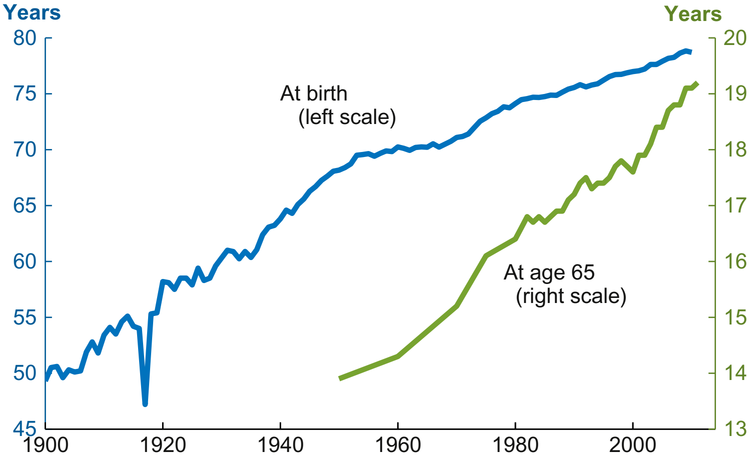

Fig. 14 Life expectancy at birth and at age 65, United States. Source: *Health, United States 2013 and https://www.clio-infra.eu*.

the mortality rate itself seems to grow exponentially with age, a phenomenon known as the Gompertz–Makeham Law; see Dalgaard and Strulik (2014).

3.3 Hours Worked and Leisure

A standard stylized fact in macroeconomics is that the fraction of the time spent working shows no trend despite the large upward trend in wages. The next two figures show that this stylized fact is not really true over the longer term, although the evidence is somewhat nuanced.

Fig. 15 shows average annual hours worked per person engaged in work from the Penn World Tables, which takes its data in turn from the Total Economy Database of the Conference Board. Among advanced countries, annual hours worked has fallen significantly since 1950. Average hours worked in the United States, for example, fell from 1909 in 1950 to 1704 in 2011. In France, the decline is even more dramatic, from 2159 to 1476. The decline starts slightly later in Japan after their recovery from World War II, with hours falling from 2222 in 1960 to 1706 in 2011.

Fig. 16 breaks the US evidence down into more detail, courtesy of Ramey and Francis (2009). First, the figure shows the split between men and women. Average weekly hours of market work by men fell sharply between 1900 and 1980, before leveling off. In contrast, market work by women has been on an upward trend. Ramey and Francis (2009) also use time diaries to estimate home production, and this is where the story gets more complicated. As men are substituting away from market work, they are also substituting into home production. Home production by men rose from just 4 h per week in 1900 to more than 16 h per week in 2005. The increase in leisure, then, was much smaller than the decline in market hours suggests.

3.4 Fertility

The facts we have presented thus far in this section—the decline in agriculture and the rise in services like health, the rise in life expectancy, the decline in hours worked—are all consistent with a particular kind of income effect. As people get richer, the marginal

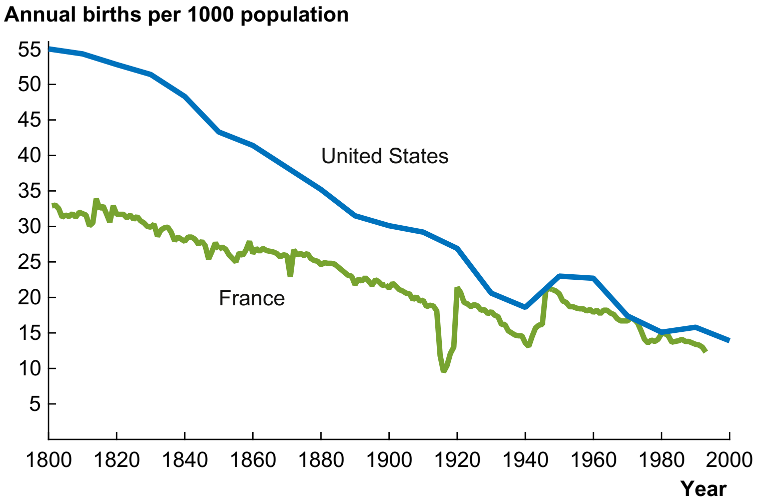

Fig. 17 Fertility in the United States and France. Source: *Data for the United States are from Haines, M. 2008, Fertility and mortality in the United States. In: Whaples, R., (Ed.), EH.Net Encyclopedia, http://eh.net/encyclopedia/fertility-andmortality-in-the-united-states/ and data for France are from Greenwood, J., Vandenbroucke, G. 2004. The baby boom and baby bust: O.E.C.D. fertility data. http://guillaumevdb.net/BabyBoom-data.pdf*.

utility of consumption falls and people substitute away from consumption and toward actions that conserve on the precious time endowment. Time is the one thing that technological progress cannot create!

The next fact on fertility raises interesting questions about this hypothesis. In particular, Fig. 17 shows the large decline in fertility dating back at least to 1800, known as the demographic transition. Since 1800, the birth rate has fallen from 5.5% in the United States and 3.3% in France down to less than 1.5% in recent years.

In dynastic models like Barro and Becker (1989), in which having more children is essentially a way of increasing one's own effective lifetime or time endowment, there is a force that tends to raise fertility, at least if income effects dominate substitution effects. But instead, we see strong declines in fertility in the data. A large literature seeks to understand the declines in fertility and the hump-shape in population growth that are together known as the demographic transition. A key part of the standard explanation is that children are themselves time intensive, in which case conserving on children also conserves on time as people get richer.[p]

[p] For example, see Galor and Weil (1996), Doepke (2005), Greenwood et al. (2005), Jones et al. (2010), Cordoba and Ripoll (2014), and Jones and Tertilt (forthcoming).

3.5 Top Inequality

One of the more famous facts documented during the last decade is shown in Fig. 18. This is the top income inequality graph of Piketty and Saez (2003). In both the United States and France, the share of income earned by the top 0.1% of households was around 9% in 1920, and in both countries the share declined sharply until the 1950s to around 2%. It stayed at this low level until around 1980. But then a very large difference emerged, with top income shares rising in the United States to essentially the same level as in 1920, while the share in France remains relatively low. Much of the decline in the first part of the century is associated with capital income, and much of the rise in US inequality since 1980 is associated with labor (and business) income.[q]

It is also worth stepping back to appreciate the macroeconomic consequences of this inequality. Fig. 19 merges the Piketty–Saez top inequality data with the long-run data on GDP per person for the United States shown at the start of this paper in Fig. 1. In particular, the figure applies the Piketty–Saez inequality shares to average GDP per person to produce an estimate of GDP per person for the top 0.1% and the bottom 99.9%.[r]

[q] Possible explanations for this pattern are discussed by Castaneda et al. (2003), Cagetti and Nardi (2006), Atkinson et al. (2011), Benhabib et al. (2011), Aoki and Nirei (2013), Jones and Kim (2014), Piketty (2014), Piketty et al. (2014), and Saez and Zucman (2014).

[r] It is important to note that this estimate is surely imperfect. GDP likely does not follow precisely the same distribution as the Adjusted Gross Income data that forms the basis of the Piketty–Saez calculations: health benefits are more equally distributed, for example.

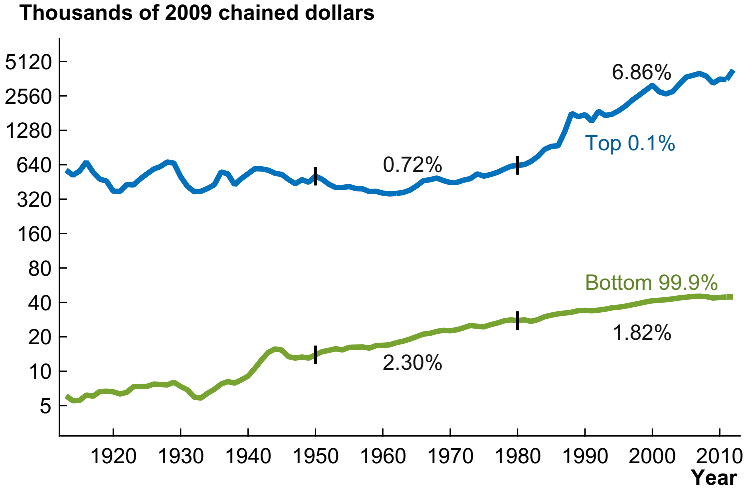

Fig. 19 GDP per person, top 0.1% and bottom 99.9%. *Note:* This figure displays an estimate of average GDP per person for the top 0.1% and the bottom 99.9%. Average annual growth rates for the periods 1950–1980 and 1980–2007 are also reported. Source: *Aggregate GDP per person data are from Fig. 1. The top income share used to divide the GDP is from the October 2013 version of the world top incomes database, from http://g-mond.parisschoolofeconomics.eu/topincomes/.*

Two key results stand out. First, until recently, there is surprisingly little growth in average GDP per person at the top: the value in 1977 is actually *lower* than the value in 1913. Instead, all the growth until around 1960 occurs in the bottom 99.9%. The second point is that this pattern changed in recent decades. For example, average growth in GDP per person for the bottom 99.9% declined by around half a percentage point, from 2.3% between 1950 and 1980 to only 1.8% between 1980 and 2007. In contrast, after being virtually absent for 50 years, growth at the top accelerated sharply: GDP per person for the top 0.1% exhibited growth more akin to China's economy, averaging 6.86% since 1980. Changes like this clearly have the potential to matter for economic welfare and merit the attention they've received.

3.6 The Price of Natural Resources

This next fact is very different from what we've been discussing, but it is one of the more surprising facts related to frontier growth. Fig. 20 shows the real price of industrial commodities, consisting of an equally-weighted basket of aluminum, coal, copper, lead, iron ore, and zinc, deflated by the consumer price index. During the 20th century, world demand for these industrial commodities exploded with the rise of the automobile, electrification, urbanization, and the general industrialization that occurred in the United States and around the world. The surprise shown in the figure is that the real price of these commodities *declined* over the 20th century. Moreover, the magnitude of the

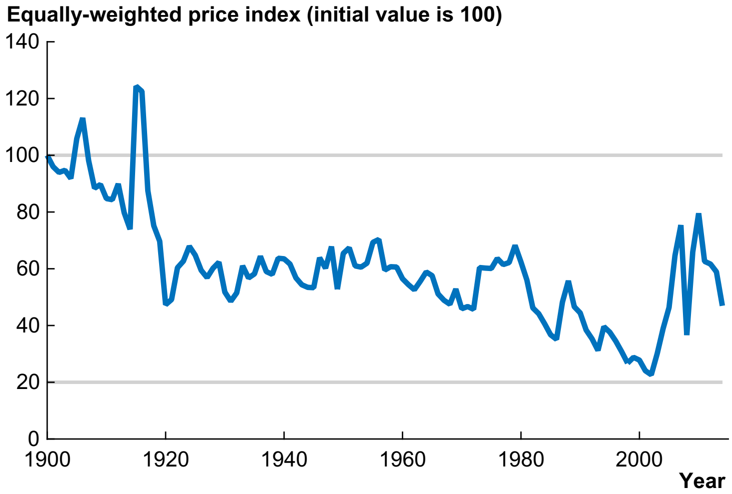

Fig. 20 The real price of industrial commodities. Source: *The price of an equally-weighted basket of aluminum, coal, copper, lead, iron ore, and zinc, deflated by the consumer price index. Commodity prices are from www.globalfinancialdata.com and the CPI is from www.measuringworth.com.*

decline was large—a factor of 5 between the year 1900 and 2000. Evidently, some combination of increased discoveries and technological changes led the effective supply to grow even faster than the enormous rise in demand.[s]

Also striking, though, is the large increase in the real price of these commodities since 2000. Part of the explanation could be the rapid growth of China and India over this period and the large increase in the demand for commodities that their growth entailed. Interestingly, we will see later that many developing countries performed quite well in the 2000s. Some of that growth contributed to the rise in demand for commodities, but some of that success may also reflect commodity-driven growth resulting from the rise in demand from China and India.

4. THE SPREAD OF ECONOMIC GROWTH

Up until now, we've been primarily concerned with the growth of the frontier: what are the facts about how the frontier is moving over time? Now, we turn to how growth is spreading across countries: how are different countries moving relative to the frontier?

4.1 The Long Run

One of the key facts about the spread of growth over the very long run is that it occurred at different points in time, resulting in what is commonly referred to as

[s] This fact has been noted before, for example by Simon (1981).

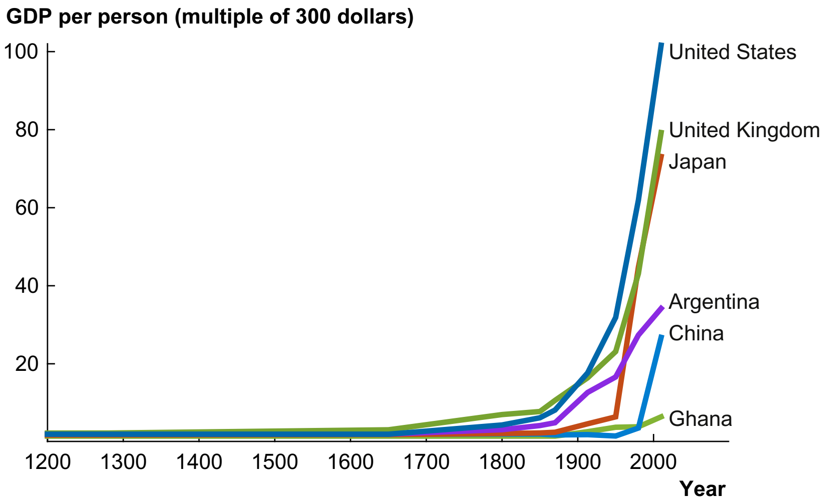

Fig. 21 The great divergence. *Note*: The graph shows GDP per person for various countries. The units are in multiples of 300 dollars and therefore correspond roughly to the ratio between a country's per capita income and the income in the poorest country in the world. Source: *Bolt, J., van Zanden, J.L. 2014. The Maddison Project: collaborative research on historical national accounts. Econ. Hist. Rev. 67 (3), 627–651.*

"The Great Divergence."[t] Fig. 21 illustrates this point. GDP per person differs modestly prior to the year 1600 according to The Maddison Project data. For example, GDP per person in the year 1300 ranges from a high of $1620 in the Netherlands (in 1990 dollars) to a low of $610 in Egypt. But Egypt was surely not the poorest country in the world at the time. Following an insight by Pritchett (1997), notice that the poorest countries in the world in 1950 had an income around $300, and this level—less than one dollar per day—seems very close to the minimum average income likely to prevail in any economy at any point in time. Therefore in 1300, the ratio of the richest country to the poorest was on the order of $\$1620/\$300 \approx 5$. Even smaller ratios are observed in Maddison's data prior to the year 1300.

Fig. 21 shows how this ratio evolved over time for a small sample of countries, and one sees the "Great Divergence" in incomes that occurs after the year 1600. The ratio of richest to poorest rises to more than 10 by 1870 (for the United Kingdom) and then to more than 100 by 2010 (for the United States). Across the range of countries, rapid growth takes hold at different points in time. Argentina is relatively rich by 1870 and growth takes off in Japan after World War II. In 1950, China was substantially poorer than Ghana—by more than a factor of two according to Maddison. Rapid growth since

[t] See Maddison (1995), Pritchett (1997), Lucas (2000), and Pomeranz (2009).

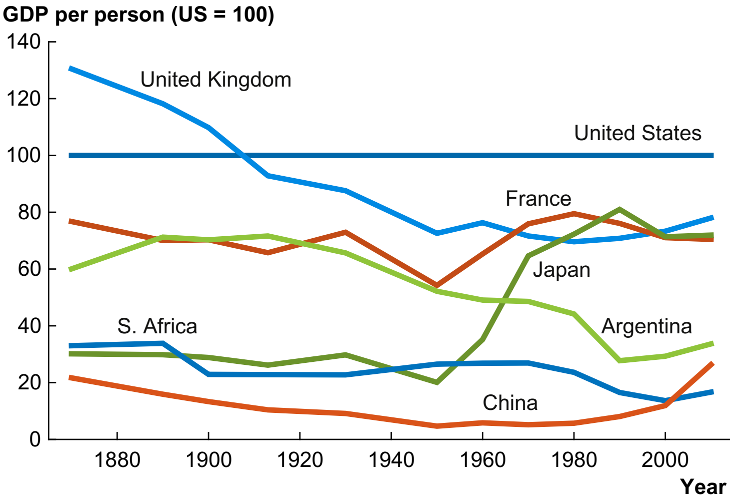

Fig. 22 The spread of economic growth since 1870. Source: *Bolt, J., van Zanden, J.L. 2014. The Maddison Project: collaborative research on historical national accounts. Econ. Hist. Rev. 67 (3), 627–651.*

1978 raises China's living standards to more than a factor of 25 over the benchmark level of $300 per year.

Fig. 22 shows the spread of growth since 1870 in an alternative way, by plotting incomes relative to the US level. A key fact that stands out when the data are viewed this way is the heterogeneity of experiences. Some countries like the United Kingdom, Argentina, and South Africa experience significant declines in their incomes relative to the United States, revealing the fact that their growth rates over long periods of time fell short of the 2% growth rate of the frontier. Other countries like Japan and China see large increases in relative incomes.

4.2 The Spread of Growth in Recent Decades

Fig. 23 focuses in on the last 30 years using the Penn World Tables 8.0 data, again showing GDP per person relative to the US Several facts then stand out. First, incomes in the countries of Western Europe have been roughly stable, around 75% of the US level. It is perhaps surprising that countries like France, Germany, and the United Kingdom are this far behind the United States. Prescott (2004) observes that a large part of the difference is in hours worked: GDP per hour is much more similar in these countries, and it is the fact that work hours per adult are substantially lower in Western Europe that explains their lower GDP per person. Jones and Klenow (2015) note that in addition to the higher leisure, Western Europeans tend to have higher life expectancy and lower consumption inequality. Taking all of these factors into account in constructing a consumption-equivalent welfare measure, the Western European countries look

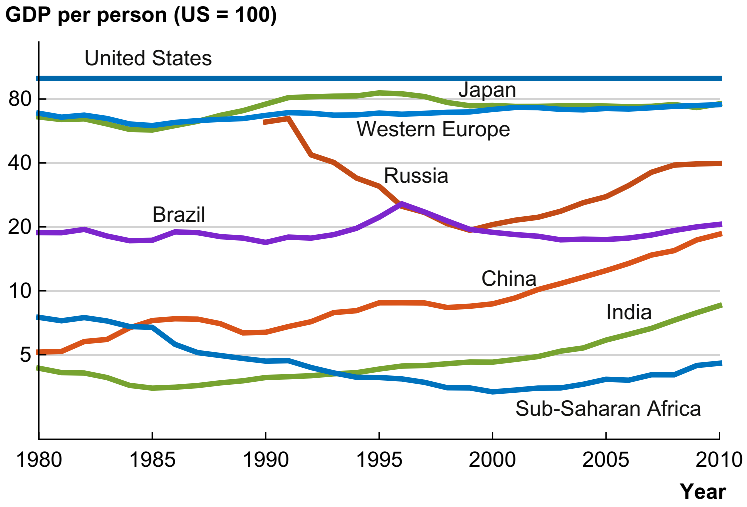

Fig. 23 The spread of economic growth since 1980. Source: *The Penn World Tables 8.0.*

much closer to US levels than the simple GDP per person numbers imply; this point is discussed further below in Section 3.

Fig. 23 also illustrates the "lost decades" that Japan has experienced. After rapid growth in the 1980s (and before), Japan peaked at an income relative to the United States of 85% in 1995. Since 1995, though, Japan has fallen back to around 75% of the US level. The rapid growth of China since 1980 and India since around 1990 are also evident in this figure. The contrast with sub-Saharan Africa is particularly striking, as that region as a whole falls from 7.5% of US income in 1980 to just 3.3% by 2000. Since 2000, many of the countries and regions shown in Fig. 23 exhibit catch-up to the United States.

Fig. 24 shows GDP per person relative to the United States in 1960 and 2011 for 100 countries. Countries scatter widely around the 45-degree line, and the first impression is that there is no systematic pattern to this scattering. Some countries are moving up relative to the United States and some countries are falling further behind, and the movements can be large, as represented by the deviations from the 45-degree line.

Looking more closely at the graph, there is some suggestion that there are more middle-income countries above the 45-degree line than below. At least between 1960 and 2011, countries in the middle of the distribution seemed more likely to move closer to the United States than to fall further behind. In contrast, for low income countries, the opposite pattern appears in the data: poor countries are on average more systematically below the 45-degree line rather than above.

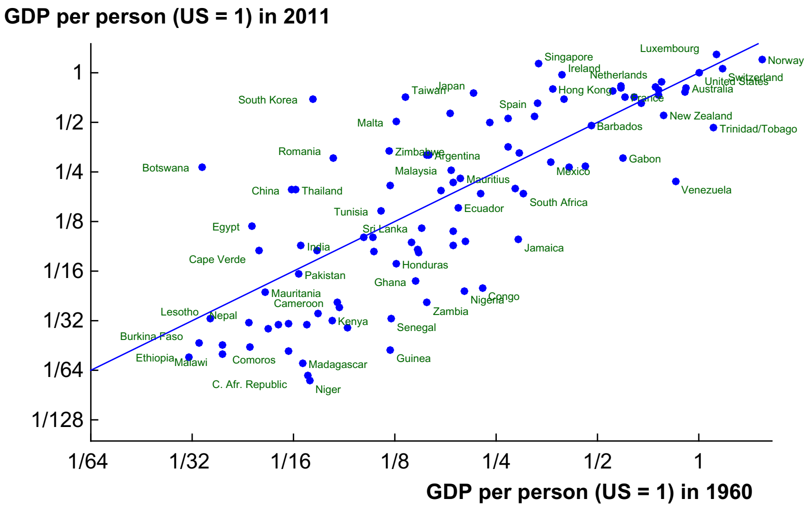

Fig. 24 GDP per person, 1960 and 2011. Source: *The Penn World Tables 8.0.*

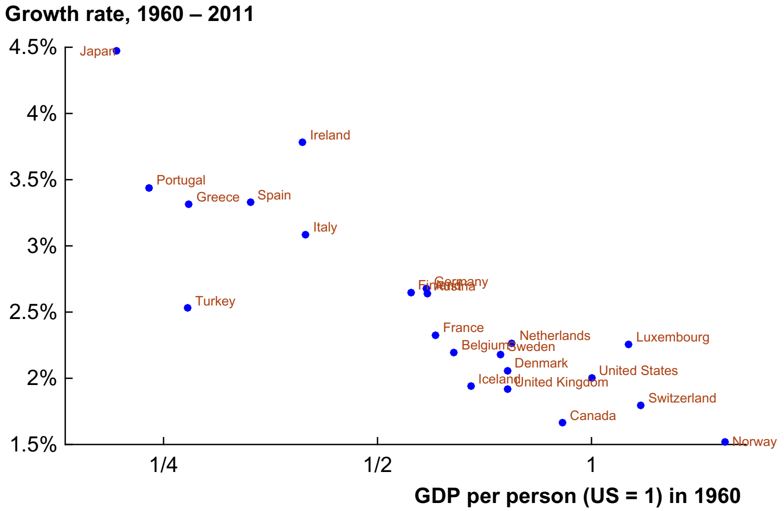

Fig. 25 Convergence in the OECD. Source: *The Penn World Tables 8.0. Countries in the OECD as of 1970 are shown.*

Fig. 25 shows one of the more famous graphs from the empirical growth literature, illustrating the "catch-up" behavior of OECD countries since 1960. Among OECD countries, those that were relatively poor in 1960—like Japan, Portugal, and Greece—grew rapidly, while those that were relatively rich in 1960—like Switzerland, Norway, and

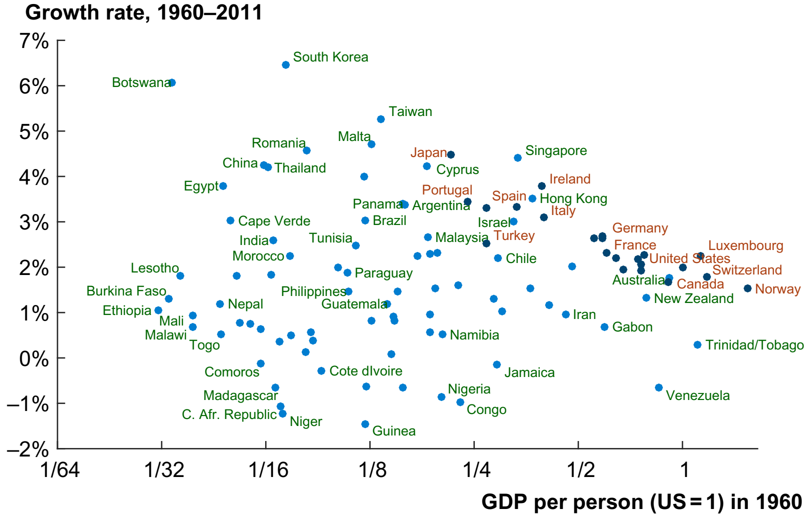

Fig. 26 The lack of convergence worldwide. Source: *The Penn World Tables 8.0.*

the United States—grew more slowly. The pattern is quite strong in the data; a simple regression line leads to an R-squared of 75%.[u]

Fig. 26 shows that a simplistic view of convergence does not hold for the world as a whole. There is no tendence for poor countries around the world to grow either faster or slower than rich countries. For every Botswana and South Korea, there is a Madagascar and Niger. Remarkably, 14 out of the 100 shown in the figure exhibited a negative growth rate of GDP per person between 1960 and 2011.

There is some question as to whether or not these persistent negative growth rates are entirely accurate. Young (2012) notes that the data on which these growth rates are based is often of very poor quality. For example, the United Nations National Accounts database publishes current and constant-price GDP numbers for 47 sub-Saharan African countries between 1991 and 2004, but as of mid-2006, the UN Statistical Office had actually received data for only one half of the observations, and had received no constant-price data at all for this period for 15 of these countries. Young uses measures of consumer durables (eg, radios, television sets, and bicycles) and other information from the Demographic and Health Surveys for developing countries to provide an alternative estimate of growth rates. He finds that living standards in sub-Saharan African countries were growing at around 3.5% per year during the last two decades, comparable to growth rates in other developing countries.

Barro (1991), Barro and Sala-i-Martin (1992), and Mankiw et al. (1992) provide a key insight into why the convergence pattern appears in Fig. 25 but not in Fig. 26. In

[u] See also Baumol (1986) and DeLong (1988).

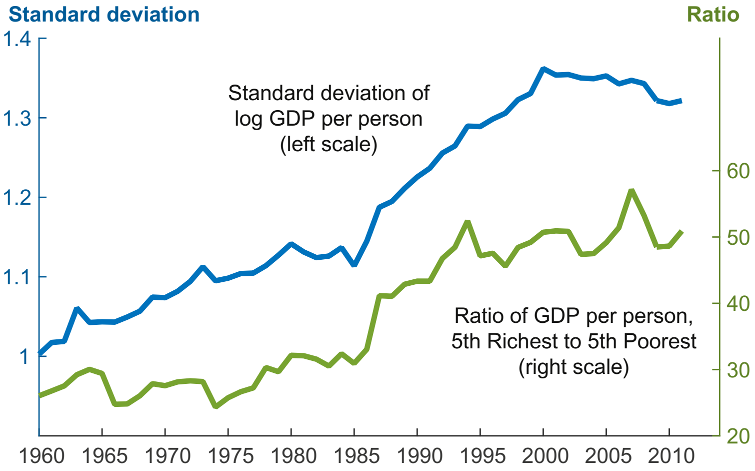

Fig. 27 Divergence since 1960. Source: *The Penn World Tables 8.0, calculated across a stable sample of 100 countries.*

particular, they show that the basic predictions of neoclassical growth theory hold for the world as a whole. Countries around the world are converging—but to their own steady-states, rather than to the frontier. If one conditions on determinants of a country's steady state (such as the investment rates in physical and human capital), then one sees that countries below their steady states grow rapidly and those above their steady states grow slowly (or even decline). The rate at which countries converge to their own steady state—often called the "speed of convergence"—seems to be around 2% per year, a fact sometimes known as "Barro's iron law of convergence." The interpretation of the OECD countries in Fig. 25, then, is that these countries have relatively similar steady state positions, so that even if we do not condition on these determinants formally, the convergence phenomenon appears. Confirming this logic, the implied speed of convergence for the OECD countries estimated from the slope of the best-fit line for Fig. 25 is 1.8% per year.[v]

These general patterns are examined in more detail in the following graphs and tables. Fig. 27 shows a time series of the cross-sectional standard deviation of log GDP per person for this stable 100-country sample. As an alternative measure of dispersion, it also shows the ratio of GDP per person between the 5th richest and 5th poorest countries in the sample. Both measures reveal the same thing: between 1960 and the late-1990s, there was a widening of the world income distribution, at least when each country is a unit of observation. In the last decade or so, this pattern seems to have stabilized. In fact, some of this pattern was already evident back in Fig. 24. The poorest countries in 1960 such as Ethiopia were only about 32 times poorer than the

[v] See Barro (2012) for a recent discussion of convergence.

Table 4 The very long-run distribution

	Distribution			
"Bin"	**1980**	**2010**	**Long run**	**Years to "shuffle"**
Less than 5%	18	21	15	1190
Between 5% and 10%	19	16	8	1100
Between 10% and 20%	22	16	11	920
Between 20% and 40%	13	18	14	270
Between 40% and 80%	19	18	32	950
More than 80%	9	12	20	1000

Entries under "Distribution" reflect the percentage of countries with relative (to the United States) GDP per person in each bin. "Years to shuffle" indicates the number of years after which the best guess as to a country's location is given by the long-run distribution (ie, within a percentage point, bin by bin), provided that the country begins in a particular bin.
Source: Computed following Jones, C.I. 1997. On the evolution of the world income distribution. J. Econ. Perspect. 11, 19–36 using the Penn World Tables 8.0 for 134 countries.

United States. By 2011, there are many countries with relative incomes below this level, and both Niger and the Central African Republic were more than 64 times poorer than the United States.

Table 4 examines the dynamics of the distribution of incomes across countries in a more systematic fashion, following Quah (1993). First, we sort the 134 countries for which we have data in both 1980 and 2010 into bins based on their income relative to the world frontier, represented by the United States. Then, using decadal growth rates between 1980 and 2010, we calculate the sample probabilities that countries move from one bin to another. Finally, we compute the stationary distribution of countries across the bins that is implied by assuming these sample probabilities are constant forever.

To begin, consider the 1980 and 2010 distributions shown in Table 4. The fraction of countries in the highest two bins increases slightly between 1980 and 2010. There is also a decrease in the fraction of countries between 5% and 20% of the US level.

Iterating over the dynamics implied by the sample transition probabilities leads to the stationary distribution shown in the third main column of the table.[w] Many countries are projected to move out of the lower and middle portions of the distribution and into the top.

Overall, the picture that emerges from this kind of analysis is that there is a basic dynamic in the data for the last 30 years that says that once countries get on the "growth escalator," good things tend to happen and they grow rapidly to move closer to the frontier. Where they end up depends, as we will discuss, on the extent to which their institutions improve. And this process is itself captured in the Markov transition dynamics estimated in Table 4. But whereas less than 30% of the countries were in the top two bins in 1980—with incomes

[w] Mathematically, the computation is easily illustrated. We estimate the Markov transition probabilities of countries across the bins. Multiplying this matrix by the initial distribution yields an estimate of the distribution of income for the next decade. Doing this many times yields an estimate of the long-run distribution.

greater than 40% of the US level—the Markov approach suggests that more than half of all countries will achieve this level of relative income in the long run.

One thing that may be misleading about this kind of exercise is that it implies that the stationary distribution is ergodic. That is, countries move around this distribution over time, so that, given enough time, even the United Kingdom can end up in the poorest bin. (The last column of the table suggests that these dynamics are very slow.) Perhaps this is correct—think about Argentina during the past 150 years. Alternatively, Lucas (2000), in his "Macroeconomics for the 21st Century," suggests that from the standpoint of the year 2100, the most striking fact of macroeconomics may end up being how many countries have moved close to the frontier. In other words, the Great Divergence of the last 200 years may turn into a Great Convergence over the next century. Perhaps the diffusion of good rules and good institutions leads to a more or less permanent improvement in the distribution, which is only partially captured by the kind of calculation done here.[x]

4.3 The Distribution of Income by Person, Not by Country

Up until now, we've taken the country as the unit of observation. This is appropriate for some purposes, but there is also a good case to be made for taking the person as the unit of observation: why should the 500,000 people in Luxembourg get the same weight as the 1.4 billion people in China?

Fig. 28 approaches the data from the standpoint of the individual. We assume each person in a country gets that country's GDP per person and then compute the world income distribution by person. More detailed calculations along these lines incorporate the distribution of income *within* each country as well and provide further support for the basic point in Fig. 28; see Bourguignon and Morrisson (2002) and especially Sala-i-Martin (2006).

In 1960, 51% of the world's population lived on less than 3 dollars per day (measured in 2005 US dollars). By 2011, less than 5% of the world's population lived below this level. The big difference, of course, is China and India, which between them contain more than one third of the world's population. In 1960, China and India were very poor, with incomes below $2.75 per day, while by 2011 average incomes were $10 per day in India and $22 per day in China. From the standpoint of the individual, the most outstanding fact of economic growth over the last 50 years is how many people have been elevated out of poverty.

4.4 Beyond GDP

It has long been recognized that GDP is an imperfect measure of living standards. Pollution, leisure, life expectancy, inequality, crime, and even freedom are some of

[x] Buera et al. (2011b) study the diffusion of market-oriented institutions in a setting where countries learn from the growth experiences of their neighbors. Kane (2015) explores a Markov approach like that discussed here and suggests that the escalator effects have been getting more prevalent over time.

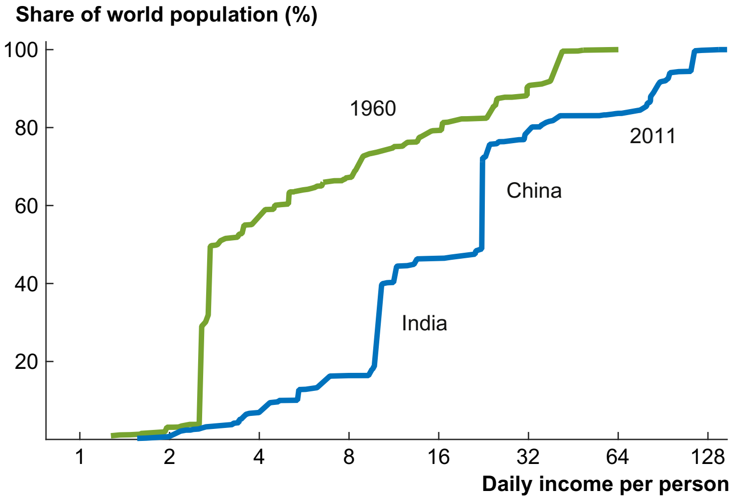

Fig. 28 The distribution of world income by population. Source: *The Penn World Tables 8.0, calculated across a stable sample of 100 countries.*

the factors that are incorporated imperfectly, if at all, in GDP. Various attempts have been made over the years to repair some of the omissions, or at least to judge how important they might be. Examples include Nordhaus and Tobin (1972), Becker et al. (2005), Fleurbaey and Gaulier (2009), and Stiglitz et al. (2009).

Jones and Klenow (2015) extend this literature by using a standard utility function and a "behind the veil of ignorance" approach to construct a consumption-equivalent welfare measure that values consumption, leisure, mortality, and inequality for a range of countries. Table 5 shows their baseline findings for a high-quality sample of countries for which household survey data can be used to compute welfare. The key finding comes in two parts. First, Western European countries like the United Kingdom and France have much higher living standards than their GDPs indicate. For example, compared to the United States, France has higher life expectancy, more leisure per person, and lower inequality of both consumption and leisure, and these differences make a substantial difference: whereas GDP per person in France is only about 2/3 of that in the United States, consumption-equivalent welfare is around 92% of the US level. Second, while many rich countries are richer than we might have thought, the opposite is true for poor countries. Life expectancy and leisure tend to be lower and inequality tends to be higher, all of which reduce welfare relative to GDP. As just one example, South Africa's GDP per person is about 16% of the US level, but consumption-equivalent welfare is only 7.4% of that in the United States.

In terms of growth rates, declining mortality has the largest impact: in most countries of the world—the notable exception being in sub-Saharan Africa—declining mortality has raised consumption-equivalent welfare growth substantially. In the United States and

Table 5 Beyond GDP: Welfare across countries

	Consumption-equivalent welfare	Income	Log ratio	Life exp.	Decomposition C/Y	Leisure	Cons. ineq.	Leis. ineq.
United States	100.0	100.0	0.000	0.000	0.000	0.000	0.000	0.000
United Kingdom	96.6	75.2	0.250	0.086	−0.143	0.073	0.136	0.097
France	91.8	67.2	0.312	0.155	−0.152	0.083	0.102	0.124
Italy	80.2	66.1	0.193	0.182	−0.228	0.078	0.086	0.075
Spain	73.3	61.1	0.182	0.133	−0.111	0.070	0.017	0.073
Mexico	21.9	28.6	−0.268	−0.156	−0.021	−0.010	−0.076	−0.005
Russia	20.7	37.0	−0.583	−0.501	−0.248	0.035	0.098	0.032
Brazil	11.1	17.2	−0.436	−0.242	0.004	0.005	−0.209	0.006
S. Africa	7.4	16.0	−0.771	−0.555	0.018	0.054	−0.283	−0.006
China	6.3	10.1	−0.468	−0.174	−0.311	−0.016	0.048	−0.014
Indonesia	5.0	7.8	−0.445	−0.340	−0.178	−0.001	0.114	−0.041
India	3.2	5.6	−0.559	−0.440	−0.158	−0.019	0.085	−0.028
Malawi	0.9	1.3	−0.310	−0.389	0.012	−0.020	0.058	0.028

Notes: The consumption-equivalent welfare numbers in the first column use a conventional utility function to "add up" the contributions from consumption, leisure, mortality, and inequality and express them in a consumption-equivalent manner. The income column reports GDP per person. The "decomposition" columns report an additive decomposition of the log difference between welfare and income.

Source: These numbers are taken from table 2 of Jones, C.I., Klenow, P.J. 2015. Beyond GDP: Welfare across countries and time. Stanford University, unpublished manuscript, and are based on data from household surveys in each country, from the World Bank (for mortality), and from the Penn World Tables 8.0 for a year close to 2005.

Western Europe, for example, growth rates since 1980 are arguably understated by around a full percentage point because of this factor.

4.5 Development Accounting

Development accounting applies the logic of Solow's growth accounting to explain differences in the levels of GDP per worker across countries. Countries can be rich because they have large quantities of inputs or because they use these inputs efficiently. Quantitatively, how important are each of these components?

An early version of development accounting is Denison (1967), who compared 8 European economies to the United States in 1960. Christensen et al. (1981) work with a similar set of countries and extend the analysis to include human capital. King and Levine (1994) focus on the role of physical capital vs TFP in a broad set of countries, and provide the first use of the phrase "development accounting" that I have found.[y] Klenow and Rodriguez-Clare (1997) and Hall and Jones (1999) incorporate human capital differences and consider a broad range of countries. Caselli (2005) provides a detailed overview and analysis of this literature.[z]

The basics of development accounting follow closely upon the analysis of growth accounting that we conducted back in Section 2 To see this link, recall the production function we considered there:

$$Y_t = \underbrace{A_t M_t}_{\text{TFP}} K_t^{\alpha} H_t^{1-\alpha}. \tag{5}$$

Some versions of development accounting work directly with this production function. The advantage is that it is the most straightforward approach. The disadvantage is familiar from growth accounting and the standard neoclassical growth model: differences in TFP induce capital accumulation that leads to differences in K across countries. Hence some of what is attributed to K in this approach might more naturally be attributed to TFP.

An alternative approach—pursued by Klenow and Rodriguez-Clare (1997) and Hall and Jones (1999)—is to rewrite the production function in a way that assigns any induced capital accumulation to TFP. This is accomplished by dividing both sides of the production function by Y_t^{α} and solving for Y_t to get

[y] Bob Hall and I (Hall and Jones, 1996) proposed the phrase "levels accounting" which doesn't have nearly the same ring!

[z] The papers cited to this point assume a known production function—typically Cobb-Douglas with an exponent on capital around 1/3. A related set of papers including Mankiw et al. (1992), Islam (1995), and Caselli et al. (1996) conduct a similar exercise in a regression framework. The limitation of the regression framework in its simplest form is that it imposes an orthogonality between inputs and total factor productivity which seems inappropriate. Estimating production functions is notoriously difficult.

$$\frac{Y_t}{L_t} = \left(\frac{K_t}{Y_t}\right)^{\frac{\alpha}{1-\alpha}} \frac{H_t}{L_t} \cdot Z_t \tag{6}$$

where $Z_t \equiv (A_t M_t)^{\frac{1}{1-\alpha}}$ is total factor productivity measured in labor-augmenting units. To understand why this equation assigns the induced capital accumulation to TFP, notice that in the steady state of a neoclassical growth model, the capital–output ratio K/Y is proportional to the investment rate and independent of TFP. Hence the contributions from productivity and capital deepening are separated in this version, in a way that they were not in Eq. (5). This was the equation on which we based our growth accounting, and we will use the same equation for development accounting.

The Penn World Tables, starting with Version 8.0, contains all the information needed to conduct the simplest form of development accounting as in Eq. (6). That data set contains measures of the economy's stock of physical capital and measures of human capital that are based on educational attainment data from Barro and Lee (2013) and Mincerian returns to education of 13.4% for the first 4 years, 10.1% for the second 4 years, and 6.8% for all additional years, as in Hall and Jones (1999). We conduct our growth accounting exercise using this data and Eq. (6), assuming $\alpha = 1/3$.[aa]

Table 6 shows the basic development accounting exercise using the Penn World Tables data for a sample of countries.[ab] To see how the accounting works, consider the row for Mexico. According to the Penn World Tables, Mexico has a GDP per worker that is about 1/3 that in the United States in 2010. This 1/3 number is the product of the next three terms in the row, following the formula in Eq. (6).

Remarkably little of the difference is due to physical capital: the capital–output ratio in Mexico is about 87% of that in the United States. Because of diminishing returns, though, it is the square root ($\alpha/(1-\alpha) = 1/2$ when $\alpha = 1/3$) of this difference that matters for income, and $\sqrt{0.87} \approx 0.93$, so differences in physical capital only lead to about a 7% difference in GDP per worker between the United States and Mexico.

In the next column, we see a larger contribution from human capital. In 2010, people aged 15 and over in Mexico had on average around 8.8 years of education according to Barro and Lee (2013). In contrast, educational attainment in the United States was 13.2. The difference is 4.6 years of schooling. With a return to each year of education of around 7%, this implies about a 32% difference due to education. The entry from human capital for Mexico is 0.76, and $1/0.76 \approx 1.32$, consistent with this reasoning.

The implied difference in TFP between the United States and Mexico is then $0.338/(0.931 \times 0.760) \approx 0.477$. Put another way, GDP per worker was 3 times higher

[aa] The Penn World Tables now contains its own measure of TFP as well. This measure is based on a Tornqvist index of inputs that incorporates variations in factor shares. The data appendix of Feenstra et al. (2015) contains a helpful and extensive discussion of the data and methods.

[ab] Data on all countries can be obtained in the data files available on the author's web page; see the file "DevelopmentAccounting.log."

Table 6 Basic development accounting, 2010

	GDP per worker, y	Capital/GDP $(K/Y)^{\alpha/(1-\alpha)}$	Human capital, h	TFP	Share due to TFP
United States	1.000	1.000	1.000	1.000	–
Hong Kong	0.854	1.086	0.833	0.944	48.9%
Singapore	0.845	1.105	0.764	1.001	45.8%
France	0.790	1.184	0.840	0.795	55.6%
Germany	0.740	1.078	0.918	0.748	57.0%
United Kingdom	0.733	1.015	0.780	0.925	46.1%
Japan	0.683	1.218	0.903	0.620	63.9%
South Korea	0.598	1.146	0.925	0.564	65.3%
Argentina	0.376	1.109	0.779	0.435	66.5%
Mexico	0.338	0.931	0.760	0.477	59.7%
Botswana	0.236	1.034	0.786	0.291	73.7%
South Africa	0.225	0.877	0.731	0.351	64.6%
Brazil	0.183	1.084	0.676	0.250	74.5%
Thailand	0.154	1.125	0.667	0.206	78.5%
China	0.136	1.137	0.713	0.168	82.9%
Indonesia	0.096	1.014	0.575	0.165	77.9%
India	0.096	0.827	0.533	0.217	67.0%
Kenya	0.037	0.819	0.618	0.073	87.3%
Malawi	0.021	1.107	0.507	0.038	93.6%
Average	0.212	0.979	0.705	0.307	63.8%
1/Average	4.720	1.021	1.418	3.260	69.2%

The product of the three input columns equals GDP per worker. The penultimate row, "Average," shows the geometric average of each column across 128 countries. The "Share due to TFP" column is computed as described in the text. The 69.2% share in the last row is computed looking across the columns, ie, as approximately 3.5/(3.5 + 1.5).
Source: Computed using the Penn World Tables 8.0 for the year 2010 assuming a common value of $\alpha = 1/3$.

in the United States than in Mexico. A factor of $1.07 \times 1.32 \approx 1.4$ of this difference is due to inputs, meaning a factor of 2.1 was due to TFP, since $1.4 \times 2.1 \approx 3$. From these numbers, one can also see easily how the "Share due to TFP" column is calculated. Notice that both 1.4 and 2.1 are simple multiples of 7: for each 2 parts due to inputs, 3 parts are due to TFP, hence the share due to TFP is around 60% (that is, 3/(2+3)).

More generally, several key findings stand out from Table 6. First, the capital-output ratio is remarkably stable across countries. Its average value is very close to one, and even the poorest country in the table, Malawi, is reported by the Penn World Tables to have a capital-output ratio very close to the US value. So differences in physical capital contribute almost nothing to differences in GDP per worker across countries. Caselli and Feyrer (2007) document a closely-related fact in great detail: the marginal product of capital (which here is proportional to the inverse of the capital-output ratio) is very similar in rich and poor countries.[ac]

[ac] The general lack of correlation between the capital-output ratio and GDP per person is discussed by Feenstra et al. (2015).

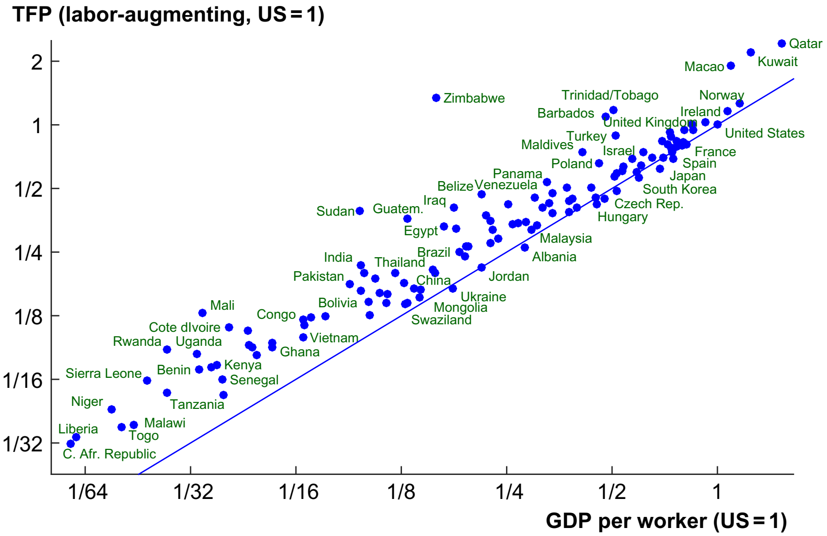

Fig. 29 Total factor productivity, 2010. Source: *Computed using the Penn World Tables 8.0 assuming a common value of* $\alpha = 1/3$.

Second, the contribution from educational attainment is larger, but still modest. For example, countries like India and Malawi only see their incomes reduced by a factor of 2 due to educational attainment. Loosely speaking, the poorest countries of the world have 4 or 5 years of education, while the richest have 13. Eight years of education with a Mincerian return of around 10% leads to a 0.8 difference in logs, and $exp(0.8) \approx 2$.

Finally, the implication of these first two points is that differences in TFP are the largest contributor to income differences in an accounting sense. Fig. 29 shows the levels of TFP plotted against GDP per worker for 128 countries in 2010. The two series are highly correlated at 0.96. And the differences in TFP are very large: the Central African Republic is about 64 times poorer than the United States and its TFP is about 32 times lower than the US level.

The large contribution from TFP is verified by the last column of Table 6, where the share explained by TFP ranges from just under 50% for Singapore and Hong Kong to more than 90% for Malawi. To understand the "Share due to TFP" column, consider the last row of Table 6. According to that row, the average country in the 128-country sample is just over 5 times poorer than the United States. Essentially none of this difference (a factor of 1.021) is due to differences in K/Y, while a factor of 1.42 is due to differences in educational attainment. Taken together, this means a factor of $1.021 \times 1.42 \approx 1.5$ is due to inputs, leaving a factor of about 3.5 attributed to TFP. We then compute the "Share due to TFP" as $3.5/(1.5 + 3.5) \approx 70\%$, as shown in the last entry in Table 6.[ad] The rest of the shares are computed in an analogous way. For example, for Malawi, about a factor

[ad] Or more exactly as $3.26/(3.26 + 1.021 * 1.418) \approx 69.2\%$.

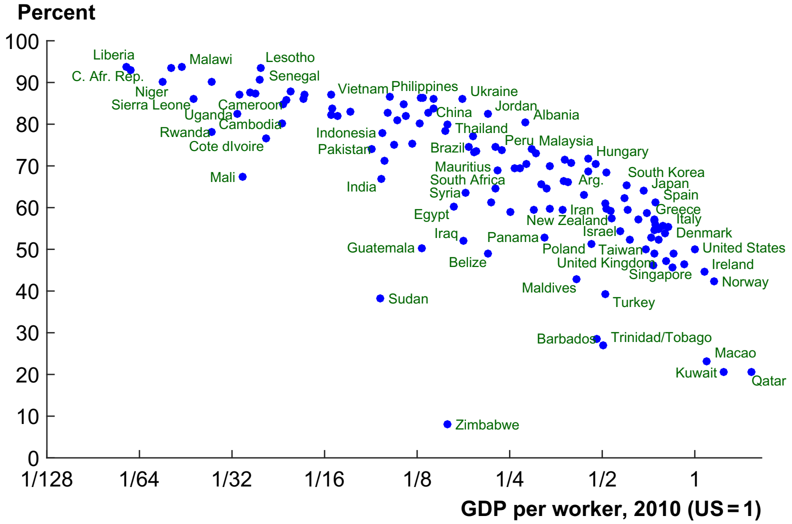

Fig. 30 The share of TFP in development accounting, 2010. Source: *Computed as described in the text and in Table 6 using the Penn World Tables 8.0 assuming a common value of* $\alpha = 1/3$.

of 2 is due to inputs and a factor of 26 is due to TFP, meaning that 26/28 ≈ 93% is due to TFP.

More generally, the share across all 128 countries is shown in Fig. 30. There, a systematic pattern is obvious. In the poorest countries of the world, well over 80% of the difference in GDP per worker relative to the United States is due to TFP differences. Moving across the graph to richer countries, one sees that less and less is due to TFP, and for the richest countries as a whole, TFP contributes around 50% of the differences.

4.6 Understanding TFP Differences

The basic finding that TFP differences account for the bulk of income differences across countries has led to a large body of research designed to explain what these differences are. This is exemplified by the title of a famous paper by Prescott (1998): "Needed: A Theory of TFP."

In the last 15 years, this challenge has been approached in two ways. First, several papers have improved our measures of inputs in various ways, chipping away at the contribution of the "measure of our ignorance." Second, the literature on misallocation has emerged to provide the kind of theory that Prescott was seeking. The remainder of this section will review the efforts to improve input measurement, while the next several sections will consider misallocation and its implications.

Caselli (2005) provides a detailed survey and analysis of the state of development accounting as of 2005. The interested reader should certainly look there to get up to speed. Caselli reviews progress on many dimensions: measuring the quality of education using test scores (Hanushek and Kimko, 2000); considering differences in the experience of the labor force across countries (Klenow and Rodriguez-Clare, 1997); sectoral differences in productivity, especially agriculture (Restuccia et al., 2008); differences in labor productivity due to health (Weil, 2007); differences in the quality of capital (Caselli and Wilson, 2004); and the potential role of nonneutral productivity (Caselli and Coleman, 2006).

Much additional progress has been made in the decade since Caselli's review was published, especially with respect to misallocation, as discussed in the next section. But there has also been much valuable work on measuring the inputs into development accounting. Lagakos et al. (2012) use household survey data from 35 countries to show that the returns to experience vary substantially across countries, with poorer countries typically having much flatter age-earnings profiles. Incorporating differential returns to experience in development accounting boosts the importance of the human capital term by about 50%. Hendricks and Schoellman (2014) use data on immigrants from 50 source countries into 11 different host countries to improve our measurement of labor quality differences, providing another boost to the human capital term—of about 30%. Hanushek and Woessmann (2008) survey the broad range of evidence highlighting the importance of educational quality and cognitive skills more generally.

Two recent papers study the role of human capital once we depart from the assumption that workers with different human capital (such as education) are perfect substitutes. Jones (2014) proposes a generalized aggregator over workers with heterogeneous education levels and argues that the traditional perfect-substitutes case delivers a lower bound for the role of human capital. If workers with different human capital are less than perfect substitutes, the share of income differences explained by human capital may rise dramatically. Caselli and Ciccone (2013), however, take a similar approach but find the opposite result: the perfect substitutes case gives an upper bound on the importance of human capital differences, which therefore must be small.

How can these two papers be reconciled? To see an answer, consider a factor-augmenting productivity term that multiplies the amount of labor of each type. Caselli and Ciccone effectively keep this parameter unchanged when they do their development accounting and find large neutral TFP differences. Jones implicitly assumes these productivities change when the quantities of the different types of human capital change across countries, so as to keep the relative wages across types (eg, the skilled wage premium) constant. In other words, (Ben) Jones requires large productivity residuals in his development accounting as well, it's just that he labels these residuals as being inside the "human capital" aggregator rather than being neutral TFP differences.[ae]

4.7 Misallocation: A Theory of TFP

One of the great insights of the growth literature in the last 15 years is that misallocation at the micro level can show up as a reduction in total factor productivity at a more aggregated level. This insight appears in various places, including Banerjee and Duflo (2005), Chari et al. (2007), Restuccia and Rogerson (2008) and Hsieh and Klenow (2009).

As we discussed briefly in the context of misallocation and frontier growth (in Section 2.6), the essence of this insight is quite straightforward: when resources are allocated optimally, the economy will operate on its production possibilities frontier. When resources are misallocated, the economy will operate inside this frontier. But that is just another way of saying that TFP will be lower: a given quantity of inputs will produce less output.

A simple example illustrates this point. Suppose output is produced using two tasks according to $Y = X_1^{\alpha} X_2^{1-\alpha}$. This could describe a firm, and the tasks could be management and the production line, or this could be the economy as a whole and the tasks could be manufacturing and services. Suppose that each task is accomplished very simply: one unit of labor can produce one unit of either task, and the economy is endowed with L units of labor. Finally, suppose that the allocation of labor is such that a fraction s works in the first task, and the fraction $1 - s$ works in the second task. We leave the source of this allocation unspecified: labor could be optimally allocated, or it could be misallocated because of taxes, poor management, information problems, unions, or many other reasons. But given this allocation, there is a reduced-form production function given by

$$Y = M(s)L \quad \text{where} \quad M(s) \equiv s^{\alpha}(1-s)^{1-\alpha} \tag{7}$$

[ae] This finding is related to an observation made by Caselli and Coleman (2006). They noted that the ratio of "skilled" to "unskilled" workers varies enormously across countries. For example, if we let high school completion be the dividing line, the ratio of skilled to unskilled workers is just 0.025 in Kenya vs 1.8 in the United States—a difference of a factor of 70. If college completion is the dividing line, the factor proportions differ by even more. When workers with different human capital levels are no longer perfect substitutes, this ratio becomes relevant. The difficulty is that it can then imply implausibly large differences in the return to schooling across countries if one is not careful. Caselli and Coleman introduce additional TFP terms so they can match the returns to education, but then the large differences in factor proportions shows up as enormous differences in these nonneutral TFP terms. A similar issue seems to arise in the approach taken by (Ben) Jones; in this sense, there is implicitly an omitted nonneutral (ie, skill biased) TFP term that differs across countries and that is not being taken into account.

In other words, total factor productivity in this economy is $M(s)$, which depends on the allocation of labor in the economy.[af] Moreover, it is easy to see that the output-maximizing allocation of labor in this example has $s^* = \alpha$, and any departure of the allocation from s^* will reduce total factor productivity. This is the essence of the literature on misallocation and TFP.

This insight is at the heart of our best candidate explanations for answering the question of why some countries are so much richer than others. Development accounting tells us that poor countries have low levels of inputs, but they are also remarkably inefficient in how they use those inputs. Misallocation provides the theoretical connection between the myriad distortions in poor economies and the TFP differences that we observe in development accounting.

The remainder of this section explores various facts related to misallocation.

4.8 Institutions and the Role of Government

Countries are a natural unit of analysis for growth economists for the simple reason that national borders are the places where different political and economic institutions begin and end. It has long been conjectured that differences in these institutions are fundamental determinants of long-run economic success. But what is the evidence for such a claim? How do we know that the income differences we see across countries are not primarily driven by differences in natural resources or other aspects of geography?

One of the best sources of evidence on this question was provided by Olson (1996). Olson observed that history itself provides us with “natural experiments” that allow us to see the large impact of institutions on economic success. For example, prior to World War II, North and South Korea were not separate countries. As a rough approximation, the north and south of Korea contained people that shared a cultural heritage, a government, institutions, and even a geography. In fact, if anything, North Korea was economically advantaged relative to the South, containing a disproportionate share of electricity production and heavy industry.[ag] After the Korean War ended in 1953, North and South Korea were divided and governed according to very different rules. The resulting economic growth of the next half century was dramatically different, as illustrated in

[af] One could easily assume both capital and labor are used to produce each X so that the result in Eq. (7) would be $Y = M(s)K^{\beta}L^{1-\beta}$, which makes the connection between $M(s)$ and TFP even more apparent.

[ag] “[Under Japanese rule before World War II], the colonial industries were unevenly distributed between South Korea and North Korea. Heavy and chemical industries were concentrated in the North, while many light industries, such as textile, food, printing and wood, were located in the South. In 1940, North Korea’s share of the total production in the metal industry was 96%, and 82% for the chemical industry. Also, 92% of the total electricity production originated from the North in 1945 (Lee, D-G, 2002: 39). Thus, in 1945 when Japan withdrew from Korea and when Korea was divided into two separate political regimes, the South Korean economy in general and industry in particular were severely crippled.” Yang (2004), p. 16.

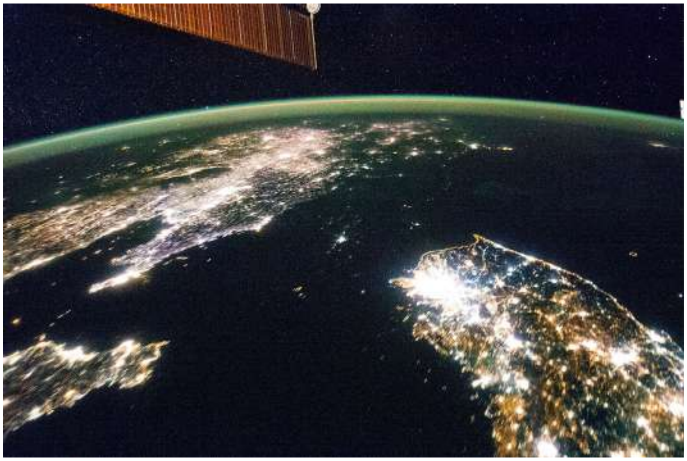

Fig. 31 Korea at night. *Note*: North Korea is the dark area in the center of the figure, between China to the north and South Korea to the south. Pyongyang is the isolated cluster in the center of the picture. Source: *http://commons.wikimedia.org/wiki/File:North_and_South_Korea_at_night.jpg*.

Fig. 31. The picture in this figure was taken by an astronaut on the International Space Station in early 2014 and shows North and South Korea at night. South Korea is brightly lit, while North Korea is almost completely dark, barely indistinguishable from the ocean. Whatever was different between North and South Korea after 1953 apparently had an enormous influence on their long-term economic success.

As a brief aside, it is worth noting that during the last several years, a number of papers have used satellite data on lights at night to study economic growth. Henderson et al. (2012) introduce this data and argue that it provides useful information on growth and standards of living. They also note that it can be used to study growth at the regional level, where income measures are not often available in developing countries. Michalopoulos and Papaioannou (2014) take up this latter point and compare the importance of national policies with subnational/cultural institutions using the light data.

"Natural" experiments similar to the North/South Korea example can be observed in East and West Germany after World War II, Hong Kong and southeastern China, and across the Rio Grande between Mexico and Texas. These examples make clear that something malleable matters for economic success even if they do not specifically identify what that something is.

Another fascinating piece of evidence comes from Acemoglu et al. (2002) and is illustrated in Fig. 32, the so-called reversal of fortune. Restricting our attention to former European colonies, economic success 500 years ago is *negatively* correlated with economic

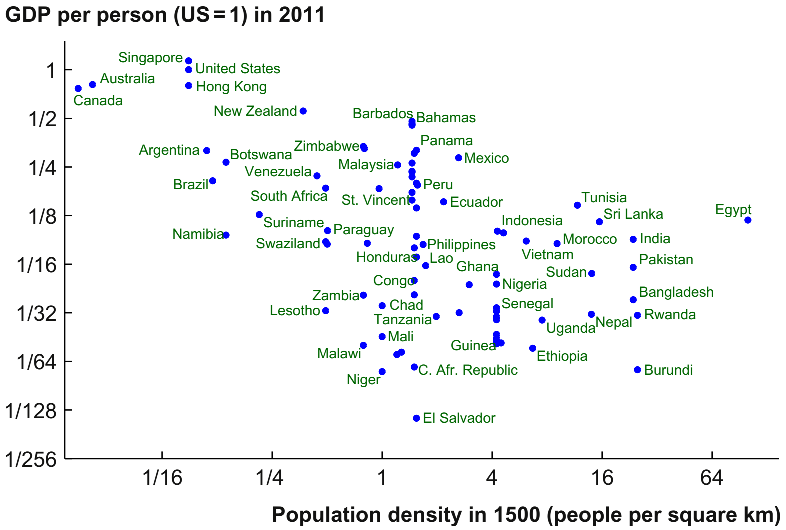

Fig. 32 The reversal of fortune. *Note:* Former European colonies that were proserous (at least in terms of population density) in 1500 are on average poorer today rather than richer. Source: *Population density is from Acemoglu, D., Johnson, S., Robinson, J.A. 2002. Reversal of fortune: geography and institutions in the making of the modern world income distribution. Q. J. Econ. 117 (4), 1231–1294 and GDP per person is from the Penn World Tables 8.0.*

success today. That is, the places that were most successful 500 years ago, as measured by population density or urbanization, are on average comparatively poor today.

A classic example of this phenomenon, highlighted by Engerman and Sokoloff (1997), is the New World:

> *[Latin America] began with—by European standards of the time—vast supplies of land and natural resources per person and were among the most prosperous and coveted of the colonies in the seventeenth and eighteenth centuries. Indeed, so promising were these other regions that Europeans of the time generally regarded the thirteen British colonies on the North American mainland and Canada as of relatively marginal economic interest—an opinion evidently shared by Native Americans who had concentrated disproportionately in the areas the Spanish eventually developed. Yet, despite their similar, if not less favorable, factor endowments, the United States and Canada ultimately proved to be far more successful than the other colonies in realizing sustained economic growth over time (pp. 260–261).*

These examples suggest that economic success is not permanently given, for example by geographic endowments, but rather can be changed by the rules that are put in place. Engerman and Sokoloff (1997), Acemoglu et al. (2002), and others suggest that the institutions adopted by Europeans in response to these initial conditions influenced subsequent growth. In places that were already economically successful in 1500, Europeans tended to set up “extractive” institutions to transfer the economic gains back to Europe.

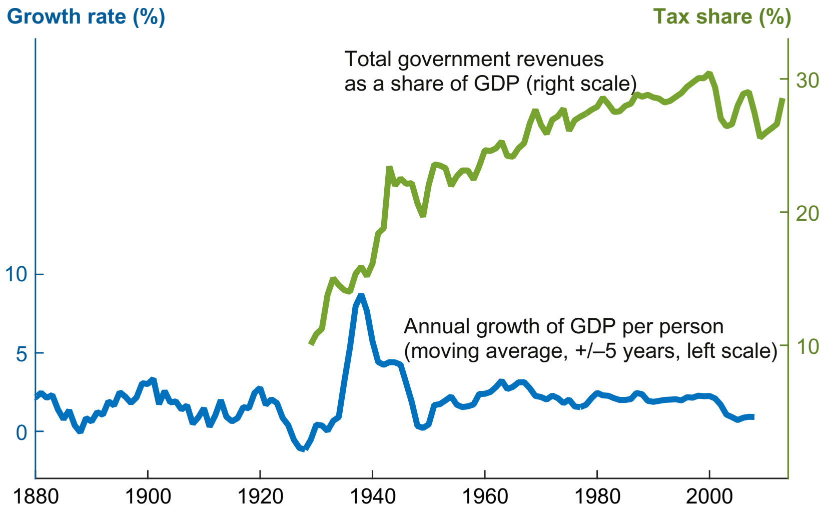

Fig. 33 Taxes and growth in the United States. Source: *This graph updates a similar figure in Stokey, N.L., Rebelo, S. 1995. Growth effects of flat-rate taxes. J. Polit. Econ. 103, 519–550. Total government current receipts are from NIPA table 3.1 via the FRED database and include federal, state, and local revenues. Real GDP per person is constructed as in Fig. 1. The growth rate is smoothed by taking a moving average across the 5 years before and after the relevant date.*

In contrast, Europeans themselves migrated to places that were sparsely populated in 1500, setting up "European" institutions that were conducive to long-run economic success.[ah]

Dell (2010) provides a detailed analysis of the long-reaching nature of one such institution in Peru. The "mita" was a forced labor system conscripting one seventh of the adult male population in a region of Peru to work in local silver and mercury mines between 1573 and 1812. A regression discontinuity analysis reveals that today—200 years later after this system ended—consumption is lower inside the former mita by 25%, educational attainment is lower, and the region is less well connected by roads and infrastructure.

4.9 Taxes and Economic Growth

One of the most obvious and readily quantified measures of government involvement in the economy is taxes. It is easy to write down models in which governments that tax heavily reduce the long-run success of their economies. The facts, however, are not so clear.

Fig. 33 shows the growth rate of real GDP per person in the United States since 1980 as well as the total government tax revenues (including state and local) as a share of GDP, updating a graph first highlighted by Stokey and Rebelo (1995). The remarkable fact that

[ah] For example, see also Hall and Jones (1999), Acemoglu et al. (2001), and Acemoglu and Robinson (2012).

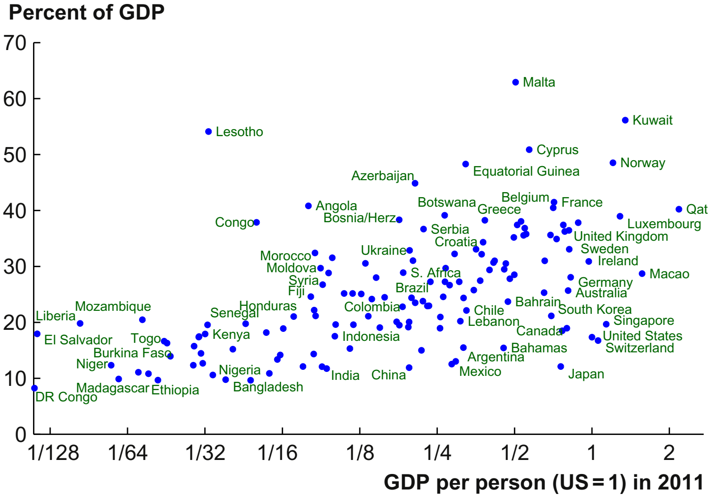

Fig. 34 Tax revenues as a share of GDP. *Note:* Tax revenue is averaged for the available years between 2000 and 2014, is for the central government only, and includes receipts for social insurance programs. Source: *This is an updated graph of a figure from Acemoglu, D. 2005. Politics and economics in weak and strong states. J. Monet. Econ. 52 (7), 1199–1226. http://ideas.repec.org/a/eee/moneco/v52y2005i7p1199-1226.html. The World Bank,* World Development Indicators. *GDP per person is from the Penn World Tables 8.0.*

emerges from this graph is that taxes have increased enormously, from around 10% of GDP in 1929 to more than 30% of GDP at their peak in 2000. But as we already noted earlier, growth rates over the 20th century were remarkably stable—if anything, they were higher after 1950 than before.

Fig. 34 shows a related fact by looking across the countries of the world: tax revenues as a share of GDP are *positively* correlated with economic success, not negatively correlated.

Of course, these are just simple correlations, and the nature of causality is likely to be very complicated. Governments do not simply throw the tax revenue that they collect into the ocean. Instead, this revenue—at least to some extent—is used to fund the good purposes that governments serve: providing a stable rule of law, a judicial system, education, public health, highways, basic research, and so on. Alternatively, perhaps only rich countries can afford large governments. Besley et al. (2013) and Pritchett and Aiyar (2015) consider issues along these lines.

4.10 TFPQ vs TFPR

An important realization related to the measurement of either labor productivity or TFP emerged during the last decade. Specifically, to measure true productivity, one needs detailed information on micro level prices. Foster et al. (2008) introduced the labels "TFPQ" and "TFPR," which will be explained in detail below. This distinction plays a crucial role in Hsieh and Klenow (2009). For more discussion, see the recent survey by Syverson (2011).

To see this point most easily, consider the following setup. The economy consists of a unit measure of heterogeneous varieties that enter the utility function via a CES aggregator:

$$C = \int_0^1 (\alpha_i Y_i)^\rho di \tag{8}$$

where α_i are taste parameters related to each variety and $0 < \rho < 1$ governs the elasticity of substitution between varieties.

Each variety is assumed to be produced by different monopolistically-competitive firms using labor:

$$Y_i = A_i L_i \tag{9}$$

where A_i is the (exogenous) productivity with which each variety is produced. Finally, assume labor is homogenous and can be hired by any firm at a wage rate w.

It is well known that in this kind of setup, monopolistically-competitive firms charge a price p_i for their variety that is a markup over marginal cost:

$$p_i = \frac{1}{\rho} \cdot \frac{w}{A_i}. \tag{10}$$

This implies that sales revenue for each firm is $p_i Y_i = wL_i/\rho$.

Now consider measuring firm-level productivity in this economy. Since we've left capital out of this example, we focus on labor productivity. But exactly the same issues apply to TFP as well.

In general, the data we have available on firms include sales revenues $p_i Y_i$ and employment L_i. This leads immediately to an important point: if one does not have data on the firm-level price p_i, then one cannot recover A_i. For example, deflating revenue by an industry-level price deflator is not the same as deflating by p_i because firms are heterogeneous and have different productivity levels. In the absence of firm-level prices, one typically recovers

$$\text{Revenue Productivity, TFPR}_\text{i}: \ \frac{p_i Y_i}{L_i} = \frac{w}{\rho}.$$

If firms have identical markups and do not face any distortions, revenue productivity should be equated across heterogeneous firms. Workers have to earn the same wage at each firm, and this equates the marginal revenue product of labor across firms, which is all that is being recovered here.

The same argument applies to total factor productivity, and gives rise to the label TFPR, where the "R" denotes "revenue" TFP. The marginal revenue product of capital should also be equated across firms in a simple model like this one, so weighted averages of the average revenue products of capital and labor—which is what TFPR is—should be equated across firms.

By this point, the reader should realize that in a world of heterogeneous goods, it is not even obvious how to compare "true productivity." How do we compare Ford's productivity in making pickup trucks to Tesla's productivity in making electric cars? Or how do we compare Dell's productivity at making PC's with Apple's productivity at making Macs? Even if we had detailed data on the price of Ford trucks and Tesla cars—even if we recovered the A_i's using these prices—they would not be comparable, because the products are different!

Both of these issues are addressed by having knowledge of the utility function, in this case the C aggregator in Eq. (8). In particular, knowledge of the utility function allows one to compute the marginal rate of substitution between different products—it tells us how to compare Fords and Teslas or Apples and Dells.

To see how, notice that the demand curve from utility maximization of (8) is

$$\lambda p_i = \rho \alpha_i^\rho Y_i^{\rho-1}. \tag{11}$$

where λ is the Lagrange multiplier from the budget constraint; we'll choose units so that $\lambda = 1$ in what follows. Sales revenue for variety i is then

$$p_i Y_i = \rho(\alpha_i Y_i)^\rho \tag{12}$$

and we can invert this equation to obtain

$$\alpha_i Y_i = \left(\frac{p_i Y_i}{\rho}\right)^{1/\rho}. \tag{13}$$

But this is what we require: $\alpha_i Y_i$ is the term that enters the utility aggregator C. The α_i tell us how to combine Fords and Teslas:[ai]

$$\text{True Productivity, TFPQ}_\text{i}: \ \frac{\alpha_i Y_i}{L_i} = \frac{(p_i Y_i)^{1/\rho}}{L_i} = \alpha_i A_i.$$

That is, TFPQ (the "Q" denotes "quantity" TFP) indicates how effective a firm is at taking a unit of labor (in this case, with no capital) and using it to produce Fords or Teslas in comparable units.

Notice that TFPQ is measured in this case using only the data we typically have—sales revenue and employment—together with knowledge of the elasticity of demand.

[ai] I'm dropping the $\rho^{1/\rho}$ term in the equation to keep things clear.

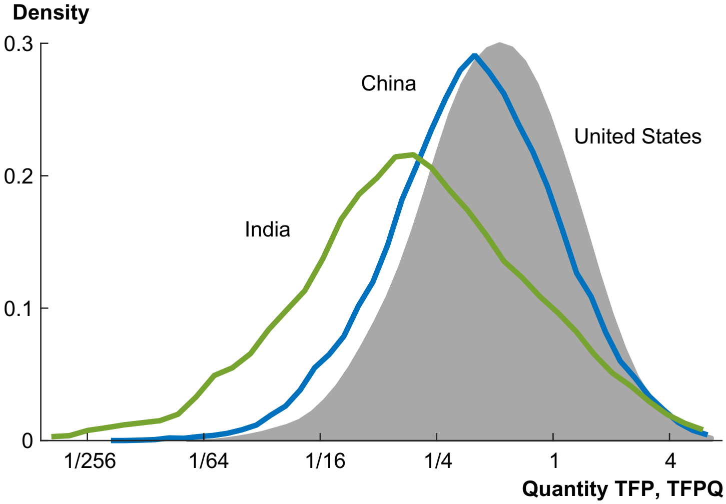

Fig. 35 The distribution of TFPQ in 4-digit manufacturing industries. *Note:* This is the average distribution of TFPQ within 4-digit manufacturing industries for the United States in 1997, China in 2005, and India in 1994, computed as described in the text. The means across countries are not meaningful. Source: *Hsieh, C.T., Klenow, P.J. 2009. Misallocation and manufacturing TFP in China and India. Q. J. Econ. 124 (4), 1403–1448; data provided by Chang Hsieh.*

TFPQ reflects both A_i and α_i—these are both part of fundamental productivity in this economic environment. In contrast, the somewhat conventional measure TFPR is actually independent of A_i and α_i.[aj]

4.11 The Hsieh–Klenow Facts

To quantify the effect of misallocation on aggregate TFP, Hsieh and Klenow (2009) use the insight that TFPR should be equated across plants if resources are allocated optimally. In particular, they use variation in TFPR across plants within 4-digit manufacturing industries to measure misallocation in the United States, China, and India.

The first part of their approach has already been explained in the previous section: they assume CES demand and use the constant elasticity to back out prices and real output from sales revenue. This allows them to measure "true" TFP, called "TFPQ," for each establishment in their data. The average distribution of TFPQ within 4 digit manufacturing that they recover is shown in Fig. 35.

As shown in this figure, the distributions within industry of TFPQ in the United States and China are relatively similar, while the distribution is significantly wider in

[aj] In richer settings, TFPR can depend on A_i, for example if there are fixed costs in production.

India.[ak] What is surprising, perhaps, is just how large the differences in TFPQ are within an industry. Hsieh and Klenow (2009) find that the 90–10 ratio of TFPQ across plants is 8.8 in the United States, 22.4 in India, and 11.5 in China. One way of thinking about these large differences is to note that employment differences across plants is very large. Why does a large textile manufacturer employ many more workers than a family shop? One answer is that TFPQ is much higher for the large plant.

Hsieh and Klenow's most valuable contribution, however, is to quantify misallocation. To see how they do this, consider a plant that produces with a Cobb–Douglas production function, using capital and labor, and that faces distortions τ_K and τ_L in choosing its inputs. These distortions are modeled as if they are taxes, but the literature interprets the distortions much more broadly to include credit market frictions, hiring and firing costs, quantity restrictions, and so on. The profit-maximizing firm will hire capital and labor until the marginal revenue product of these factors equals their gross-of-distortion rental price.[al] Written differently, payments to factors will equal the product of the factor exponents and the distortion terms:

$$\frac{rK_i}{p_i Y_i} = \alpha_K \cdot \frac{1}{1+\tau_K} \tag{14}$$

and

$$\frac{wL_i}{p_i Y_i} = \alpha_L \cdot \frac{1}{1+\tau_L}. \tag{15}$$

Roughly speaking, Hsieh and Klenow observe the left-hand side of these expressions in the data—they observe the share of revenues spent on labor and capital. They then use these observed spending shares to back out the distortions.

The key identification issue in recovering the τ_K and τ_L is this: when a manufacturing plant pays a large fraction of its revenue to labor, is that because it faces a low τ_L, or is that because its technology is labor intensive (a high α_L)? Hsieh and Klenow solve this identification problem by assuming that all firms within a 4-digit industry have common α_K and α_L Cobb–Douglas exponents. Then variation in factor shares across plants reflects distortions rather than technologies. This is one of the reasons why their approach works well within industries but would run into problems across industries.

TFPR is a summary measure of distortions, equal to a weighted average of the marginal revenue product of capital and the marginal revenue product of labor, relative to the

[ak] However, the authors note that small firms are underrepresented in the Chinese data, so this could reflect differences in the sample.

[al] For example, assuming no depreciation, the firm's profit maximization problem can be written as

$$\max_{K,L} \;\; p_i F(K_i, L_i) - w(1+\tau_L)L_i - r(1+\tau_K)K_i.$$

The first order conditions are then given in the text.

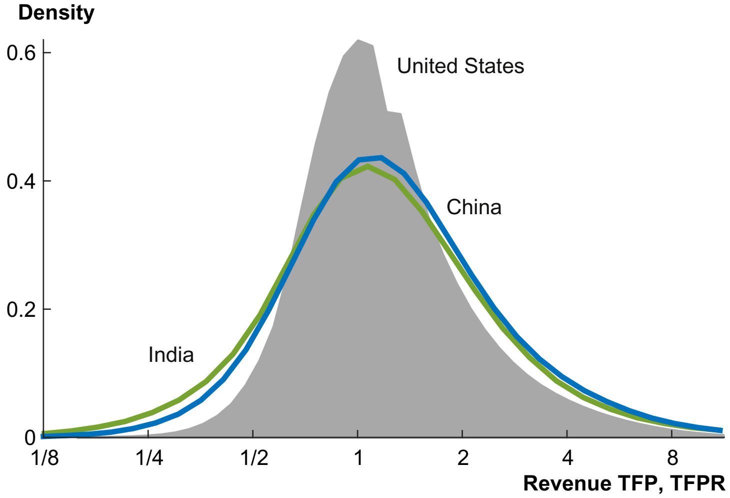

Fig. 36 The distribution of TFPR in 4-digit manufacturing industries. *Note:* This is the average distribution of TFPR within 4-digit manufacturing industries for the United States in 1997, China in 2005, and India in 1994, computed as described in the text. Source: *Hsieh, C.T., Klenow, P.J. 2009. Misallocation and manufacturing TFP in China and India. Q. J. Econ. 124 (4), 1403–1448; data provided by Chang Hsieh.*

average values in the industry. With no distortions, TFPR would take a value of one, as marginal revenue products get equated across firms in an efficient allocation. In the presence of distortions, TFPR equals a weighted average of the $1 + \tau_K$ and $1 + \tau_L$ distortions, where the weights are the Cobb–Douglas exponents in the production function.[am]

The average distribution of TFPR within 4-digit manufacturing industries is shown in Fig. 36. The first thing to note about this figure is that TFPR is not equal to one for every firm, not even in the United States. One interpretation of this fact is that resources are misallocated even in the United State and the deviations from unity can be used to measure US misallocation. An alternative interpretation is that there is measurement error in the US data, and some of the deviations reflect this measurement error. Both interpretations presumably have merit.

The second point to note in Fig. 36 is that the dispersion of TFPR in India and China is significantly larger than the dispersion in the United States. To the extent that this does not reflect larger measurement error in India and China, it suggests that the misallocation of capital and labor across establishments within 4-digit industries in China and India is a factor reducing GDP in those economies. Hsieh and Klenow quantify these effects and find that if China and India had the same dispersion of TFPR as the United States, their aggregate TFP would be higher by 30% to 50% in China and 40% to

[am] For aggregating the τ_K and τ_L into a single index of "TFPR" and to measure the effect of the distortions on TFP, Hsieh and Klenow therefore require values for the Cobb–Douglas exponents. They assume the US average shares are undistorted and assume China and India have the same Cobb–Douglas technology as the United States.

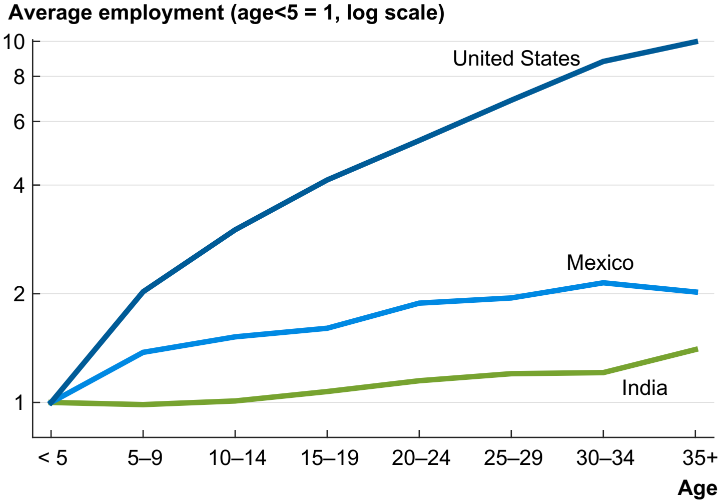

Fig. 37 Average employment over the life cycle. *Note:* The graph compares average employment per surviving plant in a later year to average employment per operating plant in an earlier year from the same cohort using census data for the manufacturing industry in the United States, Mexico, and India. Source: *Hsieh, C.T., Klenow, P.J. 2014. The life cycle of plants in India and Mexico. Q. J. Econ. 129 (3), 1035–1084; data provided by Chang Hsieh.*

60% in India. Long-run GDP would be higher by approximately twice this amount as capital accumulates in response to the higher TFP.

In a recent follow-up paper, Hsieh and Klenow attempt to understand what could be causing this misallocation. Hsieh and Klenow (2014) looks at how establishments in the United States, India, and Mexico grow as they age. Their remarkable finding is summarized in Fig. 37: plants in the United States get much larger as they age, while this is barely true at all in India.

To be more precise, plants that are more than 35 years old in the United States have more than 8 times the employment of plants that are less than 5 years old. In contrast, old plants in Mexico are only twice as large as young plants, while plants in India exhibit even less employment growth. The suggestion, explored in detail in this paper, is that distortions in Mexico and India prevent the most productive plants from growing in size, and this is one cause of the lower aggregate TFP in these economies. Hsieh and Klenow estimate that moving from the US life cycle to the Indian or Mexican life cycle of plant growth could reduce aggregate TFP by about 25%.

Motivated by facts like these, a growing number of recent papers explore various kinds of misallocation their effects on TFP. Asker et al. (2011) examine the role of volatility and adjustment costs in explaining variation in TFPR and TFPQ. Buera et al. (2011a), Midrigan and Xu (2014) and Moll (2014) study the extent to which credit market frictions can generate misallocation and TFP losses. Peters (2013) considers the role of heterogeneous markups in accounting for misallocation. Guner et al. (2008), Gourio and Roys (2014), and Garicano et al. (2014) consider the effect of regulations

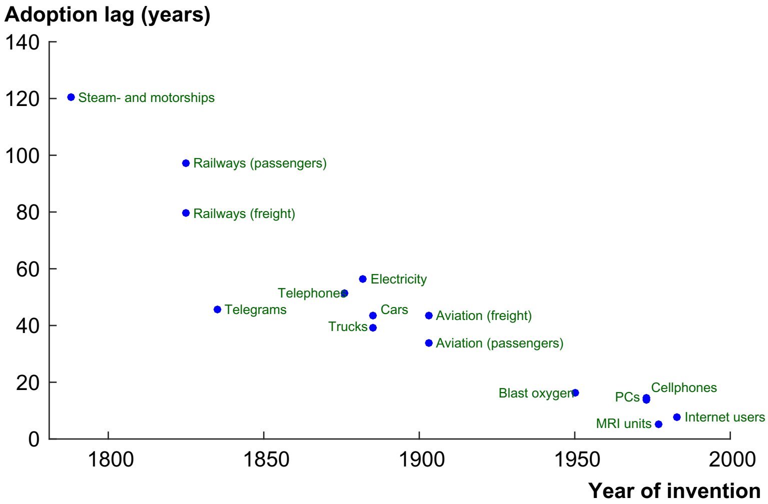

Fig. 38 Technology adoption is speeding up over time. *Note:* Adoption lags for each country measure the amount of time between when a technology is invented and when it was adopted in the country. The figure reports averages estimated across 166 countries spanning the period 1820–2003. Source: *Comin, D., Hobijn, B. 2010. An exploration of technology diffusion. Am. Econ. Rev. 100 (5), 2031–2059. doi:10.1257/aer.100.5.2031.*

tied to the size of firms. Akcigit et al. (2014a) suggest that incentive problems for managers limit the ability of potentially highly-productive small firms to expand, leading to lower TFP. Hopenhayn (2014) and Buera et al. (2015) provide excellent overviews of the recent literature.

4.12 The Diffusion of Ideas

Fig. 38 shows our next fact: lags in the adoption of new technologies have declined sharply over the last 200 years. This fact is taken from Comin and Hobijn (2010) and is based on the CHAT ("Cross-country Historical Adoption of Technology") database that these authors previous assembled. The database contains information on the diffusion of more than 100 technologies, in more than 150 countries, since 1800.

For 15 technologies, the graph plots the year of invention of each technology vs an average adoption lag across the sample of countries. More precisely, the adoption lag for each country/technology observation measures the number of years between the date a technology was invented and the date it was adopted in the country. The adoption lag shown in Fig. 38 is the average of this statistic across 166 countries.

A strong negative correlation is evident in the graph, suggesting the fact that technology adoption lags have been shrinking over time. Comin and Hobijn (2010) estimate that technologies invented 10 years later are on average adopted 4.3 years faster.

4.13 Urbanization

We remarked earlier on the inverse correlation between urbanization in the year 1500 and income per person today. Fig. 39 highlights the large trend in urbanization over time.

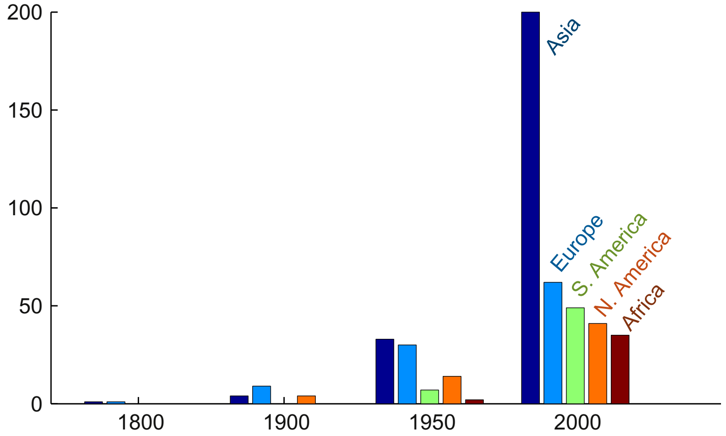

Fig. 39 The number of "million cities." *Note:* The histogram shows the number of cities on each continent with populations greater than 1 million. Oceania is included with Asia. Source: *Satterthwaite, D. 2005. The scale of urban change worldwide 1950–2000 and its underpinnings. International Institute for Environment and Development, unpublished paper, table 3.*

The figure shows the number of cities containing more than a million people, by continent, since 1800. This figure also emphasizes the extent to which urbanization is even stronger in Asia than in Europe and North America, at least as measured by the number of large cities.

5. CONCLUSION

While this paper has covered a large number of facts, there are still important facts that I have neglected. Partly this is because the paper is long enough, and partly this is because some of these facts are not as fully established as we might like. Therefore, this final discussion also can be read as a suggestion for places where further research might be particularly helpful.

One of the important facts omitted here is globalization and its effects on growth: the decline of trade barriers, the decline in transportation and communication costs, the rise of vertical supply chains. There is an old stylized fact from Sachs and Warner (1995) that "open" economies grew more rapidly over the period 1970 to 1989 than countries that were "closed." However, the definition they used of open and closed is so broad as to include other forces, and this dichotomy is surely correlated with institutional quality more generally.[an]

There are many other facts related to institutions that we wish we understood better. It is relatively clear from the kinds of evidence reviewed earlier that "institutions matter." But how important are different institutions, and how do institutions change?

[an] See also Ben-David (1993), Frankel and Romer (1999), and Feyrer (2009).

Is democracy conducive to growth, or does democracy typically result from growth, or both (Barro, 1999; Acemoglu et al., 2014)? Does human capital accumulation lead to good institutions, or vice versa, or both (Glaeser et al., 2004)? What is the relationship between culture, "fractionalization," institutions, and growth (Alesina et al., 2003)?

Another fact that we'd like to know more about is the extent of knowledge spillovers across countries. It is well appreciated that each country benefits from knowledge created elsewhere in the world, but quantifying these benefits is difficult. Eaton and Kortum (1999) suggest that only 60% of US growth in recent decades comes from knowledge created in the United States, and the numbers for local knowledge in Japan (35%) and the United Kingdom (13%) are even smaller. A related fact courtesy of Freeman (2010) is this: In the 1970s, China produced a negligible number of Ph.D.'s in science and engineering, but by 2010, China was producing 26% *more* than the United States. In a world of ideas, the economic development of China and India may have a profound effect on growth in the future. How many future Thomas Edisons, Albert Einsteins, Steve Jobs, and Sam Waltons are out there, waiting for their talents to be appropriately nurtured?

CHAPTER 2

Macroeconomic Shocks and Their Propagation

Abstract

This chapter reviews and synthesizes our current understanding of the shocks that drive economic fluctuations. The chapter begins with an illustration of the problem of identifying macroeconomic shocks, followed by an overview of the many recent innovations for identifying shocks. It then reviews in detail three main types of shocks: monetary, fiscal, and technology. After surveying the literature, each section presents new estimates that compare and synthesize key parts of the literature. The penultimate section briefly summarizes a few additional shocks. The final section analyzes the extent to which the leading shock candidates can explain fluctuations in output and hours. It concludes that we are much closer to understanding the shocks that drive economic fluctuations than we were 20 years ago.

1. INTRODUCTION

At the beginning of the 20th century, economists began to recognize the importance of impulses and propagation mechanisms for explaining business cycle fluctuations. A key question was how to explain regular fluctuations in a model with dampened oscillations. In 1927, the Russian statistician Slutsky published a paper titled “The Summation of Random Causes as a Source of Cyclic Processes.” In this paper, Slutsky demonstrated the surprising result that moving sums of random variables could produce time series that looked very much like the movements of economic time series—"sequences of rising and falling movements, like waves…with marks of certain approximate uniformities and regularities."[a] This insight, developed independently by British mathematician Yule in 1926 and extended by Frisch (1933) in his paper "Propagation Problems and Impulse Problems in Dynamic Economics," revolutionized the study of business cycles. Their insights shifted the focus of research from developing mechanisms to support a metronomic view of business cycles, in which each boom created conditions leading to the next bust, to a search for the sources of the random shocks. Since then, economists have offered numerous candidates for these "random causes," such as crop failures, wars, technological innovation, animal spirits, government actions, and commodity shocks.

Research from the 1940s through the 1970s emphasized fiscal and monetary policy shocks, identified from large-scale econometric models or single equation analyses. The 1980s witnessed two important innovations that fundamentally changed the direction of the research. First, Sims' (1980a) paper "Macroeconomics and Reality" revolutionized the study of systems driven by random impulses by introducing vector autoregressions (VARs). Sims' VARs made the link between innovations to a linear system and macroeconomic shocks. Using his method, it became easier to talk about identification assumptions, to estimate impulse response functions, and to do innovation accounting using forecast error decompositions. The second important innovation was the expansion of the inquiry beyond policy shocks to consider important nonpolicy shocks, such as technology shocks (Kydland and Prescott, 1982).

These innovations led to a flurry of research on shocks and their effects. In his 1994 paper "Shocks," John Cochrane took stock of the state of knowledge at that time by using the by-then standard VAR techniques to conduct a fairly comprehensive search for the shocks that drove economic fluctuations. Surprisingly, he found that none of the popular candidates could account for the bulk of economic fluctuations. He proffered the rather pessimistic possibility that "we will forever remain ignorant of the fundamental causes of economic fluctuations" (Cochrane, 1994, abstract).

Are we destined to remain forever ignorant of the fundamental causes of economic fluctuations? Are Slutsky's "random causes" unknowable? In this chapter, I will summarize the new methodological innovations and what their application has revealed about the propagation of the leading candidates for macroeconomic shocks and their importance in explaining economic fluctuations since Cochrane's speculation.

The chapter progresses as follows. Section 2 begins by defining what a macroeconomic shock is. It then summarizes the many tools used for identifying macroeconomic shocks and computing impulse responses. It also highlights some of the complications and pitfalls, such as the effects of foresight and nonlinearities.

[a] Page 105 of the 1937 English version of the article published in *Econometrica*.

The topic of Section 3 is monetary shocks and their effects on the macroeconomy. The section summarizes the existing literature and the challenges to identification. It then explores the effects of several leading monetary shocks in a framework that incorporates some of the newer innovations.

Section 4 discusses fiscal shocks. It begins by summarizing results on government spending shocks and highlights the importance of anticipations. It estimates the effects of several leading identified shocks in a common framework. The second part of the section looks at tax shocks. It summarizes the literature on both unanticipated tax shocks and news about future tax changes and conducts some robustness checks.

Section 5 summarizes the literature on technology shocks, including total factor productivity (TFP) shocks, investment-specific technology (IST) shocks, and marginal efficiency of investment (MEI) shocks. It also discusses news about future technology. It compares a wide variety of identified shocks from the literature.

Section 6 briefly discusses four other candidate shocks: oil shocks, credit shocks, uncertainty shocks, and labor supply (or "wage markup") shocks.

Section 7 concludes by synthesizing what we have learned about shocks. It conducts a combined forecast error variance decomposition for output and hours to determine how much of the fluctuations can be accounted for by some of the leading shocks discussed in the earlier sections. It concludes that we have made substantial progress in understanding the shocks that drive the macroeconomy.

2. METHODS FOR IDENTIFYING SHOCKS AND ESTIMATING IMPULSE RESPONSES

2.1 Overview: What Is a Shock?

What, exactly, are the macroeconomic shocks that we seek to estimate empirically? There is some ambiguity in the literature about the definition because of some researchers' use of the term *shock* when they mean *innovation* (ie, the residuals from a reduced form VAR model) or *instrument*. Sims (1980a) equated innovations with macroeconomic shocks, despite claiming to be atheoretical. Others have used the word *shock* when they mean *instrument* (eg, Cochrane, 2004). In this chapter, I view shocks, VAR innovations, and instruments to be distinct concepts, although *identification assumptions* may equate them in many cases. Shocks are most closely related to the structural disturbances in a simultaneous equation system. I adopt the concept of shocks used by researchers such as Blanchard and Watson (1986), Bernanke (1986), and Stock and Watson (forthcoming). According to Bernanke (1986), the shocks should be *primitive* exogenous forces that are uncorrelated with each other and they should be *economically meaningful* (pp. 52–55).

I view the shocks we seek to estimate as the empirical counterparts to the shocks we discuss in our theories, such as shocks to technology, monetary policy, and fiscal policy. Therefore, the shocks should have the following characteristics: (1) they should be exogenous with respect to the other current and lagged endogenous variables in the model; (2) they should be uncorrelated with other exogenous shocks; otherwise, we cannot identify the unique causal effects of one exogenous shock relative to another; and (3) they should represent either unanticipated movements in exogenous variables or *news* about future movements in exogenous variables. With regard to condition (2), one might counter with situations in which both fiscal and monetary policies respond to some event and argue that therefore the fiscal and monetary shocks would be correlated. I would respond that these are not primitive shocks, but rather the *endogenous* responses of policies to a primitive shock. A primitive shock may directly enter several of the equations in the system. For example, a geopolitical event might lead to a war that causes both fiscal and monetary policy to respond endogenously. The geopolitical event would be the primitive shock from the standpoint of our economic models (though it might be considered an endogenous response from the standpoint of a political science model).[b]

To match these theoretical shocks, we can link the innovations in a structural vector autoregression (SVAR) to these theoretical (structural) shocks, estimate them in a structural dynamic stochastic general equilibrium (DSGE) model, or measure them directly using rich data sources.

2.2 Illustrative Framework

In this section, I lay out a simple framework in order to discuss the problem of identification and to illustrate some of the leading identification methods. I begin with the problem of identifying shocks to fiscal policy in a simple model with no dynamics. I then generalize the model to a dynamic trivariate model.

Consider first a simple model of the link between fiscal variables and GDP in a static setting. Suppose the structural relationships are given by the following equations:

$$\begin{aligned} \tau_t &= b_{\tau g} g_t + b_{\tau y} y_t + \varepsilon_{\tau t} \\ g_t &= b_{g\tau} \tau_t + b_{gy} y_t + \varepsilon_{gt} \\ y_t &= b_{y\tau} \tau_t + b_{yg} g_t + \varepsilon_{yt} \end{aligned} \tag{1}$$

where τ is taxes, g is government spending, and y is GDP. The εs are the macroeconomic shocks we seek to identify. We assume that they are uncorrelated and that, in this simple example, each one affects only one equation. $\varepsilon_{\tau t}$ is the tax shock; it might represent legislation resulting from a change in political power. ε_{gt} might capture the sudden outbreak of war, which raises desired military spending. ε_{yt} might capture technological progress. The *b*s capture the usual interactions. For example, we would expect that government spending would raise output, while taxes would lower it, so $b_{yg} > 0$ and $b_{y\tau} < 0$. Because

[b] Of course, the war might be caused by something like rainfall, in which case the primitive shock would be the rainfall. This shock would enter even more equations, such as the equations for government spending, GDP, and productivity.

of automatic stabilizers, however, the fiscal variables might also respond to GDP, ie, $b_{gy} < 0$ and $b_{\tau y} > 0$. This means that a simple regression of GDP on government spending and taxes will not uncover b_{yg} and $b_{y\tau}$ because g_t and τ_t are correlated with the shock to GDP, ε_{yt}. For example, we might observe no correlation between GDP and government spending, but this correlation is consistent both with no structural relationship between GDP and government spending (ie, $b_{yg} = b_{gy} = 0$) and with b_{yg} and b_{gy} being large, but with opposite signs. Without further assumptions or data, we cannot identify either the parameters or the shocks.

Now let us move to a simple trivariate model with three endogenous variables, Y_1, Y_2, and Y_3 in which dynamics are potentially important.[c] In the monetary context, these variables could be industrial production, a price index, and the federal funds rate; in the fiscal context, they could be GDP, government purchases, and tax revenue; and in the technology shock context, they could be labor productivity, hours, and investment. Let $Y_t = [Y_{1t}, Y_{2t}, Y_{3t}]$ be the vector of endogenous variables. Suppose that the dynamic behavior of Y_t is described by the following structural model:

$$Y_t = B(L)Y_t + \Omega\varepsilon_t \tag{2}$$

where $B(L) = B_0 + \sum_{k=1}^{p} B_k L^k$ and $E\left[\varepsilon_t \varepsilon_s'\right] = D$ if $t = s$, and 0 otherwise, where D is a diagonal matrix. The εs are the primitive structural shocks. Since a primitive shock can in principle affect more than one variable, I initially allow Ω to have nonzero off-diagonal elements.

The elements of B_0 are the same as the bs from Eq. (1), with $b_{jj} = 0$. Thus, the easiest way to address the dynamics is to recast the problem in terms of the *innovations* from a reduced form VAR:

$$A(L)Y_t = \eta_t \tag{3}$$

where $A(L)$ is a polynomial in the lag operator and $A(L) = I - \sum_{k=1}^{p} A_k L^k$. $\eta_t = [\eta_{1t}, \eta_{2t}, \eta_{3t}]$ are the reduced form VAR innovations. We assume that $E[\eta_t] = 0$, $E\left[\eta_t \eta_t'\right] = \Sigma_\eta$ and that $E\left[\eta_t \eta_s'\right] = 0$ for $s \neq t$. We then can link the innovations η in the reduced form VAR equation (3) to the unobserved structural shocks, ε, in the structural equation (2) as follows:

$$\eta_t = B_0 \eta_t + \Omega\varepsilon_t \quad \text{or} \tag{4a}$$

$$\eta_t = H\varepsilon_t, \quad \text{where } H = [I - B_0]^{-1}\Omega \tag{4b}$$

I will now write out the system in Eq. (4a) explicitly in a way that incorporates a commonly used identification assumption and a normalization. These restrictions are (i) Ω is the identity matrix (meaning each shock enters only one equation); and (ii) the structural

[c] See chapter Stock and Watson (forthcoming) in this handbook for a more precise analysis of identification using SVARs.

shocks have unit effect (ie, the diagonal elements of H are unity).[d] The system can then be written as

$$\begin{aligned}\eta_{1t} &= b_{12}\eta_{2t} + b_{13}\eta_{3t} + \varepsilon_{1t}\\ \eta_{2t} &= b_{21}\eta_{1t} + b_{23}\eta_{3t} + \varepsilon_{2t}\\ \eta_{3t} &= b_{31}\eta_{1t} + b_{32}\eta_{2t} + \varepsilon_{3t}\end{aligned} \tag{5}$$

This equation is the dynamic equivalent of Eq. (1). The only difference is that instead of writing the structural relationships in terms of the variables such as GDP, government spending, and taxes themselves, we now write them in terms of the reduced form VAR innovations. The interpretations of the bs, however, are the same if the structural relationships depend on contemporaneous interactions.

As discussed at the start of this section, we cannot identify the coefficients or the shocks without more restrictions. We require at least three more restrictions for identification of all three shocks, potentially fewer if we want to identify only one shock. Since a number of the common identification methods depend on contemporaneous restrictions, I will refer to the system of equations in Eq. (5) when discussing them.

2.3 Common Identification Methods

In this section, I briefly overview some of the most common methods for identification. This section is not meant to be comprehensive. See Stock and Watson (forthcoming) for more detailed treatments of the methods I summarize, as well as for a few other methods I do not summarize, such as set identification and identification through heteroscedasticity. I use the term "policy variable" for short, but it should be understood that it can represent any variable from which we want to extract a shock component.

2.3.1 Cholesky Decompositions

The most commonly used identification method in macroeconomics imposes alternative sets of recursive zero restrictions on the contemporaneous coefficients. This method was introduced by Sims (1980a) and is also known as "triangularization." The following are two widely used alternatives:

A. The policy variable does not respond within the period to the other endogenous variables. This could be motivated by decision lags on the part policymakers or other adjustment costs. Let Y_1 be the policy variable and η_1 be its reduced form innovation. Then this scheme involves constraining $b_{12} = b_{13} = 0$ in Eq. (5), which is equivalent to ordering the policy variable first in the Cholesky ordering. For example, Blanchard and Perotti (2002) impose this constraint to identify the shock to government

[d] An alternative normalization to (ii) is the assumption that the structural shocks have unit standard deviation (ie, the variances of the εs are unity).

spending; they assume that government spending does not respond to the contemporaneous movements in output or taxes.[e]

B. The other endogenous variables do not respond to the policy shock within the period. This could be motivated by sluggish responses of the other endogenous variables to shocks to the policy variable. This scheme involves constraining $b_{21}=b_{31}=0$, which is equivalent to ordering the policy variable last in the Cholesky ordering. For example, Bernanke and Blinder (1992) were the first to identify shocks to the federal funds rate as monetary policy shocks and used this type of identification.[f]

Several of the subsequent sections will discuss how these timing assumptions are not as innocuous as they might seem at first glance. For example, forward-looking behavior or superior information on the part of policymakers may invalidate these restrictions.

2.3.2 *Other Contemporaneous Restrictions*

Another more general approach (that nests the Cholesky decomposition) is what is known as a *structural VAR*, or SVAR, introduced by Blanchard and Watson (1986) and Bernanke (1986). This approach uses either economic theory or outside estimates to constrain parameters. Consider, for example, Blanchard and Perotti's (2002) identification of government spending and net tax shocks. Let Y_1 be net taxes, Y_2 be government spending, and Y_3 be GDP. They identify the shock to government spending using a Cholesky decomposition in which government spending is ordered first (ie, $b_{21}=b_{23}=0$). They identify exogenous shocks to net taxes by setting $b_{13}=2.08$, an outside estimate of the cyclical sensitivity of net taxes.[g] These three restrictions are sufficient to identify all of the remaining parameters and hence all three shocks.

2.3.3 *Narrative Methods*

Narrative methods involve constructing a series from historical documents to identify the reason and/or the quantities associated with a particular change in a variable. Friedman and Schwartz (1963) is the classic example of using historical information to identify policy shocks. Hamilton (1985) and Hoover and Perez (1994) used narrative methods to identify oil shocks. These papers isolated political events that led to disruptions in world

[e] To implement this identification using ordinary least squares (OLSs), one would simply regress government spending on p lags of all of the variables in the system and call the residual the government spending shock.

[f] To implement this identification using OLSs, one would regress the federal funds rate on contemporaneous values of the other variables in the system, as well as p lags of all of the variables, and call the residual the monetary policy shock.

[g] One way to implement the tax shock identification is to construct the variable $\eta_1-2.08\eta_3$ from the estimated reduced form residuals. One would then regress η_3 on η_1 and η_2, using $\eta_1-2.08\eta_3$ as the instrument for η_1. (Note that the assumption that $b_{21}=b_{23}=0$ identifies η_2 as ε_{2t}, which is uncorrelated with ε_{3t} by assumption) This regression identifies b_{31} and b_{32}. The residual is the estimate of ε_{3t}.

oil markets. Other examples of the use of narrative methods are Poterba's (1986) tax policy announcements, Romer and Romer's (1989, 2004) monetary shock series based on FOMC minutes, Ramey and Shapiro (1998) and Ramey's (2011a) defense news series based on *Business Week* articles, and Romer and Romer's (2010) narrative series of tax changes based on reading legislative documents.

Until recently, these series were used either as exogenous shocks in sets of dynamic single equation regressions or embedded in a Cholesky decomposition. For example, in the framework above, we could set Y_1 to be the narrative series and constrain $b_{12} = b_{13} = 0$. As a later section details, recent innovations have led to additional methods for incorporating these series.

A cautionary note on the potential of narrative series to identify exogenous shocks is in order. Some of the follow-up research has operated on the principle that the narrative alone provides exogeneity. It does not. Shapiro (1994) and Leeper (1997) made this point for monetary policy shocks. Another example is in the fiscal literature. A series on fiscal consolidations, quantified by narrative evidence on the expected size of these consolidations, is not necessarily exogenous. If the series includes fiscal consolidations adopted in response to bad news about the future growth of the economy, the series cannot be used to establish a causal effect of the fiscal consolidation on future output.

2.3.4 High-Frequency Identification

Research by Bagliano and Favero (1999), Kuttner (2001), Cochrane and Piazzesi (2002), Faust et al. (2004), Gürkaynak et al. (2005), Piazzesi and Swanson (2008), Gertler and Karadi (2015), Nakamura and Steinsson (2015), and others has used high-frequency data (such as news announcements around FOMC dates) and the movement of federal funds futures to identify unexpected Fed policy actions. This identification is also based in part on timing, but because the timing is so high frequency (daily or higher), the assumptions are more plausible than those employed at the monthly or quarterly frequency. As I will discuss in the foresight section later, the financial futures data are ideal for ensuring that a shock is unanticipated.

It should be noted, however, that without additional assumptions the unanticipated shock is not necessarily exogenous to the economy. For example, if the implementation does not adequately control for the Fed's private information about the future state of the economy, which might be driving its policy changes, these shocks cannot be used to estimate a causal effect of monetary policy on macroeconomic variables.

2.3.5 External Instruments/Proxy SVARs

The "external instrument," or "proxy SVAR," method is a promising new approach for incorporating external series for identification. This method was developed by Stock and Watson (2008) and extended by Stock and Watson (2012) and Mertens and Ravn (2013). This approach takes advantage of information developed from "outside" the VAR, such as series based on narrative evidence, shocks from estimated DSGE models, or high-frequency information. The idea is that these external series are noisy measures of the true shock.

Suppose that Z_t represents one of these external series. Then this series is a valid instrument for identifying the shock ε_{1t} if the following two conditions hold:

$$E[Z_t \varepsilon_{1t}] \neq 0 \tag{6a}$$

$$E[Z_t \varepsilon_{it}] = 0, \; i = 2, 3 \tag{6b}$$

Condition (6a) is the instrument *relevance* condition: the external instrument must be contemporaneously correlated with the structural policy shock. Condition (6b) is the instrument *exogeneity* condition: the external instrument must be contemporaneously uncorrelated with the other structural shocks. If the external instrument satisfies these two conditions, it can be used to identify the shock ε_{1t}.

The procedure is very straightforward and takes place with the following steps[h]:

Step 1: Estimate the reduced form system to obtain estimates of the reduced form residuals, η_t.

Step 2: Regress η_{2t} and η_{3t} on η_{1t} using the external instrument Z_t as the instrument. These regressions yield unbiased estimates of b_{21} and b_{31}. Define the residuals of these regressions to be ν_{2t} and ν_{3t}.

Step 3: Regress η_{1t} on η_{2t} and η_{3t}, using the ν_{2t} and ν_{3t} estimated in Step 2 as the instruments. This yields unbiased estimates of b_{12} and b_{13}.

As an example, Mertens and Ravn (2014) reconcile Romer and Romer's (2010) estimates of the effects of tax shocks with the Blanchard and Perotti (2002) estimates by using the Romer's narrative tax shock series as an external instrument Z to identify the structural tax shock. Thus, they do not need to impose parameter restrictions, such as the cyclical elasticity of taxes to output. As I will discuss in Section 2.4, one can extend this external instrument approach to estimating impulse responses by combining it with Jordà's (2005) method.

2.3.6 Restrictions at Longer Horizons

Rather than constraining the contemporaneous responses, one can instead identify a shock by imposing long-run restrictions. The most common is an infinite horizon long-run restriction, first used by Shapiro and Watson (1988), Blanchard and Quah (1989), and King et al. (1991). Consider the moving average representation of Eq. (3):

$$Y_t = C(L)\eta_t \tag{7}$$

[h] This exposition follows Merten and Ravn (2013, online appendix). See Mertens and Ravn (2013a,b) and the associated online appendices for generalizations to additional external instruments and to larger systems.

where $C(L) = [A(L)]^{-1}$. Combining Eq. (4b) with Eq. (7), we can write the Ys in terms of the structural shocks:

$$Y_t = D(L)\varepsilon_t \tag{8}$$

where $D(L) = C(L)H$. Suppose we wanted to identify a technology shock as the only shock that affects labor productivity in the long run. In this case, Y_1 would be the *growth rate* of labor productivity and the other variables would also be transformed to induce stationary (eg, first-differenced). Letting $D^{ij}(L)$ denote the (i,j) element of the D matrix and $D^{11}(1)$ denote the lag polynomial with $L=1$, we impose the long-run restriction by setting $D^{12}(1) = 0$ and $D^{13}(1) = 0$. This restriction constrains the unit root in Y_1 to emanate only from the shock that we are calling the technology shock. This is the identification used by Galí (1999).

An equivalent way of imposing this restriction is to use the estimation method suggested by Shapiro and Watson (1988). Let Y_1 denote the first difference of the log of labor productivity and Y_2 and Y_3 be the stationary transformations of two other variables (such as hours). Then, imposing the long-run restriction is equivalent to identifying the error term in the following equation as the technology shock:

$$Y_{1t} = \sum_{j=1}^{p} \omega_{11,j} Y_{1t-j} + \sum_{j=1}^{p-1} \omega_{12,j} \Delta Y_{2t-j} + \sum_{j=1}^{p-1} \omega_{13,j} \Delta Y_{3t-j} + \zeta_t \tag{9}$$

We have imposed the restriction by specifying that only the *first differences* of the other stationary variables enter this equation. Because the current values of those differences might also be affected by the technology shock, and therefore correlated with the error term, we use lags 1 through p of Y_2 and Y_3 as instruments for the terms involving the current and lagged values of those variables. The estimated residual is the identified technology shock. We can then identify the other shocks, if desired, by orthogonalizing the error terms with respect to the technology shock.

This equivalent way of imposing long-run identification restrictions highlights some of the problems that can arise with this method. First, identification depends on the relevance of the instruments. Second, it requires additional identifying restrictions in the form of assumptions about unit roots. If, for example, hours have a unit root, then in order to identify the technology shock one would have to impose that only the second difference of hours entered in Eq. (9).[i]

Another issue is the behavior of infinite horizon restrictions in small samples (eg, Faust and Leeper, 1997). Recently, researchers have introduced new methods that overcome these problems. Building on earlier work by Faust (1998) and Uhlig (2003, 2004), Francis

[i] To be clear, all of the Y variables must be trend stationary in this system. If hours have a unit root, then Y_2 must be equal to Δhours_t, so the constraint in Eq. (9) would take the form $\Delta^2\text{hours}_t$.

et al. (2014) identify the technology shock as the shock that maximizes the forecast error variance share of labor productivity at some finite horizon h. A variation by Barsky and Sims (2011) identifies the shock as the one that maximizes the *sum* of the forecast error variances up to some horizon h. See those papers for details on how to implement these methods.

2.3.7 Sign Restrictions

A number of authors had noted the circularity in some of the reasoning analyzing VAR specifications in practice. In particular, whether a specification or identification method is deemed "correct" is often judged by whether the impulses they produce are "reasonable," ie, consistent with the researcher's priors. Faust (1998) and Uhlig (1997, 2005) developed a new method to incorporate "reasonableness" without undercutting scientific inquiry by investigating the effects of a shock on variable Y, where the shock was identified by sign restrictions on the responses of *other* variables (excluding variable Y). Work by Canova and De Nicolo (2002) and Canova and Pina (2005) introduced other variations.

The sign restriction method has been used in many contexts, such as monetary policy, fiscal policy, and technology shocks. Recently, there have been a number of new papers on sign restrictions using Bayesian methods. For example, Arias et al. (2015b) propose methods involving agnostic priors in one dimension and Baumeister and Hamilton (2015) propose methods involving agnostic priors in another dimension. Amir Ahmadi and Uhlig (2015) combine sign restrictions with Bayesian factor-augmented VARs (FAVARs). See Stock and Watson (forthcoming) for more discussion of sign restrictions as an identification method.

2.3.8 Factor-Augmented VARs

A perennial concern in identifying shocks is that the variables included in the VAR do not capture all of the relevant information. The comparison of price responses in monetary VARs with and without commodity prices is one example of the difference a variable exclusion can make. To address this issue more broadly, Bernanke et al. (2005) developed the FAVARs based on earlier dynamic factor models developed by Stock and Watson (2002) and others. The FAVAR, which typically contains over 100 series, has the benefit that it is much more likely to condition on relevant information for identifying shocks. In most implementations, though, it still typically relies on a Cholesky decomposition. Amir Ahmadi and Uhlig's (2015) new method using sign restrictions in Bayesian FAVARs is one of the few examples that does not rely on Cholesky decompositions. One shortcoming of FAVAR methods is that all variables must be transformed to a stationary form, which requires pretesting and its concomitant problems (eg, Elliott, 1998; Gospodinov et al., 2013). See Stock and Watson (forthcoming) for an in depth discussion of dynamic factor models.

2.3.9 Estimated DSGE Models

An entirely different approach to identification is the estimated DSGE model, introduced by Smets and Wouters (2003, 2007). This method involves estimating a fully specified model (a new Keynesian model with many frictions and rigidities in the case of Smets and Wouters) and extracting a full set of implied shocks from those estimates. In the case of Smets and Wouters, many shocks are estimated including technology shocks, monetary shocks, government spending shocks, wage markup shocks, and risk premium shocks. One can then trace out the impulse responses to these shocks as well as do innovation accounting. Other examples of this method appear in work by Justiniano et al. (2010, 2011) and Schmitt-Grohe and Uribe (2012). Christiano et al. (2005) take a different estimation approach by first estimating impulse responses to a monetary shock in a standard SVAR and then estimating the parameters of the DSGE model by matching the impulse responses from the model to those of the data.

These models achieve identification by imposing structure based on theory. It should be noted that identification is less straightforward in these types of models. Work by Canova and Sala (2009), Komunjer and Ng (2011), and others highlights some of the potential problems with identification in DSGE models. On the other hand, this method overcomes some of the potential problems of unrestricted VARs highlighted by Fernandez-Villaverde et al. (2007).

2.4 Estimating Impulse Responses

Suppose that one has identified the economic shock through one of the methods discussed earlier. How do we measure the effects on the endogenous variables of interest? The most common way to estimate the impulse responses to a shock uses nonlinear (at horizons greater than one) functions of the estimated VAR parameters. In particular, estimation of the reduced form system provides the elements of the moving average representation matrix $C(L)=[A(L)]^{-1}$ in Eq. (7) and identification provides the elements of B_0. Recalling that $D(L)=C(L)H$, we write out $D(L)=D_0+D_1L+D_2L^2+D_3L^3+\cdots$, and denoting $D_h=[d_{ijh}]$, we can express the impulse response of variable Y_i at horizon $t+h$ to a shock to ε_{jt} as:

$$\frac{\partial Y_{i,t+h}}{\partial \varepsilon_{j,t}}=d_{ijh} \tag{10}$$

These d_{ijh} parameters are nonlinear functions of the reduced form VAR parameters.

If the VAR adequately captures the data-generating process, this method is optimal at all horizons. If the VAR is mispecified, however, then the specification errors will be compounded at each horizon. To address this problem, Jordà (2005) introduced a *local projection* method for estimating impulse responses. The comparison between his procedure and the standard procedure has an analogy with direct forecasting vs iterated forecasting (eg, Marcellino et al., 2006). In the forecasting context, one can forecast future values of a variable using either a horizon-specific regression ("direct" forecasting) or iterating on a one-period ahead estimated model ("iterated" forecasting). Jordà's method is analogous to the direct forecasting, whereas the standard VAR method is analogous to the iterated forecasting method. Chang and Sakata (2007) introduce a related method they call *long autoregression* and show its asymptotic equivalence to Jordà's method.

To see how Jordà's method works, suppose that ε_{1t} has been identified by one of the methods discussed in the previous section. Then, the impulse response of Y_i at horizon h can be estimated from the following single regression:

$$Y_{i,t+h} = \theta_{i,h} \cdot \varepsilon_{1t} + \text{control variables} + \xi_{t+h} \tag{11}$$

$\theta_{i,h}$ is the estimate of the impulse response of Y_i at horizon h to a shock ε_{1t}. The control variables need not include the other Ys as long as ε_{1t} is exogenous to those other Ys. Typically, the control variables include deterministic terms (constant, time trends), lags of the Y_i, and lags of other variables that are necessary to "mop up"; the specification can be chosen using information criteria. One estimates a separate regression for each horizon and the control variables do not necessarily need to be the same for each regression. Note that except for horizon $h=0$, the error term ξ_{t+h} will be serially correlated because it will be a moving average of the forecast errors from t to $t+h$. Thus, the standard errors need to incorporate corrections for serial correlation, such as a Newey–West (1987) correction.

Because the Jordà method for calculating impulse response functions imposes fewer restrictions, the estimates are often less precisely estimated and are sometimes erratic. Nevertheless, this procedure is more robust than standard methods, so it can be very useful as a heuristic check on the standard methods. Moreover, it is much easier to incorporate state dependence with this method (eg, Auerbach and Gorodnichenko, 2013).

One can extend the Jordà method in several ways that incorporates some of the new methodology. First, one can incorporate the advantages of the FAVAR method (see Section 2.3.8) by including estimated factors as control variables. Second, one can merge the insights from the external instrument/proxy SVAR method (see Section 2.3.5). To see this, modify Eq. (11) as follows:

$$Y_{i,t+h} = \theta_{i,h} \cdot Y_{1,t} + \text{control variables} + \zeta_{t+h} \tag{12}$$

where we have replaced the shock ε_{1t} with $Y_{1,t}$. As discussed earlier, an OLS regression of Y_i on Y_1 cannot capture the structural effect if Y_1 is correlated with ζ_{t+h}. We can easily deal with this issue, however, by estimating this equation using the external instrument Z_t as an instrument for $Y_{1,t}$. For example, if Y_i is real output and $Y_{1,t}$ is the federal funds rate, we can use Romer and Romer's (2004) narrative-based monetary shock series as an instrument. As I will discuss later, in some cases there are multiple potential external instruments. We can readily incorporate these in this framework by using multiple instruments for Y_1. In fact, these overidentifying restrictions can be used to test the restrictions of the model (using a Hansen's *J*-statistic, for example).

2.5 The Problem of Foresight

The problem of foresight presents serious challenges to, but also opportunities for, the identification of macroeconomic shocks.[j] There are two main foresight problems: (i) foresight on the part of private agents; and (ii) foresight on the part of policymakers. I will discuss each in turn.

It is likely that many changes in policy or other exogenous shocks are anticipated by private agents in advance. For example, Beaudry and Portier (2006) explicitly take into account that news about future technology may have effects today even though it does not show up in current productivity. Ramey (2011a) argues that the results of Ramey and Shapiro (1998) and Blanchard and Perotti (2002) differ because most of the latter's identified shocks to government spending are actually anticipated. Building on work by Hansen and Sargent (1991), Leeper et al. (2013) work out the econometrics of "fiscal foresight" for taxes, showing that foresight can lead to a nonfundamental moving average representation. The growing importance of "forward guidance" in monetary policy means that many changes in policy rates may be anticipated.

Consider the following example, based on Leeper et al. (2013), of a simple growth model with a representative household with log utility over consumption, discount factor β, and a production function $Y_t = A_t K_{t-1}^{\alpha}$, with $\alpha < 1$. The government taxes output Y at a rate τ_t and there are i.i.d. shocks, $\hat{\tau}_t$, to the tax rate relative to its mean τ. Shocks to technology, ε_{At}, are also i.i.d. Suppose that agents potentially receive news in period t of what the tax rate will be in $t+q$, so that $\hat{\tau}_t = \varepsilon_{\tau,t-q}$. If the shocks are unanticipated ($q=0$), the rule for capital accumulation is:

$$k_t = \alpha k_{t-1} + \varepsilon_{A,t}$$

which reproduces the well-known result that unanticipated i.i.d. tax rate shocks have no effect on capital accumulation. If the tax rate shock is anticipated two periods in advance ($q=2$), however, then optimal capital accumulation is:

$$k_t = \alpha k_{t-1} + \varepsilon_{A,t} - k\{\varepsilon_{\tau,t-1} + \theta \varepsilon_{\tau,t}\}$$

where $\theta = \alpha\beta(1-\tau) < 1$ and $k = (1-\theta)\dfrac{\tau}{1-\tau}$. Can we uncover the tax shocks by regressing capital on its own lags? No, we cannot. Because $\theta < 1$, this representation is not invertible in the current and past ks; we say that $\{\varepsilon_{\tau,t-j}\}_{j=0}^{\infty}$ is not *fundamental* for

[j] The general problem was first recognized and discussed decades ago. For example, Sims (1980a) states: "It is my view, however, that rational expectations is more deeply subversive of identification than has yet been recognized."

$\left\{k_{t-j}\right\}_{j=0}^{\infty}$. If we regress k_t on its own lags and recover the innovations, we would be recovering the discounted sum of tax news observed at date t and earlier, ie, "old" news. Adding lagged taxes to the VAR does not help.

Beaudry et al. (2015) develop a diagnostic to determine whether nonfundamentalness is quantitatively important. They argue that in some cases the nonfundamental representation is close to the fundamental representation.

The second foresight problem is foresight on the part of policymakers. Sometimes policymakers have more information about the state of the economy than private agents. If this is the case, and we do not include that information in the VAR, part of the identified shock may include the endogenous response of policy to expectations about the future path of macroeconomic variables. Consider the "price puzzle" in monetary VARs, meaning that some identified monetary policy shocks imply that a monetary contraction raises prices in the short run. Sims (1992) argued that the "price puzzle" was the result of typical VARs not including all relevant information for forecasting future inflation. Thus, the identified policy shocks included not only the exogenous shocks to policy but also the endogenous policy responses to forecasts of future inflation. In the fiscal context, governments may undertake fiscal consolidations based on private information about declining future growth of potential GDP. If this is not taken into account, then a finding that a fiscal consolidation lowers output growth may be confounding causal effects with foresight effects.

The principal methods for dealing with the problem of foresight are measuring the expectations directly, time series restrictions, or theoretical model restrictions. For example, Beaudry and Portier (2006) extracted news about future technology from stock prices; Ramey (2011a) created a series of news about future government spending by reading *Business Week* and other periodicals; Fisher and Peters (2010) created news about government spending by extracting information from stock returns of defense contractors; Poterba (1986) and Leeper et al. (2012) used information from the spread between federal and municipal bond yields for news about future tax changes; and Mertens and Ravn (2012) decomposed Romer and Romer's (2010) narrative tax series into one series in which implementation was within the quarter (unanticipated) and another series in which implementation was delayed (news). In the monetary shock literature, many papers use high-frequency financial futures prices to decompose the anticipated and unanticipated components of interest rates changes (eg, Rudebusch, 1998; Bagliano and Favero, 1999; Kuttner, 2001; Gürkaynak et al., 2005).

The typical way that news has been incorporated into VARs is by adding the news series to a standard VAR, and ordering it first. Perotti (2011) has called these "EVARs" for "Expectational VARs." Note that in general one cannot use news as an external instrument in Mertens and Ravn's proxy SVAR framework. The presence of foresight invalidates the interpretation of the VAR reduced form residuals as prediction errors, since the conditioning variables may not span the information set of forward-looking agents (Mertens and Ravn, 2013, 2014).

2.6 The Problem of Trends

Most macroeconomic variables are nonstationary, exhibiting behavior consistent with either deterministic trends or stochastic trends. A key question is how to specify a model when many of the variables may be trending. Sims et al. (1990) demonstrate that even when variables might have stochastic trends and might be cointegrated, the log levels specification will give consistent estimates. While one might be tempted to pretest the variables and impose the unit root and cointegration relationships to gain efficiency, Elliott (1998) shows that such a procedure can lead to large size distortions in theory. More recently, Gospodinov et al. (2013) have demonstrated how large the size distortions can be in practice.

Perhaps the safest method is to estimate the SVAR in log levels (perhaps also including some deterministic trends) as long as the imposition of stationarity is not required for identification. One can then explore whether the imposition of unit roots and cointegration lead to similar results but increase the precision of the estimates. For years, it was common to include a linear time trend in macroeconomic equations. Many analyses now include a broken trend or a quadratic trend to capture features such as the productivity slowdown in 1974 or the effect of the baby boom moving through the macroeconomic variables (eg, Perron, 1989; Francis and Ramey, 2009).

2.7 Some Brief Notes on Nonlinearities

In the previous sections, we have implicitly assumed that the relationships we are trying to capture can be well approximated with linear functions. There are many cases in which we believe that nonlinearities might be important. To name just a few possible nonlinearities, positive shocks might have different effects from negative shocks, effects might not be proportional to the size of the shock, or the effect of a shock might depend on the state of the economy when the shock hits.

A thorough analysis of nonlinearities is beyond the scope of this chapter, so I will mention only three items briefly. First, Koop et al. (1996) provide a very useful analysis of the issues that arise when estimating impulse responses in nonlinear models. Second, if one is interested in estimating state-dependent models, the Jordà (2005) local projection method is a simple way to estimate such a model and calculate impulse response functions. Auerbach and Gorodnichenko (2013) and Ramey and Zubairy (2014) discuss this application and how it relates to another leading method, smooth transition VARs.

The third point is a cautionary note when considering the possibility of asymmetries. Many times researchers posit that only positive, or only negative, shocks matter. For example, in the oil shock literature, it is common to assume that only oil price *increases* matter and to include a variable in the VAR that captures increases but not decreases.

Kilian and Vigfusson (2011) demonstrate the serious biases and faulty inference that can result from this specification. Their explanation is simple. Suppose Y is a linear function of X, where X takes on both negative and positive values. If one imposes the restriction that only positive values matter, one is in essence setting all of the negative values of X to zero. Figure 1 of Kilian and Vigfusson's (2011) paper demonstrates how this procedure that truncates on the X variable produces slope coefficients that are biased upward in magnitude. Thus, one would incorrectly conclude that positive Xs have a greater impact than negative Xs, even when the true relationship is linear. To guard against this faulty inference, one should always make sure that the model nests the linear case when one is testing for asymmetries. If one finds evidence of asymmetries, then one can use Kilian and Vigfusson's (2011) methods for computing the impulse responses correctly.

2.8 DSGE Monte Carlos

Much empirical macroeconomics is linked to testing theoretical models. A question that arises is whether shocks identified in SVARs, often with minimal theoretical restrictions, are capable of capturing the true shocks. Fernandez-Villaverde et al. (2007) study this question by comparing the state-space representation of a theoretical model with the VAR representation. They note that in some instances an invertibility problem can arise and they offer a method to check whether the problem is present.

Erceg et al. (2005) were perhaps the first to subject an SVAR involving long-run restrictions to what I will term a "DSGE Monte Carlo." In particular, they generated artificial data from a calibrated DSGE model and applied SVARS with long restrictions to the data to see if the implied impulse responses matched those of the underlying model.

This method has now been used in several settings. Chari et al. (2008) used this method to argue against SVARs' ability to test the real business cycle (RBC) model, Ramey (2009) used it to show how standard SVARs could be affected by anticipated government spending changes, and Francis et al. (2014) used this method to verify the applicability of their new finite horizon restrictions method. This method seems to be a very useful tool for judging the ability of SVARs to test DSGE models. Of course, like any Monte Carlo, the specification of the model generating the artificial data is all important.

3. MONETARY POLICY SHOCKS

Having discussed the definition of macroeconomic shocks and the leading methods for identifying them, I now turn to the first of the candidate shocks that will be discussed in detail: monetary policy shocks. In this section, I review the main issues and results from the empirical literature seeking to identify and estimate the effects of monetary policy shocks. I begin with a brief overview of the research before and after Christiano et al.'s (1999) *Handbook of Macroeconomics* chapter on the subject. I revisit Christiano, Eichenbaum and Evan's specification and then focus on two leading types of externally identified monetary policy shocks, Romer and Romer's (2004) narrative/Greenbook shock and Gertler and Karadi's (2015) recent high-frequency identification (HFI) shocks identified using federal funds futures. I focus on these two types of shocks in part because they both imply very similar effects of monetary policy on output, despite using different identification methods and different samples.

Before beginning, it is important to clarify that the "shocks" identified in the monetary shock literature are not always the empirical counterparts to the shocks from our theoretical models, as discussed in Section 2.1. Because monetary policy is typically guided by a rule, most movements in monetary policy instruments are due to the *systematic* component of monetary policy rather than to deviations from that rule.[k] We do not have many good economic theories for what a structural monetary policy shock should be. Other than "random coin flipping," the most frequently discussed source of monetary policy shocks is shifts in central bank preferences, caused by changing weights on inflation vs unemployment in the loss function or by a change in the political power of individuals on the FOMC. A few papers explicitly link the empirically identified shocks to shifts in estimated central bank preferences (eg, Owyang and Ramey, 2004; Lakdawala, 2015), but most treat them as innovations to a Taylor rule, with no discussion of their economic meaning.[l]

If many macroeconomists now believe that monetary policy shocks themselves contribute little to macroeconomic outcomes, why is there such a large literature trying to identify them? The reason is that we want to identify nonsystematic movements in monetary policy so that we can estimate *causal* effects of money on macroeconomic variables. As Sims (1998) argued in his response to Rudebusch's (1998) critique of standard VAR methods, we need instruments in order to identify key structural parameters. Analogous to the supply and demand framework where we need demand shift instruments to identify the parameters of the supply curve, in the monetary policy context we require deviations from the monetary rule to identify the response of the economy to monetary policy. Thus, much of the search for "shocks" to monetary policy is a search for instruments rather than for primitive macroeconomic shocks.

3.1 A Brief History Through 1999

The effect of monetary policy on the economy is one of the most studied empirical questions in all of macroeconomics. The most important early evidence was Friedman and Schwartz's path-breaking 1963 contribution in the form of historical case studies

[k] Friedman argued, however, that most fluctuations in monetary instruments before 1960 were due to nonsystematic components of monetary policy.

[l] Christiano et al. (1999) discuss a few other possibilities, such as measurement error in preliminary data (pp. 71–73).

and analysis of historical data. The rational expectations revolution of the late 1960s and 1970s highlighted the importance of distinguishing the part of policy that was part of a rule vs shocks to that rule, as well as anticipated vs unanticipated parts of the change in the policy variable. Sims (1972, 1980a,b) developed modern time series methods that allowed for that distinction while investigating the effects of monetary policy. During the 1970s and much of the 1980s, shocks to monetary policy were measured as shocks to the stock of money (eg, Sims, 1972; Barro, 1977, 1978). This early work offered evidence that (i) money was (Granger-) causal for income; and (ii) that fluctuations in the stock of money could explain an important fraction of output fluctuations. Later, however, Sims (1980b) and Litterman and Weiss (1985) discovered that the inclusion of interest rates in the VAR significantly reduced the importance of shocks to the money stock for explaining output, and many concluded that monetary policy was not important for understanding economic fluctuations.[m]

There were two important rebuttals to the notion that monetary policy was not important for understanding fluctuations. The first rebuttal was by Romer and Romer (1989), who developed a narrative series on monetary policy shocks in the spirit of Friedman and Schwarz's (1963) work. Combing through FOMC minutes, they identified dates at which the Federal Reserve "attempted to exert a contractionary influence on the economy in order to reduce inflation" (p. 134). They found that industrial production decreased significantly after one of these "Romer Dates." The Romer and Romer series rapidly gained acceptance as an indicator of monetary policy shocks.[n] A few years later, though, Shapiro (1994) and Leeper (1997) showed that Romer and Romer's dummy variable was, in fact, predictable from lagged values of output (or unemployment) and inflation. Both argued that the narrative method used by Romer and Romer did not adequately separate *exogenous* shocks to monetary policy, necessary for establishing the strength of the causal channel, from the *endogenous* response of monetary policy to the economy.[o]

The second rebuttal to the Sims and Litterman and Weiss argument was by Bernanke and Blinder (1992). Building on an earlier idea by McCallum (1983), Bernanke and Blinder turned the money supply vs interest rate evidence on its head by arguing that interest rates, and in particular the federal funds rate, were *the* key indicators of monetary policy. They showed that both in Granger-causality tests and in variance decompositions of forecast errors, the federal funds rate outperformed both M1 and M2, as well as the 3-month Treasury bill and the 10-month Treasury bond for most variables.

[m] Of course, this view was significantly strengthened by Kydland and Prescott's (1982) seminal demonstration that business cycles could be explained with technology shocks.

[n] Boschen and Mills (1995) also extended the Romer and Romer's dummy variables to a more continuous indicator.

[o] See, however, Romer and Romer's (1997) response to Leeper.

The 1990s saw numerous papers that devoted attention to the issue of the correct specification of the monetary policy function. These papers used prior information on the monetary authority's operating procedures to specify the policy function in order to identify correctly the shocks to policy. For example, Christiano and Eichenbaum (1992) used nonborrowed reserves, Strongin (1995) suggested the part of nonborrowed reserves orthogonal to total reserves, and Bernanke and Mihov (1998) generalized these ideas by allowing for regime shifts in the type of monetary instrument that is targeted.[p] Another issue that arose during this period was the "Price Puzzle," a term coined by Eichenbaum (1992) to describe the common result that a contractionary shock to monetary policy appeared to raise the price level in the short-run. Sims (1992) conjectured that the Federal Reserve used more information about future movements in inflation than was commonly included in the VAR. He showed that the price puzzle was substantially reduced if commodity prices, often a harbinger of future inflation, were included in the VAR.

Christiano et al.'s (1999) *Handbook of Macroeconomics* chapter "Monetary policy shocks: What have we learned and to what end?" summarized and explored the implications of many of the 1990s innovations in studying monetary policy shocks. Their benchmark model used a particular form of the Cholesky decomposition in which the first block of variables consisting of output, prices, and commodity prices was assumed not to respond to monetary policy shocks within the quarter (or month). They called this identification assumption the "recursiveness assumption." On the other hand, they allowed contemporaneous values of the first-block variables to affect monetary policy decisions. Perhaps the most important message of the chapter was the robustness of the finding that a contractionary monetary policy shock, whether measured with the federal funds rate or nonborrowed reserves, had significant negative effects on output. On the other hand, the price puzzle continued to pop up in some specifications.

3.2 Some Alternatives to the Standard Model

Not all research on monetary policy shocks has been conducted in the canonical time-invariant linear SVAR model. In this section, I briefly highlight some of the research that generalizes the linear models or uses completely different methods.

3.2.1 Regime-Switching Models

In addition to the switch between interest rate targeting and nonborrowed reserve targeting (discussed by Bernanke and Mihov, 1998), several papers have estimated regime-switching models of monetary policy. The idea in these models is that monetary policy is driven not just by shocks but also by changes in the policy parameters. In an early

[p] An important part of this literature was addressed to the "liquidity puzzle," that is, the failure of some measures of money supply shocks to produce a negative short-run correlation between the supply of money and interest rates.

contribution to this literature, Owyang and Ramey (2004) estimated a regime-switching model in which the Fed's preference parameters could switch between "hawk" and "dove" regimes. They found that the onset of a dove regime leads to a steady increase in prices, followed by decline in output after approximately a year. Primiceri (2005) investigated the roles of changes in systematic monetary policy vs shocks to policy in the outcomes in the last 40 years. While he found evidence for changes in systematic monetary policy, he concluded that they are not an important part of the explanation of fluctuations in inflation and output. Sims and Zha (2006a) also considered regime-switching models and found evidence of regime switches that correspond closely to changes in the Fed chairmanship. Nevertheless, they also concluded that changes in monetary policy regimes do not explain much of economic fluctuations.

3.2.2 Time-Varying Effects of Monetary Policy

In their summary of the monetary policy literature in their chapter in the *Handbook of Monetary Economics*, Boivin et al. (2010) focus on time variation in the estimated effects of monetary policy. I refer the reader to their excellent survey for more detail. I will highlight two sets of results that emerge from their estimation of a FAVAR, using the standard Cholesky identification method. First, they confirm some earlier findings that the responses of real GDP were greater in the pre-1979Q3 period than in the post-1984Q1 period.[q] For example, they find that for the earlier period, a 100 basis point increase in the federal funds rate leads to a decline of industrial production of 1.6% troughing at 8 months. In the later period, the same increase in the funds rate leads to a -0.7% decline troughing at 24 months. The second set of results concerns the price puzzle. They find that in a standard VAR the results for prices are very sensitive to the specification. Inclusion of a commodity price index does not resolve the price puzzle, but inclusion of a measure of expected inflation does resolve it in the post-1984:1 period. In contrast, there is no price puzzle in the results from their FAVAR estimation. Boivin et al. (2010) discuss various reasons why the monetary transmission mechanism might have changed, such as changes in the regulatory environment affecting credit and the anchoring of expectations.

Barakchian and Crowe (2013) estimate many of the standard models, such as by those by Bernanke and Mihov (1998), CEE (1999), Romer and Romer (2004), and Sims and Zha (2006b), splitting the estimation sample in the 1980s and showing that the impulse response functions change dramatically. In particular, most of the specifications estimated from 1988 to 2008 show that a positive shock to the federal funds rate *raises* output and prices in most cases.

Another source of time variation is state-dependent or sign-dependent effects of monetary shocks on the economy. Cover (1992) was one of the first to present evidence

[q] See, for example, Faust (1998), Barth and Ramey (2002), and Boivin and Giannoni (2006).

that negative monetary policy shocks had bigger effects (in absolute value) than positive monetary shocks. Follow-up papers such as by Thoma (1994) and Weise (1999) found similar results. Recent work by Angrist et al. (2013) finds related evidence that monetary policy is more effective in slowing economic activity than it is in stimulating economic activity. Tenreyro and Thwaites (forthcoming) also find that monetary shocks seem to be less powerful during recessions.

Olivei and Tenreyro (2007) estimate important seasonality in the effects of monetary shocks that is well explained by sticky wage models. They find that monetary shocks that take place in the first two quarters of the year have sizeable, but temporary, effects on output, whereas shocks that take place in the third and fourth quarters of the year have little effect on output. They explain these results with evidence on uneven staggering of labor contracts over the year: a shock that hits near the end of the year has little effect because the bulk of wage contracts is reset then, so wages can adjust immediately.

Since fall 2008, the federal funds rate has been near the zero lower bound. Thus, a key question that has arisen is how to measure shocks in light of this nonlinear constraint. Wu and Xia (2016) use a multifactor Shadow Rate Term Structure Model to estimate a shadow federal funds rate. This shadow rate can capture additional features, such as quantitative easing. Wu and Xia find that unconventional monetary policy has a noticeable impact on the macroeconomy.

3.2.3 Historical Case Studies

Given the important impact of Friedman and Schwartz's (1963) case study of monetary policy during the Great Depression, it is surprising that more case studies have not been conducted. Romer and Romer (1989)'s first narrative monetary analysis was designed to be a quasi-case study in the spirit of Friedman and Schwartz. Their dummy variable series was assigned to episodes in which the Fed decided to risk a recession in order to reduce inflation.

Velde (2009) presents one of the most striking case studies of monetary nonneutrality, based on an episode in 1724 France. In that year, the French government cut the money supply three times, resulting in a cumulative drop of 45%! The action was taken for a variety of reasons, such as long-term price targeting and worries that soldiers and creditors of the state were being hurt by the rise in prices during the previous 6 years. Velde finds that while prices on foreign exchange markets adjusted instantly, other prices adjusted slowly and incompletely and industrial output fell by 30%. The circumstances of that episode are unusually clean for a historical case study, so his evidence of monetary nonneutrality is quite compelling.

3.3 Main Identification Challenges

Several parts of Section 2 discussed some of the challenges to identification in general. Here, I review the issues that are particular important for the identification of monetary policy shocks.

3.3.1 The Recursiveness Assumption

A key assumption used by Christiano et al. (1999) was the "recursiveness assumption." Consider the trivariate model from Eq. (5) in the last section, rewritten here for convenience:

$$\begin{aligned}\eta_{1t} &= b_{12}\eta_{2t} + b_{13}\eta_{3t} + \varepsilon_{1t} \\ \eta_{2t} &= b_{21}\eta_{1t} + b_{23}\eta_{3t} + \varepsilon_{2t} \\ \eta_{3t} &= b_{31}\eta_{1t} + b_{32}\eta_{2t} + \varepsilon_{3t}\end{aligned} \tag{13}$$

CEE include more than three variables in the system, so we should think of each η_t as representing a block of variables: η_{1t} includes output, a general price index, and a commodities price index; η_{2t} is the federal funds rate; and η_{3t} contains a monetary stock measure such as M1 or M2, nonborrowed reserves, and total reserves. CEE interpret the equation for η_{2t} as the Fed's feedback rule and ε_{2t} as the monetary policy shock. They assume that current values of the η_{1t} enter the Fed's rule, so $b_{21} \neq 0$, but the money stock and reserves do not enter the rule, so $b_{23} = 0$. These are still not enough assumptions to identify the monetary policy shock because if the monetary policy shock can affect output, etc., within the period, η_{1t} will be correlated with ε_{2t} so we cannot use OLSs. CEE thus add the additional recursiveness assumptions that none of the η_{1t} variables (output and prices) is affected by the monetary policy shock or the monetary aggregates within the period, ie, $b_{12} = b_{13} = 0$. In practice, this is just a Cholesky decomposition generalized to blocks of variables. Since CEE focused only on the monetary policy shock, they did not need to make more assumptions to identify shocks within the first and third block.

It is important to emphasize, however, the importance of the recursiveness assumption for identification. All of CEE's results depend on setting $b_{12} = 0$, meaning that output and prices are not allowed to respond to changes in the federal funds rate within the period. Note that this assumption is at odds with some later estimated New Keynesian DSGE models. For example, Smets and Wouters' (2007) estimated model implies that output, hours, and inflation should respond immediately to the monetary policy shock (see figure 6 of their paper). The estimated DSGE model of CEE (2005) does not imply an immediate response, but only because they assume that no agents can react to the monetary policy shock within the period. They make this theoretical assumption because they estimate their model parameters to match the impulse responses of their VARs which identify the monetary policy shock with the recursiveness assumption.

Even research that develops external instruments typically uses the recursiveness assumption. For example, Romer and Romer (2004) develop a new measure of monetary policy shocks using narrative methods and Greenbook forecasts, but when they study the effects on output and prices, they impose the additional constraint that $b_{12} = b_{13} = 0$. They do so because they do not view their estimated shock as being pure, and thus also use the recursivity assumption as "exogeneity insurance." Coibion's (2012) generalization of the Romer and Romer procedures also imposes the constraint. Barakchian and

Crowe (2013) use HFI from fed funds futures, but nevertheless invoke the recursiveness assumption in their VARs. The typical FAVAR models, such as those by Bernanke et al. (2005) and Boivin et al. (2010), use the recursiveness assumption as well.

Some of the few papers that do not use the recursiveness assumption are those that use sign restrictions. Uhlig (1997, 2005), Faust (1998), Faust et al. (2004), Arias et al. (2015a), and Amir Ahmadi and Uhlig (2015) are able to avoid imposing the zero restriction associated with the recursiveness assumption by instead using sign restriction, also known as "set identification" or partial identification. For example, Uhlig (1997, 2005) imposes the restriction that contractionary monetary policy shocks cannot raise prices. Faust et al. (2004) constrain $-0.1 \leq b_{12} \leq 0$ for the output and price equations. The sign restriction papers can often yield confidence sets that imply possibly positive effects of contractionary monetary policy on output (eg, Uhlig, 2005; Faust et al., 2004; Amir Ahmadi and Uhlig, 2015).

In Section 3.4, I will investigate the importance of the recursiveness assumption in more detail.

3.3.2 Foresight Problems

Section 2.5 discussed how two types of foresight could create problems in identifying shocks and their effects. Both types of foresight are particularly important for monetary policy, and significant progress has been made recently both in appreciating their importance and in developing methods for addressing them.

The first type of foresight problem is foresight on the part of policymakers. As an illustration of the problem, suppose the Fed follows a simple policy rule:

$$ff_{\mathrm{t}} = \alpha_1 E_t(\Delta_h y_{t+h}) + \alpha_2 E_t(\Delta_h \pi_{t+h}) + \varepsilon_{ft} \tag{14}$$

where ff is the federal funds rate, y is the log output, and π is the inflation. Δ_h is the change in the variable from t to $t+h$. The Fed sets interest rates based on its expectations of the future path of output and inflation because it is aware of the lags in the effects of monetary policy. I have modeled this simply as expectations of changes from t to t+h, but the argument applies for more general notions of expectations about the path.

The usual SVAR specification assumes that the Fed's expectations about the future paths of output and inflation are adequately captured by the current and lagged values of the (typically) few macroeconomic variables included in the SVAR. This is a strong assumption. The idea that identified monetary shocks might be incorrectly mixing systematic responses to the Fed's expectations was first highlighted by Sims (1992), who argued that the price puzzle was due to the Fed observing more information on inflation. He advocated the incorporation of sensitive commodity prices to address the problem. However, this inclusion does not always get rid of the price puzzle. Bernanke et al.'s (2005) FAVARs are another method for incorporating more information. The FAVAR, which typically contains over one hundred series, has the benefit that it is much more likely to condition on relevant information for identifying shocks. The FAVAR method nonetheless relies on the assumption that linear combinations of publicly available series fully capture the Fed's expectations.

In a 2000 paper, Romer and Romer presented evidence suggesting that the Fed had superior information when constructing inflation forecasts compared to the private sector. To see the problem this asymmetric information presents, rewrite Eq. (14) as:

$$\begin{aligned} ff_t = {} & \alpha_1 E_t^p(\Delta_h y_{t+h}) + \alpha_2 E_t^p(\Delta_h \pi_{t+h}) + \alpha_1 \left[E_t^f(\Delta_h y_{t+h}) - E_t^p(\Delta_h y_{t+h})\right] \\ & + \alpha_2 \left[E_t^f(\Delta_h \pi_{t+h}) - E_t^p(\Delta_h \pi_{t+h})\right] + \varepsilon_{ft} \end{aligned} \tag{15}$$

In this equation, E_t^p denotes expectations based on private agent information and E_t^f denotes expectations based on the Fed's information. If information is symmetric and publicly available, then the two terms in square brackets will be zero and methods that incorporate sufficient amounts of public information should be able to identify the monetary policy shock ε_{ft} correctly. If, on the other hand, the Fed has superior information, the terms in brackets will not be zero and an SVAR or an FAVAR will produce an incorrectly identified monetary policy shock, $\widetilde{\varepsilon}_{ft}$ that consists of two components, the true shock as well as a component based on the informational superiority of the Fed:

$$\widetilde{\varepsilon}_{ft} = \varepsilon_{ft} + \alpha_1 \left[E_t^f(\Delta_h y_{t+h}) - E_t^p(\Delta_h y_{t+h})\right] + \alpha_2 \left[E_t^f(\Delta_h \pi_{t+h}) - E_t^p(\Delta_h \pi_{t+h})\right] \tag{16}$$

Barth and Ramey (2002) suggested that the problem might be corrected by controlling for Fed forecasts in VARs. They augmented their monetary VARs with Greenbook forecasts of inflation and output in order to determine whether controls for the Fed's superior information would make the price puzzle disappear in their early sample from 1965 to 1979. They found that even with the controls for the Greenbook forecasts, the price puzzle was still very strong in this early sample (see figure 7 of their paper).

Romer and Romer (2004) (R&R) combined the use of Greenbook forecasts with narrative methods to construct a new measure of monetary policy shocks. First, they derived a series of *intended* federal funds rate changes during FOMC meetings using narrative methods. Second, in order to separate the endogenous response of policy to information about the economy from the exogenous shock, they regressed the intended funds rate change on the current rate and on the Greenbook forecasts of output growth and inflation over the next two quarters. They then converted the estimated residuals based on the FOMC meeting frequency data to monthly and used them in dynamic regressions for output and other variables. They found very large effects of these shocks on output.

John Cochrane's (2004) NBER EFG discussion of the Romer and Romer paper highlights how their method can identify movements in monetary policy instruments that are exogenous to the error term of the model. If the Greenbook forecast of future GDP growth contains all of the information that the FOMC uses to make its decisions, then that forecast is a "sufficient statistic." Any movements in the target funds rate that are not predicted by the Greenbook forecast of future *output* can be used as an instrument to identify the causal effect of monetary policy on *output*. Analogously, any movements in the target funds rate that are not predicted by the Greenbook forecast of *inflation* can be used as an instrument to identify the causal effect of monetary policy on *inflation*. The idea is that if the Fed responds to a shock for reasons other than its effect on future output or future inflation, that response can be used as an instrument for output or inflation. Cochrane states the following proposition in his discussion:

> Proposition 1: To measure the effects of monetary policy on output, it is enough that the shock is orthogonal to output forecasts. The shock does not have to be orthogonal to price, exchange rate, or other forecasts. It may be predictable from time *t* information; it does not have to be a shock to the agent's or the Fed's entire information set (Cochrane, 2004).

Cochrane's conceptualization of the issue of identifying movements in monetary policy that are exogenous to the error term in the equation is an important step forward. Note, however, that what Cochrane calls a "shock" is not the same as the definition of shock that I use in this chapter. Cochrane's notion of a shock is not a primitive structural shock, but rather a useful instrument for estimating the effect of monetary policy on output, etc.

The possibility of asymmetric information between the Fed and the private sector leads to a further complication, though. If the Federal Reserve has superior information, then any action or announcement by the Fed presents a signal extraction problem for private agents. Private agents observe $\widetilde{\varepsilon}_{ft}$ in Eq. (14), but they know that it is composed of the true shock as well as the systematic component of the Fed's rule based on the Fed's informational advantage. The problem can easily be extended to include the possibility that $\widetilde{\varepsilon}_{ft}$ also contains time-varying inflation or output targets that are unobserved by the public. Gürkaynak et al. (2005) argue that their estimated negative effects of an unanticipated rise in the federal funds rate on long-term forward rates can be explained as the response to information revealed by the Fed action about inflation targets.

The second type of foresight problem is news about future policy actions. Campbell et al. (2012) argue that the Fed has been using forward guidance since the early 1990s. This means that many changes in the federal funds rate are in fact *anticipated* in advance. As discussed in Section 2.5 on foresight, foresight about future movements in policy variables can lead to a nonfundamental moving average representation. This would imply that standard VARs typically cannot be used to identify the shocks.

Fortunately, the monetary literature has developed excellent methods for identifying news shocks. As discussed in Section 2.3.4, research by many, such as Kuttner (2001), Cochrane and Piazzesi (2002), Gürkaynak et al. (2005), Piazzesi and Swanson (2008), Barakchian and Crowe (2013), Gertler and Karadi (2015), and Nakamura and

Steinsson (2015), has used the movements of federal funds and other interest rate futures in small windows around FOMC announcements to identify unexpected Fed policy actions. Exploiting the information in interest rate futures is an ideal way to construct "news" series. D'Amico and King (2015) study the effects of anticipated monetary policy by combining information on expectations, as in Campbell et al. (2012), with sign restrictions in an SVAR. In particular, they identify a monetary news shock by restricting the responses of the expected short term rate to move in the opposite direction of expected inflation and expected output.

3.4 Summary of Recent Estimates

Table 1 summarizes some of the main results from the literature on the impact of the identified monetary shock on output, the contribution of monetary shocks to output fluctuations, and whether the price puzzle is present. Rather than trying to be encyclopedic in listing all results, I have chosen leading examples obtained with the various identifying assumptions. In addition, I attempted to standardize the results by normalizing the peak of response of the federal funds rate to 100 basis points; this standardization does not control for differences in persistence of the response as I discuss later.

As Table 1, the standard Christiano et al. (1999) SVAR, the Faust et al. (2004) HFI, Uhlig's (2005) and Amir Ahmadi and Uhlig's (2015) sign restrictions, Smets and Wouters' (2007) estimated DSGE model, and Bernanke et al.'s (2005) FAVAR all produce rather small effects of monetary policy shocks. Also, most are plagued by the price puzzle to greater or lesser degree. On the other hand, Romer and Romer (2004), Coibion (2012), Barakchian–Crowe (2013), and Gertler–Karadi (2015) all find larger impacts of a given shock on output.

I will also summarize briefly the effects on other variables from some of the leading analyses. A particularly comprehensive examination for many variables is conducted by Boivin et al.'s (2010) with their FAVAR. Recall that they obtained different results for the pre- vs post-1980 period. For the period from 1984m1 to 2008m12, they found that a positive shock to the federal funds rate leads to declines in a number of variables, including employment, consumption expenditures, investment, housing starts, and capacity utilization.

3.5 Explorations with Three Types of Monetary Shocks

I now explore the robustness of the effects of monetary policy shocks using some of the new methods introduced in the literature to deal with both the foresight problems and the recursiveness assumption. For reference, I begin by estimating the classic Christiano et al.'s (1999) type of specification and then move on to the Romer and Romer (2004) shock and Gertler and Karadi's (2015) HFI shock.

Table 1 Summary of monetary policy shock effects on output and prices

Paper	Method, sample	Trough effect of 100 basis point funds peak	% of output explained by shock	Price puzzle?
Christiano et al. (1999)–FFR identification	SVAR, 1965q3–1995q3	−0.7% at 8 quarters	4.4% at 2 years	Yes, but very small
Faust et al. (2004)	HFI, 1991m2–2001m7	−0.6% at 10 months		
Romer and Romer (2004)	Narrative/Greenbook 1970m1–1996m12	−4.3% at 24 months	Major part	No, but prices do not change for 22 months
Uhlig (2005)	Sign restrictions, 1965m1–1996m12	Positive, but not statistically different from 0	5–10% at all horizons.	No (by construction)
Bernanke et al. (2005)	FAVAR, 1959m1–2001m7	−0.6% at 18 months	5% at 5 years	Yes
Smets–Wouters (2007)	Estimated DSGE model, 1966Q1–2004Q4	−1.8 at 4 quarter trough	10% at 1 year (trough)	No
Boivin et al. (2010)	FAVAR, 1962m1–1979m9, 1984m1–2008m12	−1.6% at 8 months in early period −0.7% at 24 months in later period		Only in the early period
Coibion (2012)	"Robust" Romer–Romer methods, 1970m1–1996m12	−2% at 18 months	"Medium" part	Yes, sometimes
Barakchian–Crowe (2013)	HFI, Romer hybrid VAR, 1988m12–2008m6	−5% at 23 months	50% at 3 years	Yes
Gertler–Karadi (2015)	HFI-proxy SVAR, 1979m7–2012m6 (1991m1–2012m6 for instruments)	−2.2% at 18 months	?	No
Amir Ahmadi and Uhlig (2015)	Bayesian FAVAR with sign restrictions, 1960m2–2010m6	−1.3% at 9 months	7% at 24 months	No (by construction)

3.5.1 The Christiano et al. (1999) Benchmark

Christiano et al. (1999) presented estimates based on shocks identified using the recursiveness assumption and showed robust results that were generally consistent with conventional views on the effect of monetary shocks. Here I study how the results change when the sample is updated.

I estimate a specification similar to Christiano et al.'s (1999) specification but use Coibion's (2012) macroeconomic variables for the first block. In particular, I use monthly data and include log industrial production, the unemployment rate, the log of the CPI, and the log of a commodity price index in the first block. The second block consists of the federal funds rate. The third block consists of the logs of nonborrowed reserves, total reserves, and M1. Thus, the innovation to the federal funds rate (orthogonal to contemporaneous values of the first block variables and lags of all of the variables) is identified as the monetary policy shock.

Fig. 1 shows the estimated impulses for this SVAR. The solid black line and shaded areas are the point estimates and 90% bootstrap confidence bands for the system estimated over CEE's sample period, 1965m1–1995m6. The responses look like classic effects of monetary policy shocks. The Federal funds rate jumps up temporarily but then falls back to 0 by 6 months. This temporary blip in the funds rate, however, sets off a prolonged recession. Industrial production begins to fall in the next month and troughs 21 months later. Unemployment rises and peaks around 23 months later. Both unemployment and industrial production return to normal after 4 years. Prices rise slightly for the first few months, but then follow a steady path down, settling at the new lower level after 4 years. Nonborrowed reserves, total reserves, and M1 fall and then recover after 3 years. Nonborrowed reserves display some unusual oscillations, though. For the most part, these responses look very similar to the ones shown in figure 3 of CEE (1999).

The blue short dashed lines in the same figures show the responses for the sample from 1983m1 to 2007m12. The sample stops in 2007 both to exclude the financial crisis and for the practical reason that nonborrowed reserves became negative starting in 2008. The results change dramatically and imply that increases in the federal funds rate lower the unemployment rate. These results echo those of Barakchian and Crowe (2013), who show that the leading specifications imply expansionary effects in the sample from 1988 through 2007.

The red long-dashed lines show the results of a simplified model for the sample 1983m1–2007m12. This model omits M1, nonborrowed reserves, and total reserves. In this specification, there is still a small amount of expansionary effect on output and unemployment at the beginning, but then the more standard contractionary effects take hold. Prices never fall, however.

Table 2 shows various measures of the importance of monetary policy shocks for industrial production in CEE's specification. The first column shows the trough effect on output of a shock that raises the funds rate to a peak of 100 basis points. Even in CEE's original sample, the effects are very modest, less than a −0.5% fall. When estimated over the period

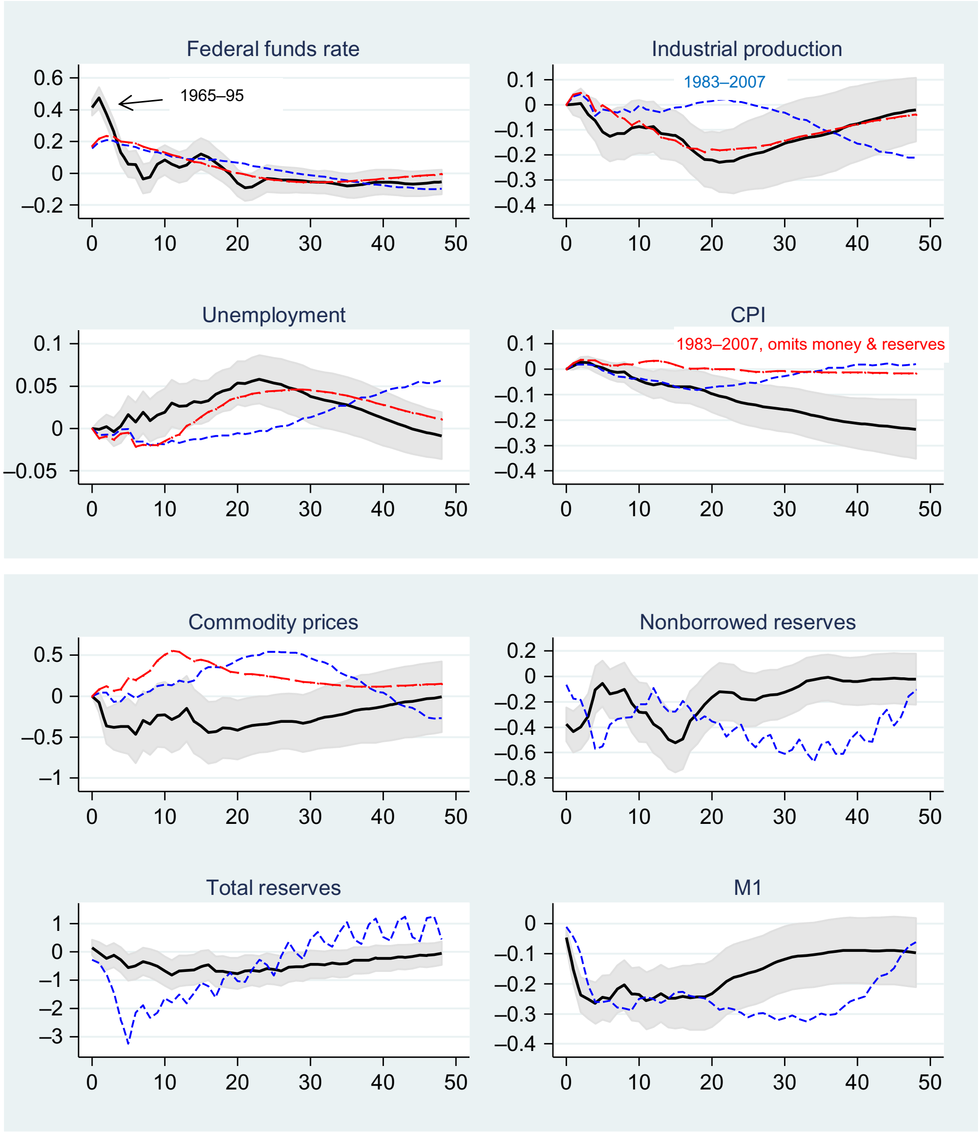

Fig. 1 Christiano et al. (1999) identification. 1965m1–1995m6 full specification: *solid black lines*; 1983m1–2007m12 full specification: *short dashed blue* (*dark gray* in the print version) *lines*; 1983m1–2007m12, omits money and reserves: *long-dashed red* (*gray* in the print version) *lines*. Light gray bands are 90% confidence bands.

1959 through 2007, the effects are less than half. The other columns show the forecast error variance decompositions at 24 months. These indicate that monetary policy shocks account for less than 7% of the forecast error variance in the original sample and less than 1% in the longer sample. A reasonable interpretation of the decline in the contribution of monetary shocks to output volatility is improved, less erratic monetary policy.

Table 2 Effects of Monetary Policy Shocks on Industrial Production: My Estimates

Method and sample	Trough effect of 100 basis point funds peak (%)	Forecast error variance decompositions (%) 24 months
CEE: 1965m1–1996m6	−0.48	6.6
CEE: 1959m1–2007m12	−0.20	0.5
R&R VAR: 1969m3–1996m12	−1.38	8.8
R&R VAR: 1969m3–2007m12	−0.83	2.7
R&R, Jordà method: 1969m3–1996m12	−0.83	
R&R, Jordà method, no recursiveness assumption: 1969m3–1996m12	−0.90	
Gertler–Karadi, proxy SVAR: 1990m1–2012m6	−2.2	
Gertler–Karadi Jordà method: 1990m1–2012m6	−1, but then rises to +4	

Notes: See text for the description of the CEE (Christiano et al., 1999), R&R (Romer and Romer, 2004) VARs, and Gertler–Karadi proxy SVARs.

3.5.2 Greenbook/Narrative Identification of Shocks

Next, I consider the effects of the shocks identified by Romer and Romer (2004). As discussed in Section 3.3.2, Romer and Romer (2004) (R&R) sought to overcome the problem of superior Federal Reserve information by regressing the federal funds target rate on the Greenbook forecasts at each FOMC meeting date and using the residual as the monetary policy shock. They find much larger effects of monetary policy than CEE do. Coibion (2012) explores many possible reasons for the differences and provides very satisfactory and revealing answers. In particular, he finds that R&R's main results, based on measuring the effect of their identified shock using a single dynamic equation, are very sensitive to the inclusion of the period of nonborrowed reserves targeting, 1979–82, and the number of lags (the estimated impact on output is monotonically increasing in the number of lags included in the specification). In addition, their large effects on output are linked to the more persistent effects of their shock on the funds rate. In contrast, R&R's hybrid VAR specification, in which they substituted their (cumulative) shocks for the federal funds rate (ordered last) in a standard VAR, produces results implying that monetary policy shocks have "medium" effects. Coibion (2012) goes on to show that the hybrid model results are consistent with numerous other specifications, such as GARCH estimates of Taylor Rules (as suggested by Hamilton, 2010; Sims–Zha, 2006a) and time-varying parameter models as in Boivin (2006) and Coibion and Gorodnichenko (2011). Thus, he concludes that monetary policy shocks have "medium" effects. In particular, a 100 basis point rise in the federal funds rate leads industrial production to fall 2–3% at its trough at around 18 months.

In my explorations, I use the Coibion version of the R&R hybrid VAR, a monthly VAR with the log of industrial production, the unemployment rate, the log of the CPI, the log of a commodity price index in the first block, and the cumulative Romer and Romer shock replacing the federal funds rate. This specification uses the recursiveness assumption as well, placing the funds rate last in the ordering and thus assuming that the monetary shock cannot affect the macroeconomic variables within the month.

Fig. 2A shows the results, with the solid lines and confidence bands estimated using the original R&R shocks on the original R&R sample of 1969m3–1996m12. These results also match the classic monetary policy effects. Output falls within a month or two, while unemployment rises. Prices remain constant until around 9 months, when they fall steadily until they bottom out during the 4th year after the shock. A qualitative difference with the CEE results is that the response of the federal funds rate is more persistent in the R&R VAR.

The short dashed blue lines show the responses based on the sample from 1983m1 to 2007m12. I constructed new R&R shocks by reestimating their FOMC meeting regression for the later sample, using the updates by Wieland and Yang (2015). I converted these shocks to monthly and then used them in the VAR estimated over the same later sample. The results are similar to those found by Barakchian and Crowe (2013): contractionary monetary policy shocks appear to be expansionary.

The long-dashed red lines show the responses based on the sample from 1969m3 to 2007m12. The R&R shock is based on reestimating their FOMC meeting regression for the entire sample. The results for the full sample look more like those for the original R&R sample, but with more muted effects on output and unemployment.

Rows 3 and 4 of Table 2 show the trough effects and variance decompositions for the R&R VAR. In their original sample, the trough effect on output is −1.38, which is substantially larger than the results using CEE.[r] The forecast error variance decomposition implies that monetary policy shocks account for 9% of the variance for horizons at 24 months.[s] As with most monetary shock specifications, however, the effects are considerably less if we include more recent periods in the sample.

An odd feature of the impulse responses shown in Fig. 2A is the robust rebound of industrial production after 2 years of recession. The peak of industrial production at 48 months is the same magnitude as the trough at 13 months. One possible explanation is that

[r] My numbers are slightly different from those of Coibion's for the original sample because he normalized by the impact effect on the funds rate rather than the peak response of the funds rate. Emi Nakamura has suggested that it might be better to compare the integral of the output response to the integral of the funds rate response because this measure incorporates persistence. I found that this measure sometimes behaved oddly because of the tendency of some of the variables to oscillate around zero.

[s] Neither Romer and Romer (2004) nor Coibion (2012) conducted forecast error variance decompositions. Their claim of large or "medium" effects was based on comparing the actual paths of output to the predicted paths implied by the estimated monetary policy shocks.

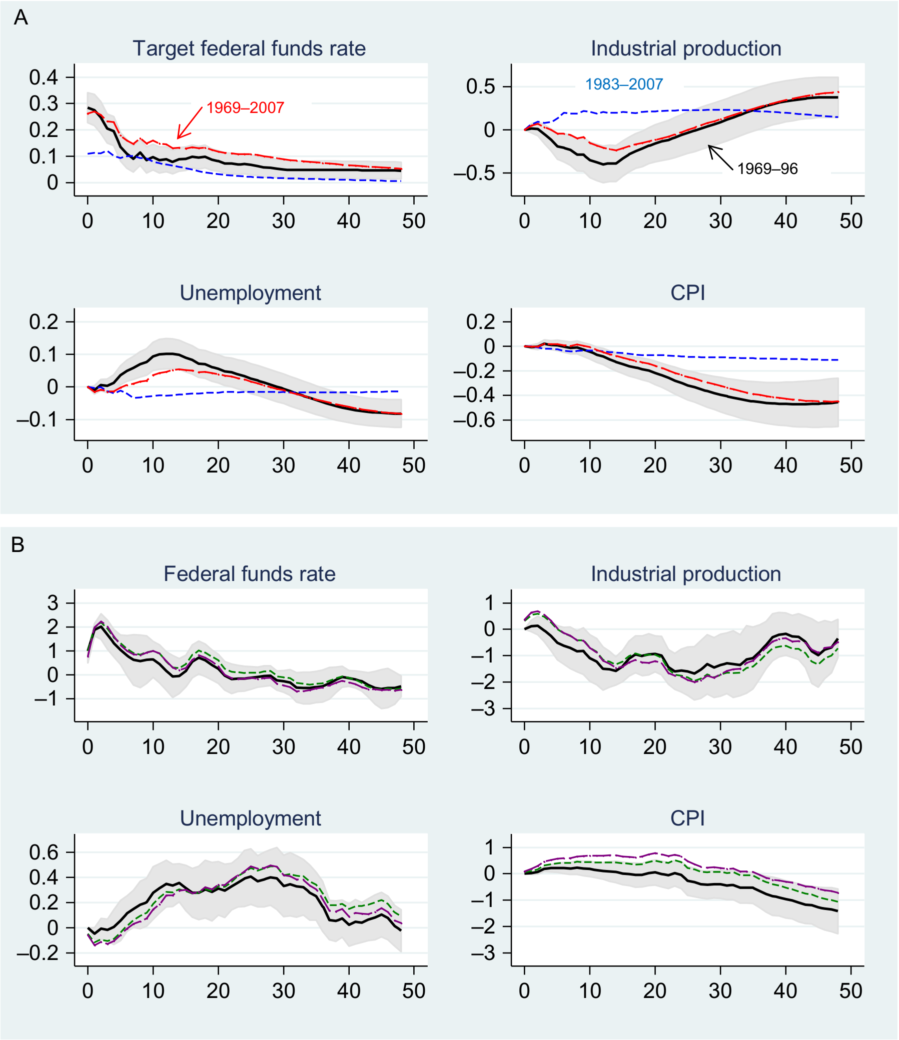

Fig. 2 Romer and Romer monetary shock. (A) Coibion VAR 1969m3–1996m12: *solid black lines*; 1983m1–2007m12: *short dashed blue* (*dark gray* in the print version) *lines*; 1969m3–2007m12: *long-dashed red* (*gray* in the print version) *lines*. (B) Jordà local projection method, 1969m3–1996m12 recursiveness assumption: *solid black lines*; no recursiveness assumption: *short dashed green* (*dark gray* in the print version) *lines*; no recursiveness assumption, FAVAR controls: *long dashed purple* (*dark gray* in the print version) *lines*. Light gray bands are 90% confidence bands.

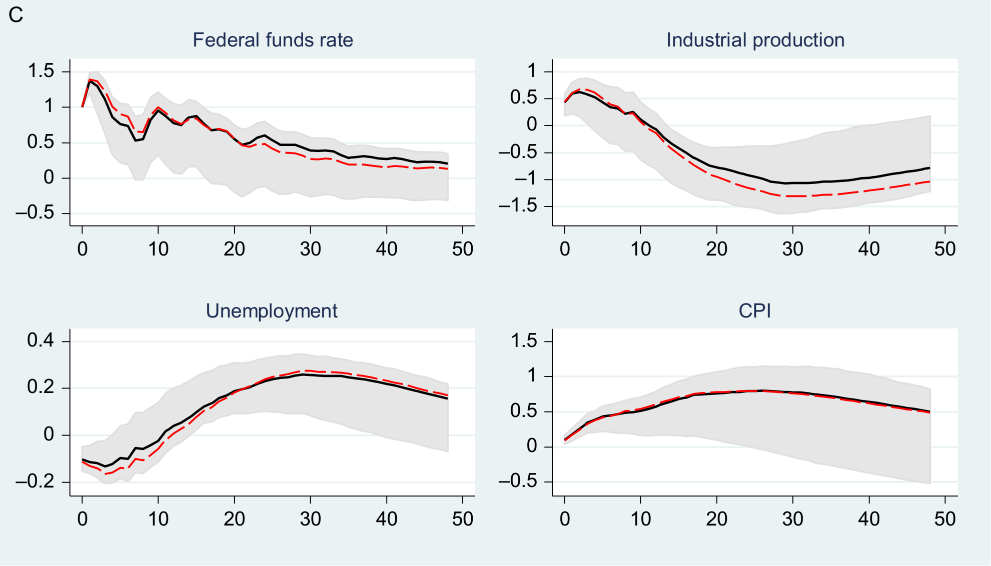

Fig. 2—Cont'd (C) Proxy SVAR, 1969m3–1996m12: *solid black lines*; 1969m3–2007m12: *long-dashed red* (*gray* in the print version) *lines*.

misspecification of the VAR is distorting the estimated impulse responses. One way to assess this hypothesis is to use Jordà's (2005) local projection method. As discussed in Section 2.4, the Jordà method puts fewer restrictions on the impulse responses. Rather than estimating impulse responses based on nonlinear functions of the reduced form parameters, the Jordà method estimates regressions of the dependent variable at horizon $t+h$ on the shock in period t and uses the coefficient on the shock as the impulse response estimate.

To investigate the results of this less restrictive specification, I estimate the following series of regressions:

$$z_{t+h} = \alpha_h + \theta_h \cdot \text{shock}_t + \text{control variables} + \varepsilon_{t+h} \tag{17}$$

The z is the variable of interest. The control variables include two lags of the R&R shock, the federal funds rate, the log of industrial production, the unemployment rate, the log of the CPI, and the log of the commodity price index.[t] In addition, to preserve the recursiveness assumption, I include *contemporaneous* values of the log of industrial production, unemployment rate, and the logs of the two price indices. The coefficient θ_h gives the response of z at time $t+h$ to a shock at time t. As discussed in Section 2, ε_{t+h} will be serially correlated, so the standard errors must incorporate a correction, such as Newey–West.

Fig. 2B shows the impulse responses estimated using the Jordà method on R&R's original sample 1969m3–1996m12. The relevant impulse responses are indicated by

[t] The point estimates are similar if more lags are included.

the black solid lines. While the responses are somewhat more erratic, they display more coherent dynamics. In particular, rather than the swing from recession to boom for industrial production implied by the VAR estimates, the Jordà estimates imply a more persistent decline in output (and rise in unemployment) that slowly returns to normal.

As discussed earlier, the R&R VAR still imposes the recursiveness assumption. If one believes that the Greenbook forecasts incorporate all relevant information used by the Fed, then one does not need to impose the additional CEE recursiveness assumption. To determine the effect of removing the restriction that output and prices cannot respond to the shock within the month, I reestimate the Jordà regressions omitting the contemporaneous values of all variables other than the R&R shock. The results of this estimation are shown by the green short dashed lines in Fig. 2B. Many aspects of the responses are similar to those obtained with the recursiveness assumptions. However, there are several key differences. First, the estimates imply that a shock that raises the funds rate is initially expansionary: industrial production rises and the unemployment rate falls for the first several months, and the point estimates are statistically different from zero (not shown). Second, there is a pronounced price puzzle for the first 2 years, and most of those estimates are statistically different from zero.

One possible explanation for these puzzles is a failure of the Greenbook forecasts to capture all of the information the Federal Reserve uses. To examine whether expanding the information set helps eliminate the price puzzle, I reestimate the nonrecursive Jordà model with the following alternative controls: two lags each of the R&R shock, the federal funds rate, the dependent variable, and updates of Boivin et al.'s (2010) five FAVAR factors.[u] The results are shown as the long dashed purple (*dark gray* in the print version) line in Fig. 2B. In this case, the price puzzle is even worse and the initial expansionary effects on output and unemployment are no better. Thus, including FAVAR-type factors does not reproduce the results obtained using the recursiveness assumption.

The proxy SVAR is another method that can be used to relax the recursiveness assumption. Kliem and Kriwoluzky (2013) use this method to reconcile VAR monetary shocks with the Romers' narrative shocks. They do not, however, explore effects on output, prices, or other variables. To investigate the results using this method, I estimate the reduced form of Coibion's system with the federal funds rate substituted for the cumulative R&R shock and with R&R's monetary policy shock as an external instrument following Stock and Watson's (2012) and Mertens and Ravn's (2013) proxy SVAR method (see Section 2 for a description).

Fig. 2C shows the results for the original sample (1969–1996) and the full sample from 1969 through 2007. The shaded areas are 90% confidence bands using Mertens and Ravn's methods for the original sample estimates. In both samples, a shock to monetary policy raises the federal funds rate, which peaks at 1.4% by the month after the shock and

[u] I am indebted to Shihan Xie for providing her updates of the Boivin et al. estimated factors.

falls slowly to 0% thereafter. The response of industrial production (shown as the red long-dashed line in Fig. 2) is different from the one obtained using the hybrid VAR. In particular, industrial production now rises above normal for about 10 months and then begins falling, hitting a trough at about 29 months. Normalized by the funds rate peak, the results imply that a shock that raises the funds rate to a peak of 100 basis points first raises industrial production by 0.5% at its peak a few months after the shock and then lowers it by −0.9% by 29 months. The unemployment rate exhibits the same pattern in reverse. After a contractionary monetary policy shock, it falls by 0.1 percentage points in the first year and then begins rising, hitting a peak of about 0.2 percentage points at month 30. The behavior of the CPI shows a pronounced, statistically significant prize puzzle.

In sum, relaxing the recursiveness assumption imposed by Romer and Romer's hybrid VAR leads to several puzzles. A contractionary monetary policy shock is now expansionary in its first year and the price puzzle is very pronounced.

The most obvious explanation for these results is that the FOMC responds to more information than even the Greenbook forecast and FAVAR factors capture, and making the R&R shock orthogonal to current output and prices (ie, the recursiveness assumption) helps cleanse the shock of these extra influences. However, this means that even with the R&R shock, one is forced to make the recursiveness assumption, which does not have a solid economic basis. As discussed earlier, leading New Keynesian models, such as Smets and Wouters (2007), imply immediate effects of monetary policy shocks on output and prices.

This exploration highlights the importance of additional restrictions imposed in standard monetary models, as well as the importance of the sample period when estimating the effects of monetary shocks. Without the additional recursiveness assumption, even narrative methods can produce puzzling results. Furthermore, as highlighted by Barakchian and Crowe (2013), many of the methods that produce classic monetary shock results in samples through the mid-1990s produce puzzles when estimated over later samples. In particular, contractionary monetary shocks seem to have expansionary effects in the first year and the price puzzle is pervasive. A plausible explanation for the breakdown in results in the later sample is an identification problem: because monetary policy has been conducted so well in the last several decades, true monetary policy shocks are rare. Thus, it is difficult to extract meaningful monetary shocks that are not contaminated by problems with foresight on the part of the monetary authority.

3.5.3 HFI Shocks

As discussed in the previous sections, numerous papers have used HFI methods to deal with possible foresight about monetary policy changes. Part of the literature focuses only on the effects on interest rates and asset prices (eg, Krishnamurthy and Vissing-Jorgensen, 2011; Hanson and Stein, 2015). Nakamura and Steinsson (2015) link their estimated interest rate changes to output effects by calibrating a New Keynesian model. The strength of the effect, however, depends crucially on the assumed intertemporal elasticity of substitution. For this reason, it is also important to estimate direct links in the data as well.

A recent paper by Gertler and Karadi (2015) combines HFI methods with proxy SVAR methods to investigate the effects on macroeconomic variables. They have two motivations for using these methods. First, they seek to study the effect of monetary policy on variables measuring financial frictions, such as interest rate spreads. The usual Cholesky ordering with the federal funds rate ordered last imposes the restriction that no variables ordered earlier respond to the funds rate shocks within the period. This is clearly an untenable assumption for financial market rates. Second, they want to capture the fact that over time the Fed has increasingly relied on communication to influence market beliefs about the future path of interest rates (forward guidance).

In the implementation, Gertler and Karadi estimate the residuals using monthly data from 1979 to 2012, but then execute the proxy SVAR from 1991 to 2012 since the instruments are only available for that sample. Fig. 3A replicates the results from Gertler and Karadi's baseline proxy SVAR for figure 1 of their paper.[v] This system uses the 3-month ahead fed funds futures (ff4_tc) as the shock and the 1-year government bond rate as the policy instrument. The other variables included are log of industrial production, log CPI, and the Gilchrist and Zakrajšek (2012) excess bond premium spread. The results show that a shock raises the 1-year rate, significantly lowers industrial production, does little to the CPI for the first year, and raises the excess bond premium. In order to put the results on the same basis as other results, I also estimated the effect of their shock on the funds rate. The results imply that a shock that raises the federal funds rate to a peak of 100 basis points (not shown) lowers industrial production by about −2%.

I explore the robustness of the results by estimating the effects of their shocks in a Jordà local projection framework. The control variables are two lags of the shock itself, the interest rate on 1-year government bonds, industrial production, the CPI, and the Gilchrist–Zakrajsek (2012) excess bond premium spread. I do not include current values of these other variables, so I am not imposing the recursiveness assumption.

Fig. 3B shows the results. The impulse responses look very different from those using the proxy SVAR method. The interest rate rises more slowly, but then remains high for a much longer time. Output does not respond for a year, but then rises. Prices respond little for the first 30 months, but then finally fall.

I then conducted some further investigations of the Gertler-Karadi shock. Several features emerge. First, the shock is not zero mean. The mean is −0.013 and is statistically different from zero. Second, it is serially correlated; if I regress it on its lagged value, the coefficient is 0.31 with a robust standard error of 0.11. This is not a good feature since it is

[v] The only difference is that I used 90% confidence intervals to be consistent with my other graphs.

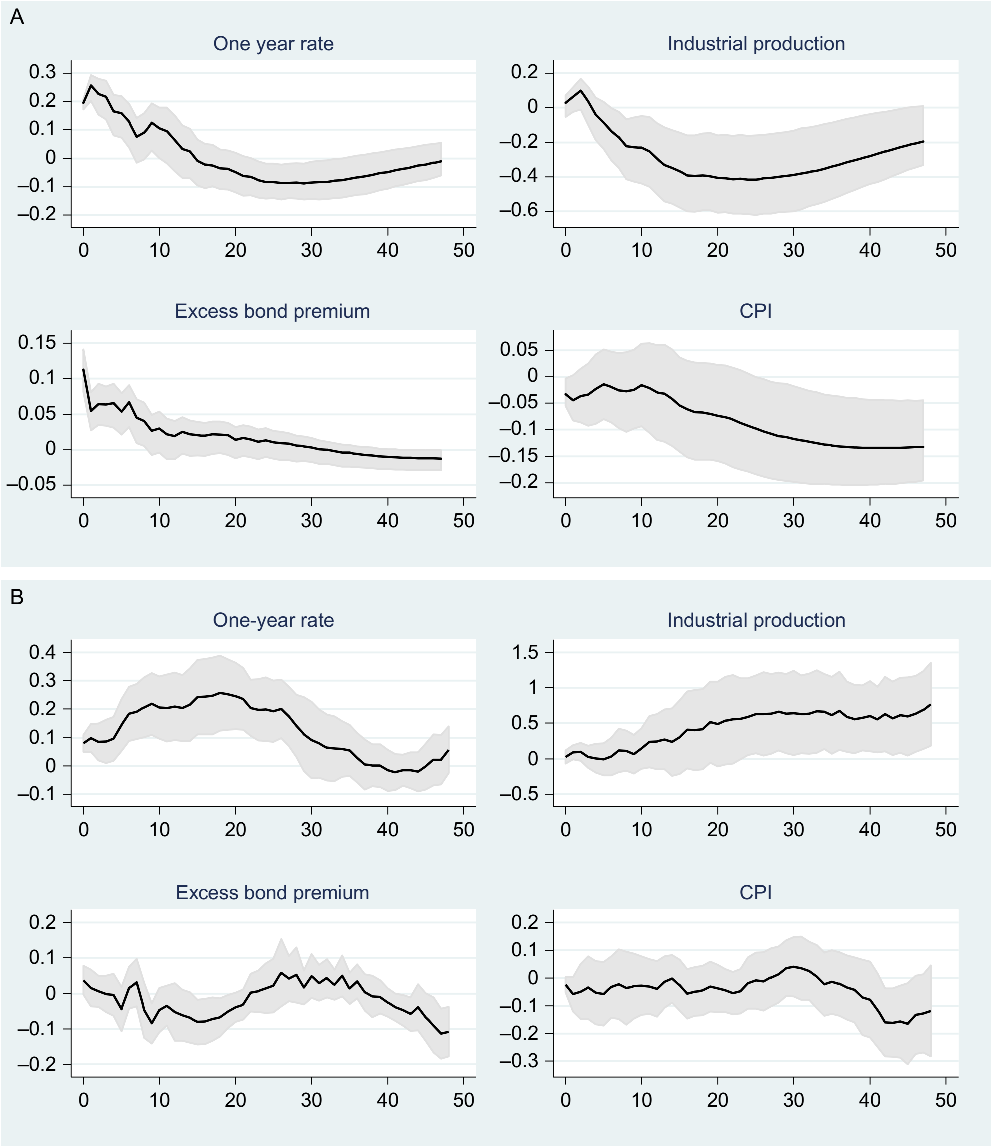

Fig. 3 Gertler–Karadi's monetary shock. (A) Gertler–Karadi's monetary proxy SVAR, VAR from 1979m7 to 2012m6, instrument from 1991m1 to 2012m6. (B) Gertler–Karadi monetary shock, Jordà 1990m1–2012m6. Light gray bands are 90% confidence bands.

supposed to capture only unanticipated movements in interest rates. In my local projection framework implementation, I include lagged values of the shock, so my procedure purges the shock of this serial correlation. I discovered that the serial correlation is induced by the method that Gertler and Karadi use to convert the announcement day shocks to a monthly series.[w] Third, if I used FOMC-frequency data to regress the shock on all of the Greenbook variables that the Romers used to create their shock, the R-squared of the regression is 0.21 and I can reject that the coefficients are jointly zero with a p-value of 0.027.[x] Thus, the Gertler–Karadi variable is predicted by Greenbook projections. Gertler and Karadi also worried about this issue, but they performed a robustness check based only on the *difference* between private forecasts and Greenbook forecasts. They found a much lower R-squared (see their table 4). When they use their purged measure, they find greater falls in industrial production. I explored the effect of using a version of their measure that was (i) orthogonal to the Romer Greenbook variables; and (ii) converted to a monthly basis the same way that the Romer's converted their data, in the Jordà framework. The results (not shown) were still puzzling.

Why does the Jordà method give such different estimates from the proxy SVAR? One possible explanation is the different method and sample used to estimate the impulse response function. Gertler and Karadi's impulse responses functions are constructed as nonlinear functions of the reduced form VAR parameters estimated on data from 1979 through 2012; the Jordà method estimates are for the 1991–2012 sample and are direct projections rather than functions of reduced form VAR parameters. Since the estimates of the impact effects on industrial production are near zero for both methods, the entire difference in the impulse responses is due to the differences in the dynamics implied by Gertler and Karadi's reduced form VAR parameter estimates. A second possible explanation for the difference is that the rising importance of forward guidance starting in the mid-1990s means that the VAR underlying the proxy SVAR is misspecified. As discussed in Section 2.5, anticipations of future policy actions can lead to the problem of a nonfundamental moving average representation. Gertler and Karadi's fed funds futures variable captures news well, but they do not include it directly in the SVAR; they only use it as an instrument.

3.6 Summary of Monetary Shocks

When Christiano et al. (1999) wrote their Handbook chapter, they provided what became a benchmark framework for identifying monetary policy shocks and tracing their effects. As long as the recursiveness assumption was incorporated, the results were quite robust. Since then, the literature has incorporated new methods and faced new challenges. Researchers now take instrument identification and relevance much more seriously when estimating monetary policy shocks. New methods, such as FAVARs and Greenbook forecasts, have improved the conditioning set for estimating monetary policy shocks. Structural VARs (SVARs), sign restrictions, and regime-switching models have provided alternatives to the usual Cholesky decomposition. Moreover, new measures of

[w] See footnote 11 of Gertler and Karadi (2015) for details.

[x] I am indebted to Peter Karadi for sharing with me the announcement date series.

monetary shocks have been developed using rich external data, such as narrative data, Greenbook projections, and high-frequency information from financial markets. Recently published work using shocks estimated with external data results in similar conclusions. In particular, Coibion's (2012) reconciliation of the Romer results with the VAR results suggests that a 100 basis point rise in federal funds rate lowers industrial production by about −2% at 18 months. Those results are based on data from 1969 through 1996. Gertler and Karadi's (2015) research uses HFI from fed funds futures and external instruments/proxy SVAR methods to find very similar results for a later sample.

This rosy reconciliation picture disappears, however, when the specifications are subjected to some robustness tests. My explorations have highlighted several potential issues, some of which were already noted in the literature. First, the original Christiano et al. (1999) specification, as well as many other specifications, does not hold up well in later samples. Second, lifting the recursiveness assumption can lead to estimates that imply expansionary effects of contraction monetary policy in the short run. Third, one needs to be very careful when estimating models in samples where anticipation effects may be important. For example, it is not clear that HFI shocks should be used as external instruments for otherwise standard VARs.

How should we interpret these results? I would argue that the most likely reason for the breakdown of many specifications in the later sample is simply that we can no longer identify monetary policy shocks well. Monetary policy is being conducted more systematically, so true monetary policy shocks are now rare. It is likely that what we now identify as monetary policy shocks are really mostly the effects of superior information on the part of the Fed, foresight by agents, and noise. While this is bad news for econometric identification, it is good news for economic policy.

What, then, are we to conclude about the output effects of monetary shocks? I would argue that the best evidence still remains the historical case studies, such as Friedman and Schwarz, and the times series models estimated on samples that exclude recent decades. Of course, one worries that the structure of the economy may have changed in the last few decades, but we simply do not have enough information to produce estimates with any great certainty. Monetary policy can have big effects, but it is likely that monetary shocks are no longer an important source of macro instability.

4. FISCAL SHOCKS

This section reviews the main identification methods and summarizes existing results from the empirical literature seeking to identify and estimate the effects of fiscal policy shocks. It also presents some new results comparing several leading identified shocks.

In contrast to a monetary policy shock, a fiscal shock is a more straightforward economic concept. Because the legislative and executive branches of government often make tax and spending decisions based on concerns that are orthogonal to the current state of the macroeconomy, the notion of regularly occurring fiscal policy shocks is more plausible than regularly occurring monetary policy shocks.

Measuring the empirical effects of changes in government spending and taxes on aggregate GDP and its components was an active research area for a number of decades. The large Keynesian models of the 1960s included fiscal variables and numerous academic papers estimated their effects in behavioral equations. For several decades afterward, though, research on the aggregate effects of tax and spending shocks experienced a lull, punctuated by only a few papers. Most empirical research on shocks during the 1980s, 1990s, and 2000s instead focused on monetary policy. With the onset of the Great Recession and the zero lower bound, however, research energy immediately shifted to the effects of fiscal policy. The recent literature has built on and extended the strides made by the few authors working on the topic during the long dormant period.

The following sections will discuss some of the literature since 1990 that has sought to analyze the effects of fiscal shocks. I will begin by considering government spending shocks and then discuss tax shocks.

4.1 Government Spending Shocks

In this section, I discuss shocks to government spending. When I use the term *government spending*, I mean government *purchases*, ie, G in the NIPA identity. In common parlance, however, government spending typically refers to government *outlays*, which include both government purchases and transfer payments. Economists usually consider transfer payments to be negative taxes. Thus, I will include a discussion of transfer payments in the section on the effects of tax shocks.

4.1.1 Summary of Identification Methods

Many of the identification methods summarized in Section 2 are used in the literature that analyzes the effects of shocks to government spending. These methods include SVARs with contemporaneous restrictions, sign restrictions, medium-horizon restrictions, narrative methods, and estimated DSGE models.

Perhaps the first example of what looks like a VAR-type analysis of the effects of fiscal shocks is Rotemberg and Woodford's (1992) analysis of the effects of military spending and employment on macroeconomic variables. Their purpose was to provide evidence in favor of their countercyclical markup model, showing that a "demand" shock would lead to countercyclical markups. To do this, they estimated systems with military spending, military employment, and a macroeconomic variable of interest (such as private value added and private hours worked). They included lags of the variables in the system, but restricted the VAR so that there was no feedback of the macroeconomic variables onto the military variables. In their system, identification was achieved as follows. To identify government purchases shocks that were exogenous to the economy, they followed Hall (1980, 1986) and Barro (1981) who argued that defense spending is driven by military events rather than by macroeconomic events. To identify *unanticipated* shocks, they regressed the military variables on their own lags and used the residuals. This identification strategy assumes that all relevant information for predicting military spending and employment is contained in lags of military spending and employment. They showed that their identified shocks to defense spending raised real wages.

In a paper analyzing the effects of sectoral shifts in the presence of costly mobility of capital across sectors, Ramey and Shapiro (1998) used narrative techniques to create a dummy variable capturing major military buildups. They read through *Business Week* in order to isolate the political events that led to the buildups in order to create a series that was exogenous to the current state of the economy. They also used this narrative approach to ensure that the shock was unanticipated. They stated: "We believe this approach gives a clearer indicator of unanticipated shifts in defense spending than the usual VAR approach, since many of the disturbances in the VAR approach are due solely to timing effects on military contracts and do not represent unanticipated changes in military spending" (Ramey and Shapiro, 1998, p. 175). Ramey and Shapiro (1998) estimated the effects of "war dates" by regressing each variable of interest on current values and lags of the war dates and lags of the left-hand side variable. A number of follow-up papers embedded the war dates in VARs, ordered first in the Cholesky decomposition, creating "EVARs", a term coined by Perotti (2011). These papers include Edelberg et al. (1999) and Burnside et al. (2004). Most applications typically found that while government spending raised GDP and hours, it lowered investment, consumption, and real wages. Most of these papers did not specifically estimate a multiplier, though one can typically back out the implied multiplier from the impulse responses.

In contrast, Blanchard and Perotti (2002) used an SVAR to identify both government purchases and tax shocks. They assumed that government purchases were predetermined within the quarter, and identified the shock to government purchases using a standard Cholesky decomposition with government spending ordered first. They found that government purchases shocks raised not only GDP but also hours, consumption, and real wages. Follow-up work, such as by Fatás and Mihov (2001), Perotti (2005), Pappa (2009) and Galí et al. (2007), found similar results. Mountford and Uhlig (2009) used sign restrictions and found only weak effects on GDP and no significant effect on consumption.

In Ramey (2011a), I sought to reconcile why the war dates were producing different results from the SVARs that used Cholesky decompositions. I argued that most government spending is anticipated at least several quarters in advance, so that the standard SVAR method was not identifying unanticipated shocks. In support of this idea, I showed that the shocks from an SVAR were indeed Granger-caused by the Ramey and Shapiro (1998) war dates. To create a richer narrative variable to capture the "news" part of government spending shocks, I read *Business Week* starting in 1939 and created a quantitative series of estimates of changes in the expected present value of government purchases, caused by military events. I then embedded the news series in a standard VAR, with the news ordered first in the Cholesky decomposition. In that work, I found results that were broadly consistent with the estimates based on the simple war dates.

In follow-up work, Owyang et al. (2013) and Ramey and Zubairy (2014) extended the military news series back to 1889. The military news variable tends to have low instrument relevance for samples that begin after the Korean War, though. In Ramey (2011a), I augmented my analysis by also considering shocks that were orthogonal to professional forecasts of future government purchases. Fisher and Peters (2010) created an alternative series of news based on the excess returns of defense contractor stocks for the period starting in 1958. Recent work by Ben Zeev and Pappa (forthcoming) uses the medium-horizon identification methods of Barsky and Sims (2011) to identify news shocks to defense spending from a time series model. In particular, Ben Zeev and Pappa identify defense spending news as a shock that (i) is orthogonal to current defense spending; and (ii) best explains future movements in defense spending over a horizon of 5 years.

All of these measures of anticipations have weaknesses, though. First, because they are associated with military events, there are likely confounding effects (eg, rationing, price controls, conscription, patriotic increases in labor supply). Second, as I show below, some of the shocks suffer from low first-stage *F*-statistics in some samples, indicating that they might not be relevant instruments for estimating multipliers.

Thus, there are two main differences in the shocks identified across these two classes of models. First, the SVAR shocks are more likely to be plagued by foresight problems. As I discussed in Section 2, this problem of foresight can be a serious flaw in SVARs. Second, the news alternatives are not rich enough in some subsamples and there may be confounding influences.

A more structural way to identify shocks to government purchases is through an estimated DSGE model. For example, one of the shocks identified by Smets and Wouters (2007) is a government purchases shock. Cogan et al. (2010) also estimate government spending multipliers in the context of an estimated DSGE model.

4.1.2 Summary of the Main Results from the Literature

Typically, the literature on government spending has sought to answer one or both of two main questions: (1) Are the empirical results consistent with theoretical DSGE models? (2) What are the government spending multipliers?

Let us begin by considering results that shed light on the first question. Most versions of standard neoclassical theory and standard new Keynesian theory predict that a rise in government purchases (financed with deficits or lump-sum taxes and not spent on public infrastructure, etc.) should raise GDP and hours, but should decrease consumption and real wages. Whether investment initially rises or falls depends on the persistence of the increase in government spending. It is only when one adds extra elements, such as rule-of-thumb consumers and off-the-labor supply behavior of workers that one can produce rises in consumption and real wages in a model (eg, Galí et al., 2007).

Both SVARs and EVARs that use a news variable produce qualitative similar results for some variables. For example, both typically estimate an increase in GDP and hours and a fall in investment (at least after the first year) in response to a positive government spending shock. In contrast, the SVAR typically implies a rise in consumption and real wages, whereas the EVAR predicts a fall in consumption and real wages.

The second question the literature seeks to answer is the size of "the" government purchases multiplier. Unfortunately, most estimates are not for pure deficit-financed multipliers since most rises in government spending are accompanied by a rise in distortionary taxes, typically with a lag. This caveat should be kept in mind in the subsequent discussion of multiplier estimates.

One might assume that SVARs produce bigger multipliers since they predict increases in consumption. They do not. In Ramey (2013), I compared the effects of government spending on private spending, ie, GDP minus government spending, of several shocks based on the various identification methods. If the government spending multiplier is greater than unity, then private spending must increase. I found that all of the shocks lowered private spending, but that the Blanchard–Perotti (2002) shocks lowered it more, implying a smaller multiplier.

The estimated DSGE models of Smets and Wouters (2007) and Cogan et al. (2010) produce results that are close to the neoclassical model. In both cases, a shock to government spending lowers consumption and results in multipliers below unity.

In my survey of the literature on multipliers in Ramey (2011b), I found that most estimates of the government spending multiplier in aggregate data were between 0.8 and 1.2. The only multipliers that were larger were (1) those estimated on states or regions; and (2) some of those estimated allowing state dependence. As suggested in my survey, and as shown formally by Nakamura and Steinsson (2014) and Farhi and Werning (2012), the link between estimates of multipliers in a fiscal union (eg, across US states or regions) for aggregate multipliers is not entirely clear. Most of the cross-state or cross-region studies look at the effect of federal spending on a locality. Unfortunately, because constant terms or time fixed effects are included, these regressions difference out the effects of the financing, since taxes that finance federal spending are levied at the national level.[y] This explains why multipliers on federal spending at the state level will be higher than the aggregate multipliers. I will discuss the issue of state dependence in more detail momentarily.

[y] A notable exception is the paper by Clemens and Miran (2012), which identifies exogenous variation in state-level spending. Interestingly, they find multipliers around 0.5, which is closer to those found at the national level.

Since writing that survey, I realized that there were two potential biases in the way that many researchers calculated their multiplier, and as a result, many reported estimates are not comparable. First, many researchers followed Blanchard and Perotti's (2002) lead and calculated multipliers by comparing the *peak* output response to the *initial* government spending impact effect. While comparing values of impulse responses at peaks or troughs is a useful way to compare impulse responses, it is not a good way to calculate a multiplier. As argued by Mountford and Uhlig (2009), Uhlig (2010), and Fisher and Peters (2010), multipliers should instead be calculated as the *integral* (or present value) of the output response divided by the *integral* government spending response. The integral multipliers address the relevant policy question because they measure the cumulative GDP gain relative to the cumulative government spending during a given period. In many cases, Blanchard and Perotti's ratio of peak-to-impact method gives a higher number for the multiplier than the integral method. Second, most researchers estimating VARs use logarithms of variables. To convert the estimates to multipliers, they usually multiply the estimates by the sample mean of GDP to government spending ratio. As Owyang et al. (2013) point out, this can lead to serious biases in samples with significant trends in the GDP to government spending ratio. In the few cases where I have been able to adjust the estimates of multipliers to be integral multipliers, I have found that the multipliers are often below one.

With this additional caveat in mind, Table 3 shows a summary of a few of the estimates of multipliers for government purchases. Even with the variety of ways of calculating multipliers from the estimated impulse response functions, most of the estimates are from 0.6 to 1.5.

A number of researchers and policy makers have suggested that multipliers may be state dependent. Auerbach and Gorodnichenko (2012) use a smooth transition vector autoregression model and find evidence of larger multipliers in recessions. Ramey and Zubairy (2014) use the Jordà (2005) method (also used by Auerbach and Gorodnichenko, 2013 in a panel of countries) and find little evidence of state dependence, based on recessions, elevated unemployment rates, or the zero lower bound. They argue that their different finding is not so much due to the underlying parameter estimates but rather due to the additional assumptions that Auerbach and Gorodnichenko (2012) made when transforming those estimates into multipliers.

Most of the studies I have summarized focus on government purchases that do not involve infrastructure spending. The reason for the paucity of research on infrastructure spending is the difficulty of identifying shocks to infrastructure spending, particularly in the United States. The US highway system was an important part of government purchases starting in the late 1950s through the early 1970s. The problem with identifying the aggregate effects is that most of the spending was anticipated once the highway bill was passed in 1956. Most of the credible analyses have used clever indirect methods or used variation in cross-state expenditures. Fernald (1999) provides very strong evidence for a causal effect of the highway system on productivity by showing its greater effect on

Table 3 Summary of government spending multiplier estimates for the aggregate United States

Study	Sample	Identification	Implied spending multiplier
Barro (1981), Hall (1986), Hall (2009), Barro–Redlick (2011)	Annual historical samples	Use military spending as instrument for government spending	0.6–1
Rotemberg–Woodford (1992)	Quarterly, 1947–1989	Residuals from regression of military spending on own lags and lags of military employment	1.25
Ramey–Shapiro (1998), Edelberg et al. (1999), Burnside et al. (2004)	Quarterly, 1947 to the late 1990s or 2000s	Ramey–Shapiro dates, which are based on narrative evidence of anticipated military buildups	0.6–1.2, depending on sample and whether calculated as cumulative or peak
Blanchard–Perotti (2002)	Quarterly, 1960–1997	SVARS, Cholesky decomposition with *G* ordered first	0.9–1.29, calculated as peak multipliers
Mountford–Uhlig (2009)	Quarterly, 1955–2000	Sign restrictions on an SVAR	0.65 for a deficit-financed increase in spending
Bernstein and Romer (2009)	Quarterly	Average multipliers from FRB/US model and a private forecasting firm model	Rising to 1.57 by the 8th quarter
Cogan et al. (2010)	Quarterly, 1966–2004	Estimated Smets–Wouters model	0.64 at peak
Ramey (2011a,b)	Quarterly, 1939–2008 and subsamples	VAR using shocks to the expected present discounted value of government spending caused by military events, based on narrative evidence	0.6 −1.2, depending on sample
Fisher–Peters (2010)	Quarterly, 1960–2007	VAR using shocks to the excess stock returns of military contractors	1.5 based on cumulative effects
Auerbach and Gorodnichenko (2012)	Quarterly, 1947–2008	SVAR that controls for professional forecasts, Ramey news Key innovation is regime-switching model	Expansion: −0.3 to 0.8 Recession: 1–3.6 (uses a variety of ways to calculate multipliers)
Ben Zeev and Pappa (forthcoming)	Quarterly, 1947–2007	Shock that (i) is orthogonal to current defense spending; and (ii) best explains future movements in defense spending over a horizon of 5 years	2.1 based on integral multiplier at 6 quarters

vehicle-intensive industries. These estimates do not directly inform us about aggregate effects, though. Leduc and Wilson (2013) identify news shocks about highway spending in a panel of US states using the arrival of new information about institutional formula factors. However, as discussed earlier, the multipliers they find cannot be converted to aggregate multipliers.

Gechert (2015) conducts a meta-analysis of 104 studies of multiplier effects across a variety of countries, including many different types of analyses from reduced form empirical to estimated DSGE models. With the caveat that the context and experiment varies across studies, Gechert finds that public spending multipliers are close to one, while public investment multipliers are around 1.5.

4.1.3 Explorations with Several Identified Shocks

I now study the effects of several of the leading identified government spending shocks in the Jordà local projection framework. This exploration is useful not only for gauging the robustness of the results to local projection methods but also for comparing the effects of the identified shocks using the same data, same specification, and the same way to calculate multipliers. Thus, any differences in results will be due to the identification methods rather than differences in data or implementation.

The three main shocks I study are (i) the shock identified using Blanchard and Perotti's (2002) method (which simply orders government spending first in a Cholesky decomposition); (ii) my narrative military news shock, updated in Ramey and Zubairy (2014); and (iii) Ben Zeev and Pappa's (forthcoming) defense news shock identified using Barsky and Sims' (2012) medium-run horizon method.[z] I also comment briefly on results using Fisher and Peters' (2010) military contractor excess returns.

In all cases, I use the following data transformations and functional forms. The first set of transformations is intended to facilitate the direct estimation of multipliers in order to avoid ad hoc transformation of estimates based on logs, as discussed by Owyang et al. (2013). One can use either the Hall (2009) and Barro–Redlick (2011) transformation or a Gordon–Krenn (2010) transformation. The Hall–Barro–Redlick transformation constructs variables as $(X_{t+h}-X_{t-1})/Y_{t-1}$, where X is the NIPA variable deflated by the GDP deflator and Y_{t-1} is real GDP before the shock hits in period t. The Gordon–Krenn transformation divides all NIPA variables by "potential GDP," estimated as an exponential trend. Both methods give similar results. I follow the Gordon–Krenn procedure, fitting log real GDP to a quadratic trend.[aa] Thus, the NIPA variables are

[z] I estimated the Blanchard–Perotti shock using logarithms of real government spending, GDP, and taxes and four lags. One could instead estimate it directly in the regression using the Gordon-Krenn transformed variables. Ben Zeev and Pappa kindly provided me with estimates of their shock.

[aa] One could use the CBO estimate of real potential GDP instead. I found, however, that when I used the CBO estimate, the implied multipliers were noticeably smaller than when I used Hall–Barro–Redlick or Gordon–Krenn with either a quadratic or a quartic log trend.

transformed to be $z_t = X_t / Y_t^*$, where Y_t^* is the estimated trend in real GDP. The impulse responses using this transformation look qualitatively similar to those using log levels, but often have more narrow confidence bands.

The non-NIPA variables are transformed as follows. The average tax rate is federal current receipts divided by nominal GDP. The hours variable is the log of total hours per capita, where the total population is used in the denominator. Wages are given by the log of nominal compensation in the business sector, deflated by the price deflator for private business. The real interest rate is the 3-month Treasury bill rate minus the rate of inflation calculated using the GDP deflator.

The equation used to estimate the impulse responses for each variable z at each horizon h is given by

$$z_{t+h} = \alpha_h + \theta_h \cdot \text{shock}_t + \varphi_h(L) y_{t-1} + \text{quadratic trend} + \varepsilon_{t+h} \tag{18}$$

where z is the variable of interest, *shock* is the identified shock, y is a vector of control variables, and $\varphi_h(L)$ is a polynomial in the lag operator. All regressions include two lags of the shock (to mop up any serial correlation), transformed real GDP, transformed real government purchases, and the tax rate. Regressions for variables other than real GDP, government purchases, and tax rates also include two lags of the left-hand side variable. The coefficient θ_h gives the response of z at time $t+h$ to the shock at time t.

As discussed earlier, the correct way to calculate a multiplier is as the integral under the impulse response of GDP divided by the integral of the impulse response of government spending. We could compute the multiplier using the following multistep method: (1) estimate Eq. (18) for GDP for each horizon and sum the coefficients θ_h up to some horizon H; (2) estimate Eq. (18) for government purchases for each horizon and sum the coefficients θ_h up to some horizon H; and (3) construct the multiplier as the answer from step (1) divided by the answer from step (2). Estimating the standard error, however, requires some ingenuity, such as estimating all of the regressions jointly in a panel estimation.

Alternatively, we can easily estimate the multiplier estimate and its standard error in one step if we cumulate the variables and reformulate the estimation problem as an instrumental variables (IV) estimation. In particular, we can estimate the following equation:

$$\sum_{i=0}^{h} z_{t+i} = \beta_h + m_h \cdot \sum_{i=0}^{h} g_{t+i} + \chi_h(L) y_{t-1} + \text{quadratic trend} + \nu_{t+h} \tag{19}$$

where the dependent variable is the *sum* of real GDP (or other NIPA variable) from t to $t+h$ and the government spending variable is the *sum* of the government purchases variable. We use the identified shock as the *instrument* for the sum of government purchases. The estimated coefficient, m_h, is the multiplier for horizon h. There are several advantages to this one-step IV method. First, the standard error of the multiplier is just the standard

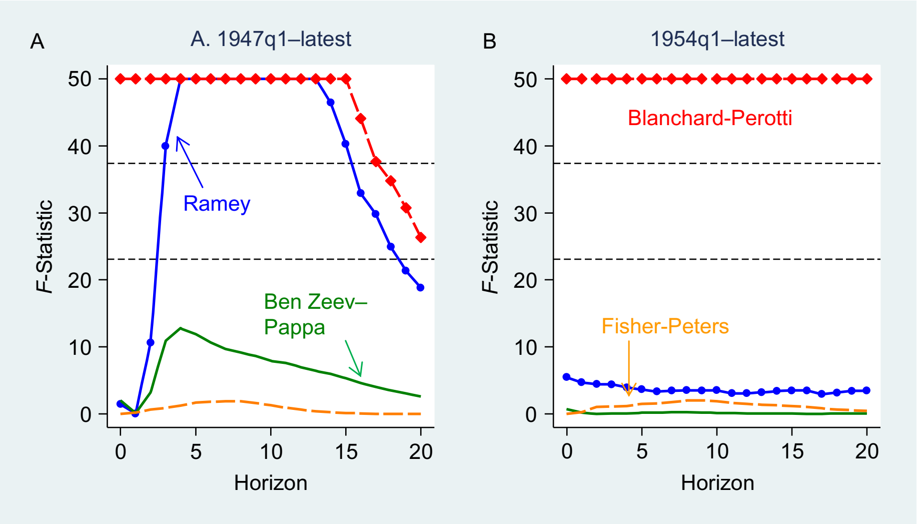

Fig. 4 First-stage *F*-statistics for government spending shocks. Note: The *F*-statistics are based on the regression of the sum of government spending from *t* to *t*+*h* on the shock at *t*, plus the lagged control variables. Values above 50 have been capped at 50. The *horizontal dashed lines* are the Montiel Olea and Pflueger (2013) 5% worst case bias (*upper line*) and 10% worst case bias (*lower line*) thresholds.

error of the coefficient m_h.[bb] Second, the shock can have measurement error as long as the measurement error is not correlated with any measurement error in government spending. Third, formulating the estimation as an IV problem highlights the importance of instrument relevance.

Thus, I first consider how relevant each of the identified shocks is as an instrument for the integral of government spending. Stock et al. (2002) argue that the first-stage *F*-statistic should be above 10 for the IV estimates to be reliable, but their threshold applies only to first-stage regressions with serially uncorrelated error terms. Fortunately, follow-up work by Montiel Olea and Pflueger (2013) constructs thresholds for cases with serial correlation. For the first stage of Eq. (19), the thresholds are 23 for the 10% level and 37 for the 5% level.[cc] *F*-Statistics below those thresholds indicate a possible problem with instrument relevance.

Fig. 4 shows the first-stage *F*-statistics for the sum of government purchases on each identified shock for each horizon up to 20 quarters. Values above 50 have been capped at 50 for ease of viewing. The graph at the left shows the results for the sample starting in 1947 and the graph on the right shows the results for the sample starting in 1954, after the

[bb] Because of the serial correlation in the errors, any procedures for estimating standard errors should use methods that account for serial correlation.

[cc] These F-statistics and thresholds were derived using Pflueger and Wang's (2015) "weakivtest" Stata module.

Korean War. Several results emerge. First, the Blanchard–Perotti (BP) identified shock always has very high *F*-statistics. This is not surprising because the shock is equal to the portion of government spending not predicted by four lags of government spending, GDP, and taxes. Second, the Fisher–Peters defense contractor excess returns shock has very low *F*-statistics for all horizons and both samples, indicating that the return variable is not a good instrument for government spending. Third, the Ramey and Ben Zeev–Pappa (BZP) news shocks have low relevance for short horizons, but this is to be expected since those shocks capture news about *future* government spending. Fourth, in the full sample at horizons beyond three quarters, the Ramey news shock has *F*-statistics above the Montiel–Pflueger thresholds, whereas the BZP news shock *F*-statistics lie below them and range between 8 and 13. Fifth, in the sample that excludes the Korean War, all of the *F*-statistics are very low except for the Blanchard–Perotti shock. Thus, the BP shock surpasses the relevance safety threshold for all horizons in both samples, the Ramey news shock does so for the full sample for horizons at four to 20 quarters, while the BZP shock may have relevance problems at most horizons and the Fisher–Peters shock always has very low relevance. I thus exclude the Fisher–Peters shock from the rest of the analysis.

Fig. 5 shows the impulse responses estimated using Eq. (18), with estimates normalized across specifications to have the same peak in government purchases. The scales in the graphs of the NIPA variables should be interpreted as dollars; ie, a rise in government purchases that peaks at $1 leads to rise in GDP that peaks at 75 cents. The scales of the other graphs are in percentage points. The confidence bands are 90% bands based on Newey–West corrections of standard errors. They do not, however, take into account that two of the shocks are generated regressors.

Consider first the upper left graph in Fig. 5. Both the Ramey and BZP news variables imply similar paths of government purchases, with little effect for the first few quarters rising to a peak around five quarters after the shock. In contrast, the BP shock leads to an immediate rise in government spending. The graph in the top right shows that in response to all three shocks, GDP jumps immediately. The response of GDP is greatest for the BZP shock, but GDP begins to fall back to normal even before government purchases have hit their peak.

The tax rate series is simply federal receipts divided by GDP. This variable can rise either because of tax legislation or because higher GDP pushes more households into higher tax brackets. According to the estimates, tax rates begin to rise immediately for the BZP shock but only gradually for the Ramey news shock. Tax rates gradually fall after BP shock. Real interest rates (measured as the 3-month T-bill rate minus inflation) fall after a news shock, but rise slightly after a BP shock. Examination of the responses of the components of the real interest rate (not shown) reveals that the fall is due to both a drop in the nominal interest rate and a rise in inflation. As explained by Ramey (2011a), the rise in inflation is in large part driven by the spike up in prices at the beginning of the

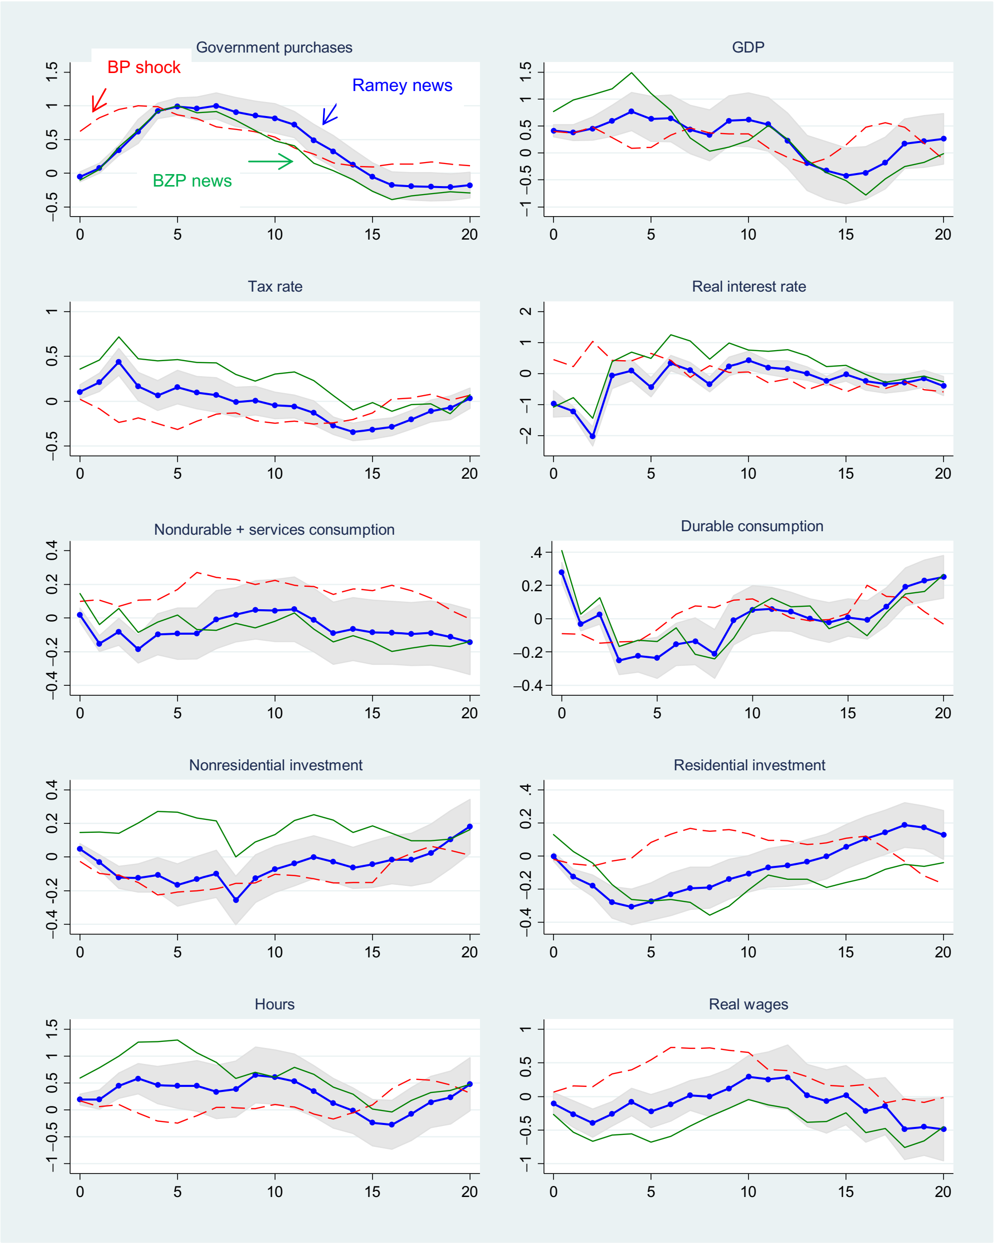

Fig. 5 Comparison of the effects of government spending shocks (*BP*: Blanchard–Perotti; *BZP*: Ben Zeev–Pappa). Light gray bands are 90% confidence bands.

Table 4 Multiplier estimates (HAC standard errors in parenthesis)

Horizon (in quarters)	Blanchard–Perotti	Ramey news	Ben Zeev–Pappa news
0	0.65 (0.24)	−7.53 (7.26)	−7.37 (5.85)
4	0.37 (0.23)	1.37 (0.33)	2.91 (1.13)
8	0.39 (0.32)	0.80 (0.25)	1.41 (0.61)
12	0.39 (0.44)	0.77 (0.27)	1.24 (0.71)
16	0.40 (0.58)	0.60 (0.36)	1.10 (1.01)
20	0.44 (0.63)	0.69 (0.48)	1.17 (1.46)

Notes: Multipliers estimated using Eq. (19). All regressions also include two lags of the shock (to mop up any serial correlation), real GDP (divided by potential GDP), real government purchases (divided by potential GDP), the tax rate, and a quadratic trend.

Korean War: with recent memories of WWII, firms thought that price controls were coming and raised their prices in advance.

Consider now four components of the national income accounts, shown in the middle graphs in Fig. 5. Nondurable plus services consumption falls after a Ramey news shock, responds little after a BZP shock, but rises after a BP shock. In Ramey (2009), I show using simulations of a DSGE model that one can estimate a rise in consumption if one treats an anticipated shock as an unanticipated shock. I argue that the rise in consumption after a BP shock can be explained by this type of identification problem.

Durable consumption spikes up initially and then falls after the two news shocks. As in the cast of prices, this initial spike on the arrival of news is driven mostly by the response of consumers to the beginning of the Korean War in 1950: with recent memories of WWII, consumers worried that rationing of durable goods was imminent so they hurried out to buy durable goods. Nonresidential investment rises in response to the BZP shock, but falls in response to both the Ramey news and BP shock. Residential investment falls in response to the two news shocks, but rises after a year in response to the BP shock.

Finally, both news shocks imply a rise in hours and a fall in the real wage, while the BP shock predicts very little response of hours, but a rise in the real wage.

Table 4 shows the estimated multipliers for various horizons.[dd] The impact multipliers for the two news shocks are negative because output jumps up, while government spending falls slightly. For the next few quarters, the multipliers for the two news shocks are large because output responds immediately to news of future government spending which has not yet fully transpired. Once government spending has risen to its peak, the implied multipliers using the Ramey news shock are just below unity, whereas those using the BZP news shock are above unity. For example, the BZP news shock multiplier is 1.4 at 8 quarters and 1.1 at 16 quarters. The responses in Fig. 5 reveal that the reason for the larger multiplier after a BZP shock is the large rise in nonresidential investment.

[dd] These estimates are based on the one-step method shown in Eq. (19).

It should be noted, though, that the BZP multipliers are estimated rather imprecisely as evidenced by the standard errors. This is one manifestation of the possible low instrument relevance of the BZP news shock. On the other hand, the multipliers implied by the Blanchard and Perotti shock are all low, most below 0.5. However, the estimates are not precise enough to reject a multiplier of either 0 or 1 at standard significance levels.

I now consider what each shock implies about the contribution to the forecast error variance of output. Although one can calculate forecast error variances using the estimated local projection coefficients, I found that the shares sometimes exceeded 100%. Thus, for present purposes I calculate the forecast error variance in a standard VAR with the shock, log government spending, log real GDP, and log taxes. The shock is ordered first and four lags are included, along with a quadratic trend.

Table 5 shows the forecast error variance decompositions of each of the three identified government spending shocks for government spending and output. Despite having the lowest contribution for government spending, the BZP shock has the highest contribution for output, but it is still 13% or below. The BP and Ramey news contributions tend to be 5% of below. Thus, none of the three shocks is an important contributor to the variance of output.

To summarize, most of the aggregate analyses find government spending multipliers between 0.6 and 1.5. The BP shock leads to smaller multipliers, but does imply that government spending leads to rises in consumption and real wages along with GDP and hours. In contrast, both the Ramey news and BZP news shocks lead to falls in real wages. Both news shock lead to an initial spike in durable consumption (due to the consumer fears of rationing), followed by a decline. The BZP shock produces a temporary blip in nondurable consumption, but then it falls to 0. The Ramey news shock implies a decline nondurable consumption. None of the methods suggests that government spending shocks explain an important part of GDP fluctuations.

Table 5 Shock contribution to the forecast error variance of government spending and output

	Blanchard–Perotti		Ramey news		Ben Zeev–Pappa news	
Horizon (in quarters)	Government spending	Output	Government spending	Output	Government spending	Output
0	100.0	5.5	1.0	2.2	1.4	5.6
4	96.2	3.3	31.8	2.6	14.0	10.1
8	90.5	2.9	50.2	2.9	27.0	12.6
12	86.5	2.5	50.5	2.5	29.8	12.1
16	83.1	2.4	46.7	2.4	29.4	11.8
20	80.2	2.3	43.0	2.2	28.7	11.7

Notes: Based on standard VAR with the shock, log output, log government spending, log taxes, and a quadratic trend. The shock is ordered first and four lags of the variables are included.

4.2 Tax Shocks

I now turn to the literature on tax shocks. Taxes were often an important component of the big Keynesian econometric models of the 1960s. The public finance literature has analyzed many details of the effects of taxes. In this section, I will focus on estimates of the effects of taxes in the macroeconomic literature since the 1990s.

4.2.1 Unanticipated Tax Shocks

4.2.1.1 Summary of the Literature

Macroeconomists have used both estimated DSGE models and time series models to estimate the effects of taxes. One of the first systematic analyses of macroeconomic tax effects in an estimated DSGE model was by McGrattan (1994). She extended the Kydland and Prescott (1982) model to include government consumption, labor income taxes, and capital income taxes and estimated the parameters using maximum likelihood. She found that the role of technology in business cycle fluctuations was much reduced, 41% rather than Kydland and Prescott's 75% estimate. She found that shocks to government consumption accounted for 28% of the forecast error variance of output, labor income tax shocks for 27%, and capital income tax shocks for 4%.

Among time series approaches, Blanchard and Perotti (2002) used an SVAR approach in which they identified tax shocks by imposing the elasticity of net taxes to GDP estimated from other studies. Returning to the discussion of the simple trivariate model from Section 2, consider the following system:

$$\begin{aligned}\eta_{1t} &= b_{12}\eta_{2t} + b_{13}\eta_{3t} + \varepsilon_{1t}\\ \eta_{2t} &= b_{21}\eta_{1t} + b_{23}\eta_{3t} + \varepsilon_{2t}\\ \eta_{3t} &= b_{31}\eta_{1t} + b_{32}\eta_{2t} + \varepsilon_{3t}\end{aligned} \tag{20}$$

where η_{1t} is the reduced form residual of net taxes, η_{2t} is the reduced form residual of government spending, and η_{3t} is the reduced form residual of GDP. Blanchard and Perotti (2002) identify the shock to government spending using a Cholesky decomposition in which government spending is ordered first (ie, $b_{21} = b_{23} = 0$). They identify exogenous shocks to net taxes by setting $b_{13} = 2.08$, an outside estimate of the cyclical sensitivity of net taxes. These three restrictions are sufficient to identify all of the remaining parameters and hence all three shocks. Blanchard and Perotti's estimated "impact multiplier" was -0.78. Their impact multiplier was calculated as the *trough* of GDP relative to the *initial* shock to taxes.

Mountford and Uhlig (2009) use sign restrictions to identify tax and spending shocks. Their results imply a multiplier of -5 at 12 quarters for a deficit-financed tax cut, when the multiplier is calculated as the ratio of the present value of the impulse response functions. In order to compare their results to Blanchard and Perotti, they also calculate "impact multipliers," meaning the value of the GDP response at a certain quarter to the initial shock impact on the fiscal variable. They find that whereas the Blanchard and Perotti method implies a peak-to-impact multiplier of −1.3 at quarter 7, Mountford and Uhlig's results imply a peak-to-impact multiplier of −3.6.

In the context of the Blanchard and Perotti (2002) model, Caldara and Kamps (2012) demonstrate how the estimated multiplier depends crucially on their assumption about the elasticity of net tax revenue to GDP. Particularly important is their demonstration of how a small change in the assumed cyclical elasticity parameter can result in large changes in the estimated tax multiplier; to wit, this seems to be a case of a "multiplier multiplier" on the assumed elasticity. Caldara and Kamps (2012) propose a new method, which involves imposing probability restrictions on the output elasticities of taxes and spending. When they implement this method, they find peak-to-impact multipliers of −0.65 for tax shocks and peak-to-impact multipliers greater than unity for government spending shocks.

Barro and Redlick (2011) construct a new series of average marginal tax rates using IRS data and analyze its effects in a system that also considers government spending in annual data extending back to 1917. In their baseline specification, they find that an increase in the average marginal tax rate of 1 percentage point lowers GDP by 0.5%. Their calculations indicate a tax multiplier of −1.1.

Romer and Romer (2010) (R&R) use narrative methods to identify tax shocks. Based on presidential speeches and congressional reports, they construct several series of legislated tax changes and distinguish those series based on the motivation for enacting them. They argue that tax changes motivated by a desire to pay down the deficit or long-run growth considerations can be used to establish the causal effect of tax changes on output. When they estimate their standard dynamic single equation regression of output growth on its lags and on current and lagged values of the "exogenous" tax changes, they obtain estimates implying tax multipliers of −2.5 to −3 at 3 years. Leigh et al. (2010) use a similar narrative method to study fiscal consolidations across countries.[ee] Cloyne (2013) uses this method to identify exogenous tax shocks in the United Kingdom.

Favero and Giavazzi (2012) embed the R&R series in a somewhat restricted VAR and find smaller multipliers. In a series of papers, Mertens and Ravn (2011b, 2012, 2013, 2014) exploit the R&R narrative tax information in a way that significantly expands our understanding of the effects of tax shocks on the economy. I will focus on several of their contributions in this section and discuss the others in the next section. First, Mertens and Ravn (2011b, 2012) split the Romer and Romer series into anticipated vs unanticipated shocks based on the delay between the passing of the legislation and the implementation of the legislation. R&R had timed all of their shocks to coincide with the implementation rather the legislation. I will discuss the findings using unanticipated shocks here and discuss the findings using anticipated shocks below. Second, in their 2013

[ee] The Leigh et al. attempts to address measurement concerns in the very large literature on the effects of fiscal consolidations across countries, perhaps best exemplified by Giavazzi and Pagano (1990, 1996), Alesina and Perotti (1995, 1997), and Alesina and Ardagna (1998, 2010).

paper, Mertens and Ravn (2013) decomposed the unanticipated parts of the R&R series into personal income tax changes and corporate income tax changes and showed the differences in the two types of cuts on the economy. In their 2014 paper, Mertens and Ravn (2014) reconciled the Blanchard and Perotti SVAR estimates with the narrative estimates by introducing the proxy SVAR method discussed in detail in previous sections.

As discussed in Section 2.3.5, Mertens and Ravn's (2014) proxy SVAR provides a new method for identifying shocks using external instruments. In particular, they regress the reduced form residual of GDP, η_{3t}, from Eq. (20) on the reduced form residual of taxes, η_{1t}, using the R&R shock as an instrument. This leads to an unbiased estimate of b_{31} (since it is assumed that η_{2t} is the structural shock to government spending, which is uncorrelated with the other structural shocks). We can then use the estimated residual from that regression as one of the instruments in the regression of η_{1t} on η_{2t} and η_{3t}. This regression identifies b_{12} and b_{13}. When they implement their method, they estimate $b_{13} = 3.13$ with a 95% confidence band of (2.73, 3.55). Thus, their results suggest that Blanchard and Perotti's preset estimate of $b_{13} = 2.08$ is too low. Setting the output elasticity of tax revenue too low results in estimated tax shocks that include a reverse causality component (ie, there is a positive correlation between the cyclical components of taxes and output because of the positive causal effect of output on tax revenues). This is also an excellent illustration of Caldara and Kamps' (2012) insight on the link between the assumed structural tax elasticity and the estimated multipliers. Table 6 shows various tax multiplier estimates from the literature.

Mertens and Ravn (2013) split the unanticipated Romer shocks into changes in personal income tax rates vs corporate income tax rates. They find that cuts in either tax rate have positive effects on output, employment, hours, and the tax base. Interestingly, a cut in the corporate tax rate does not decrease corporate tax revenues because the corporate income tax base responds so robustly. Personal income tax cuts tend to raise consumption and investment more than corporate income tax cuts do. See figures 2, 9, and 10 of Mertens and Ravn (2013) for more detail.

Oh and Reiss (2012) highlight the importance of transfers in the stimulus packages adopted in response to the Great Recession. They formulate a heterogeneous agent model and explore the predicted multipliers on transfers. There has been, however, very little empirical work on the multipliers associated with government transfers.[ff] A major challenge has been identifying exogenous movements in transfers. Hausman (2016) studied the large veteran's bonus of 1936, equaling 2% of GDP, and found that it led to immediate effects on consumption spending. His calculations suggest that it led to faster GDP growth in 1936, but followed by a quick reversal in growth in 1937. Romer and Romer (2016) study the effects of changes in Social Security benefit payments in aggregate US

[ff] There is a large literature on the effects of various transfers on individual household consumption and saving. However, these estimates do not translate directly to aggregate multipliers.

Table 6 Summary of some tax multiplier estimates for the aggregate Unites States

Study	Main sample	Identification	Implied tax multiplier
Evans (1969)	Quarterly, 1966–1974	Based on estimates of equations of Wharton, Klein–Goldberger, and Brookings models	−0.5 to −1.7, depending on horizon, type of tax, and model
Blanchard–Perotti (2002)	Quarterly, 1960–1997	Assumed output elasticities in an SVAR. "Taxes" are actually taxes less transfers	−0.78 to −1.33 (peak to impact)
Mountford–Uhlig (2009)	Quarterly, 1955–2000	Sign restrictions on a VAR. Use same variables as BP	−5 for a tax increase that reduces the deficit
Romer–Romer (2010)	Quarterly, 1947–2007	Legislated tax changes driven by an inherited government budget deficit or to promote future growth, based on narrative evidence	−3, based on peak effect. Romer–Romer (2009) show that these tax shocks do not raise government spending significantly, so these are close to pure tax shocks
Barro–Redlick (2011)	Annual, 1917–2006 and subsamples	Average marginal income tax rate	−1.1
Favero and Giavazzi (2012)	Quarterly, 1950–2006	Romer–Romer shocks embedded in an SVAR	−0.5
Caldara and Kamps (2012)	Quarterly, 1947–2006	SVAR using outside elasticities	−0.65 (peak to impact)
Mertens–Ravn (2014)	Quarterly, 1950–2006	Proxy SVAR using Romer–Romer unanticipated shocks	−3 at 6 quarters

data. They find very rapid responses of consumption to permanent changes in benefit, but the results dissipate within a few months. Moreover, there is no clear evidence of effects on aggregate output or employment.

Gechert (2015) conducts a meta-analysis of various types of multipliers. He finds that tax and transfer multiplier tend to be around 0.6–0.7.

4.2.1.2 Further Explorations

I now investigate the Mertens and Ravn (2014) reconciliation of the tax results in more detail. To do this, I first use Mertens and Ravn's (2014) specification, data, and sample. The specification is a trivariate SVAR with federal government spending, output, and federal tax revenue, all in real per capita logarithms.[gg] The SVAR includes four lags of the variables in addition to a quadratic trend and a dummy variable for the second quarter of 1975 (following Blanchard and Perotti, 2002). The tax shock is Mertens and Ravn's unanticipated shocks extracted from the R&R narrative, demeaned as they describe.

Fig. 6A shows the impulse responses for tax revenue and output from their proxy SVAR using their programs.[hh] The results show that a positive R&R tax shock that has an impact effect on tax revenues equal to 1% of GDP raises tax revenue for several quarters and then lowers it below zero (though not statistically different). Output falls significantly on impact and troughs around -3 after a year. The magnitude of the results is similar to those found by R&R (2010) with their entire exogenous series.

My further investigation reveals some potentially problems with instrument relevance, though. The first-stage regression of tax revenue on the unanticipated tax shock (controlling for the lags of the other variables in the VAR) has an *F*-statistic of 1.6 (based on robust standard errors), which suggests a possible problem with instrument relevance.[ii] Stock and Watson (2012) also noticed problems with first-stage *F*-statistics of some of these external instruments in their dynamic factor model.[jj] Of course, the feedback from GDP to tax revenues is a potential complication. An exogenous tax increase should raise revenue, holding GDP constant; however, the decline in GDP exerts a downward effect on tax revenues. Thus, perhaps it is better to think of the R&R tax shock as an instrument for tax *rates*. Ideally, one would use statutory rates, since the actual rate paid is partly endogenous (since a change in income can push an entity into a different tax bracket).

[gg] Blanchard and Perotti actually used *net* taxes, meaning taxes less transfers. I follow Mertens and Ravn and use taxes. One could augment the system to include transfers as a fourth variable and use Romer and Romer's (2014) narrative-based transfer shock series as an external instrument.

[hh] This is the same as Mertens and Ravn's (2014) figure 4 with the signs reversed to examine the effect of a tax increase.

[ii] These additional results are based on the same data definitions and specification as Mertens and Ravn (2014), but on revised data. The results are similar if I use their original data.

[jj] See Lundsford (2015) and Montiel Olea et al. (2015) for discussions of instrument relevance in the external instruments framework.

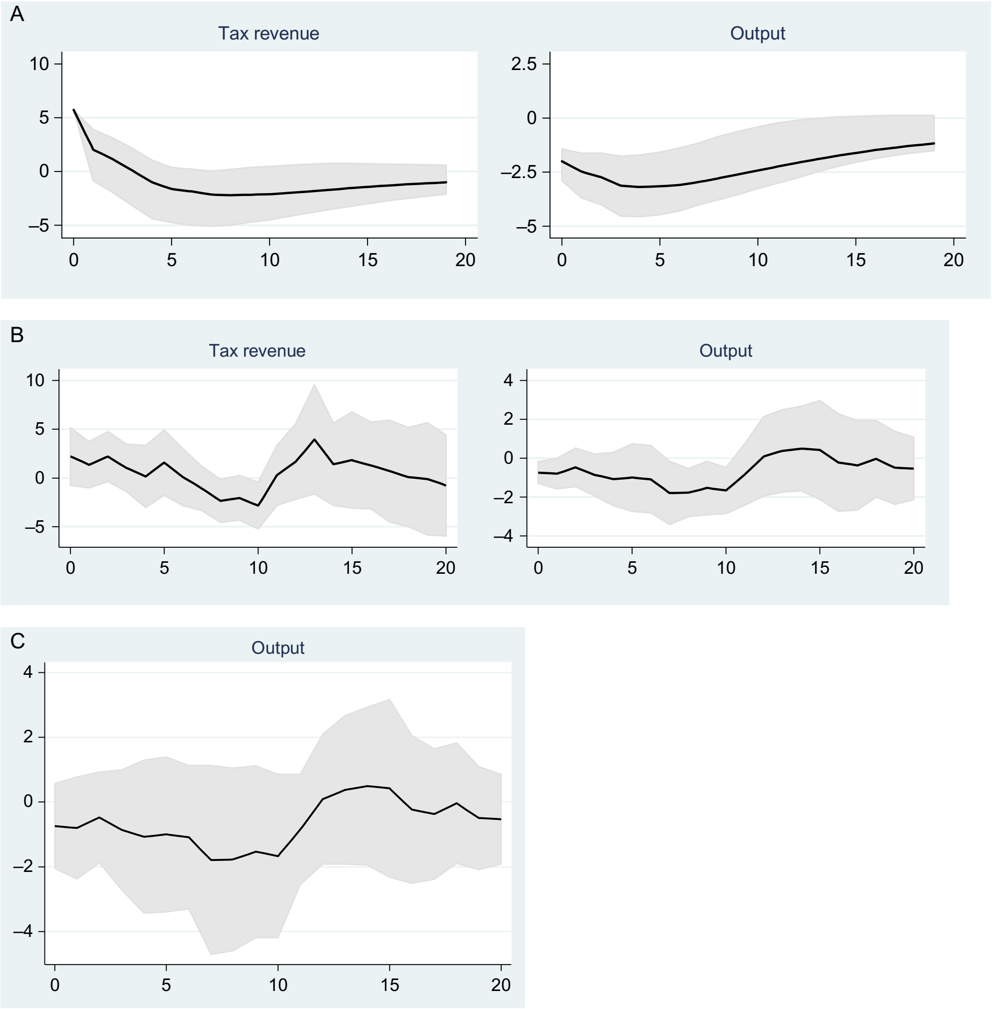

Fig. 6 Effects of unanticipated Romer tax shock, trivariate VAR, 1950q1–2006q4. (A) Mertens–Ravn (2014) proxy SVAR. (B) Jordà local projection, reduced form. (C) Jordà local projection, IV regression of output on tax revenue. Light gray bands are 90% confidence bands.

I do not have those data, so I simply construct an average tax rate as federal tax revenues divided by nominal GDP. I then estimate the first-stage regression described earlier with the average tax rate substituted for the log of taxes. The *F*-statistic on the R&R shock in this regression is 3.2, twice as high as the previous case but still well below the threshold for instrument relevance.

With the caveats about instrument relevance in mind, I further explore the robustness of Mertens and Ravn's (2014) results by estimating impulse responses using the Jordà local projection method and the Romer tax shock. I first estimate the reduced forms.

Table 7 Tax shock contribution to the forecast error variance of output

Horizon (in quarters)	Romer-Romer unanticipated	Leeper et al. (2012) anticipated tax series
0	1.6	0.4
4	0.4	5.7
8	0.5	4.8
12	1.1	4.4
16	1.8	4.3
20	2.1	4.3

Notes: Based on standard VAR with the shock, log output, log government spending, log taxes, and a quadratic trend. The shock is ordered first and four lags of the variables are included.

As discussed earlier, this involves regressing the dependent variable at $t+h$ on the shock at t, controlling for lags of other variables. To be consistent with Mertens and Ravn's specification, I use the same lags and variables in their proxy SVAR. Fig. 6B shows the impulse responses from the reduced form. Tax revenue increases in response to the shock initially and then falls below normal. In response to the tax shock, output falls on impact and then declines further to about −2 at 2 years, before beginning to recover. The confidence bands are wider, both because the Jordà method imposes fewer restrictions on the dynamics and because they incorporate the uncertainty about the impact of the tax shock on tax revenue. However, the point estimates for output for the first few years are broadly consistent with both Romer and Romer's (2010) original results and Mertens and Ravn's (2014) proxy SVAR.[kk] Table 7 shows the forecast error variance decomposition based on a standard VAR.[ll] Unanticipated tax shocks appear to account for very little of the forecast error variance of output.

As Mertens and Ravn (2014) note, however, external instruments tend to have measurement error, so they should not be used directly in an SVAR. A natural way to adjust for this in the Jordà setup is to estimate things as an IV regression, as discussed in Section 2. Thus, in a second specification I regress output at $t+h$ on the change in tax revenue at t, instrumented with the unanticipated part of the Romer tax shock, also controlling for the same variables as in the proxy SVAR (four lags of output, tax revenue, and government spending, as well as the deterministic terms). Fig. 6C shows the estimated impulse response of output for this specification. The point estimates for these results look very similar to those for output in Fig. 6B. The difference is that the confidence intervals are

[kk] If I use the Jordà method on the Romer's original specification and tax shock, I obtain results that are very close to theirs. This is as one would expect since they do not calculate impulses from a VAR.

[ll] As discussed in Section 4.1.3, although one can calculate forecast error variances using the estimated local projection coefficients, I found that the shares sometimes exceeded 100%. Thus, for present purposes I calculate the forecast error variance in a standard VAR with the shock, log government spending, log real GDP, and log taxes. The shock is ordered first and four lags are included, along with a quadratic trend.

very wide, always encompassing zero. Moreover, when I test whether the integral of the response for the first 12 quarters is different from zero, I cannot reject that it is zero.[mm]

To summarize, the literature on the effects of tax shocks has employed numerous methods, such as SVARs with calibrated elasticities, narrative approaches, and sign restrictions. Mertens and Ravn's (2014) reconciliation of some of the various approaches tends to support Romer and Romer's (2010) large estimated elasticities. My robustness checks suggest that while there might be a problem with instrument relevance, less restrictive ways to estimate impulse responses also generally support Romer and Romer's (2010) estimates of tax multipliers of −2 to −3.

4.2.2 News About Future Tax Changes

4.2.2.1 Summary of the Literature

Theory predicts that anticipated tax changes should have very different effects from unanticipated tax shocks (eg, Yang, 2005). If agents know that tax rates will increase in the future, they should respond by intertemporally substituting taxable activity into the present. Moreover, as discussed in Section 2, foresight about future tax changes can lead to identification problems in a standard SVAR. I will now review some recent results on the effects of anticipated tax changes on aggregate outcomes and provide some new results.

Mertens and Ravn (2011b, 2012) explore the effects of anticipated tax changes by splitting the Romers' narrative tax shock series into anticipated vs unanticipated shocks based on the delay between the passing of the legislation and the implementation of the legislation. Romer and Romer had timed all of their shocks to coincide with the implementation rather the legislation. Mertens and Ravn argue that the response of macroeconomic variables should be very different for anticipated vs unanticipated shocks.

Mertens and Ravn separate out the tax changes that were legislated more than 90 days before they were implemented. Because there are not a large number of these kinds of tax changes and because the lags between legislation and implementation vary significantly, Mertens and Ravn preserve the degrees of freedom in their estimation by combining various anticipated tax shocks according to the number of quarters left before implementation. Thus, their study does not trace out the effect of "news" per se; rather, it is more similar to an event study of the behavior of variables before and after the tax changes are implemented. Mertens and Ravn (2011b, 2012) estimate that anticipated and unanticipated tax shocks together account for 20% of the historical variation in output at business cycle frequencies. Particularly interesting is their finding that the so-called Volcker recession was in fact mostly caused by the Reagan tax cuts. The legislation was passed in summer 1981, but the actual tax cuts were phased in between 1982 and 1984. Mertens and Ravn's estimates imply that most of the decline in output from the second half of 1981 through 1982 was due to the negative output effects of anticipated future tax cuts.

[mm] Reducing the number of lags or control variables changes the results little.

Leeper, Richter, and Walker (2012) (LRW) construct an alternative measure of expected tax changes based on the spread between federal bonds and municipal bonds. They use their new series to inform their theoretical model but do not estimate effects of shocks to their series directly from the data. In the unpublished supplement to their 2013 *Econometrica* paper, Leeper et al. (2013) investigate the effect of their measure on output and show that expectations of a future tax increase raise output when the news arrives.

4.2.2.2 Further Explorations

I now explore the effects of several of the leading identified tax news shocks. Fig. 7 reproduces Mertens and Ravn (2011a,b) estimates of the effects of Romer tax shocks that were anticipated. Quarter 0 is the date of the implementation, negative quarters are quarters

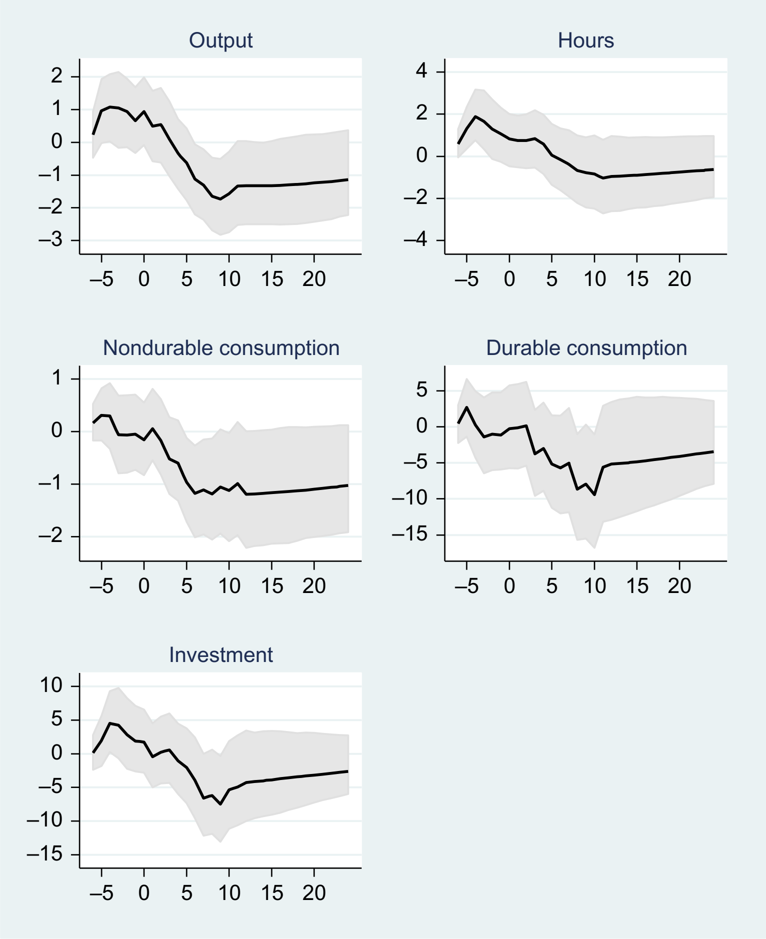

Fig. 7 Effects of news of future tax increases, Mertens–Ravn estimates based on Romer–Romer narrative, 1950q1–2006q4. Light gray bands are 90% confidence bands.

between the arrival of the news and before the implementation, and positive quarters are after the implementation. The graphs show clear evidence of anticipation effects and intertemporal substitution. Most variables, including output, hours, investment, and durable goods consumption expenditures, are higher than average in the interval between the announcement of a tax increase and its actual implementation. After implementation, all variables fall below normal, including nondurable consumption. Thus, the behavior of the data is very consistent with the theory.

To see how the results compare to Mertens and Ravn's results, I analyze the effects of Leeper et al.'s (2012) measure of average expected future tax rates from 1 to 5 years forward (AFTR15). Using a Jordà local projection, I estimate several sets of regressions at each horizon. In particular, I regress the endogenous variable of interest at $t+h$ on AFTR15 in period t, as well as on four lags of AFTR15, four lags of the endogenous variable and four lags of the average federal tax rate (total federal receipts divided by GDP). Because I do not orthogonalize the shock with respect to current values of any of the other variables, this identification scheme is similar to the one used by Leeper et al. (2013), where they order the tax news first in the Cholesky decomposition.

Fig. 8 shows the estimated responses to "news" that future tax rates will rise. The results are quite similar to those of Mertens and Ravn's results, even though the tax news variable is from a completely difference source and the model is estimated as responses to news rather than as an event study around the implementation. Output, hours, and investment start rising when news arrives at period 0 that tax rates will increase in the interval between 1 and 5 years. The variables remain high for a while and then fall below normal after a year or so.

Table 7 shows the forecast error variance decomposition for the LRW measure of expected tax changes. These shocks appear to account for more of the variance of output than the unanticipated tax changes, but still less than 6%.

In sum, some of the strongest and most robust findings in the fiscal literature are those associated with news about future tax changes. Expectations that future tax rates will increase lead to boom now followed by "busts." This is perhaps some of the strongest evidence that "news" can drive economic fluctuations.

4.3 Summary of Fiscal Results

In this section, I have summarized some of the main methods and findings concerning the effects of fiscal shocks. For both government spending and taxes, the methods that use external narrative series tend to find bigger effects on output than the more traditional SVAR method. For both government spending and taxes, anticipation effects are found to be very important.

Some of the literature has studied the effects of government spending and tax shocks jointly and made statements about "which" multiplier is larger. Some find larger

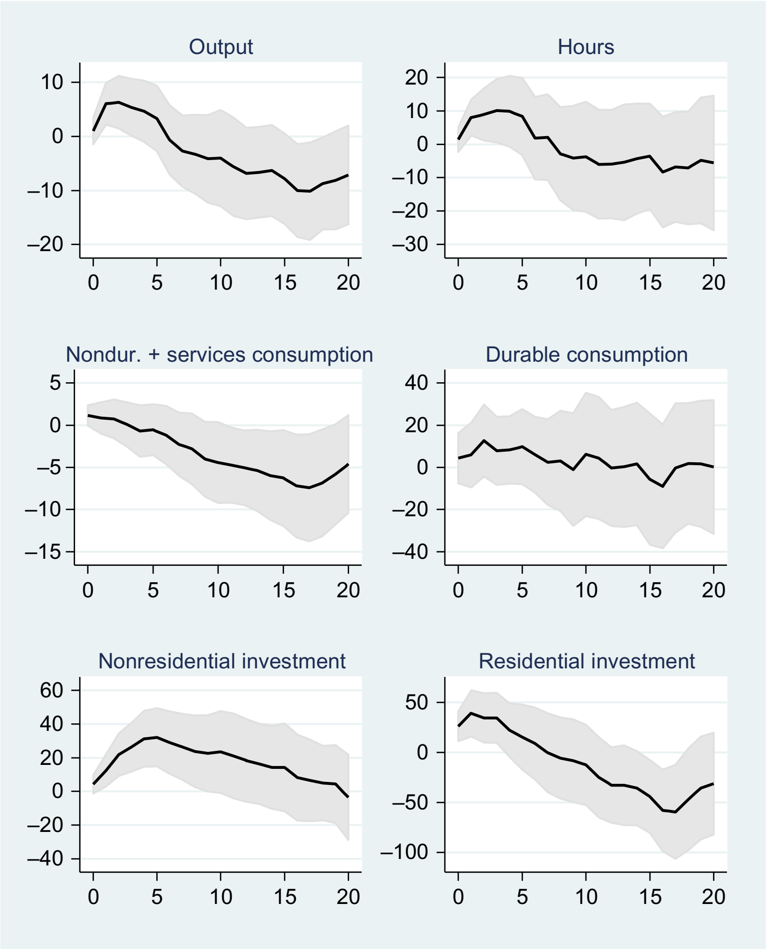

Fig. 8 Effect of news of future tax increase, Leeper et al. (2012) measure, Jordà local projection, 1954q1–2005q4. Light gray bands are 90% confidence bands.

government spending multipliers, and others find larger tax multipliers. My assessment is that the existing methods do not yield precise enough and robust enough estimates to be able to make this comparison.

5. TECHNOLOGY SHOCKS

Technology shocks are the most important type of nonpolicy shocks. In this section, I review the literature on technology shocks and present some new results comparing various shocks from the literature. I discuss both the classic unanticipated technology shocks and news about future changes in technology. I also distinguish between neutral and investment-specific technology (IST) shocks.

5.1 Neutral Technology Shocks

In 1982, Kydland and Prescott (1982) demonstrated the (then) surprising result that one could produce business cycle movements of key variables from a DSGE growth model beset by only one type of shock: variations in the growth rate of exogenous total factor productivity (TFP). To be concrete, consider the following aggregate production function:

$$Y_t = A_t F(L_t, K_t) \tag{21}$$

where Y_t is output, A_t is TFP, L_t is labor, and K_t is the capital stock at the beginning of period t. Neutral technology shocks, or TFP shocks, are shocks to the process driving A_t.

Several empirical regularities supported Kydland and Prescott's (1982) hypothesis. First, Solow (1957) showed that 87% of the growth in average labor productivity from 1909 to 1949 was due to TFP growth. If TFP growth was so important for growth, why not also for business cycles? Second, at the time that Kydland and Prescott published their article, a long-standing stylized fact was the procyclicality of labor productivity. In fact, this stylized fact was a problem for Keynesian "aggregate demand" explanations of business cycles, since diminishing returns would predict countercyclical labor productivity. Typically, the aggregate demand-driven business cycle literature had to resort to stories of labor hoarding or increasing returns to explain the procyclicality of labor productivity.

In follow-up work, Prescott (1986) used the Solow residual as his measure of exogenous TFP and used the standard deviation of that series along with his model to argue that the bulk of business cycle fluctuations could be explained by technology shocks. Beginning in the 1990s, though, several new results emerged that cast doubt on using the Solow residual as an exogenous technological progress for the purpose of business cycle analysis. First, Evans (1992) showed that variables such as money, interest rates, and government spending Granger-caused the Solow residual. Second, Hall (1988, 1990) developed a generalization of the Solow residual framework that relaxed the assumptions of competition and constant returns to scale. This framework demonstrated how endogenous components could enter the Solow Residual. Third, a number of papers, such as Shapiro (1993), Burnside et al. (1995), and Basu and Kimball (1997), used proxies such as the workweek of capital, electricity, or average hours to adjust the Solow residual for variations in the utilization of labor and/or capital. They found that much of the procyclicality of the Solow residual disappeared once it was adjusted.

Two approaches called into question whether technology shocks even led to business cycle-like movements. Galí (1999) and Basu et al. (2006) used different methods but both found results, suggesting that a positive technology shock led to a decline in labor inputs, such as hours. Both of these analyses assumed that all technology shocks were neutral technology shocks. I will discuss each of the approaches with the follow-up work in turn.

Galí (1999) used long-run restrictions to identify neutral technology shocks. He argued that a standard RBC model predicted that technology shocks were the only shocks that could have permanent effects on labor productivity. As discussed in

Section 2.3.6, Galí (1999) estimated a bivariate VAR with labor productivity and hours (or employment) and imposed the long-run restriction that technology shocks were the only shocks that could have a permanent effect on labor productivity. Francis and Ramey (2005) derived additional long-run restrictions from the theory and used them as an overidentification test and found that one could not reject the overidentifying restrictions. Francis and Ramey (2006) constructed new historical data for the United States and extended the analysis back to 1889. They found that a positive technology shock raised hours in the pre-WWII period but lowered them in the post-WWII period. They explained the switch with the difference in the serial correlation properties of productivity. In the early period, an identified technology shock raised productivity immediately, whereas in the later period an identified technology shock raised productivity more gradually. This gradual rise in the later period provides an incentive to reduce hours worked in the short run in anticipation of higher productivity in the long run.

Galí (1999) and Francis and Ramey (2005) both assumed that both (log) labor productivity and hours had a unit root and that their first differences were stationary. As Section 2.3.6 demonstrated, imposing long-run restrictions also requires the imposition of assumptions on stationarity. Christiano et al. (2003) argued that it makes no sense to model hours per capita as having a unit root since it is bounded above and below. They showed that if instead one assumes that hours are stationary and then impose the Galí long-run restriction, a positive technology shock leads to a rise in hours worked. Fernald (2007) noted the structural break in labor productivity growth, and when he allowed for that feature of the data, he found that hours fell after a positive technology shock. Francis and Ramey (2009) argued that the baby boom led to low-frequency movements in both labor productivity growth and hours worked per capita and that failure to correct for these led to the positive correlations found by Christiano et al. When they corrected for demographics, they found that a positive technology shock led to a decrease in hours. Gospodinov et al. (2013) discuss various econometric issues that arise in this setting with low-frequency movements.

Building on ideas of Uhlig (2003), Francis et al. (2014) introduced a new method of imposing long-run restrictions that overcame many of these problems. They identify the technology shock as the shock that maximizes the forecast error variance share of labor productivity at some finite horizon *h*. Using that scheme, they find that their identified technology leads to a fall in hours worked. They estimate that technology shocks contribute 15–40% of the forecast error variance of output at business cycle horizons. A variation by Barsky and Sims (2011) identifies the technology shock as the one that maximizes the *sum* of the forecast error variances up to some horizon *h*.

Several papers have questioned Galí's (1999) basic identifying assumption that technology shocks are the only shocks that have a long-run effect on labor productivity. Uhlig (2004) argues that capital taxation and shifts in preferences involving "leisure in the workplace" can also have long-run effects on labor productivity. He also introduces a "medium-run" identification procedure that anticipates the procedures discussed earlier. He finds that the impact effect on hours is zero and that there is a small rise afterward. Mertens and Ravn (2011a) include the Romer and Romer (2010) exogenous tax shocks in a vector error correction model and find that once taxes are controlled and cointegration is allowed, a positive TFP shock raises hours in the short run. They also find that technology shocks account for 50–55% of the forecast error variance of output.

Basu et al. (2006) found that technology shocks were contractionary using a completely different method. Employing theoretical insights from Basu and Kimball (1997), they adjusted the annual Solow residual for utilization using hours per worker as a proxy. When they examined shocks to this purged Solow residual, they found that positive shocks to technology led to a decline in hours worked. Fernald (2014) has now constructed a quarterly version of this utilization-adjusted TFP series.[nn]

Alexopoulos (2011) identified technology shocks by creating an entirely new data series for measuring technology. Meticulously collecting and counting book publications for several types of technologies, she constructed several annual series on new technologies. She found that these series were not Granger-caused by standard macroeconomic variables. Using her new series in VARs, she found that a positive technology raises output and productivity. Contrary to the findings of Galí (1999) and Basu et al. (2006), she estimated that a positive shock to technology raises output, though the effect is weak.

Table 8 summarizes some of the estimates of the contribution of TFP shocks to output fluctuations at business cycle frequencies, based on approaches that identify technology shocks in time series models.

Numerous papers have identified technology shocks through estimated DSGE models. McGrattan (1994) estimated a neoclassical DSGE model with technology and fiscal shocks. Smets and Wouters (2007) estimated a New Keynesian DSGE model using Bayesian methods in order to explore the effects of various shocks. They incorporate a number of different shocks in the model, including neutral technology shocks, IST shocks (discussed in the next section), monetary shocks, government spending shocks, markup shocks, and risk premium shocks. Their estimates imply that a positive neutral technology shock lowers hours worked. Justiniano et al. (2010, 2011) also estimate a New Keynesian model, but incorporate also investment-specific shocks and MEI shocks. Schmitt-Grohe and Uribe (2012) estimate a DSGE model which allows all of their shocks to have an unanticipated component and a "news," or unanticipated, component. Miyamoto and Nguyen (2015) extend their estimation method by including series on survey expectations in the estimation. I will discuss these papers in more detail in the sections on IST shocks and news. Blanchard et al. (2013) estimate a DSGE model allowing for both "news" and "noise." Table 9 summarizes the estimates from DSGE models

[nn] The series is regularly updated and made available by John Fernald at http://www.frbsf.org/economic-research/economists/jfernald/quarterly_tfp.xls.

Table 8 Estimated importance of technology shocks in SVAR models

Study	Method	Type	News?	% of output explained
Galí (1999), Francis–Ramey (2005)	Long-run restrictions, hours in first differences	TFP	No	Very little
Christiano et al. (2004)	Long-run restrictions, hours in levels	TFP	No	31–45% for horizons up to 20 quarters
Christiano et al. (2004)	Long-run restrictions, hours in first differences	TFP	No	1–17% for horizons up to 20 quarters
Basu et al. (2006)	Utilization and effort adjusted TFP	TFP	No	17–40% from 1 to 3 years
Beaudry and Portier (2006)	Short-run or long-run restrictions	TFP	Yes	50%
Fisher (2006)	Long-run restrictions involving both labor productivity and investment goods prices	TFP	No	32% at 12 quarters (see papers for more details)
Fisher (2006)	Long-run restrictions involving both labor productivity and investment goods prices	IST	No	26% (49%) at 12 quarters in early (late) sample
Mertens and Ravn (2010)	Long-run restrictions, cointegration, include taxes	TFP	No	50–55% at business cycle frequencies
Barsky and Sims (2011)	Medium-horizon restrictions	TFP	Yes	9–43% for horizons up to 24 quarters.
Barsky and Sims (2011)	Medium-horizon restrictions	TFP	No	6–20% for horizons up to 24 quarters
Francis et al. (2014)	Medium-horizon restrictions	TFP	No	15–40% for horizons up to 32 quarters.
Francis et al. (2014)	Long-run restrictions	TFP	No	40–55% for horizons up to 32 quarters
Ben Zeev and Khan (2015)	Medium-horizon restrictions	IST	Yes	73% at 8 quarters
Ben Zeev and Khan (2015)	Medium-horizon restrictions	IST	No	Very little
Ben Zeev and Khan (2015)	Medium-horizon restrictions	TFP	No	10% at 8 quarters

Notes: TFP denotes neutral total factor productivity technology, IST denotes investment-specific technology, and MEI denotes marginal efficiency of investment.

Table 9 Estimated importance of technology shocks in DSGE models

Study	Model features	Type	News?	% of output explained at business cycle frequencies
Prescott (1986)	Calibrated neoclassical DSGE model	TFP	No	75%
McGrattan (1994)	Neoclassical model with distortionary taxes and government spending	TFP	No	41%
Greenwood et al. (2000)	Calibrated DSGE model, technology identified with relative price of investment	IST	No	30%
Smets and Wouters (2007)	New Keynesian model with many types of shocks	TFP	No	15–30% from horizon 1–10 quarters
Justiniano et al. (2011)	New Keynesian model with many types of shocks	TFP	No	25%
Justiniano et al. (2011)	New Keynesian model with many types of shocks	IST	No	0%
Justiniano et al. (2011)	New Keynesian model with many types of shocks	MEI	No	60%
Schmitt-Grohe and Uribe (2012)	Distinguishes unanticipated vs anticipated, TFP vs investment specific, no sticky prices	TFP	No	25%
Schmitt-Grohe and Uribe (2012)	Distinguishes unanticipated vs anticipated, TFP vs investment specific, no sticky prices	TFP	Yes	3%
Schmitt-Grohe and Uribe (2012)	Distinguishes unanticipated vs anticipated, TFP vs investment specific, no sticky prices	IST	No	21%
Schmitt-Grohe and Uribe (2012)	Distinguishes unanticipated vs anticipated, TFP vs investment specific, no sticky prices	IST	Yes	7%
Khan and Tsoukalas (2012)	New Keynesian model, distinguishes unanticipated vs anticipated	TFP	No	24%
Khan and Tsoukalas (2012)	New Keynesian model, distinguishes unanticipated vs anticipated	MEI	No	47%
Khan and Tsoukalas (2012)	New Keynesian model, distinguishes unanticipated vs anticipated	IST	No	1.2%
Khan and Tsoukalas (2012)	New Keynesian model, distinguishes unanticipated vs anticipated	TFP + MEI + IST	Yes	1.4%
Miyamoto and Nguyen (2013)	Extends Schmitt–Grohe–Uribe analysis by using data on expectations	TFP	No	19%
Miyamoto and Nguyen (2013)	Extends Schmitt–Grohe–Uribe analysis by using data on expectations	TFP	Yes	7%
Miyamoto and Nguyen (2013)	Extends Schmitt–Grohe–Uribe analysis by using data on expectations	IST	No	27%
Miyamoto and Nguyen (2013)	Extends Schmitt–Grohe–Uribe analysis by using data on expectations	IST	Yes	12%

Notes: TFP denotes neutral total factor productivity technology, IST denotes investment-specific technology, and MEI denotes marginal efficiency of investment.

of the contribution of various types of technology shocks to output fluctuations at business cycle frequencies.

5.2 Investment-Related Technology Shocks

Greenwood et al. (1988) were the first to examine in a DSGE model Keynes' idea that shocks to the marginal efficiency of investment (MEI) could be a source of business cycle volatility. In follow-up work, Greenwood et al. (2000) used a calibrated DSGE model to examine the importance of IST change in business cycles. They used the relative price of new equipment to identify the process driving IST shocks and concluded that these shocks could account for 30% of business cycle volatility.

Fisher (2006) extended Galí's (1999) analysis of neutral technology shocks by incorporating additional data and restrictions that separately identify neutral and IST shocks. In particular, he assumed that only IST shocks affect the relative price of investment goods in the long run and only neutral technology and IST technology shocks affect labor productivity in the long run. Because of some sample instability, he estimated his model over two periods: 1955q1–1979q2 and 1982q3–2000q4. He found that both technology shocks together accounted for a substantial shared of the forecast error variance of output, 60% at 12 quarters in the early sample, 83% in the later sample.

Justiniano et al. (2010, 2011) estimate a New Keynesian DSGE model with a variety of unanticipated shocks. Justiniano et al. (2011) distinguish between IST shocks and MEI shocks. To be concrete, consider simplified versions of two equations from their DSGE model:

$$I_t = \Psi_t Y_t^I \tag{22a}$$

$$K_{t+1} = (1-\delta)K_t + \mu_t I_t \tag{22b}$$

I_t is the production of investment goods and Ψ_t denotes the rate of transformation of final goods, Y_t^I, into investment goods. Ψ_t is IST which, according to their model, should be equal to the inverse of the relative price of investment goods to consumption goods. K_{t+1} is the level of capital at the beginning of period $t+1$, δ is the depreciation rate, and μ_t is the rate of transformation between investment goods and installed capital, or the *MEI*. Previous research, such as by Greenwood et al. (2000) and Fisher (2006), had not distinguished IST from MEI and had assumed their product was equal to the inverse of the relative price of investment goods. Justiniano et al. (2011) estimate that (unanticipated) MEI shocks contribute 60% of the variance of output at business cycle frequencies.

Schmitt-Grohe and Uribe (2012), Khan and Tsoukalas (2012), and Miyamoto and Nguyen (2015) estimate DSGE models that incorporate both TFP and IST shocks. An important focus of their estimation is the distinction between unanticipated technology changes and news about future changes, so I will discuss their work in the next section on news.

Although there is a wide range of results, a general pattern that emerges is that when models include IST and/or MEI shocks, they tend to explain a significant portion of the variation in output at business cycle frequencies.

5.3 News About Future Technology Changes

Both Pigou (1927) and Keynes (1936) suggested that changes in expectations about the future may be an important driver of economic fluctuations. Beaudry and Portier (2006) reignited interest in the idea by providing time series evidence that news about future productivity could explain half of output fluctuations over the business cycle. Furthermore, their estimates implied that hours and output rose when the news arrived, thus creating business cycle-type comovements. They identified news shocks using two methods; both involved identifying shocks that moved stock prices immediately, but affected productivity only with a lag. Beaudry and Lucke (2010) and Kurmann and Otrok (2013) used other techniques to reach similar conclusions. More recently, however, Barsky and Sims (2011) and Barsky et al. (2014) have used medium-run restrictions and series on consumer confidence to identify news shocks and found that news shocks did not generate business cycle fluctuations. In particular, hours fell when news arrived. Fisher (2010), Kurmann and Mertens (2014), and Forni et al. (2014) have highlighted problems with Beaudry and Portier's identification method. For example, Kurmann and Mertens (2014) show that the larger VECM in Beaudry and Portier's (2006) paper is not identified. Forni et al. (2014) argue that the small-scale SVARs are affected by the "nonfundamentalness" problem discussed in Section 2.5. Thus, the empirical work based on time series identification is in flux. Beaudry and Portier (2014) present a comprehensive summary of the literature.

I would add that another potential problem with Beaudry and Portier's (2006) method for identifying TFP news shocks is the implicit assumption they make about stock prices. They assume that the future profits from the TFP shock will show up in current stock prices. It is not clear that this assumption holds for major innovations. Greenwood and Jovanovic (1999) and Hobijn and Jovanovic (2001) present theory and evidence that major technological innovations (such as information technology) actually lead to a temporary *decline* in stock market values because they lower the value of the existing technology. Revolutionary innovations usually arise in private companies and claims to future dividend streams only show up in stock prices after the initial public offerings. Thus, we should not necessarily see positive effects of news about future TFP on stock prices.

Ben Zeev and Khan (2015) identify both unanticipated IST shocks and IST news shocks. To do this, they extend Barsky and Sims (2011) medium-horizon restriction method for identifying news and employ Fisher's (2006) assumptions linking IST and the relative price of investment goods. They find that IST news shocks explain 73% of the forecast error variance of output at a horizon of eight quarters. They show that the IST shocks originally identified by Fisher (2006) were a combination of the unanticipated IST shocks and news about IST. Ben Zeev and Khan's paper thus corroborates Fisher's finding that IST shocks are the major source of fluctuations, but goes on to show that it is the news part that is the most important.

Another strategy for identifying news is through estimation of a DSGE model, as pioneered by Schmitt-Grohe and Uribe (2012). This approach achieves part of its identification by assuming particular lags between the arrival of news and the realization of the change. Schmitt-Grohe and Uribe (2012) allow for a variety of unanticipated and news shocks for variables such as TFP, IST, and wage markups. They estimate that all news variables combined (including nontechnology shocks such as wage markup shocks) account for 50% of output fluctuations according to their estimates. An extension by Miyamoto and Nguyen (2015) uses actual survey forecasts for the expectations variables.

Khan and Tsoukalas (2012) estimate a New Keynesian DSGE model with both IST and MEI shocks and allow for both unanticipated changes and news shocks. They find that unanticipated MEI shocks contribute an important part of the variance of output (47%), but that technology news shocks are not important at all. Nontechnology news shocks do, however, contribute to the variance decomposition of hours. In particular, wage markup shocks account for over 40% of the variance of hours. Thus, their results on the importance of unanticipated technology shocks contrast with those of Schmitt-Grohe and Uribe (2012), but their results on the importance of news about wage markups are consistent with their findings. The estimates of the importance of technology news are summarized in Table 9.

5.4 Explorations with Estimated Technology Shocks

I now study the relationship between some of the leading shocks and explore the effects of a few of them in the Jordà local projection framework. I reestimate the Galí (1999), Christiano et al. (2003) (CEV), and Beaudry and Portier (2006) systems using updated data. In each case, I used a simple bivariate system. Both the Galí and CEV shocks use long-run restrictions, with the former assuming a unit root in hours per capita and the latter assuming a quadratic trend in hours. I use Beaudry and Portier's shock estimated with the short-run restriction; ie, it is the shock to stock prices that does not affect TFP on impact; the correlation of this shock with their shock estimated using long-run restrictions is 0.97. The Fernald shocks are simply the growth rate of Fernald's (2014) utilization-adjusted TFP for the aggregate economy or for the investment goods sector. The rest of the estimated shocks were kindly provided by Francis et al. (2014) (medium-horizon restrictions), Barsky and Sims (2011) (medium-run restrictions, consumer confidence), Justiniano et al. (2011) (estimated DSGE model), Ben Zeev and Khan (2015) (SVAR with medium-run restrictions), and Miyamoto and Nguyen (2015) (estimated DSGE model with forecast data). The joint sample is 1955q2–2006q4, except for the TFP news sample, which is limited to 1961q1–2006q4 by the Barsky and Sims shock availability. Correlations between subsets of shocks that are available over longer samples are similar to those reported for the joint sample. Table 10 shows the correlations, broken

Abbreviations: *bp*, Beaudry-Portier; *bs*, Barsky–Sims; *bzk*, Ben Zeev and Khan; *cev*, Christiano, Eichenbaum, Vigfusson; *ford*, Francis, Owyang, Roush, DiCecio; *gali*, Gali; *ist*, investment-specific technology; *jf*, John Fernald; *jpt*, Justiniano, Primiceri, Tambolotti; *mei*, marginal efficiency of invest; *mn*, Miyamoto and Nguyen; *n4*, news with 4 quarter lead; *n8*, news with 8 quarter lead; *_p*, permanent; *_s*, stationary; *tfp*, total factor productivity.

down according to whether the shock is to TFP or IST (or MEI) and whether it is unanticipated or is news.

Table 10A shows the results for unanticipated TFP shocks, which have received the most attention. Most of the shocks have a correlation above 0.6 with the shock estimated using Galí's (1999) method. The exception is the Miyamoto and Nguyen (2015) permanent TFP shock. It is surprising that the Miyamoto and Nguyen stationary TFP shock has a higher correlation than the permanent TFP shock, since the Galí method only identifies permanent TFP shocks.

Table 10B shows news shocks about TFP. The correlation between Beaudry and Portier's (2006) shock estimated using short-run restrictions and Barsky and Sims' (2011) shock estimated using medium-horizon restrictions is only 0.25. The correlations of both of those SVAR-based shocks with the Miyamoto and Nguyen (2015) DSGE-based shocks are essentially 0.

Table 10C shows correlations of various estimates of unanticipated IST or MEI shocks. The correlations between the various estimates are quite low. For example, the correlation between Fernald's utilization-adjusted TFP for the investment goods sector and Justiniano et al.'s (2011) IST shock is only 0.19 and is −0.27 for Justiniano et al.'s MEI shock. The highest correlation of 0.49 is between Justiniano et al.'s IST shock and Ben Zeev and Khan's (2015) IST shock. The higher correlation is not surprising since both methods associate the IST shock with the inverse of the relative price of equipment.

Table 10D shows correlations of various estimates of IST news shocks. There is essentially no correlation between Ben Zeev and Khan's (2015) SVAR-based estimates and Miyamoto and Nguyen's (2015) DSGE-estimated shocks.

If we were simply trying to develop instruments for estimating structural parameters, it would not matter if various instruments had low correlation.[oo] If, however, we are trying to estimate shocks in order to determine their importance for macroeconomic fluctuations, a low correlation across various estimates is troubling. The large number of low correlations across methods and the widely varying results reported across papers suggest that we are still far from a consensus on the nature and importance of technology shocks. The problem is not one of lack of consensus of estimated DSGE vs SVAR methods. Even within each class of method, the results vary widely, as evidenced in Tables 8 and 9.

Moreover, many of the estimated shocks do not satisfy the property that they are unanticipated or news. Table 11 shows the *p*-values from two sets of tests. The first one tests for serially correlation of the shock by regressing the shock on its own two lags and testing their joint significance. The SVAR-estimated shocks do well on this test, but quite a few of the DSGE-estimated shocks fail this test. The second set of tests is for Granger causality (Granger, 1969). To conduct these tests, I augment this regression with two lags each of log real GDP, log real consumption, and log real stock prices. I chose

[oo] Sims (1998) made this argument in his discussion of Rudebusch's (1998) monetary shock critique.

Notes: The tests for serial correlation are conducted by regressing the shock on its own two lags and testing the joint significance. The tests for Granger causality are conducted by regressing the shock on its own two lags, as well as two lags of log real GDP, log real consumption, and log real stock prices. The test is on the joint significance of the lags of the three additional variables. P-values less than 0.1 are indicated in bold.

Abbreviations: *bp*, Beaudry–Portier; *bs*, Barsky–Sims; *bzk*, Ben Zeev and Khan; *cev*, Christiano, Eichenbaum, Vigfusson; *ford*, Francis, Owyang, Roush, DiCecio; *gali*, Gali; *ist*, investment-specific technology; *Jpt*, Justiniano, Primiceri, Tambolotti; *mei*, marginal efficiency of invest; *mn*, Miyamoto and Nguyen;*n4*, news with 4 quarter lead; *_p*, permanent; *_s*, stationary; *tfp*, total factor productivity.

consumption and stock prices because those variables have forward-looking components to them. Half of the shocks fail this test. Of course, the Galí and CEV shocks were estimated using a simple bivariate model. Had I augmented those systems with these variables, the shocks would have passed the tests by construction. The Francis et al., Beaudry and Portier, and Ben Zeev and Kahn shocks pass this test, as do about half of the DSGE-estimated shocks.

Next, I explore the effects of a few of the estimated shocks on several macroeconomic variables in a Jordà local projection framework. To do this, I estimate the following series of regressions:

$$z_{t+h} = \alpha_h + \theta_h \cdot \text{shock}_t + \varphi_h(L)y_{t-1} + \text{quadratic trend} + \varepsilon_{t+h} \tag{23}$$

The z is the variable of interest. The control variables include two lags each of the shock (to mop up any serial correlation in the shocks), log real GDP per capita, log real stock prices per capita, log labor productivity (equal to real GDP divided by total hours worked), and the dependent variable. The coefficient θ_h gives the response of z at time $t+h$ to a shock at time t. As discussed in Section 2, ε_{t+h} will be serially correlated, so the standard errors must incorporate a correction, such as Newey–West.

Fig. 9 shows the responses of real GDP, labor productivity hours, stock prices, consumption, and nonresidential investment to three different measures of unanticipated TFP shocks: the Francis, Owyang, Roush, and DiCecio (2014) (FORD) measure, which

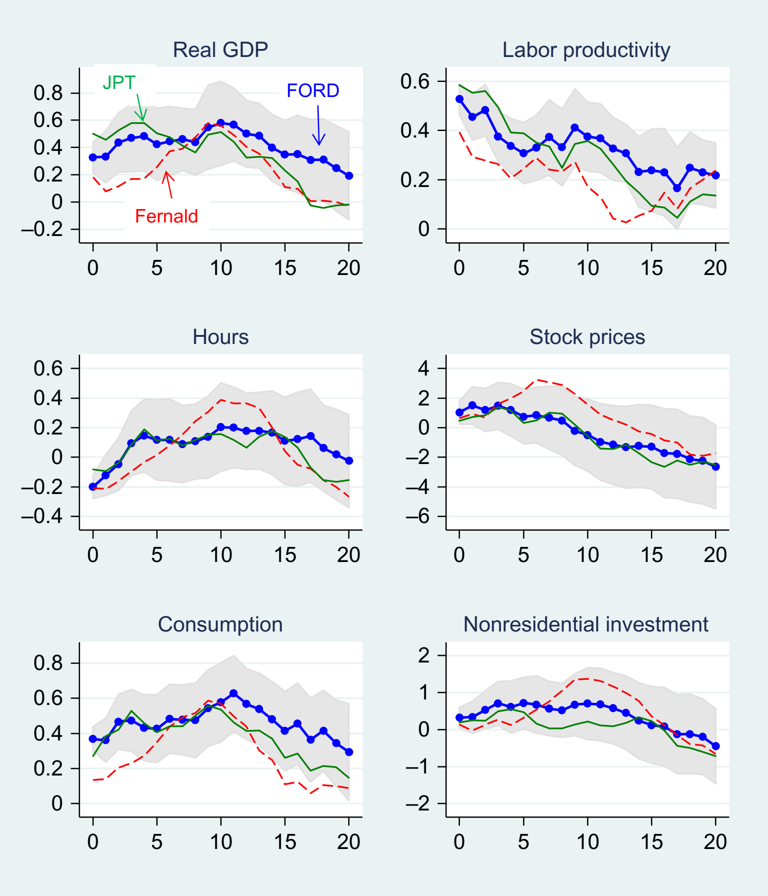

Fig. 9 Effects of TFP shock, Jordà local projection, various samples. Francis, Owyang, Roush, DiCecio (FORD): *blue lines with circles* (*black* in the print version); Fernald utilization-adj TFP: *dashed red* (*gray* in the print version) *lines*; Justiniano, Primiceri, Tambalotti (JPT) DSGE TFP: *solid green* (*gray* in the print version) *lines*. Light gray bands are 90% confidence bands.

uses medium-run restrictions; Fernald's (2014) utilization-adjusted TFP growth, and Justiniano, Primiceri, and Tambalotti's (2011) (JPT) estimate from their DSGE model. The responses to the FORD and JPT shocks are quite similar: GDP, labor productivity, stock prices, and consumption all jump immediately and significantly. Hours fall for a few quarters before rising. The Fernald shock implies a more hump-shaped response of GDP, hours, stock prices, consumption, and investment. Labor productivity rises immediately but then returns to normal at around 16 quarters. The Fernald shock also shows an initial decline in hours before they rise.

Fig. 10 shows the effects of the Ben Zeev and Khan (2015) IST news shock. Recall that this shock is an extension of Fisher's (2006) method, estimated using the Barsky–Sims (2011) medium-horizon method combined with information on relative prices of investment. This shock appears to generate a classic business cycle pattern. GDP, hours, stock

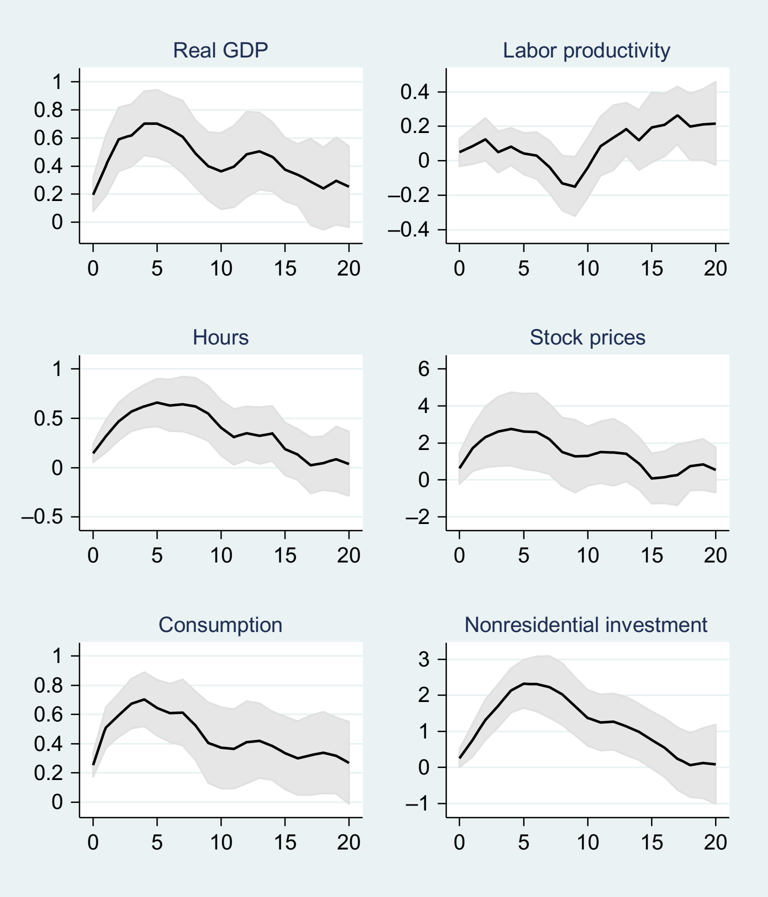

Fig. 10 Effects of news of investment-specific technology shocks, Ben Zeev–Khan (2015) measure, Jordà local projection, 1952q1–2012q1. Light gray bands are 90% confidence bands.

prices, consumption, and nonresidential investment increase with a prolonged hump shape. Labor productivity does nothing for about six quarters, falls around nine quarters, and then rises.

Fig. 11 shows the effects of JPT's MEI shock, estimated from their DSGE model. While this shock leads to temporary rises (for a year or less) in real GDP, labor productivity, consumption, and nonresidential investment, it leads to a fall in stock prices, which is puzzling.

Tables 12A and 12B show the forecast error variance decompositions for these five shocks for both output and hours. The decompositions are calculated from a standard VAR with the shock, and log per capita values of real GDP, hours, stock prices, consumption, and nonresidential investment. Although some of the unanticipated TFP shocks can account for up to 16% of output, none accounts for much of the variance

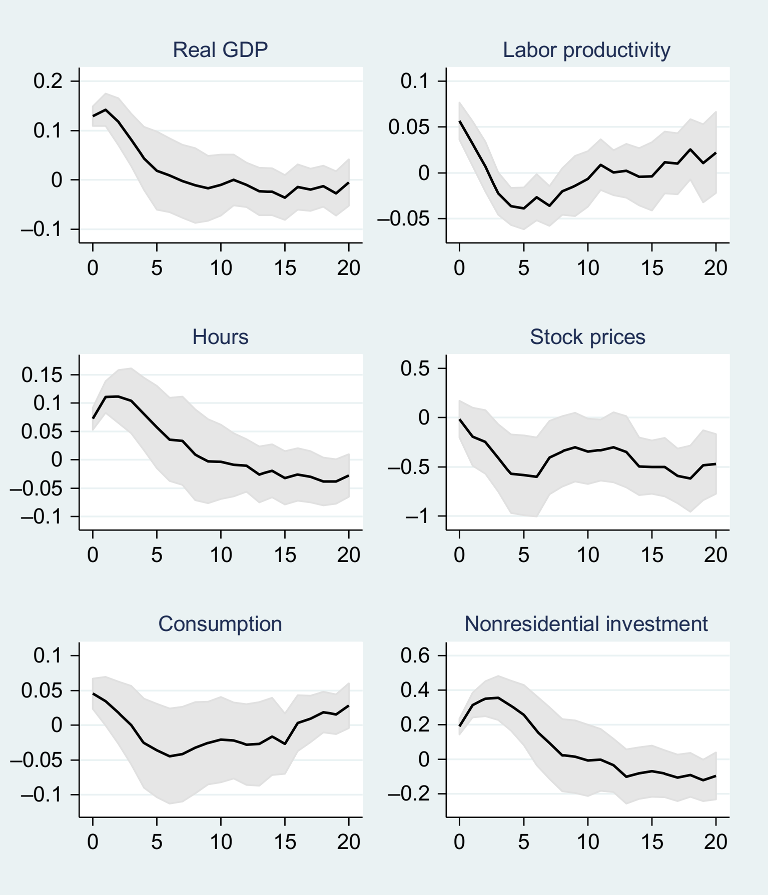

Fig. 11 Effects of marginal efficiency of investment shock, Justiniano et al. (2011) measure, Jordà local projection, 1954q3–2009q1. Light gray bands are 90% confidence bands.

Table 12A TFP shock contribution to the forecast error variance of output and hours

	FORD TFP		Fernald TFP		JPT TFP	
Horizon (in quarters)	**Output**	**Hours**	**Output**	**Hours**	**Output**	**Hours**
0	16.2	10.5	6.1	10.5	28.2	1.0
4	13.1	2.0	2.0	2.4	15.1	0.9
8	14.3	1.9	2.8	1.3	15.9	1.6
12	14.3	1.6	3.1	1.2	16.3	1.6
16	14.0	1.5	3.1	1.5	16.0	1.6
20	13.7	1.5	3.0	2.0	15.7	1.9

Notes: These results are based on a standard VAR with the shock, output, hours stock prices, consumption, and nonresidential investment. The shock is ordered first. Four lags are included, along with a quadratic trend.

Table 12B Investment-related technology shock contribution to the forecast error variance of output and hours

	Ben Zeev–Khan IST news		JPT MEI	
Horizon (in quarters)	**Output**	**Hours**	**Output**	**Hours**
0	7.8	6.9	49.6	26.4
4	33.2	31.3	19.8	20.9
8	36.8	38.5	11.9	12.1
12	36.8	38.8	11.4	10.5
16	36.4	37.9	11.3	10.1
20	35.9	36.8	11.1	9.8

Notes: These results are based on a standard VAR with the shock, output, hours stock prices, consumption, and nonresidential investment. The shock is ordered first. Four lags are included, along with a quadratic trend.

of hours. In contrast, the Ben Zeev and Khan IST news shock accounts for well over a third of the forecast error variance of both output and hours. JPT's MEI shock accounts for large fractions on impact, 50% for output and 26% for hours, but the effects dissipate fairly quickly.

5.5 Summary of Technology Shocks

The literature investigating the effects of technology shocks has moved far beyond the simple Solow residual. Various methods have been introduced to deal with changes in measured TFP that are due to variable utilization. Moreover, the literature has moved beyond neutral technology shocks to recognize the potential importance of IST shocks and MEI shocks. In addition, recent contributions have investigated the importance of news shocks.

My analysis shows, however, that some of the estimated shocks are not highly correlated with other versions. Moreover, many of the shocks are serially correlated or Granger-caused by other variables. This suggests that more research needs to be done to refine these shock measures. One of the shocks that seem to be promising both for generating business-cycle comovement and for contributing significant amounts to the variance of output is the shock that captures news about IST change.

6. ADDITIONAL SHOCKS

So far, this chapter has focused on only three types of shocks—monetary, fiscal, and technology shocks. There are numerous other candidates for potentially important macroeconomic shocks. Here, I will briefly review a few.

One obvious additional candidate for a macroeconomic shock is oil shocks. Hamilton (1983) argued that oil supply shocks were a major driver of economic fluctuations. Since then, a large literature has examined the effects of oil supply shocks. One of the major themes of the literature is the changing estimated effects of oil price shocks, identified by ordering oil prices first in a linear VAR. In particular, after the 1970s oil price changes seemed to have smaller effects. One potential explanation is asymmetries. Several analyses, such as by Davis and Haltiwanger (2001) and Hamilton (2003), argued that oil price increases have larger effects than oil price decreases. Subsequent research, however, found that there was not strong evidence of asymmetry (eg, Kilian and Vigfusson, 2011). A second potential explanation for the changing effects of oil supply shocks is that the oil price increases in earlier periods were accompanied by price controls, which led to many distortions (Ramey and Vine, 2011). When they constructed an implicit cost of oil that incorporated a proxy for the distortion costs, they did not find much evidence of changing effects. A third explanation was by Kilian (2009) and was a critique of standard identification methods. He argued that many of the changes in oil prices are driven now driven by demand shocks, not supply shocks, so a standard Cholesky decomposition with oil prices ordered first does not properly identify oil supply shocks. Stock and Watson's (forthcoming) chapter in this *Handbook* uses oil shocks as a case study of their methods. They find that oil supply shocks, identified using Kilian's (2009) method, do not account for a significant fraction of the forecast error variance of output.

Credit shocks are another possible candidate for a macroeconomic shock. There is huge literature analyzing the importance of credit and credit imperfections in economic fluctuations and growth. Most of this literature focuses on credit as an important propagation and amplification mechanism (eg, "the credit channel" of monetary policy), rather than as an important independent source of shocks. Gilchrist and Zakrajšek's (2012) recent analysis of the effects of innovations to their new excess bond premium variable can be interpreted as an analysis of credit market shocks. They showed that innovations to the excess bond premium that were orthogonal to the current state of the economy had significant effects on macroeconomic variables. They interpret a negative "shock" to this variable as signaling a reduction in the effective risk-bearing capacity of the financial sector.

The role of uncertainty in the business cycle has received heightened attention recently. In addition to standard firm-level uncertainty and financial uncertainty, recent work has suggested a possible role for policy uncertainty. More research needs to be done to untangle uncertainty as an endogenous propagation mechanism vs uncertainty as an independent source of macroeconomic shocks.

Labor supply shocks are yet another possible source of macroeconomic shocks. It is well known that cyclical variations in the "labor wedge" are an important component of business cycles. Shapiro and Watson (1988) estimated an SVAR with long-run restrictions and found that labor supply shocks were the dominant driver of business cycles. In estimated DSGE models with many shocks, wage markup shocks are often found to play an important role. This is particularly the case for *news* about wage markups. For example, both Khan and Tsoukalas (2012) and Schmitt-Grohe and Uribe (2012) find that wage markup news shocks account for 60% of the variance share of hours. A key question is whether exogenous shocks to the labor market are an important part of fluctuations or whether we are accidentally identifying an internal propagation mechanism as an exogenous shock.

7. SUMMARY AND CONCLUSIONS

This chapter has summarized the new methods and new findings concerning macroeconomic shocks and their propagation. Identification is particularly challenging in macroeconomics because researchers ask questions for which *dynamics* are all important, *general equilibrium* effects are crucial, and *expectations* have powerful effects.

The literature has made substantial progress in thinking seriously about identification of shocks since the early days of Cholesky decompositions. It now exploits new data sources, such as narrative records, survey expectations, and high-frequency financial data, combines theory with extra data series (eg, the relative price of investment goods), and incorporates that information in estimated DSGE models and SVARs.

The introduction to this chapter posed the question: Are we destined to remain forever ignorant of the fundamental causes of economic fluctuations? I would argue "no." Although we still have far to go, substantial progress has been made since Cochrane (1994) asked that question.

In support of my answer, I offer the following forecast error variance decomposition that combines some of the leading shocks I have discussed in this chapter. I specify a VAR that contains the shocks as well as some macroeconomic variables. In particular, it contains (in this order) Ben Zeev and Pappa's (forthcoming) military news shock, Leeper et al. (2012) news about future taxes from bond prices, the Romer and Romer's (2010) unanticipated tax shocks (as constructed by Mertens and Ravn, 2012), Francis et al.'s (2014) medium-horizon restriction TFP shock, Ben Zeev and Khan's (2015)

IST news shock, and Justiniano et al.'s (2011) MEI shock. The macroeconomic variables include the logs real per capita values of GDP and total hours, as well as the log of commodity prices and the GDP deflator. Ordered last is the federal funds rate. Four lags are used and a quadratic trend is included.

Table 13 shows the forecast error variance decomposition of log real GDP per capita and log hours per capita. Because of data limitations on some of the shocks, the sample starts after the Korean War. It should not be surprising, then, that the government spending shocks are not very important. The tax news shocks contribute a small amount, less than 10%. The unanticipated tax shocks are unimportant.

Which shocks are important? The most important for both output and hours is Ben Zeev and Khan's (2015) news about IST change. This variable contributes an important part of the forecast error variance of both output and hours. For example, at 8 quarters the contribution to hours is 40%. The 90% confidence interval (not shown in the table) is (25, 54). Justiniano et al.'s (2011) MEI shock contributes 42% on impact, with a 90% confidence interval of (34, 50), but this falls to 24% by 1 year. If we associate the innovations to the federal funds rate with monetary policy shocks, then monetary policy shocks contribute up to 8% of the variance of output, but up to 18% of the variance in hours.

Table 13 Combined VAR: shock contribution to the forecast error variance of output and hours: 1954q3–2005q4

Horizon	bzp_gov	lrw	rrtaxu	ford_tfp	bzk_ist_news	jpt_mei	ffr
A. Output							
0	5.5	0.1	2.4	15.8	11.8	42.1	0.0
4	1.6	5.6	1.6	15.1	28.8	23.9	2.0
8	1.4	4.8	1.5	13.9	26.9	16.3	6.1
12	3.0	4.8	1.2	12.6	22.1	13.6	8.1
16	4.4	6.9	1.2	11.2	19.6	12.5	7.8
20	4.9	8.5	1.2	10.7	18.6	11.9	7.4
B. Hours							
0	2.3	0.8	0.3	17.6	13.2	20.5	0.0
4	0.5	6.6	0.8	3.7	38.3	22.1	3.2
8	0.9	6.3	0.9	2.4	39.5	14.2	10.9
12	4.1	5.2	0.7	1.8	33.4	11.5	16.8
16	7.3	6.0	0.7	1.7	28.6	10.6	18.3
20	8.9	7.0	0.8	2.0	26.7	10.2	18.1

Notes: These results are from a standard VAR with four lags and a quadratic trend estimated from 1954q3 to 2005q4. The variables are as follows, in this order: Bzp_gov, lrw, rrtaxu, ford_tfp, bzk_ist_news, jpt_mei, log real GDP per capita, log total hours per capita, log commodity prices, log GDP deflator, federal funds rate.
Abbreviations: *bzk*, Ben Zeev and Khan; *bzp*, Ben Zeev and Pappa; *ffr*, federal funds rate; *ford*, Francis, Owyang, Roush, DiCecio; *lrw*, Leeper, Richter, Walker anticipated future tax; *ist*, investment-specific technology; *Jpt*, Justiniano, Primiceri, Tambolotti; *mei*, marginal efficiency of invest; *rrtaxu*, Romer–Romer unanticipated tax; *tfp*, total factor productivity.

In sum, the three fiscal shocks, the three technology shocks, and the federal funds rate shock contribute 63–79% of the variances of output and hours at horizons of 4–20 quarters. While much more work should be done exploring the plausibility of the identifying assumptions, testing the robustness of these shock estimates, and making sure that they do satisfy the properties a shock should satisfy, these results suggest that we are indeed closer to understanding Slutsky's random shocks that drive macroeconomic fluctuations.

ACKNOWLEDGMENTS

I wish to thank John Cochrane, Marco Del Negro, Graham Elliott, Neville Francis, Marc Giannoni, Robert Hall, Arvind Krishnamurthy, Kurt Lunsford, Karel Mertens, Christina Romer, David Romer, James Stock, John Taylor, Harald Uhlig, Mark Watson, Johannes Wieland, and participants at the Stanford Handbook of Macro conference and NBER Monetary Economics conference for very helpful discussions. I am grateful to the numerous authors who sent their estimated technology shocks and to Shihan Xie for providing her updated FAVAR factors. I would also like to express appreciation to the American Economic Association for requiring that all data and programs for published articles be posted. In addition, I am grateful to researchers who publish in journals without that requirement but still post their data and programs on their websites.

Abstract

Many economic time series exhibit dramatic breaks associated with events such as economic recessions, financial panics, and currency crises. Such changes in regime may arise from tipping points or other nonlinear dynamics and are core to some of the most important questions in macroeconomics. This chapter surveys the literature for studying regime changes and summarizes available methods. Section 1 introduces some of the basic tools for analyzing such phenomena, using for illustration the move of an economy into and out of recession. Section 2 focuses on empirical methods, providing a detailed overview of econometric analysis of time series that are subject to changes in regime. Section 3 discusses theoretical treatment of macroeconomic models with changes in regime and reviews applications in a number of areas of macroeconomics. Some brief concluding recommendations for applied researchers are offered in Section 4.

1. INTRODUCTION: ECONOMIC RECESSIONS AS CHANGES IN REGIME

Fig. 1 plots the US unemployment rate since World War II. Shaded regions highlight a feature of the data that is very familiar to macroeconomists—periodically the US economy enters an episode in which the unemployment rate rises quite rapidly. These shaded regions correspond to periods that the Dating Committee of the National Bureau of Economic Research chose to designate as economic recessions. But what exactly does such a designation signify?

One view is that the statement that the economy has entered a recession does not have any intrinsic objective meaning. According to this view, the economy is always subject to unanticipated shocks, some favorable, others unfavorable. A recession is then held to be nothing more than a string of unusually bad shocks, with the bifurcation of the observed sample into periods of "recession" and "expansion," an essentially arbitrary way of summarizing the data.

Such a view is implicit in many theoretical models used in economics today insofar as it is a necessary implication of the linearity we often assume in order to make our models more tractable. But the convenience of linear models is not a good enough reason to assume that no fundamental changes in economic dynamics occur when the economy goes into a recession. For example, we understand reasonably well that in an expansion, GDP will rise more quickly at some times than others, depending on the pace of new technological innovations. But what exactly would we mean by a negative technology shock? The assumption that such events are just like technological improvements but

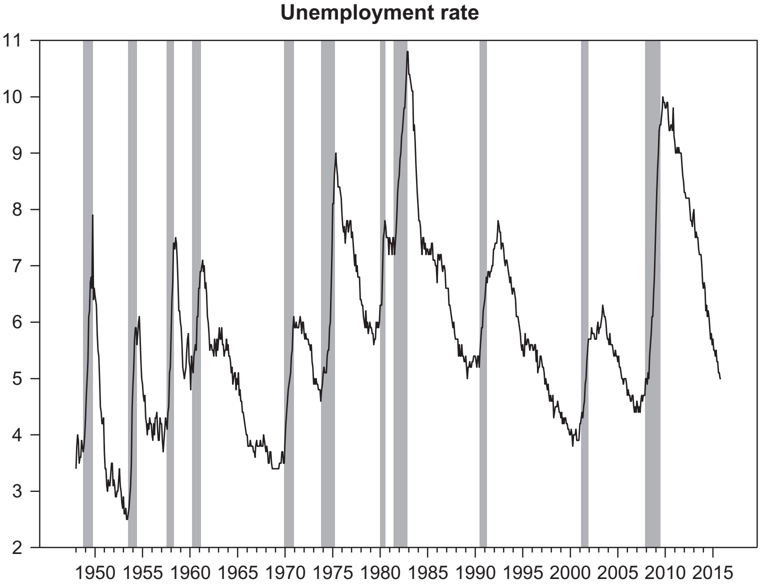

Fig. 1 US civilian unemployment rate, seasonally adjusted, 1948:M1–2015:M11. *Shaded regions* correspond to NBER recession dates.

with a negative sign does not seem like the place we should start if we are trying to understand what really happens during an economic downturn.

An alternative view is that on occasion some forces that are very different from the usual technological growth take over to determine employment and output, resulting for example when a simultaneous drop in product demand across different sectors and a rapid increase in unemployed workers introduce new feedbacks of their own. The idea that there might be a tipping point at which different economic dynamics begin to take over will be a recurrent theme in this chapter.

Let us begin with a very simple model with which we can explore some of the issues. We could represent the possibility that there are two distinct phases for the economy using the random variable s_t. When $s_t = 1$, the economy is in expansion in period t and when $s_t = 2$, the economy is in recession. Suppose that an observed variable y_t such as GDP growth has an average value of $m_1 > 0$ when $s_t = 1$ and average value $m_2 < 0$ when $s_t = 2$, as in

$$y_t = m_{s_t} + \varepsilon_t \tag{1}$$

where $\varepsilon_t \sim$ i.i.d. $N(0,\sigma^2)$. Suppose that the transition between regimes is governed by a Markov chain that is independent of ε_t,

$$\text{Prob}(s_t = j | s_{t-1} = i, s_{t-2} = k, \ldots, y_{t-1}, y_{t-2}, \ldots) = p_{ij} \qquad i, j = 1, 2. \tag{2}$$

Note that if both s_t and ε_t were observed directly, (1)–(2) in fact could still be described as a linear process. We can verify directly from (2) that[a]

$$E(m_{s_t}|m_{s_{t-1}}, m_{s_{t-2}}, \ldots) = a + \phi m_{s_{t-1}} \tag{3}$$

where $a = p_{21}m_1 + p_{12}m_2$ and $\phi = p_{11} - p_{21}$. In other words, m_{s_t} follows an AR(1) process,

$$m_{s_t} = a + \phi m_{s_{t-1}} + v_t. \tag{4}$$

The innovation v_t can take on only one of four possible values (depending on the realization of s_t and s_{t-1}) but by virtue of (3), v_t can be characterized as a martingale difference sequence.

Suppose however that we do not observe s_t and ε_t directly, but only have observations of GDP up through date $t-1$ (denoted $\Omega_{t-1} = \{y_{t-1}, y_{t-2}, \ldots\}$) and want to forecast the value of y_t. Notice from Eq. (1) that y_t is the sum of an AR(1) process (namely (4)) and a white noise process ε_t. Recall (eg, Hamilton, 1994, p. 108) that the result could be described as an ARMA(1,1) process. Thus the linear projection of GDP on its own lagged values is given by

$$\hat{E}(y_t|\Omega_{t-1}) = a + \phi y_{t-1} + \theta[y_{t-1} - \hat{E}(y_{t-1}|\Omega_{t-2})] \tag{5}$$

where θ is a known function of ϕ, σ^2, and the variance of v_t (Hamilton, 1994, eq. [4.7.12]). Note that we are using the notation $\hat{E}(y_t|\Omega_{t-1})$ to denote a linear projection (the forecast that produces the smallest mean squared error among the class of all linear functions of Ω_{t-1}) to distinguish it from the conditional expectation $E(y_t|\Omega_{t-1})$ (the forecast that produces the smallest mean squared error among the class of all functions of Ω_{t-1}).

Because of the discrete nature of s_t, the linear projection (5) would not yield the optimal forecast of GDP. We can demonstrate this using the law of iterated expectations (White, 1984, p. 54):

$$\begin{aligned} E(y_t|\Omega_{t-1}) &= \sum_{i=1}^{2} E(y_t|s_{t-1} = i, \Omega_{t-1})\text{Prob}(s_{t-1} = i|\Omega_{t-1}) \\ &= \sum_{i=1}^{2} (a + \phi m_i)\text{Prob}(s_{t-1} = i|\Omega_{t-1}). \end{aligned} \tag{6}$$

Because a probability is necessarily between 0 and 1, the optimal inference $\text{Prob}(s_{t-1} = i|\Omega_{t-1})$ is necessarily a nonlinear function of Ω_{t-1}. If data through $t-1$ have persuaded us that the economy was in expansion at that point, the optimal forecast is going to be close

[a] That is,

$$\begin{aligned} E(m_{s_{t+1}}|m_{s_t} = m_1) &= p_{11}m_1 + p_{12}m_2 = p_{11}m_1 + a - p_{21}m_1 = a + \phi m_1 \\ E(m_{s_{t+1}}|m_{s_t} = m_2) &= p_{21}m_1 + p_{22}m_2 = a - p_{12}m_2 + p_{22}m_2 = a - (1 - p_{11})m_2 + (1 - p_{21})m_2 = a + \phi m_2. \end{aligned}$$

to $a + \phi m_1$, whereas if we become convinced the economy was in recession, the optimal forecast approaches $a + \phi m_2$. It is in this sense that we could characterize (1) as a nonlinear process in terms of its observable implications for GDP.

Calculation of the nonlinear inference $\text{Prob}(s_{t-1} = i|\Omega_{t-1})$ is quite simple for this process. We could start for $t = 0$ for example with the ergodic probabilities of the Markov chain:

$$\text{Prob}(s_0 = 1|\Omega_0) = \frac{p_{21}}{p_{21} + p_{12}}$$

$$\text{Prob}(s_0 = 2|\Omega_0) = \frac{p_{12}}{p_{21} + p_{12}}.$$

Given a value for $\text{Prob}(s_{t-1} = i|\Omega_{t-1})$, we can arrive at the value for $\text{Prob}(s_t = j|\Omega_t)$ using Bayes's law:

$$\text{Prob}(s_t = j|\Omega_t) = \frac{\text{Prob}(s_t = j|\Omega_{t-1}) f(y_t|s_t = j, \Omega_{t-1})}{f(y_t|\Omega_{t-1})}. \tag{7}$$

Here $f(y_t|s_t = j, \Omega_{t-1})$ is the $N(m_j, \sigma^2)$ density,

$$f(y_t|s_t = j, \Omega_{t-1}) = \frac{1}{\sqrt{2\pi\sigma}} \exp\left[\frac{-(y_t - m_j)^2}{2\sigma^2}\right], \tag{8}$$

$\text{Prob}(s_t = j|\Omega_{t-1})$ is the predicted regime given past observations,

$$\text{Prob}(s_t = j|\Omega_{t-1}) = p_{1j}\text{Prob}(s_{t-1} = 1|\Omega_{t-1}) + p_{2j}\text{Prob}(s_{t-1} = 2|\Omega_{t-1}), \tag{9}$$

and $f(y_t|\Omega_{t-1})$ is the predictive density for GDP:

$$f(y_t|\Omega_{t-1}) = \sum_{i=1}^{2} \text{Prob}(s_t = i|\Omega_{t-1}) f(y_t|s_t = i, \Omega_{t-1}). \tag{10}$$

Given a value for $\text{Prob}(s_{t-1} = i|\Omega_{t-1})$, we can thus use (7) to calculate $\text{Prob}(s_t = j|\Omega_t)$, and proceed iteratively in this fashion through the data for $t = 1, 2, \ldots, T$ to calculate the necessary magnitude for forming the optimal nonlinear forecast given in (6).

Note that another by-product of this recursion is calculation in (10) of the predictive density for the observed data. Thus one could estimate the vector of unknown population parameters $\boldsymbol{\lambda} = (m_1, m_2, \sigma, p_{11}, p_{22})'$ by maximizing the log-likelihood function of the observed sample of GDP growth rates,

$$\mathcal{L}(\boldsymbol{\lambda}) = \sum_{t=1}^{T} \log f(y_t|\Omega_{t-1}; \boldsymbol{\lambda}). \tag{11}$$

If the objective is to form an optimal inference about when the economy was in a recession, one can use the same principles to obtain an even better inference as more data accumulate. For example, an inference using data observed through date $t + k$ about the regime at date t is known as a k-period-ahead smoothed inference,

$$\text{Prob}(s_t = i|\boldsymbol{\Omega}_{t+k}),$$

calculation of which will be explained in Eq. (22).

Though this is a trivially simple model, it seems to do a pretty good job at capturing what is being described by the NBER's business cycle chronology. If we select only those quarters for which the NBER declared the US economy to be in expansion, we calculate an average annual growth rate of 4.5%, suggesting a value for the parameter $m_1 = 4.5$. And we observe that if the NBER determined the economy to be in expansion in quarter t, 95% of the time it said the same thing in quarter $t + 1$, consistent with a value of $p_{11} = 0.95$. These values implied by the NBER chronology are summarized in column 3 of Table 1. On the other hand, if we ignore the NBER dates altogether, but simply maximize the log likelihood (11) of the observed GDP data alone, we end up with very similar estimates, as seen in column 4.

Moreover, even given the challenges of data revision, the one-quarter-ahead smoothed probabilities have an excellent out-of-sample record at tracking the NBER dates. Fig. 2 plots historical values for $\text{Prob}(s_t = 2|\boldsymbol{\Omega}_{t+1}, \hat{\boldsymbol{\lambda}}_{t+1})$ where only GDP data as they were actually released as of date $t + 1$ were used to estimate parameters and form the inference plotted for date t. Values before the vertical line are "simulated real-time" inferences from Chauvet and Hamilton (2006), that is, values calculated in 2005 using a separate historical real-time data vintage for each date t shown. Values after the vertical line are true real-time out-of-sample inferences as they have been published individually on www.econbrowser.com each quarter since 2005 without revision.

One attractive feature of this approach is that the linearity of the model conditional on s_t makes it almost as tractable as a fully linear model. For example, an optimal

Table 1 Parameter values for describing U.S. recessions

Parameter (1)	Interpretation (2)	Value from NBER classifications (3)	Value from GDP alone (4)
m_1	Average growth in expansion	4.5	4.62
m_2	Average growth in recession	−1.2	−0.48
σ	Standard deviation of growth	3.5	3.34
p_{11}	Prob. expansion continues	0.95	0.92
p_{22}	Prob. recession continues	0.78	0.74

Parameter estimates based on characteristics of expansions and recessions as classified by NBER (column 3), and values that maximize the observed sample log likelihood of postwar GDP growth rates (column 4), 1947:Q2–2004:Q2.

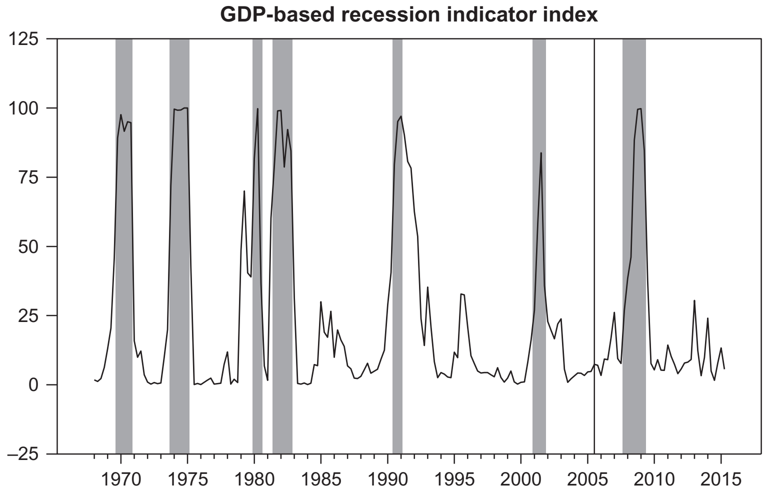

Fig. 2 One-quarter-ahead smoothed probabilities Prob$(s_t = 2|\Omega_{t+1}, \hat{\lambda}_{t+1})$, 1967:Q4–2014:Q2, as inferred using solely GDP data as reported as of date t + 1. *Shaded regions* correspond to NBER recession dates which were not used in any way in constructing the probabilities. Prior to 2005, each point on the graph corresponds to a simulated real-time inference that was constructed from a data set as it would have been available 4 months after the indicated date, as reported in Chauvet and Hamilton (2006). After 2005, points on the graph correspond to actual announcements that were publicly released 4 months after the indicated date. *Source: Updated from Hamilton, J.D., 2011. Calling recessions in real time. Int. J. Forecast. 27, 1006–1026 and www.econbrowser.com.*

k-period-ahead forecast of GDP growth based only on observed growth through date t can be calculated immediately using (4),

$$E(y_{t+k}|\Omega_t) = \mu + \phi^k \sum_{i=1}^{2} (m_i - \mu)\,\text{Prob}(s_t = i|\Omega_t) \tag{12}$$

for $\mu = a/(1-\phi)$. Results like this make this model of changes in regime very convenient to work with.

2. ECONOMETRIC TREATMENT OF CHANGES IN REGIME

This section discusses econometric inference for data that may be subject to changes in regime, while Section 3 examines methods to incorporate changes in regime into theoretical economic models.

2.1 Multivariate or Non-Gaussian Processes

Although the model in Section 1 was quite stylized, the same basic principles can be used to investigate changes in regime in much richer settings. Suppose we have a vector of variables $\mathbf{y}_t$ observed at date t and hypothesize that the density of $\mathbf{y}_t$ conditioned on its past history $\Omega_{t-1} = \{\mathbf{y}_{t-1}, \mathbf{y}_{t-2}, \ldots\}$ depends on parameters $\boldsymbol{\theta}$, some or all of which are different depending on the regime s_t:

$$f(\mathbf{y}_t | s_t = i, \Omega_{t-1}) = f(\mathbf{y}_t | \Omega_{t-1}; \boldsymbol{\theta}_i) \quad \text{for } i = 1, \ldots, N. \tag{13}$$

In the example in Section 1, there were $N = 2$ possible regimes with $\boldsymbol{\theta}_1 = (m_1, \sigma)'$, $\boldsymbol{\theta}_2 = (m_2, \sigma)'$, and $f(\mathbf{y}_t | \Omega_{t-1}; \boldsymbol{\theta}_i)$ the $N(m_i, \sigma^2)$ density. But the same basic approach would work for an n-dimensional vector autoregression in which some or all of the parameters change with the regime,

$$\begin{aligned} \mathbf{y}_t &= \boldsymbol{\Phi}_{s_t,1}\mathbf{y}_{t-1} + \boldsymbol{\Phi}_{s_t,2}\mathbf{y}_{t-2} + \cdots + \boldsymbol{\Phi}_{s_t,r}\mathbf{y}_{t-r} + \mathbf{c}_{s_t} + \boldsymbol{\varepsilon}_t \\ &= \boldsymbol{\Phi}_{s_t}\mathbf{x}_{t-1} + \boldsymbol{\varepsilon}_t \end{aligned} \tag{14}$$

$$\boldsymbol{\varepsilon}_t | s_t, \Omega_{t-1} \sim N(\mathbf{0}, \boldsymbol{\Sigma}_{s_t}), \tag{15}$$

a class of models discussed in detail in Krolzig (1997). Here $\mathbf{x}_{t-1}$ is an $(nr + 1) \times 1$ vector consisting of a constant term and r lags of $\mathbf{y}$:

$$\mathbf{x}_{t-1} = (\mathbf{y}'_{t-1}, \mathbf{y}'_{t-2}, \ldots, \mathbf{y}'_{t-r}, 1)'.$$

In this case the density of $\mathbf{y}_t$ conditional on its own past values and the regime s_t taking the value i would be

$$f(\mathbf{y}_t | s_t = i, \Omega_{t-1}) = \frac{1}{(2\pi)^{n/2} |\boldsymbol{\Sigma}_i|^{1/2}} \exp\left[-(1/2)(\mathbf{y}_t - \boldsymbol{\Phi}_i\mathbf{x}_{t-1})'\boldsymbol{\Sigma}_i^{-1}(\mathbf{y}_t - \boldsymbol{\Phi}_i\mathbf{x}_{t-1})\right]. \tag{16}$$

There is also no reason that a Gaussian density has to be used. For example, Dueker (1997) proposed a model of stock returns in which the innovation comes from a Student t distribution whose degrees of freedom parameter η changes with the regime.

2.2 Multiple Regimes

A convenient representation for a model with $N > 2$ regimes is obtained by collecting the transition probabilities in a matrix $\mathbf{P}$ whose row j, column i element corresponds to p_{ij} (so that columns of $\mathbf{P}$ sum to unity). We likewise summarize the regime at date t by an $(N \times 1)$ vector $\boldsymbol{\xi}_t$ whose ith element is unity when $s_t = i$ and is zero otherwise—in other words, $\boldsymbol{\xi}_t$ corresponds to column s_t of $\mathbf{I}_N$. Notice that $E(\boldsymbol{\xi}_t | s_{t-1} = i)$ has the interpretation

$$E(\boldsymbol{\xi}_t | s_{t-1} = i) = \begin{bmatrix} \text{Prob}(s_t = 1 | s_{t-1} = i) \\ \vdots \\ \text{Prob}(s_t = N | s_{t-1} = i) \end{bmatrix} = \begin{bmatrix} p_{i1} \\ \vdots \\ p_{iN} \end{bmatrix}$$

meaning

$$E(\boldsymbol{\xi}_t | \boldsymbol{\xi}_{t-1}) = \mathbf{P}\boldsymbol{\xi}_{t-1}$$

and

$$\boldsymbol{\xi}_t = \mathbf{P}\boldsymbol{\xi}_{t-1} + \mathbf{v}_t$$

for $\mathbf{v}_t$ a discrete-valued martingale difference sequence whose elements always sum to zero. Thus the Markov chain admits a VAR(1) representation, with k-period-ahead regime probabilities conditional on the observed data $\boldsymbol{\Omega}_t$ given by

$$\begin{bmatrix} \text{Prob}(s_{t+k} = 1|\boldsymbol{\Omega}_t) \\ \vdots \\ \text{Prob}(s_{t+k} = N|\boldsymbol{\Omega}_t) \end{bmatrix} = \mathbf{P}^k \begin{bmatrix} \text{Prob}(s_t = 1|\boldsymbol{\Omega}_t) \\ \vdots \\ \text{Prob}(s_t = N|\boldsymbol{\Omega}_t) \end{bmatrix}. \tag{17}$$

Calculation of the moments and discussion of stationarity conditions for general processes subject to changes in regime can be found in Tjøstheim (1986), Yang (2000), Timmermann (2000), and Francq and Zakoïan (2001).

Although most applications assume a relatively small number of regimes, Sims and Zha (2006) used Bayesian prior information in a model with N as large as 10, while Calvet and Fisher (2004) estimated a model with thousands of regimes by imposing a functional restriction on the ways parameters vary across regimes.

2.3 Processes That Depend on Current and Past Regimes

In the original model proposed by Hamilton (1989) for describing economic recessions, the conditional density of GDP growth y_t was presumed to depend not just on the current regime but also on the r previous regimes:

$$y_t = m_{s_t} + \phi_1(y_{t-1} - m_{s_{t-1}}) + \phi_2(y_{t-2} - m_{s_{t-2}}) + \cdots + \phi_r(y_{t-r} - m_{s_{t-r}}) + \varepsilon_t. \tag{18}$$

While at first glance this might not appear to be a special case of the general formulation given in (13), this in fact is just a matter of representing (18) using the right notation. Taking $r = 1$ for illustration, define

$$s_t^* = \begin{cases} 1 & \text{when } s_t = 1 \text{ and } s_{t-1} = 1 \\ 2 & \text{when } s_t = 2 \text{ and } s_{t-1} = 1 \\ 3 & \text{when } s_t = 1 \text{ and } s_{t-1} = 2 \\ 4 & \text{when } s_t = 2 \text{ and } s_{t-1} = 2 \end{cases}.$$

Then s_t^* itself follows a four-state Markov chain with transition matrix

$$\mathbf{P}^* = \begin{bmatrix} p_{11} & 0 & p_{11} & 0 \\ p_{12} & 0 & p_{12} & 0 \\ 0 & p_{21} & 0 & p_{21} \\ 0 & p_{22} & 0 & p_{22} \end{bmatrix}$$

and the model (18) can indeed be viewed as a special case of (13), with for example

$$f(y_t|s_t^* = 2, \Omega_{t-1}) = \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left\{-\frac{[y_t - m_2 - \phi_1(y_{t-1} - m_1)]^2}{2\sigma^2}\right\}.$$

2.4 Inference About Regimes and Evaluating the Likelihood for the General Case

For any of the examples above we could collect the set of possible densities conditional on one of N different possible regimes in an $(N \times 1)$ vector $\boldsymbol{\eta}_t$ whose ith element is $f(\mathbf{y}_t|s_t = i, \Omega_{t-1}; \boldsymbol{\lambda})$ for $\Omega_{t-1} = \{\mathbf{y}_{t-1}, \mathbf{y}_{t-2}, \ldots, \mathbf{y}_1\}$ and $\boldsymbol{\lambda}$ a vector consisting of all the unknown population parameters. For example, for the Markov-switching vector autoregression the ith element of $\boldsymbol{\eta}_t$ is given by (16) and $\boldsymbol{\lambda}$ is a vector collecting the unknown elements of $\{\boldsymbol{\Phi}_1, \ldots, \boldsymbol{\Phi}_N, \boldsymbol{\Sigma}_1, \ldots, \boldsymbol{\Sigma}_N, \mathbf{P}\}$ for $\mathbf{P}$ the $(N \times N)$ matrix whose row j column i element is $\text{Prob}(s_{t+1} = j|s_t = i)$ (so columns of $\mathbf{P}$ sum to unity). We likewise can define the $(N \times 1)$ vector $\hat{\boldsymbol{\xi}}_{t|t}$ whose ith element is the probability $\text{Prob}(s_t = i|\Omega_t; \boldsymbol{\lambda})$. One goal is to take the inference $\hat{\boldsymbol{\xi}}_{t-1|t-1}$ and update it to calculate $\hat{\boldsymbol{\xi}}_{t|t}$ using the observation on $\mathbf{y}_t$.Hamilton (1994, p. 692) showed that this can be accomplished by calculating

$$\hat{\boldsymbol{\xi}}_{t|t-1} = \mathbf{P}\hat{\boldsymbol{\xi}}_{t-1|t-1}$$

$$\hat{\boldsymbol{\xi}}_{t|t} = \frac{(\hat{\boldsymbol{\xi}}_{t|t-1} \odot \boldsymbol{\eta}_t)}{\mathbf{1}'(\hat{\boldsymbol{\xi}}_{t|t-1} \odot \boldsymbol{\eta}_t)} \tag{19}$$

where $\mathbf{1}$ denotes an $(N \times 1)$ vector of ones and $\odot$ denotes element-by-element vector multiplication.

If the Markov chain is known to be ergodic, we could begin the recursion for $t = 1$ by setting $\hat{\boldsymbol{\xi}}_{1|0}$ to the vector of unconditional probabilities, which as in Hamilton (1994, p. 684) can be found from the $(N + 1)$th column of the matrix $(\mathbf{A}'\mathbf{A})^{-1}\mathbf{A}'$ for

$$\underset{(N+1)\times N}{\mathbf{A}} = \begin{bmatrix} \mathbf{I}_N - \mathbf{P} \\ \mathbf{1}' \end{bmatrix}. \tag{20}$$

Alternative options are to treat the initial probabilities as separate parameters,

$$\begin{bmatrix} \text{Prob}(s_1 = 1|\Omega_0) \\ \vdots \\ \text{Prob}(s_1 = N|\Omega_0) \end{bmatrix} = \begin{bmatrix} \rho_1 \\ \vdots \\ \rho_N \end{bmatrix}$$

where ρ_i could reflect prior beliefs (eg, $\rho_1 = 1$ if the analyst knows the sample begins in regime 1), complete ignorance ($\rho_i = 1/N$ for $i = 1, \ldots, N$), or $\boldsymbol{\rho}$ could be a separate vector of parameters also to be chosen by maximum likelihood. Any of the last three options is particularly attractive if the EM algorithm described in Section 2.5 or Gibbs sampler in

Section 2.8 are used, or if one wants to allow the possibility of a permanent regime shift which would mean that the Markov chain is not ergodic.

In a generalization of (10) and (11), the log-likelihood function for the observed data is naturally calculated as a by-product of the above recursion:

$$\mathcal{L}(\boldsymbol{\lambda}) = \sum_{t=1}^{T} \log f(\mathbf{y}_t | \boldsymbol{\Omega}_{t-1}; \boldsymbol{\lambda}) = \sum_{t=1}^{T} \log[\mathbf{1}'(\hat{\boldsymbol{\xi}}_{t|t-1} \odot \boldsymbol{\eta}_t)]. \tag{21}$$

From (17) the k-period-ahead forecast of the regime, $\text{Prob}(s_{t+k} = j | \boldsymbol{\Omega}_t; \boldsymbol{\lambda})$ is found from the jth element of $\mathbf{P}^k \hat{\boldsymbol{\xi}}_{t|t}$.

It is also often of interest to calculate an inference about the regime at date t conditional on the full set of all observations through the end of the sample T, known as the "smoothed probability." The smoothed $\text{Prob}(s_t = i | \boldsymbol{\Omega}_T; \boldsymbol{\lambda})$ is obtained from the ith element of $\hat{\boldsymbol{\xi}}_{t|T}$ which can be calculated as in Hamilton (1994, p. 694) by iterating backward for $t = T-1, T-2, \ldots, 1$ on

$$\hat{\boldsymbol{\xi}}_{t|T} = \hat{\boldsymbol{\xi}}_{t|t} \odot \{\mathbf{P}'[\hat{\boldsymbol{\xi}}_{t+1|T} (\div) \hat{\boldsymbol{\xi}}_{t+1|t}]\} \tag{22}$$

where $(\div)$ denotes element-by-element division.

2.5 EM Algorithm

The unknown parameters $\boldsymbol{\lambda}$ could be estimated by maximizing the likelihood function (21) using numerical search methods. Alternatively, Hamilton (1990) noted that the EM algorithm is often a convenient method for finding the maximum of the likelihood function. This algorithm is simplest if we treat the initial probabilities $\hat{\boldsymbol{\xi}}_{1|0}$ as a vector of free parameters $\boldsymbol{\rho}$ rather than using ergodic probabilities from (20). This section describes how the EM algorithm would be implemented for the case of an unrestricted Markov-switching VAR (14), in which case $\boldsymbol{\lambda}$ includes $\boldsymbol{\rho}$ along with the elements of $\{\boldsymbol{\Phi}_1, \ldots, \boldsymbol{\Phi}_N, \boldsymbol{\Sigma}_1, \ldots, \boldsymbol{\Sigma}_N, \mathbf{P}\}$. The EM algorithm is an iterative procedure for generating a sequence of estimates $\{\hat{\boldsymbol{\lambda}}^{(\ell)}\}$ where the algorithm guarantees that the log likelihood (21) evaluated at $\hat{\boldsymbol{\lambda}}^{(\ell+1)}$ is greater than or equal to that at $\hat{\boldsymbol{\lambda}}^{(\ell)}$. Iterating until convergence leads to a local maximum of the likelihood function.

To calculate the value of $\hat{\boldsymbol{\lambda}}^{(\ell+1)}$ we first use $\hat{\boldsymbol{\lambda}}^{(\ell)}$ in Eq. (22) to evaluate the smoothed probabilities $\text{Prob}(s_t = i | \boldsymbol{\Omega}_T; \hat{\boldsymbol{\lambda}}^{(\ell)})$ and also smoothed joint probabilities Prob $(s_t = i, s_{t+1} = j | \boldsymbol{\Omega}_T; \hat{\boldsymbol{\lambda}}^{(\ell)})$. The latter are obtained from the row i column j element of the $(N \times N)$ matrix[b]

[b] The row i column j element of this matrix corresponds to

$$\text{Prob}(s_t = i | \boldsymbol{\Omega}_t) \frac{\text{Prob}(s_{t+1} = j | \boldsymbol{\Omega}_T)}{\text{Prob}(s_{t+1} = j | \boldsymbol{\Omega}_t)} p_{ij}$$

which from equation [22.A.21] in Hamilton (1994) equals $\text{Prob}(s_t = i, s_{t+1} = j | \boldsymbol{\Omega}_T)$.

$$\{\hat{\boldsymbol{\xi}}_{t|t}(\hat{\boldsymbol{\lambda}}^{(\ell)})[\hat{\boldsymbol{\xi}}_{t+1|T}(\hat{\boldsymbol{\lambda}}^{(\ell)})(\div)(\hat{\mathbf{P}}^{(\ell)}\hat{\boldsymbol{\xi}}_{t|t}(\hat{\boldsymbol{\lambda}}^{(\ell)}))]'\}\odot\hat{\mathbf{P}}^{(\ell)'}. \tag{23}$$

We then use these smoothed probabilities to generate a new estimate $\hat{\boldsymbol{\rho}}^{(\ell+1)}$, whose ith element is obtained from $\text{Prob}(s_1=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})$, along with a new estimate $\hat{\mathbf{P}}^{(\ell+1)}$ whose row j column i element is given by

$$\hat{p}_{ij}^{(\ell+1)}=\frac{\sum_{t=1}^{T-1}\text{Prob}(s_t=i,s_{t+1}=j|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})}{\sum_{t=1}^{T-1}\text{Prob}(s_t=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})}.$$

Updated estimates of the VAR parameters for $i = 1,\ldots,N$ are given by

$$\hat{\boldsymbol{\Phi}}_i^{(\ell+1)}=\left(\sum_{t=1}^{T}\mathbf{y}_t\mathbf{x}_{t-1}'\text{Prob}(s_t=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})\right)\left(\sum_{t=1}^{T}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\text{Prob}(s_t=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})\right)^{-1} \tag{24}$$

$$\hat{\boldsymbol{\Sigma}}_i^{(\ell+1)}=\frac{\sum_{t=1}^{T}(\mathbf{y}_t-\hat{\boldsymbol{\Phi}}_i^{(\ell+1)}\mathbf{x}_{t-1})(\mathbf{y}_t-\hat{\boldsymbol{\Phi}}_i^{(\ell+1)}\mathbf{x}_{t-1})'\text{Prob}(s_t=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})}{\sum_{t=1}^{T}\text{Prob}(s_t=i|\Omega_T;\hat{\boldsymbol{\lambda}}^{(\ell)})}.$$

We thus simply iterate between calculating smoothed probabilities and OLS regressions of $\mathbf{y}_t$ on its lags weighted by those smoothed probabilities. The algorithm will converge to a point that is at least a local maximum of the log likelihood (21) with respect to $\boldsymbol{\lambda}$ subject to the constraints that $\boldsymbol{\rho}'\mathbf{1}=1, \mathbf{1}'\mathbf{P}=\mathbf{1}'$, all elements of $\boldsymbol{\rho}$ and $\mathbf{P}$ are nonnegative, and $\boldsymbol{\Sigma}_j$ is positive semidefinite for $j = 1,\ldots,N$.

2.6 EM Algorithm for Restricted Models

Often we might want to use a more parsimonious representation to which the EM algorithm is easily adapted. For example, suppose that we assume that there are no changes in regime for the equations describing the first n_1 variables in the system:

$$\mathbf{y}_{1t}=\mathbf{A}\mathbf{x}_{t-1}+\boldsymbol{\varepsilon}_{1t} \tag{25}$$

$$\mathbf{y}_{2t}=\mathbf{B}_{s_t}\mathbf{x}_{t-1}+\boldsymbol{\varepsilon}_{2t} \tag{26}$$

$$E\left\{\begin{bmatrix}\boldsymbol{\varepsilon}_{1t}\\ \boldsymbol{\varepsilon}_{2t}\end{bmatrix}\begin{bmatrix}\boldsymbol{\varepsilon}_{1t}' & \boldsymbol{\varepsilon}_{2t}'\end{bmatrix}\middle| s_t\right\}=\begin{bmatrix}\boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12,s_t}\\ \boldsymbol{\Sigma}_{21,s_t} & \boldsymbol{\Sigma}_{22,s_t}\end{bmatrix}.$$

As in Hamilton (1994, p. 310) it is convenient to reparameterize the system by premultiplying (25) by $\boldsymbol{\Sigma}_{21,s_t}\boldsymbol{\Sigma}_{11}^{-1}$ and subtracting the result from (26) to obtain

$$\mathbf{y}_{2t}=\mathbf{C}_{s_t}\mathbf{y}_{1t}+\mathbf{D}_{s_t}\mathbf{x}_{t-1}+\mathbf{v}_{2t} \tag{27}$$

where $\mathbf{C}_{s_t}=\boldsymbol{\Sigma}_{21,s_t}\boldsymbol{\Sigma}_{11}^{-1}$, $\mathbf{D}_{st}=\mathbf{B}_{s_t}-\boldsymbol{\Sigma}_{21,s_t}\boldsymbol{\Sigma}_{11}^{-1}\mathbf{A}$, $\mathbf{v}_{2t}=\boldsymbol{\varepsilon}_{2t}-\boldsymbol{\Sigma}_{21,s_t}\boldsymbol{\Sigma}_{11}^{-1}\boldsymbol{\varepsilon}_{1t}$, and $E(\mathbf{v}_{2t}\mathbf{v}_{2t}'|s_t)=\mathbf{H}_{s_t}=\boldsymbol{\Sigma}_{22,s_t}-\boldsymbol{\Sigma}_{21,s_t}\boldsymbol{\Sigma}_{11}^{-1}\boldsymbol{\Sigma}_{12,s_t}$. Then the likelihood associated with the system (25) and (27) factors into a regime-switching component and a regime-independent component parameterized by $\mathbf{A}, \boldsymbol{\Sigma}_{11}$. In the absence of restrictions on $\mathbf{B}_{s_t}$, $\boldsymbol{\Sigma}_{21,s_t}$, and $\boldsymbol{\Sigma}_{22,s_t}$, the values for $\mathbf{A}$ and $\boldsymbol{\Sigma}_{11}$ do not restrict the likelihood for the regime-switching block, meaning full-information maximum likelihood for the complete system can be implemented by maximizing the likelihood separately for the two blocks. For the regime-independent block, the MLE is obtained by simple OLS:

$$\hat{\mathbf{A}} = \left(\sum_{t=1}^{T} \mathbf{y}_{1t}\mathbf{x}'_{t-1}\right)\left(\sum_{t=1}^{T} \mathbf{x}_{t-1}\mathbf{x}'_{t-1}\right)^{-1}$$

$$\hat{\Sigma}_{11} = T^{-1}\sum_{t=1}^{T}(\mathbf{y}_{1t} - \hat{\mathbf{A}}\boldsymbol{x}_{t-1})(\mathbf{y}_{1t} - \hat{\mathbf{A}}\boldsymbol{x}_{t-1})'.$$

The MLE for the regime-switching block can be found using the EM algorithm,

$$\hat{\mathbf{G}}_i^{(\ell+1)} = \left(\sum_{t=1}^{T} \mathbf{y}_{2t}\mathbf{z}'_t p_{it}^{(\ell)}\right)\left(\sum_{t=1}^{T} \mathbf{z}_t\mathbf{z}'_t p_{it}^{(\ell)}\right)^{-1}$$

$$\hat{\mathbf{H}}_i^{(\ell+1)} = \frac{\left(\sum_{t=1}^{T}(\mathbf{y}_{2t} - \hat{\mathbf{G}}_i^{(\ell+1)}\mathbf{z}_t)(\mathbf{y}_{2t} - \hat{\mathbf{G}}_i^{(\ell+1)}\mathbf{z}_t)' p_{it}^{(\ell)}\right)}{\left(\sum_{t=1}^{T} p_{it}^{(\ell)}\right)}$$

$$p_{it}^{(\ell)} = \text{Prob}(s_t = i|\boldsymbol{\Omega}_T;\hat{\boldsymbol{\lambda}}^{(\ell)})$$

with $\mathbf{z}_t = (\mathbf{y}'_{1t}, \mathbf{x}'_{t-1})'$ and $\mathbf{G}_j = \left[\mathbf{C}_j \quad \mathbf{D}_j\right]$. The MLE for the original parameterization is then found simply by reversing the transformation that led to (27), for example, $\hat{\boldsymbol{\Sigma}}_{21,j} = \hat{\mathbf{C}}_j\hat{\boldsymbol{\Sigma}}_{11}$ and $\hat{\mathbf{B}}_j = \hat{\mathbf{D}}_j + \hat{\boldsymbol{\Sigma}}_{21,j}\hat{\boldsymbol{\Sigma}}_{11}^{-1}\hat{\mathbf{A}}$.

Alternatively, suppose we want to restrict the switching coefficients to apply only to a subset $\mathbf{x}_{2,t-1}$ of the original regressors, as for example in a VAR in which only the intercept (the last element of $\mathbf{x}_{t-1}$) is changing with regime,

$$\mathbf{y}_t = \mathbf{A}\mathbf{x}_{1,t-1} + \mathbf{B}_{s_t}\mathbf{x}_{2,t-1} + \boldsymbol{\varepsilon}_t \tag{28}$$

with $E(\boldsymbol{\varepsilon}_t\boldsymbol{\varepsilon}'_t) = \boldsymbol{\Sigma}$. In this case the EM equations take the form[c]

$$\left[\hat{\mathbf{A}}^{(\ell+1)} \quad \hat{\mathbf{B}}_1^{(\ell+1)} \quad \hat{\mathbf{B}}_2^{(\ell+1)} \quad \cdots \quad \hat{\mathbf{B}}_N^{(\ell+1)}\right] = \mathbf{S}_{yx}(\hat{\boldsymbol{\lambda}}^{(\ell)})\mathbf{S}_{xx}^{-1}(\hat{\boldsymbol{\lambda}}^{(\ell)}) \tag{29}$$

$$\mathbf{S}_{yx}(\hat{\boldsymbol{\lambda}}^{(\ell)}) = \sum_{t=1}^{T}\mathbf{y}_t\left[\mathbf{x}'_{1,t-1} \quad \mathbf{x}'_{2,t-1}p_{1t}^{(\ell)} \quad \mathbf{x}'_{2,t-1}p_{2t}^{(\ell)} \quad \cdots \quad \mathbf{x}'_{2,t-1}p_{Nt}^{(\ell)}\right]$$

[c] See the Appendix for more details.

$$\mathbf{S}_{xx}(\hat{\boldsymbol{\lambda}}^{(\ell)}) = \sum_{t=1}^{T} \begin{bmatrix} \mathbf{x}_{1,t-1}\mathbf{x}'_{1,t-1} & \mathbf{x}_{1,t-1}\mathbf{x}'_{2,t-1}p_{1t}^{(\ell)} & \mathbf{x}_{1,t-1}\mathbf{x}'_{2,t-1}p_{2t}^{(\ell)} & \cdots & \mathbf{x}_{1,t-1}\mathbf{x}'_{2,t-1}p_{Nt}^{(\ell)} \\ \mathbf{x}_{2,t-1}\mathbf{x}'_{1,t-1}p_{1t}^{(\ell)} & \mathbf{x}_{2,t-1}\mathbf{x}'_{2,t-1}p_{1t}^{(\ell)} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{x}_{2,t-1}\mathbf{x}'_{1,t-1}p_{2t}^{(\ell)} & \mathbf{0} & \mathbf{x}_{2,t-1}\mathbf{x}'_{2,t-1}p_{2t}^{(\ell)} & \cdots & \mathbf{0} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \mathbf{x}_{2,t-1}\mathbf{x}'_{1,t-1}p_{Nt}^{(\ell)} & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{x}_{2,t-1}\mathbf{x}'_{2,t-1}p_{Nt}^{(\ell)} \end{bmatrix}$$

$$\begin{aligned} \hat{\boldsymbol{\Sigma}}^{(\ell+1)} = {} & T^{-1}\sum_{i=1}^{N}\sum_{t=1}^{T}\left[\mathbf{y}_t - \hat{\mathbf{A}}^{(\ell+1)}\mathbf{x}_{1,t-1} - \hat{\mathbf{B}}_i^{(\ell+1)}\mathbf{x}_{2,t-1}\right] \\ & \times\left[\mathbf{y}_t - \hat{\mathbf{A}}^{(\ell+1)}\mathbf{x}_{1,t-1} - \hat{\mathbf{B}}_i^{(\ell+1)}\mathbf{x}_{2,t-1}\right]' p_{it}^{(\ell)}. \end{aligned} \tag{30}$$

2.7 Structural Vector Autoregressions and Impulse-Response Functions

A Gaussian structural vector autoregression takes the form

$$\mathbf{A}_{s_t}\mathbf{y}_t = \mathbf{B}_{s_t}\mathbf{x}_{t-1} + \mathbf{u}_t$$

where $\mathbf{x}_{t-1} = (\mathbf{y}'_{t-1}, \mathbf{y}'_{t-2}, \ldots, \mathbf{y}'_{t-r}, 1)'$ and $\mathbf{u}_t|s_t, \boldsymbol{\Omega}_{t-1} \sim N(\mathbf{0}, \mathbf{D}_{s_t})$. Here the elements of $\mathbf{u}_t$ are interpreted as different structural shocks which are identified by imposing certain restrictions on $\mathbf{A}_i$, $\mathbf{B}_i$, and $\mathbf{D}_i$. For example, the common Cholesky identification assumes that the structural equations are recursive, with $\mathbf{D}_i$ diagonal and $\mathbf{A}_i$ lower triangular with ones along the diagonal. For an identified structure we could estimate parameters by setting the ith element of $\boldsymbol{\eta}_t$ in (19) to

$$\eta_{it} = \frac{1}{(2\pi)^{n/2}}\frac{\sqrt{|\mathbf{A}_i|^2}}{\sqrt{|\mathbf{D}_i|}}\exp\left[-(1/2)(\mathbf{A}_i\mathbf{y}_t - \mathbf{B}_i\mathbf{x}_{t-1})'\mathbf{D}_i^{-1}(\mathbf{A}_i\mathbf{y}_t - \mathbf{B}_i\mathbf{x}_{t-1})\right]$$

and then choosing $\{\mathbf{A}_1,\ldots,\mathbf{A}_N,\mathbf{B}_1,\ldots,\mathbf{B}_N,\mathbf{D}_1,\ldots,\mathbf{D}_N,\mathbf{P}\}$ to maximize the likelihood (21).

A faster algorithm is likely to be obtained by first finding the MLEs $\{\hat{\boldsymbol{\Phi}}_1,\ldots,\hat{\boldsymbol{\Phi}}_N,\hat{\boldsymbol{\Sigma}}_1,\ldots,\hat{\boldsymbol{\Sigma}}_N,\hat{\mathbf{P}},\hat{\boldsymbol{\rho}}\}$ for the reduced form (14)–(15) using the EM algorithm in Section 2.5. If the model is just identified, we can just translate these into the implied structural parameters $\{\hat{\mathbf{A}}_1,\ldots,\hat{\mathbf{A}}_N,\hat{\mathbf{B}}_1,\ldots,\hat{\mathbf{B}}_N,\hat{\mathbf{D}}_1,\ldots,\hat{\mathbf{D}}_N,\mathbf{P},\hat{\rho}\}$, while for an overidentified model we could find the values for the structural parameters that are closest to the reduced form using minimum chi-square estimation (eg, Hamilton and Wu, 2012). For example, for the Cholesky formulation we would just find the Cholesky factorization $\hat{\mathbf{P}}_i\hat{\mathbf{P}}_i' = \hat{\Sigma}_i$ for each i. The row j column j element of $\hat{\mathbf{D}}_i$ is then the square of the row j column j element of $\hat{\mathbf{P}}_i$. Then $\hat{\mathbf{A}}_i = \hat{\mathbf{D}}_i^{1/2}\hat{\mathbf{P}}_i^{-1}$ and $\hat{\mathbf{B}}_i = \hat{\mathbf{A}}_i\hat{\boldsymbol{\Phi}}_i$.

Users of structural vector autoregressions are often interested in structural impulse-response functions, which in this case are functions of the regime at date t:

$$\mathbf{H}_{mj}=\frac{\partial E(\mathbf{y}_{t+m}|s_t=j,\boldsymbol{\Omega}_t)}{\partial \mathbf{u}_t'}=\frac{\partial E(\mathbf{y}_{t+m}|s_t=j,\boldsymbol{\Omega}_t)}{\partial \boldsymbol{\varepsilon}_t'}\frac{\partial \boldsymbol{\varepsilon}_t}{\partial \mathbf{u}_t'}=\boldsymbol{\Psi}_{mj}\mathbf{A}_j^{-1}.$$

The nonorthogonalized or reduced-form IRF, $\boldsymbol{\Psi}_{mj}$, can be found as follows. Suppose we first condition not just on the regime j at date t but also on a particular regime j_1 for date $t+1, j_2$ for $t+2$, and j_m for $t+m$, and consider the value of

$$\tilde{\boldsymbol{\Psi}}_{m,j,j_1,\ldots,j_m}=\frac{\partial E(\mathbf{y}_{t+m}|s_t=j,s_{t+1}=j_1,\ldots,s_{t+m}=j_m,\boldsymbol{\Omega}_t)}{\partial \boldsymbol{\varepsilon}_t'}.$$

Karamé (2010) noted that this $(n \times n)$ matrix can be calculated from the recursion

$$\tilde{\boldsymbol{\Psi}}_{m,j,j_1,\ldots,j_m}=\boldsymbol{\Phi}_{1,j_m}\tilde{\boldsymbol{\Psi}}_{m-1,j,j_1,\ldots,j_{m-1}}+\boldsymbol{\Phi}_{2,j_m}\tilde{\boldsymbol{\Psi}}_{m-2,j,j_1,\ldots,j_{m-2}}+\cdots+\boldsymbol{\Phi}_{r,j_m}\tilde{\boldsymbol{\Psi}}_{m-r,j,j_1,\ldots,j_{m-r}}$$

for $m=1,2,\ldots$ where $\tilde{\boldsymbol{\Psi}}_{0j}=\mathbf{I}_n$ and $\mathbf{0}=\tilde{\boldsymbol{\Psi}}_{-1,.}=\tilde{\boldsymbol{\Psi}}_{-2,.}=\cdots$. The object of interest is found by integrating out the conditioning variables,

$$\begin{aligned}\boldsymbol{\Psi}_{mj}&=\sum_{j_1=1}^{N}\cdots\sum_{j_m=1}^{N}\tilde{\boldsymbol{\Psi}}_{m,j,j_1,\ldots,j_m}\text{Prob}(s_{t+1}=j_1,\ldots,s_{t+m}=j_m|s_t=j)\\&=\sum_{j_1=1}^{N}\cdots\sum_{j_m=1}^{N}\tilde{\boldsymbol{\Psi}}_{m,j,j_1,\ldots,j_m}p_{j,j_1}p_{j_1,j_2}\cdots p_{j_{m-1},j_m}.\end{aligned}$$

These magnitudes can either be calculated analytically for modest m and N or by simulation.

Such regime-specific impulse-response functions are of interest for questions such as whether monetary policy (Lo and Piger, 2005) or fiscal policy (Auerbach and Gorodnichenko, 2012) has different effects on the economy during an expansion or recession.

2.8 Bayesian Inference and the Gibbs Sampler

Bayesian methods offer another popular approach for econometric inference. The Bayesian begins with prior beliefs about the unknown parameters $\boldsymbol{\lambda}$ which are represented using a probability density $f(\boldsymbol{\lambda})$ that associates a higher probability with values of $\boldsymbol{\lambda}$ that are judged to be more plausible. The goal of inference is to revise these beliefs in the form of a posterior density $f(\boldsymbol{\lambda}|\boldsymbol{\Omega}_T)$ based on the observed data $\boldsymbol{\Omega}_T=\{\mathbf{y}_1,\ldots,\mathbf{y}_T\}$. Often the prior distribution $f(\boldsymbol{\lambda})$ is assumed to be taken from a particular parametric family known as a natural conjugate distribution. These have the property that the prior and posterior are from the same family, as would be the case for example if the prior beliefs were based on an earlier sample of data. Natural conjugates are helpful because they allow many of the results to be obtained using known analytic solutions.

Again we will illustrate some of the main ideas using a Markov-switching vector autoregression:

$$\mathbf{y}_t=\boldsymbol{\Phi}_{s_t}\mathbf{x}_{t-1}+\boldsymbol{\varepsilon}_t$$

$$\boldsymbol{\varepsilon}_t | s_t = i \sim N(\mathbf{0}, \boldsymbol{\Sigma}_i)$$
$$\text{Prob}(s_1 = i) = \rho_i$$
$$\text{Prob}(s_t = j | s_{t-1} = i) = p_{ij}.$$

2.8.1 Prior Distributions

The Dirichlet distribution is the natural conjugate for the parameters that determine the Markov transition probabilities. Suppose $\mathbf{z} = (z_1, \ldots, z_N)'$ is an $(N \times 1)$ vector of nonnegative random variables that sum to unity. The Dirichlet density with parameter $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_N)'$ is given by

$$f(\mathbf{z}) = \frac{\Gamma(\alpha_1 + \cdots + \alpha_N)}{\Gamma(\alpha_1) \cdots \Gamma(\alpha_N)} z_1^{\alpha_1 - 1} \cdots z_N^{\alpha_N - 1}$$

for $\Gamma(.)$ the gamma function, with the constant ensuring that the density integrates to unity over the set of vectors $\mathbf{z}$ satisfying the specified conditions. The beta distribution is a special case when $N = 2$, usually expressed as a function of the scalar $z_1 \in (0,1)$,

$$f(z_1) = \frac{\Gamma(\alpha_1 + \alpha_2)}{\Gamma(\alpha_1)\Gamma(\alpha_2)} z_1^{\alpha_1 - 1}(1 - z_1)^{\alpha_2 - 1}.$$

We then represent prior beliefs over the $(N \times 1)$ vector of initial probabilities as $(\rho_1, \ldots, \rho_N) \sim D(\alpha_1, \ldots, \alpha_N)$ and those for transition probabilities as $(p_{i1}, \ldots, p_{iN}) \sim D(\alpha_{i1}, \ldots, \alpha_{iN})$ for $i = 1, \ldots, N$. The natural conjugate for $\boldsymbol{\Sigma}_j$, the innovation variance matrix for regime j, is provided by the Wishart distribution. Let $\mathbf{z}_i$ be independent $(n \times 1)$ $N(\mathbf{0}, \boldsymbol{\Lambda}^{-1})$ vectors and consider the matrix $\mathbf{W} = \mathbf{z}_1\mathbf{z}_1' + \cdots + \mathbf{z}_\eta \mathbf{z}_\eta'$ for $\eta > n - 1$. This matrix is said to have an n-dimensional Wishart distribution with η degrees of freedom and scale matrix $\boldsymbol{\Lambda}^{-1}$, whose density is

$$f(\mathbf{W}) = c|\boldsymbol{\Lambda}|^{\eta/2}|\mathbf{W}|^{(\eta - n - 1)/2} \exp[-(1/2)\text{tr}(\mathbf{W}\boldsymbol{\Lambda})]$$

where tr(.) denotes the trace (sum of diagonal elements). For a univariate regression ($n = 1$) this becomes Λ^{-1} times a $\chi^2(\eta)$ variable, or equivalently a gamma distribution with mean η/Λ and variance $2\eta/\Lambda^2$. The constant c is chosen so that the density integrates to unity over the set of all positive definite symmetric matrices $\mathbf{W}$ (eg, DeGroot, 1970, p. 57):

$$c = \left[2^{\eta n/2} \pi^{n(n-1)/4} \prod_{j=1}^{n} \Gamma\left(\frac{\eta + 1 - j}{2}\right) \right]^{-1}.$$

The natural conjugate prior for $\boldsymbol{\Sigma}_j^{-1}$, the inverse of the innovation variance matrix in regime j, takes the form of a Wishart distribution with η_j degrees of freedom and scale $\boldsymbol{\Lambda}_j^{-1}$:

$$f(\mathbf{\Sigma}_j^{-1}) = c|\mathbf{\Lambda}_j|^{\eta_j/2}|\mathbf{\Sigma}_j|^{-(\eta_j-n-1)/2}\exp\left[-(1/2)\mathrm{tr}\left(\mathbf{\Sigma}_j^{-1}\mathbf{\Lambda}_j\right)\right].$$

Prior information about the regression coefficients $\boldsymbol{\varphi}_j = \mathrm{vec}(\mathbf{\Phi}_j')$ for regime j can be represented with an $N(\mathbf{m}_j,\mathbf{M}_j)$ distribution. The formulas are much simpler in the case of no useful prior information about these coefficients (which can be viewed as the limit of the inference as $\mathbf{M}_j^{-1} \to \mathbf{0}$), and this limiting case will be used for the results presented here.

2.8.2 Likelihood Function and Conditional Posterior Distributions

Collect the parameters that characterize Markov probabilities in a set $p = \{\rho_j, p_{1j}, \ldots, p_{Nj}\}_{j=1}^{N}$, those for variances in a set $\sigma = \{\mathbf{\Sigma}_1,\ldots,\mathbf{\Sigma}_N\}$, and VAR coefficients $\varphi = \{\mathbf{\Phi}_1,\ldots,\mathbf{\Phi}_N\}$. If we were to condition on all of these parameters along with a particular numerical value for the realization of the regime for every date $\mathcal{S} = \{s_1, \ldots, s_T\}$ the likelihood function of the observed data $\mathbf{\Omega}_T = \{\mathbf{y}_1,\ldots,\mathbf{y}_T\}$ would be

$$f(\Omega_T|p,\sigma,\varphi,\mathcal{S}) = \prod_{t=1}^{T}\frac{1}{(2\pi)^{n/2}}|\mathbf{\Sigma}_{s_t}|^{-1/2}\exp\left[-(1/2)(\mathbf{y}_t - \mathbf{\Phi}_{s_t}\mathbf{x}_{t-1})'\mathbf{\Sigma}_{s_t}^{-1}(\mathbf{y}_t - \mathbf{\Phi}_{s_t}\mathbf{x}_{t-1})\right]$$

$$= \prod_{t=1}^{T}\frac{1}{(2\pi)^{n/2}}\sum_{j=1}^{N}\delta_{jt}|\mathbf{\Sigma}_j|^{-1/2}\exp\left[-(1/2)(\mathbf{y}_t - \mathbf{\Phi}_j\mathbf{x}_{t-1})'\mathbf{\Sigma}_j^{-1}(\mathbf{y}_t - \mathbf{\Phi}_j\mathbf{x}_{t-1})\right]$$

where $\delta_{jt} = 1$ if $s_t = j$ and is zero otherwise. With independent priors the joint density of the data, parameters, and regimes is then

$$f(\Omega_T, p, \sigma, \varphi, \mathcal{S}) = f(\Omega_T|p,\sigma,\varphi,\mathcal{S})f(p)f(\sigma)f(\varphi)f(\mathcal{S}|p) \tag{31}$$

$$f(p) \propto \prod_{j=1}^{N}\rho_j^{\alpha_j-1}p_{1j}^{\alpha_{1j}-1}\cdots p_{Nj}^{\alpha_{Nj}-1}$$

$$f(\sigma) \propto \prod_{j=1}^{N}|\mathbf{\Sigma}_j|^{-(\eta_j-n-1)/2}\exp\left[-(1/2)\mathrm{tr}\left(\mathbf{\Sigma}_j^{-1}\mathbf{\Lambda}_j\right)\right]$$

$$f(\varphi) \propto 1$$

$$f(\mathcal{S}|p) = \rho_{s_1}p_{s_1,s_2}p_{s_2,s_3}\cdots p_{s_{T-1},s_T}$$

where p_{s_{t-1},s_t} denotes the parameter p_{ij} when $s_{t-1} = i$ and $s_t = j$.

Let $\Delta(j) = \{t \in 1,\ldots,T : \delta_{jt} = 1\}$ denote the set of dates for which the regime is j. From (31) the posterior distribution of $\mathbf{\Sigma}_j$ conditional on $\mathbf{\Omega}_T, p, \varphi, \mathcal{S}$ is given by

$$
\begin{aligned}
f(\Sigma_j^{-1}|\Omega_T,p,\varphi,\mathcal{S}) \propto{}& |\boldsymbol{\Sigma}_j|^{-(\eta_j-n-1)/2}\exp\left[-(1/2)\mathrm{tr}\left(\boldsymbol{\Sigma}_j^{-1}\boldsymbol{\Lambda}_j\right)\right]\times \\
&\prod_{t\in\Delta(j)}|\boldsymbol{\Sigma}_j|^{-1/2}\exp[-(1/2)(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})'\boldsymbol{\Sigma}_j^{-1}(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})] \\
={}& |\boldsymbol{\Sigma}_j|^{-(T_j+\eta_j-n-1)/2}\exp[-(1/2)\mathrm{tr}[\boldsymbol{\Sigma}_j^{-1}(\boldsymbol{\Lambda}_j+\mathbf{H}_j)] \qquad (32)
\end{aligned}
$$

for $T_j=\sum_{t=1}^{T}\delta_{jt}$ the number of dates characterized by regime j and $\mathbf{H}_j=\sum_{t=1}^{T}\delta_{jt}(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})'$ the sum of outer products of the residual vectors for those observations. In other words, $\boldsymbol{\Sigma}_j^{-1}|\Omega_T,p,\varphi,\mathcal{S}$ has a Wishart distribution with $T_j+\eta_j$ degrees of freedom and scale matrix $(\boldsymbol{\Lambda}_j+\mathbf{H}_j)^{-1}$.

Likewise for $\hat{\boldsymbol{\Phi}}_j=\left(\sum_{t=1}^{T}\delta_{jt}\mathbf{y}_t\mathbf{x}_{t-1}'\right)\left(\sum_{t=1}^{T}\delta_{jt}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\right)^{-1}$, that is for $\hat{\boldsymbol{\Phi}}_j$ the OLS regression coefficients using only observations for regime j, the posterior distribution of $\boldsymbol{\varphi}_j=\mathrm{vec}(\boldsymbol{\Phi}_j')$ conditional on $\Omega_T,p,\sigma,\mathcal{S}$ is

$$
\begin{aligned}
f(\boldsymbol{\varphi}_j|\Omega_T,p,\sigma,\mathcal{S}) &\propto \prod_{t\in\Delta(j)}\exp[-(1/2)(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})'\boldsymbol{\Sigma}_j^{-1}(\mathbf{y}_t-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})] \\
&= \prod_{t\in\Delta(j)}\exp[-(1/2)(\mathbf{y}_t-\hat{\boldsymbol{\Phi}}_j\mathbf{x}_{t-1}+\hat{\boldsymbol{\Phi}}_j\mathbf{x}_{t-1}-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})'\boldsymbol{\Sigma}_j^{-1}\times \\
&\qquad (\mathbf{y}_t-\hat{\boldsymbol{\Phi}}_j\mathbf{x}_{t-1}+\hat{\boldsymbol{\Phi}}_j\mathbf{x}_{t-1}-\boldsymbol{\Phi}_j\mathbf{x}_{t-1})] \\
&\propto \prod_{t\in\Delta(j)}\exp[-(1/2)\mathbf{x}_{t-1}'(\hat{\boldsymbol{\Phi}}_j-\boldsymbol{\Phi}_j)'\boldsymbol{\Sigma}_j^{-1}(\hat{\boldsymbol{\Phi}}_j-\boldsymbol{\Phi}_j)\mathbf{x}_{t-1}] \\
&= \prod_{t\in\Delta(j)}\exp\{-(1/2)(\hat{\boldsymbol{\phi}}_j-\boldsymbol{\varphi}_j)'[\boldsymbol{\Sigma}_j^{-1}\otimes\mathbf{x}_{t-1}\mathbf{x}_{t-1}'](\hat{\boldsymbol{\phi}}_j-\boldsymbol{\varphi}_j)\} \\
&= \exp\left\{-(1/2)(\boldsymbol{\varphi}_j-\hat{\boldsymbol{\phi}}_j)'\left[\boldsymbol{\Sigma}_j\otimes\left(\sum_{t=1}^{T}\delta_{jt}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\right)^{-1}\right]^{-1}(\boldsymbol{\varphi}_j-\hat{\boldsymbol{\phi}}_j)\right\}
\end{aligned}
$$

establishing that $\boldsymbol{\varphi}_j|\Omega_T,p,\sigma,\mathcal{S}\sim N\left(\hat{\boldsymbol{\phi}}_j,\boldsymbol{\Sigma}_j\otimes\left(\sum_{t=1}^{T}\delta_{jt}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\right)^{-1}\right)$ for $\hat{\boldsymbol{\phi}}_j=\mathrm{vec}(\hat{\boldsymbol{\Phi}}_j')$.

The conditional posterior distribution of $\boldsymbol{\rho}$ is found from

$$
f(\boldsymbol{\rho}|\Omega_T,\varphi,\sigma,\mathcal{S})\propto\rho_1^{a_1-1}\cdots\rho_N^{\alpha_N-1}\rho_{s_t}
$$

which will be recognized as $D(\alpha_1+\delta_{11},\ldots,\alpha_N+\delta_{N1})$, in other words, a Dirichlet distribution in which we have increased the parameter associated with the realized regime for observation 1 by unity and kept all other parameters the same. We similarly have $(p_{i1},\ldots,p_{iN})|\Omega_T,\varphi,\sigma,\mathcal{S}\sim D(\alpha_{i1}+T_{i1},\ldots,\alpha_{iN}+T_{iN})$ for $T_{ij}=\sum_{t=2}^{T}\delta_{i,t-1}\delta_{jt}$ the number of times that regime i is followed by j in the given sequence $\mathcal{S}$.

2.8.3 Gibbs Sampler

The idea behind the Gibbs sampler is to take advantage of the above known conditional distributions to generate a sequence of random variables whose unconditional distribution will turn out to be the object we're interested in. Suppose that as the result of a previous iteration ℓ we had generated particular numerical values for $\varphi,\sigma,p,\mathcal{S}$. We could for example begin iteration $\ell=1$ with arbitrary initial guesses for the parameters along with a possible realization of the regime for each date. Given the numbers from iteration ℓ, we could generate $\mathbf{\Sigma}_j^{(\ell+1)}$ from expression (32), namely, $\mathbf{\Sigma}_j^{(\ell+1)}$ is the inverse of a draw from a Wishart distribution with $T_j^{(\ell)}+\eta_j$ degrees of freedom and scale matrix $\left(\mathbf{\Lambda}_j+\mathbf{H}_j^{(\ell)}\right)^{-1}$, where $T_j^{(\ell)}=\sum_{t=1}^{T}\delta_{jt}^{(\ell)}$ is a simple count of the number of elements in $\{s_1^{(\ell)},\ldots,s_T^{(\ell)}\}$ that take the value j and $\mathbf{H}_j^{(\ell)}$ is the sum of the residual outer products $\sum_{t=1}^{T}\delta_{jt}^{(\ell)}(\mathbf{y}_t-\mathbf{\Phi}_j^{(\ell)}\mathbf{x}_{t-1})$ $(\mathbf{y}_t-\mathbf{\Phi}_j^{(\ell)}\mathbf{x}_{t-1})'$ for those $T_j^{(\ell)}$ observations. Doing so for each $j=1,\ldots,N$ gives us the new $\sigma^{(\ell+1)}$. We get a new value for the VAR coefficients by generating $\boldsymbol{\varphi}_j^{(\ell+1)}\sim N\left(\hat{\boldsymbol{\varphi}}_j^{(\ell+1)},\mathbf{\Sigma}_j^{(\ell+1)}\otimes\left(\sum_{t=1}^{T}\delta_{jt}^{(\ell)}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\right)^{-1}\right)$ where $\hat{\boldsymbol{\varphi}}_j^{(\ell+1)}=\text{vec}\left[\hat{\mathbf{\Phi}}_j^{(\ell+1)'}\right]$ is obtained from OLS regression on these $T_j^{(\ell)}$ observations: $\hat{\mathbf{\Phi}}_j^{(\ell+1)}=\left(\sum_{t=1}^{T}\delta_{jt}^{(\ell)}\mathbf{y}_t\mathbf{x}_{t-1}'\right)$ $\left(\sum_{t=1}^{T}\delta_{jt}^{(\ell)}\mathbf{x}_{t-1}\mathbf{x}_{t-1}'\right)^{-1}$. New initial probabilities $(\rho_1^{(\ell+1)},\ldots,\rho_N^{(\ell+1)})$ are generated from $D(\alpha_1+\delta_{11}^{(\ell)},\ldots,\alpha_N+\delta_{N1}^{(\ell)})$ and new Markov probabilities $(p_{i1}^{(\ell+1)},\ldots,p_{iN}^{(\ell+1)})$ from $D(\alpha_{i1}+T_{i1}^{(\ell)},\ldots.,\alpha_{iN}+T_{iN}^{(\ell)})$ for $T_{ij}^{(\ell)}$ the number of times $s_t^{(\ell)}=i$ is followed by $s_{t+1}^{(\ell)}=j$ within the particular realization $(s_1^{(\ell)},\ldots,s_T^{(\ell)})$.

Finally, we can get a new realization $(s_1^{(\ell+1)},\ldots,s_T^{(\ell+1)})$ as a draw from the conditional posterior $f(\mathcal{S}|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$ by iterating backward on a variant of the smoothing algorithm in Section 2.4. Specifically, given the values $(p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$ we can iterate on (19) for $t=1,\ldots,T$ to calculate the $(N\times 1)$ vector $\{\hat{\boldsymbol{\xi}}_{t|t}^{(\ell+1)}\}_{t=1}^{T}$ whose jth element is $\text{Prob}(s_t=j|\Omega_t,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$. To generate $s_T^{(\ell+1)}$, we first generate a $U(0,1)$ variate. If this is smaller than the calculated $\text{Prob}(s_T=1|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$, we set $s_T^{(\ell+1)}=1$. If the uniform variable turns out to be between $\text{Prob}(s_T=1|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$ and the sum $\text{Prob}(s_T=1|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})+\text{Prob}(s_T=2|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})$, we set $s_T^{(\ell+1)}=2$, and so on. After we have generated a particular value for $s_T^{(\ell+1)}$ we can use (23) to calculate the probability

$$\begin{aligned}\text{Prob}(s_{T-1}&=i|s_T=s_T^{(\ell+1)},\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})=\\&\frac{\text{Prob}(s_{T-1}=i,s_T=s_T^{(\ell+1)}|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})}{\text{Prob}(s_T=s_T^{(\ell+1)}|\Omega_T,p^{(\ell+1)},\sigma^{(\ell+1)},\varphi^{(\ell+1)})}\end{aligned}$$

with which we generate a draw $s_{T-1}^{(\ell+1)}$. Iterating backward in this manner gives us the full sequence $\mathcal{S}^{(\ell+1)}$.

We now have a complete new set $p^{(\ell+1)}, \boldsymbol{\sigma}^{(\ell+1)}, \boldsymbol{\varphi}^{(\ell+1)}, \mathcal{S}^{(\ell+1)}$, from which we can then generate values for $\ell + 2, \ell + 3$, and so on. The idea behind the Gibbs sampler (eg, Albert and Chib, 1993) is that the sequence corresponds to a Markov chain whose ergodic distribution under general conditions is the true posterior distribution $f(p, \sigma, \varphi, \mathcal{S}|\Omega_T)$. The proposal is then to discard the first say 10^6 draws and retain the next 10^6 draws as a sample from the posterior distribution.

One can also adapt approaches like those in Section 2.6 to apply the Gibbs sampler to restricted models. For example, if regime switching is confined to a subset of the equations, we can use the parameterization (27) and perform inference on the regime-switching subset independently from the rest of the system.

Although very convenient for many applications, one caution to be aware of in applying the Gibbs sampler is the role of label switching. Strategies for dealing with this are discussed by Celeux et al. (2000), Frühwirth-Schnatter (2001), and Geweke (2007).

2.9 Time-Varying Transition Probabilities

While the calculations above assumed that regimes are characterized by an exogenous Markov chain, this is easily generalized. We could replace (2) with

$$\operatorname{Prob}(s_t = j | s_{t-1} = i, s_{t-2} = k, \ldots, \boldsymbol{\Omega}_{t-1}) = p_{ij}(\mathbf{x}_{t-1}; \boldsymbol{\lambda}) \quad i, j = 1, \ldots, N \tag{33}$$

where $\mathbf{x}_{t-1}$ is a subset of $\boldsymbol{\Omega}_{t-1}$ or other observed variables on which one is willing to condition and $p_{ij}(\mathbf{x}_{t-1}; \boldsymbol{\lambda})$ is a specified parametric function. The generalization of (9) then becomes

$$\operatorname{Prob}(s_t = j | \boldsymbol{\Omega}_{t-1}) = \sum_{i=1}^{N} p_{ij}(\mathbf{x}_{t-1}; \boldsymbol{\lambda}) \operatorname{Prob}(s_{t-1} = i | \boldsymbol{\Omega}_{t-1}),$$

where the sequence $\operatorname{Prob}(s_t = i | \boldsymbol{\Omega}_t)$ can still be calculated iteratively as in (7),

$$\operatorname{Prob}(s_t = j | \boldsymbol{\Omega}_t) = \frac{\operatorname{Prob}(s_t = j | \boldsymbol{\Omega}_{t-1}) f(\mathbf{y}_t | \boldsymbol{\Omega}_{t-1}; \boldsymbol{\theta}_j)}{f(\mathbf{y}_t | \boldsymbol{\Omega}_{t-1})} \tag{34}$$

with the predictive density in the denominator now

$$f(\mathbf{y}_t | \boldsymbol{\Omega}_{t-1}) = \sum_{i=1}^{N} \operatorname{Prob}(s_t = i | \boldsymbol{\Omega}_{t-1}) f(\mathbf{y}_t | \boldsymbol{\Omega}_{t-1}; \boldsymbol{\theta}_i). \tag{35}$$

Diebold et al. (1994) showed how the EM algorithm works in such a setting, while Filardo and Gordon (1998) developed a Gibbs sampler. Other interesting applications with time-varying transition probabilities include Filardo (1994) and Peria (2002).

2.10 Latent-Variable Models with Changes in Regime

A more involved case that cannot be handled using the above devices is when the conditional density of $\mathbf{y}_t$ depends on the full history of regimes $(s_t,s_{t-1},\ldots,s_1)$ through date t. One important case in which this arises is when a process moving in and out of recession phase is proposed as an unobserved latent variable influencing an $(n \times 1)$ vector of observed variables $\mathbf{y}_t$. For example, Chauvet (1998) specified a process for an unobserved scalar business-cycle factor F_t characterized by

$$F_t = \alpha_{s_t} + \phi F_{t-1} + \eta_t$$

which influences the observed $\mathbf{y}_t$ according to

$$\mathbf{y}_t = \boldsymbol{\psi} F_t + \mathbf{q}_t$$

for $\boldsymbol{\psi}$ an $(n \times 1)$ vector of factor loadings and elements of $\mathbf{q}_t$ presumed to follow separate autoregressions. This can be viewed as a state-space model with regime-dependent parameters in which the conditional density (13) turns out to depend on the complete history $(s_t,s_{t-1},\ldots,s_1)$.

One approach for handling such models is an approximation to the log likelihood and optimal inference developed by Kim (1994). Chauvet and Hamilton (2006) and Chauvet and Piger (2008) demonstrated the real-time usefulness of this approach for recognizing US recessions with $\mathbf{y}_t$ a (4×1) vector of monthly indicators of sales, income, employment, and industrial production, while Camacho et al. (2014) have had success using a more detailed model for the Euro area.

The Gibbs sampler offers a particularly convenient approach for this class of models. We simply add the unobserved sequence of factors $\{F_1,\ldots,F_T\}$ as another random block to be sampled from along with p,σ,φ, and $\mathcal{S}$. Conditional on $\{F_1,\ldots,F_T\}$, draws for those other blocks can be performed exactly as in Section 2.8, while draws for $\{F_1,\ldots,F_T\}$ conditional on the regimes and other parameters can be calculated using well-known algorithms associated with the Kalman filter; see Kim and Nelson (1999a) for details.

2.11 Selecting the Number of Regimes

Often one would want to test the null hypothesis that there are N regimes against the alternative of $N+1$, and in particular to test the null hypothesis that there are no changes in regime at all $(H_0 : N = 1)$. A natural idea would be to compare the values achieved for the log likelihood (21) for N and $N+1$. Unfortunately, the likelihood ratio does not have the usual asymptotic χ^2 distribution because under the null hypothesis, some of the parameters of the model become unidentified. For example, if one thought of the null hypothesis in (1) as $m_1 = m_2$, when the null is true the maximum likelihood estimates $\hat{p}_{11}$ and $\hat{p}_{22}$ do not converge to any population values. Hansen (1992) and Garcia (1998) examined the distribution of the likelihood ratio statistic in this setting, though implementing their procedures can be quite involved if the model is at all complicated. Cho and White (2007) and Carter and Steigerwald (2012, 2013) suggested quasi-likelihood ratio tests that ignore the Markov property of s_t. For discussion of some of the subtleties and possible solutions for the case of i.i.d. regime changes, see Hall and Stewart (2005) and Chen and Li (2009).

An alternative is to calculate instead general measures that trade off the fit of the likelihood against the number of parameters estimated. Popular methods such as Schwarz's (1978) Bayesian criterion rely for their asymptotic justification on the same regularity conditions whose failure causes the likelihood ratio statistic to have a nonstandard distribution. But Smith et al. (2006) developed a simple test that can be used to select the number of regimes for a Markov-switching regression,

$$y_t = \mathbf{x}_t' \boldsymbol{\beta}_{s_t} + \sigma_{s_t} \varepsilon_t \tag{36}$$

where $\varepsilon_t \sim N(0,1)$ and s_t follows an N-state Markov chain. The authors proposed to estimate the parameter vector $\boldsymbol{\lambda} = \left(\boldsymbol{\beta}_1', \ldots, \boldsymbol{\beta}_N', \sigma_1, \ldots, \sigma_N, p_{ij, i=1,\ldots,N; j=1,\ldots,N-1}\right)^{-1}$ by maximum likelihood for each possible choice of N and calculate

$$\hat{T}_i = \sum_{t=1}^{T} \text{Prob}(s_t = i | \boldsymbol{\Omega}_T; \hat{\boldsymbol{\lambda}}_{\text{MLE}}) \quad \text{for } i = 1, \ldots, N$$

using the full-sample smoothed probabilities. They suggested choosing the value of N for which

$$\text{MSC} = -2\mathcal{L}(\hat{\boldsymbol{\lambda}}_{\text{MLE}}) + \sum_{i=1}^{N} \frac{\hat{T}_i(\hat{T}_i + Nk)}{\hat{T}_i - Nk - 2}$$

is smallest, where k is the number of elements in the regression vector $\boldsymbol{\beta}$. Other alternatives are to use Bayesian methods to find the value of N that leads to the largest value for the marginal likelihood (Chib, 1998) or the highest Bayes factor (Koop and Potter, 1999).

Another promising test of the null hypothesis of no change in regime was developed by Carrasco et al. (2014). Let $\ell_t = \log f(y_t | \boldsymbol{\Omega}_{t-1}; \boldsymbol{\lambda})$ be the log of the predictive density of the tth observation under the null hypothesis of no switching. For the Markov-switching regression (36), $\boldsymbol{\lambda}$ would correspond to the fixed-regime regression coefficients and variance $(\boldsymbol{\beta}', \sigma^2)'$:

$$\ell_t = -(1/2)\log(2\pi\sigma^2) - \frac{(y_t - \mathbf{x}_t'\boldsymbol{\beta})^2}{2\sigma^2}.$$

Define $\mathbf{h}_t$ to be the derivative of the log density with respect to the parameter vector,

$$\mathbf{h}_t = \left.\frac{\partial \ell_t}{\partial \boldsymbol{\lambda}}\right|_{\boldsymbol{\lambda} = \hat{\boldsymbol{\lambda}}_0}$$

where $\hat{\boldsymbol{\lambda}}_0$ denotes the MLE under the null hypothesis of no change in regime. For example,

$$\mathbf{h}_t = \begin{bmatrix} \dfrac{(y_t - \mathbf{x}_t'\hat{\boldsymbol{\beta}})\mathbf{x}_t}{\hat{\sigma}^2} \\ -\dfrac{1}{2\hat{\sigma}^2} + \dfrac{(y_t - \mathbf{x}_t'\hat{\boldsymbol{\beta}})^2}{2\hat{\sigma}^4} \end{bmatrix}$$

where $\hat{\boldsymbol{\beta}} = \left(\sum_{t=1}^{T}\mathbf{x}_t\mathbf{x}_t'\right)^{-1}\left(\sum_{t=1}^{T}\mathbf{x}_t y_t\right)$ and $\hat{\sigma}^2 = T^{-1}\sum_{t=1}^{T}(\mathbf{y}_t - \mathbf{x}_t'\hat{\boldsymbol{\beta}})^2$. To implement the Carrasco et al. (2014) test of the null hypothesis of no change in regime against the alternative that the first element of $\boldsymbol{\beta}$ switches according to a Markov chain, let $\ell_t^{(1)}$ denote the first element of $\mathbf{h}_t$ and calculate

$$\ell_t^{(2)} = \left.\frac{\partial^2 \ell_t}{\partial \lambda_1^2}\right|_{\boldsymbol{\lambda}=\hat{\boldsymbol{\lambda}}_0}$$

$$\gamma_t(\rho) = \ell_t^{(2)} + \left[\ell_t^{(1)}\right]^2 + 2\sum_{s<t}\rho^{t-s}\ell_t^{(1)}\ell_s^{(1)}$$

where ρ is an unknown parameter characterizing the persistence of the Markov chain. We then regress $(1/2)\gamma_t(\rho)$ on $\mathbf{h}_t$, save the residuals $\hat{\varepsilon}_t(\rho)$, and calculate

$$C(\rho) = \frac{1}{2}\left[\max\left\{0, \frac{\sum_{t=1}^{T}\gamma_t(\rho)}{2\sqrt{\sum_{t=1}^{T}[\hat{\varepsilon}_t(\rho)]^2}}\right\}\right]^2.$$

We then find the value ρ^* that maximizes $C(\rho)$ over some range (eg, $\rho \in [0.2,0.8]$) and bootstrap to see if $C(\rho^*)$ is statistically significant. This is done by generating data with no changes in regime using the MLE $\boldsymbol{\lambda} = \hat{\lambda}_0$ and calculating $C(\rho^*)$ on each generated sample.

Another option is to conduct generic tests developed by Hamilton (1996) of the hypothesis that an N-regime model accurately describes the data. For example, if the model is correctly specified, the derivative of the log of the predictive density with respect to any element of the parameter vector,

$$\left.\frac{\partial \log p(\mathbf{y}_t|\boldsymbol{\Omega}_{t-1};\boldsymbol{\lambda})}{\partial \lambda_i}\right|_{\boldsymbol{\lambda}=\hat{\boldsymbol{\lambda}}_{\mathrm{MLE}}},$$

should be impossible to predict from its own lagged values, a hypothesis that can be tested using simple regressions.

2.12 Deterministic Breaks

Another common approach is to treat the changes in regime as deterministic rather than random. If we wanted to test the null hypothesis of constant coefficients against the alternative that a certain subset of the coefficients of a regression switched at fixed known dates $t_1, t_2, \ldots, t_N$, we could do this easily enough using a standard F test (see, for example, Fisher, 1970). If we do not know the dates, we could calculate the value of the F statistic for every set of allowable N partitions, efficient algorithms for which have been described by Bai and Perron (2003) and Doan (2012), with critical values for interpreting the supremum of the F statistics provided by Bai and Perron (1998). Bai and Perron (1998) also described a sequential procedure with which one could first test the null hypothesis of no breaks against the alternative of $N = 1$ break, and then test $N = 1$ against $N = 2$, and so on.

Although simpler to deal with econometrically, deterministic structural breaks have the drawback that they are difficult to incorporate in a sensible way into models based on rational decision makers. Neither the assumption that people knew perfectly that the change was coming years in advance, nor the assumption that they were certain that nothing would ever change (when in the event the change did indeed appear) is very appealing. There is further the practical issue of how users of such econometric models are supposed to form their own future forecasts. Pesaran and Timmermann (2007) suggested estimating models over windows of limited subsamples, watching the data for an indication that it is time to switch to using a new model. Another drawback of interpreting structural breaks as deterministic events is that such approaches make no use of the fact that regimes such as business downturns may be a recurrent event.

2.13 Chib's Multiple Change-Point Model

Chib (1998) offered a way to interpret multiple change-point models that gets around some of the awkward features of deterministic structural breaks. Chib's model assumes that when the process is in regime i, the conditional density of the data is governed by parameter vector $\boldsymbol{\theta}_i$ as in (13). Chib assumed that the process begins at date 1 in regime $s_t = 1$ and parameter vector $\boldsymbol{\theta}_1$, and will stay there the next period with probability p_{11}. With probability $1 - p_{11}$ we get a new value $\boldsymbol{\theta}_2$, drawn perhaps from an $N(\boldsymbol{\theta}_1, \boldsymbol{\Sigma})$ distribution. Conditional on knowing that there were N such breaks, this could be viewed as a special case of an N-state Markov-switching model with transition probability matrix taking the form

$$\mathbf{P} = \begin{bmatrix} p_{11} & 0 & 0 & \cdots & 0 & 0 \\ 1-p_{11} & p_{22} & 0 & \cdots & 0 & 0 \\ 0 & 1-p_{22} & p_{33} & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ldots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & p_{N-1,N-1} & 0 \\ 0 & 0 & 0 & \cdots & 1-p_{N-1,N-1} & 1 \end{bmatrix}.$$

The total number of regime changes N could then be selected using one of the methods discussed above.

Again it is not clear how to form out-of-sample forecasts with this specification. Pesaran et al. (2006) proposed embedding Chib's model within a hierarchical prior with which one could forecast future changes in regime based on the size and duration of past breaks.

2.14 Smooth Transition Models

Another econometric approach to changes in regime is the smooth transition regression model (Teräsvirta, 2004):

$$y_t = \frac{\exp[-\gamma(z_{t-1} - c)]}{1 + \exp[-\gamma(z_{t-1} - c)]}\mathbf{x}'_{t-1}\boldsymbol{\beta}_1 + \frac{1}{1 + \exp[-\gamma(z_{t-1} - c)]}\mathbf{x}'_{t-1}\boldsymbol{\beta}_2 + u_t. \tag{37}$$

Here the scalar z_{t-1} could be one of the elements of $\mathbf{x}_{t-1}$ or some known function of $\mathbf{x}_{t-1}$. For $\gamma > 0$, as $z_{t-1} \to -\infty$, the regression coefficients go to $\boldsymbol{\beta}_1$, while when $z_{t-1} \to \infty$, the regression coefficients approach $\boldsymbol{\beta}_2$. The parameter γ governs how quickly the coefficients transition as z_{t-1} crosses the threshold c.

If $\mathbf{x}_{t-1} = (y_{t-1}, y_{t-2}, \ldots, y_{t-r})'$, this is Teräsvirta's (1994) smooth-transition autoregression, for which typically $z_{t-1} = y_{t-d}$ for some lag d. More generally, given a data-generating process for $\mathbf{x}_t$, (37) is a fully specified time-series process for which forecasts at any horizon can be calculated by simulation. One important challenge is how to choose the lag d or more generally the switching variable z_{t-1}. Although in some settings the forecast might be similar to that coming from (6), the weights $\text{Prob}(s_{t-1} = i|\boldsymbol{\Omega}_{t-1})$ in the latter would be a function of the entire history $\{y_{t-1}, y_{t-2}, \ldots, y_1\}$ rather than any single value.

3. ECONOMIC THEORY AND CHANGES IN REGIME

The previous section discussed econometric issues associated with analyzing series subject to changes in regime. This section reviews how these features can appear in theoretical models of the economy.

3.1 Closed-Form Solution of DSGEs and Asset-Pricing Implications

In some settings it is possible to find exact analytical solutions for a full dynamic stochastic general equilibrium model subject to changes in regime. A standard first-order condition in many macro models holds that

$$U'(C_t) = \beta E_t[U'(C_{t+1})(1 + r_{j,t+1})] \tag{38}$$

where C_t denotes consumption of a representative consumer, β a time-discount rate, and $r_{j,t+1}$ the real return on asset j between t and $t + 1$.Lucas (1978) proposed a particularly simple setting in which aggregate output comes solely from nonreproducible assets (sometimes thought of as fruit coming from trees) for which equilibrium turns out to require that C_t equals the aggregate real dividend D_t paid on equities (or the annual crop of fruit). If the utility function exhibits constant relative risk aversion ($U(C) = (1+\gamma)^{-1} C^{(1+\gamma)}$), the aggregate equilibrium real stock price must satisfy

$$P_t = D_t^{-\gamma} \sum_{k=1}^{\infty} \beta^k E_t D_{t+k}^{(1+\gamma)}.$$

Since the dividend process $\{D_{t+k}\}$ is exogenous in this model, one could simply assume that the change in the log of D_t is characterized by a process such as (1). Cecchetti et al. (1990) used calculations related to those in (12) to find the closed-form solution for the general-equilibrium stock price,

$$P_t = \rho_{s_t} D_t,$$

where the values of ρ_1 and ρ_2 are given in equations (11) and (12) in their paper.

Lucas's assumption of an exogenous consumption and dividend process is obviously quite restrictive. Nevertheless, asset-pricing relations such as (38) have to hold regardless of how we close the rest of the model. We can always use (38) or other basic asset-pricing conditions along with an assumed process for returns to find the implications of changes in regime for financial variables in more general settings. There is a very large literature investigating these issues, covering topics such as portfolio allocation (Ang and Bekaert, 2002a; Guidolin and Timmermann, 2008), financial implications of rare-event risk (Barro, 2006; Evans, 1996), option pricing (Elliott et al., 2005), and the term structure of interest rates (Ang and Bekaert, 2002b; Bansal and Zhou, 2002; Bekaert et al., 2001). For a survey of this literature, see Ang and Timmermann (2012).

3.2 Approximating the Solution to DSGEs Using Perturbation Methods

First-order conditions for a much broader class of dynamic stochastic general equilibrium models with Markov regime-switching take the form

$$E_t \mathbf{a}(\mathbf{y}_{t+1}, \mathbf{y}_t, \mathbf{x}_t, \mathbf{x}_{t-1}, \varepsilon_{t+1}, \varepsilon_t, \boldsymbol{\theta}_{s_{t+1}}, \boldsymbol{\theta}_{s_t}) = \mathbf{0}. \tag{39}$$

Here $\mathbf{a}(.)$ is an $[(n_y + n_x) \times 1]$ vector-valued function, $\mathbf{y}_t$ an $(n_y \times 1)$ vector of control variables (also sometimes referred to as endogenous jump variables), $\mathbf{x}_t$ an $(n_x \times 1)$ vector of predetermined endogenous or exogenous variables, ε_t an $(n_\varepsilon \times 1)$ vector of innovations to those elements of $\mathbf{x}_t$ that are exogenous to the model, and s_t follows an N-state Markov chain. The example considered in the previous subsection is a special case of such a system with $n_y = n_x = 1, y_t = P_t/D_t$, $x_t = \ln(D_t/D_{t-1})$, $\theta_{s_t} = m_{s_t}$, and[d]

[d] Notice (38) can be written

$$D_t^{\gamma} = \beta E_t \left[D_{t+1}^{\gamma} \frac{P_{t+1} + D_{t+1}}{P_t} \right]$$
$$1 = \beta E_t \left[\left(\frac{D_{t+1}}{D_t} \right)^{\gamma} \left(\frac{(P_{t+1}/D_{t+1}) + 1}{P_t/D_t} \right) \left(\frac{D_{t+1}}{D_t} \right) \right].$$

$$\mathbf{a}(y_{t+1}, y_t, x_t, x_{t-1}, \varepsilon_{t+1}, \varepsilon_t, m_{s_{t+1}}, m_{s_t})$$
$$= \begin{bmatrix} \beta \exp[(1+\gamma)(m_{s_{t+1}} + \varepsilon_{t+1})][(y_{t+1}+1)/y_t] - 1 \\ x_t - m_{s_t} - \varepsilon_t \end{bmatrix}.$$

For that example we were able to find closed-form solutions of the form

$$\mathbf{y}_t = \boldsymbol{\rho}_{s_t}(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t)$$
$$\mathbf{x}_t = \mathbf{h}_{s_t}(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t),$$

namely $y_t = \rho_{s_t}$ and $x_t = m_{s_t} + \varepsilon_t$.

For more complicated models, solutions cannot be found analytically but can be approximated using the partition perturbation method developed by Foerster et al. (forthcoming). Their method generalizes the now-standard perturbation methods of Schmitt-Grohe and Uribe (2004) for finding linear and higher-order approximations to the solutions to DSGEs with no regime switching. Foerster et al.'s idea is to approximate the solutions $\boldsymbol{\rho}_j(.)$ and $\mathbf{h}_j(.)$ in a neighborhood around the deterministic steady-state values satisfying $\mathbf{a}(\mathbf{y}^*, \mathbf{y}^*, \mathbf{x}^*, \mathbf{x}^*, \mathbf{0}, \mathbf{0}, \boldsymbol{\theta}^*, \boldsymbol{\theta}^*) = \mathbf{0}$ where $\boldsymbol{\theta}^*$ is the unconditional expectation of $\boldsymbol{\theta}_{s_t}$ calculated from the ergodic probabilities of the Markov chain,

$$\boldsymbol{\theta}^* = \sum_{j=1}^{N} \boldsymbol{\theta}_j \text{Prob}(s_t = j).$$

For the Lucas tree example from the previous subsection, $m^* = (m_1 p_{21} + m_2 p_{12})/(p_{12} + p_{21})$. We then think of a sequence of economies indexed by a continuous scalar χ such that their behavior as $\chi \to 0$ approaches the steady state, while the value at $\chi = 1$ is exactly that implied by (39):

$$\mathbf{y}_t = \boldsymbol{\rho}_{s_t}(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi) \tag{40}$$
$$\mathbf{x}_t = \mathbf{h}_{s_t}(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi). \tag{41}$$

As $\chi \to 0$, the randomness coming from $\boldsymbol{\varepsilon}_t$ is suppressed, and it turns out to be necessary to do the same thing for any elements of $\boldsymbol{\theta}$ that influence the steady state in order to have some fixed point around which to calculate the approximation. For elements in $\boldsymbol{\theta}_{s_t}$ that may change with regime but do not matter for the steady state, Foerster et al. (forthcoming) showed that it is not necessary to shrink by χ in order to approximate the dynamic solution. The authors thus specified

$$\boldsymbol{\theta}(s_t, \chi) = \begin{bmatrix} \boldsymbol{\theta}^{A*} + \chi(\boldsymbol{\theta}^A_{s_t} - \boldsymbol{\theta}^{A*}) \\ \boldsymbol{\theta}^B_{s_t} \end{bmatrix}$$

where $\boldsymbol{\theta}^A_{s_t}$ denotes the subset of elements of $\boldsymbol{\theta}_{s_t}$ that influence the steady state. The economy characterized by a particular value of χ thus needs to satisfy

$$\mathbf{0} = \int \sum_{j=1}^{N} p_{s_t,j} \mathbf{a}[\boldsymbol{\rho}_j(\mathbf{x}_t, \chi \boldsymbol{\varepsilon}_{t+1}, \chi), \mathbf{y}_t, \mathbf{x}_t, \mathbf{x}_{t-1}, \chi \varepsilon_{t+1}, \varepsilon_t, \boldsymbol{\theta}(j,\chi), \boldsymbol{\theta}(s_t,\chi)] dF(\boldsymbol{\varepsilon}_{t+1}) \tag{42}$$

where $F(\boldsymbol{\varepsilon}_{t+1})$ denotes the cumulative distribution function for ε_{t+1}. Note (42) is satisfied by construction when evaluated at $\mathbf{y}_t = \mathbf{y}^*$, $\mathbf{x}_t = \mathbf{x}_{t-1} = \mathbf{x}^*$, $\boldsymbol{\varepsilon}_t = \mathbf{0}$, and $\chi = 0$.

We next substitute (40) and (41) into (42) to arrive at a system of $N(n_y + n_x)$ equations of the form

$$\mathbf{Q}_{s_t}(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi) = \mathbf{0} \quad s_t = 1, \ldots, N$$

which have to hold for all $\mathbf{x}_{t-1}$, $\boldsymbol{\varepsilon}_t$, and χ. Taking derivatives with respect to $\mathbf{x}_{t-1}$ and evaluating at $\mathbf{x}_{t-1} = \mathbf{x}^*$, $\boldsymbol{\varepsilon}_t = \mathbf{0}$, and $\chi = 0$ (that is, using a first-order Taylor approximation around the steady state) yields a system of $N(n_y + n_x)n_x$ quadratic polynomial equations in the $N(n_y + n_x)n_x$ unknowns corresponding to elements of the matrices

$$\underset{(n_y \times n_x)}{\mathbf{R}_j^x} = \left.\frac{\partial \boldsymbol{\rho}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \mathbf{x}'_{t-1}}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N$$

$$\underset{(n_x \times n_x)}{\mathbf{H}_j^x} = \left.\frac{\partial \mathbf{h}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \mathbf{x}'_{t-1}}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N.$$

The authors proposed an algorithm for finding the solution to this system of equations, that is, values for the above sets of matrices. Given these, other terms in the first-order Taylor approximation to (42) produce a system of $N(n_y + n_x)n_\varepsilon$ equations that are linear in known parameters and the unknown elements of

$$\underset{(n_y \times n_\varepsilon)}{\mathbf{R}_j^\varepsilon} = \left.\frac{\partial \boldsymbol{\rho}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \varepsilon'_t}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N$$

$$\underset{(n_x \times n_\varepsilon)}{\mathbf{H}_j^\varepsilon} = \left.\frac{\partial \mathbf{h}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \varepsilon'_t}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N,$$

from which $\mathbf{R}_j^\varepsilon$ and $\mathbf{H}_j^\varepsilon$ are readily calculated. Another system of $N(n_y + n_x)$ linear equations yields

$$\underset{(n_y \times 1)}{\mathbf{R}_j^\chi} = \left.\frac{\partial \boldsymbol{\rho}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \chi}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N$$

$$\underset{(n_x \times 1)}{\mathbf{H}_j^\chi} = \left.\frac{\partial \mathbf{h}_j(\mathbf{x}_{t-1}, \boldsymbol{\varepsilon}_t, \chi)}{\partial \chi}\right|_{\mathbf{x}_{t-1} = \mathbf{x}^*, \boldsymbol{\varepsilon}_t = \mathbf{0}, \chi = 0} \quad j = 1, \ldots, N.$$

The approximation to the solution to the regime-switching DSGE is then

$$\begin{aligned}\mathbf{y}_t &= \mathbf{y}^* + \mathbf{R}^x_{s_t}(\mathbf{x}_{t-1} - \mathbf{x}^*) + \mathbf{R}^{\varepsilon}_{s_t}\boldsymbol{\varepsilon}_t + \mathbf{R}^{\chi}_{s_t} \\ \mathbf{x}_t &= \mathbf{x}^* + \mathbf{H}^x_{s_t}(\mathbf{x}_{t-1} - \mathbf{x}^*) + \mathbf{H}^{\varepsilon}_{s_t}\boldsymbol{\varepsilon}_t + \mathbf{H}^{\chi}_{s_t}.\end{aligned}$$

One could then go a step further if desired, taking a second-order Taylor approximation to (42). Once the first step (the linear approximation) has been completed, the second step (quadratic approximation) is actually easier to calculate numerically than the first step was, because all the second-step equations turn out to be linear in the remaining unknown magnitudes.

Lind (2014) developed an extension of this approach that could be used to form approximations to any model characterized by dramatic nonlinearities, even if regime-switching in the form of (39) is not part of the maintained structure. For example, the economic relations may change significantly when interest rates are at the zero lower bound. Lind's idea is to approximate the behavior of a nonlinear model over a set of discrete regions using relations that are linear (or possibly higher-order polynomials) over individual regions, from which one can then use many of the tools discussed above for economic and econometric analysis.

3.3 Linear Rational Expectations Models with Changes in Regime

Economic researchers often use a linear special case of (39) which in the absence of regime shifts takes the form

$$\mathbf{A}E(\mathbf{y}_{t+1}|\boldsymbol{\Omega}_t) = \mathbf{d} + \mathbf{B}\mathbf{y}_t + \mathbf{C}\mathbf{x}_t \tag{43}$$

$$\mathbf{x}_t = \mathbf{c} + \boldsymbol{\Phi}\mathbf{x}_{t-1} + \mathbf{v}_t$$

for $\mathbf{y}_t$ an $(n_y \times 1)$ vector of endogenous variables, $\boldsymbol{\Omega}_t = \{\mathbf{y}_t, \mathbf{y}_{t-1}, \ldots, \mathbf{y}_1\}$,$\mathbf{x}_t$ an $(n_x \times 1)$ vector of exogenous variables, and $\mathbf{v}_t$ a martingale difference sequence. Such a system might have been obtained as an approximation to the first-order conditions for a nonlinear DSGE using the standard perturbation algorithm, or often is instead simply postulated as the primitive conditions of the model of interest. If $\mathbf{A}^{-1}$ exists and the number of eigenvalues of $\mathbf{A}^{-1}\mathbf{B}$ whose modulus is less than or equal to unity is equal to the number of predetermined endogenous variables, then a unique stable solution can be found of the form[e]

$$\begin{aligned}\mathbf{k}_{t+1} &= \mathbf{h}_{k0} + \mathbf{H}_{kk}\mathbf{k}_t + \mathbf{H}_{kx}\mathbf{x}_t \\ \mathbf{d}_t &= \mathbf{h}_{d0} + \mathbf{H}_{dk}\mathbf{k}_t + \mathbf{H}_{dx}\mathbf{x}_t\end{aligned}$$

[e] Klein (2000) generalized to the case when $\mathbf{A}$ may not be invertible.

where $\mathbf{k}_t$ denotes the elements of $\mathbf{y}_t$ that correspond to predetermined variables, while $\mathbf{d}_t$ collects the control or jump variables. Algorithms for finding the values of the parameters $\mathbf{h}_{i0}$ and $\mathbf{H}_{ij}$ have been developed by Blanchard and Kahn (1980), Klein (2000), and Sims (2001).

We could also generalize (43) to allow for changes in regime,

$$\mathbf{A}_{s_t} E(\mathbf{y}_{t+1} | \Omega_t, s_t, s_{t-1}, \ldots, s_1) = \mathbf{d}_{s_t} + \mathbf{B}_{s_t} \mathbf{y}_t + \mathbf{C}_{s_t} \mathbf{x}_t \tag{44}$$

where s_t follows an exogenous N-state Markov chain and $\mathbf{A}_j$ denotes an $(n_y \times n_y)$ matrix of parameters when the regime for date t is given by $s_t = j$. To solve such a model, Davig and Leeper (2007) suggested exploiting the feature that conditional on $\mathcal{S} = \{s_t\}_{t=1}^{\infty}$ the model is linear. Let $\mathbf{y}_{jt}$ correspond to the value of $\mathbf{y}_t$ when $s_t = j$ and collect the set of such vectors for all the possible regimes in a larger vector $\mathbf{Y}_t$:

$$\underset{(Nn_y \times 1)}{\mathbf{Y}_t} = \begin{bmatrix} \underset{(n_y \times 1)}{\mathbf{y}_{1t}} \\ \vdots \\ \underset{(n_y \times 1)}{\mathbf{y}_{Nt}} \end{bmatrix}.$$

If we restrict our consideration to solutions that satisfy the minimal-state Markov property, then

$$E(\mathbf{y}_{t+1} | \mathcal{S}, \Omega_t) = E(\mathbf{y}_{t+1} | s_{t+1}, s_t, \Omega_t)$$

and

$$E(\mathbf{y}_{t+1} | s_t = i, \Omega_t) = \sum_{j=1}^{N} E(\mathbf{y}_{t+1} | s_{t+1} = j, s_t = i, \Omega_t) p_{ij}.$$

Hence when $s_t = i$,

$$\mathbf{A}_{s_t} E(\mathbf{y}_{t+1} | s_t, \Omega_t) = (\mathbf{p}_i' \otimes \mathbf{A}_i) E(\mathbf{Y}_{t+1} | \mathbf{Y}_t) \tag{45}$$

where

$$\mathbf{p}_i = \begin{bmatrix} p_{i1} \\ \vdots \\ p_{iN} \end{bmatrix}$$

denotes column i of the Markov transition probabilities, with elements of $\mathbf{p}_i$ summing to unity. Consider then the stacked structural system,

$$\mathbf{A} E(\mathbf{Y}_{t+1} | \mathbf{Y}_t) = \mathbf{d} + \mathbf{B}\mathbf{Y}_t + \mathbf{C}\mathbf{x}_t \tag{46}$$

$$\underset{(Nn_y \times Nn_y)}{\mathbf{A}} = \begin{bmatrix} \underset{(1\times N)}{\mathbf{p}_1'} \otimes \underset{(n_y\times n_y)}{\mathbf{A}_1} \\ \vdots \\ \underset{(1\times N)}{\mathbf{p}_N'} \otimes \underset{(n_y\times n_y)}{\mathbf{A}_N} \end{bmatrix} \quad \underset{(Nn_y\times 1)}{\mathbf{d}} = \begin{bmatrix} \underset{(n_y\times 1)}{\mathbf{d}_1} \\ \vdots \\ \underset{(n_y\times 1)}{\mathbf{d}_N} \end{bmatrix} \tag{47}$$

$$\underset{(Nn_y\times Nn_y)}{\mathbf{B}} = \begin{bmatrix} \mathbf{B}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \cdots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{B}_N \end{bmatrix} \quad \underset{(Nn_y\times n_x)}{\mathbf{C}} = \begin{bmatrix} \underset{(n_y\times n_x)}{\mathbf{C}_1} \\ \vdots \\ \underset{(n_y\times n_x)}{\mathbf{C}_N} \end{bmatrix}.$$

This is a simple regime-independent system for which a solution can be found using the traditional method. For example, with no predetermined variables, if all eigenvalues of $\mathbf{A}^{-1}\mathbf{B}$ are outside the unit circle, then we can find a unique stable solution of the form

$$\underset{(Nn_y\times 1)}{\mathbf{Y}_t} = \underset{(Nn_y\times 1)}{\mathbf{h}} + \underset{(Nn_y\times n_x)}{\mathbf{H}} \underset{(n_x\times 1)}{\mathbf{x}_t} \tag{48}$$

which implies that

$$\underset{(n_y\times 1)}{\mathbf{y}_t} = \underset{(n_y\times 1)}{\mathbf{h}_{s_t}} + \underset{(n_y\times n_x)}{\mathbf{H}_{s_t}} \underset{(n_x\times 1)}{\mathbf{x}_t} \tag{49}$$

for $\mathbf{h}_i$ and $\mathbf{H}_i$ the *i*th blocks of $\mathbf{h}$ and $\mathbf{H}$, respectively. If (48) is a solution to (46), then (49) is a solution to (44).[f]

[f] If (49) holds, then

$$E(\mathbf{y}_{t+1}|\Omega_t, s_t = i) = \sum_{j=1}^{N} p_{ij}[\mathbf{h}_j + \mathbf{H}_j(\mathbf{c} + \mathbf{\Phi}\mathbf{x}_t)].$$

Thus for (44) to hold it must be the case that for each $i = 1,\ldots,N$,

$$\mathbf{A}_i \sum_{j=1}^{N} p_{ij}\mathbf{H}_j\mathbf{\Phi} = \mathbf{B}_i\mathbf{H}_i + \mathbf{C}_i$$
$$\mathbf{A}_i \sum_{j=1}^{N} p_{ij}(\mathbf{h}_j + \mathbf{H}_j\mathbf{c}) = \mathbf{d}_i + \mathbf{B}_i\mathbf{h}_i.$$

But if (48) is a solution to (46), then

$$\mathbf{A}[\mathbf{h} + \mathbf{H}(\mathbf{c} + \mathbf{\Phi}\mathbf{x}_t)] = \mathbf{d} + \mathbf{B}(\mathbf{h} + \mathbf{H}\mathbf{x}_t) + \mathbf{C}\mathbf{x}_t$$

block *i* of which requires from (47) that

$$(\mathbf{p}_i' \otimes \mathbf{A}_i)\mathbf{H}\mathbf{\Phi} = \mathbf{B}_i\mathbf{H}_i + \mathbf{C}_i$$
$$(\mathbf{p}_i' \otimes \mathbf{A}_i)(\mathbf{h} + \mathbf{H}\mathbf{c}) = \mathbf{d}_i + \mathbf{B}_i\mathbf{h}_i$$

as were claimed to hold.

However, Farmer et al. (2010) demonstrated that while (48) yields one stable solution to (44), it need not be the only stable solution. For further discussion, see Farmer et al. (2009).

3.4 Multiple Equilibria

Other economists have argued that models in which there are multiple possible solutions—for example, system (43) with no predetermined variables and an eigenvalue of $\mathbf{A}^{-1}\mathbf{B}$ inside the unit circle—are precisely those we should be most interested in, given the perception that sometimes consumers or firms seem to become highly pessimistic for no discernible reason, bringing the economy into a self-fulfilling downturn; see Benhabib and Farmer (1999) for a survey of this literature. One factor that could produce multiple equilibria is coordination externalities. The rewards to me of participating in a market may be greatest when I expect large numbers of others to do the same (Cooper, 1994; Cooper and John, 1988). Multiple equilibria could also arise when expectations themselves are a factor determining the equilibrium (Kurz and Motolese, 2001). Kirman (1993) and Chamley (1999) discussed mechanisms by which the economy might tend to oscillate periodically between the possible regimes in multiple-equilibria settings.

A widely studied example is financial market bubbles. In the special case of risk-neutral investors (that is, when $U'(C)$ is some constant independent of consumption C), Eq. (38) relating the price of the stock P_t to its future dividend D_{t+1} becomes

$$P_t = \beta E_t(P_{t+1} + D_{t+1}). \tag{50}$$

One solution to (50) is the market-fundamentals solution given by

$$P_t^* = \sum_{j=1}^{\infty} \beta^j E_t(D_{t+j}).$$

But $P_t = P_t^* + B_t$ also satisfies(50) for B_t any bubble process satisfying $B_t = \beta E_t B_{t+1}$. Hall et al. (1999) proposed an empirical test of whether an observed financial price is occasionally subject to such a bubble regime. This test has been applied in dozens of different empirical studies. However, Hamilton (1985), Driffill and Sola (1998), and Gürkaynak (2008) noted the inherent difficulties in distinguishing financial bubbles from unobserved fundamentals.

3.5 Tipping Points and Financial Crises

In other models, there may be a unique equilibrium but under the right historical conditions, a small change in fundamentals can produce a huge change in observed outcomes. Such dynamics might be well described as locally linear processes that periodically experience changes in regime. Investment dynamics constitute one possible transmission mechanism. The right sequence of events can end up triggering a big investment decline that in turn contributes to a dramatic drop in output and an effective change in regime. Acemoglu and Scott (1997) presented a model where this happens as a result of intertemporal increasing returns, for example, if an investment that leads to a significant new discovery makes additional investments more profitable for a short time. Moore and Schaller (2002), Guo et al. (2005), and Veldkamp (2005) examined different settings in which investment dynamics contribute to tipping points, often through a process of learning about current opportunities. Startz (1998) demonstrated how an accumulation of small shocks could under certain circumstances trigger a dramatic shift between alternative production technologies. Learning by market participants introduces another possible source of tipping-point or regime-shift dynamics (Hong et al., 2007; Branch and Evans, 2010). Gârleanu et al. (2015) demonstrated how tipping points could emerge from the interaction of limited market integration, leveraging, and contagion.

Brunnermeier and Sannikov (2014) developed an intriguing description of tipping points in the context of financial crises. They posited two types of agents, designated "experts" and "households." Experts can invest capital more productively than households, but they are constrained to borrow using only risk-free debt. In normal times, 100% of the economy's equity ends up being held by experts. But as negative shocks cause their net worth to decline, they can end up selling off capital to less productive households, lowering both output and investment. This results in a bimodal stationary distribution in which the economy spends most of its time around the steady state in which experts hold all the capital. But a sequence of negative shocks can lead the economy to become stuck in an inefficient equilibrium from which it can take a long time to recover.

A large number of researchers have used regime-switching models to study financial crises empirically. These include Hamilton's (2005) description of banking crises in the 19th century, Asea and Blomberg's (1998) study of lending cycles in the late 20th century, and an investigation of more recent financial stress by Hubrich and Tetlow (2015).

3.6 Currency Crises and Sovereign Debt Crises

A sudden loss of confidence in a country can lead to a flight from the currency which in turn produces a shock to credit and spending that greatly exacerbates the country's problems. A sudden wave of pessimism could be self-fulfilling, giving rise to multiple equilibria that could exhibit Markov switching (Jeanne and Masson, 2000), or could be characterized by tipping point dynamics where under the right circumstances a small change in fundamentals pushes a country into crisis. Empirical investigations of currency crises using regime-switching models include Peria (2002) and Cerra and Saxena (2005).

Similar dynamics can characterize yields on sovereign debt. If investors lose confidence in a country's ability to service its debt, they will demand a higher interest rate as compensation. The higher interest costs could produce a tipping point that indeed forces a country into default or to make drastic fiscal adjustments (Greenlaw et al., 2013). Analyses of changes in regime in this context include Davig et al. (2011) and Bi (2012).

3.7 Changes in Policy as the Source of Changes in Regime

Another source of a change in regime is a discrete shift in policy itself. One commonly studied possibility is that control of monetary policy may periodically shift between hawks and doves, the latter being characterized by either a higher inflation target or more willingness to tolerate deviations of inflation from target. Analyses using this approach include Owyang and Ramey (2004), Schorfheide (2005), Liu et al. (2011), Bianchi (2013), and Baele et al. (2015).

An alternative possibility is that changes in fiscal regime can be a destabilizing factor. Ruge-Murcia (1995) showed how a lack of credibility of the fiscal stabilization in 1984 contributed to the changes in inflation Israel experienced, while Ruge-Murcia (1999) documented the close connection between changes in fiscal regimes and inflation regimes for Brazil.

4. CONCLUSIONS AND RECOMMENDATIONS FOR RESEARCHERS

We have seen that researchers have a rich set of tools and specifications on which to draw for interpreting data and building economic models for environments in which there may be changes in regime. The chapter closes with some practical recommendations for researchers as to which options are most promising.

Although a researcher might be tempted to use the most general specification possible, with all the parameters changing across a large number of regimes and time-varying transition probabilities, in practice this is usually asking more than the data can deliver. For example, for postwar US data we have only 11 recessions, which economic theory says should be difficult or impossible to predict (Hamilton, 2011). Building a richly parameterized description of the transition into and out of recession could easily result in an overfitted and misspecified model. By contrast, using a simple time-invariant Markov chain is likely to give a reasonable and robust approximation to the key features of the data. Similarly, we know from the analytic characterization of the maximum likelihood estimates (eg, Eq. (24)) that inference about parameters that only show up in regime i can only come from observations within that regime. With postwar quarterly data that would mean about 50 observations from which to estimate all the parameters operating during recessions. One or two parameters could be estimated fairly well, but overfitting is again a potential concern in models with many parameters. For this reason researchers may want to limit the focus to a few of the most important parameters that are likely to change, such as the intercept and the variance.

Where more than two regimes are required, there again are benefits to keeping the model parsimonious. For example, a common finding is that the variance of US output growth permanently decreased in 1984 (McConnell and Perez-Quiros, 2000), while the intercept periodically shifts to negative during recessions. This requires four different regimes—the economy could be in expansion or recession and the date could be before or after the Great Moderation. A useful simplification treats the variance regime as independent of the recession regime, requiring estimation of only 4 transition probabilities rather than 12, as in Kim and Nelson (1999b).

Another feature of which researchers should be aware is that there can be multiple local maxima to the likelihood function. It is therefore good practice to begin the EM iterations from a large number of different starting points to make sure we are always ending up with the same answer, and also as a practical test of whether the algorithm has indeed converged to a fixed point. Likewise with Bayesian methods we want to make sure numerical algorithms converge to the same posterior distribution under alternative starting points and chain dynamics, and the procedure should take into account the label-switching problem.

Provided researchers make note of these issues, these approaches offer a flexible way of modeling some of the key nonlinearities in macroeconomic dynamics without sacrificing the simplicity and tractability of linear models.

APPENDIX

Derivation of EM Equations for Restricted VAR

As noted by Hamilton (1990, p. 47), the M or maximization step of the EM algorithm can be implemented by finding the first-order conditions associated with maximizing the likelihood conditional on a particular set of realizations for the regimes $\mathcal{S}=\{s_1,\ldots,s_T\}$ and then weighting these by the smoothed probability of $\mathcal{S}$ and summing over all the possible realizations of $\mathcal{S}$. For a VAR restricted as in (28), the conditional likelihood is

$$\frac{1}{(2\pi)^{nT/2}|\boldsymbol{\Sigma}|^{T/2}}\exp\left[-(1/2)\sum_{t=1}^{T}(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})'\boldsymbol{\Sigma}^{-1}(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})\right]$$

with first-order conditions

$$\sum_{t=1}^{T}(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})\mathbf{x}'_{1,t-1}=\mathbf{0} \qquad \text{(A.1)}$$

$$\sum_{t=1}^{T}(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})\mathbf{x}'_{2,t-1}\delta(s_t=i)=\mathbf{0}\quad \text{for } i=1,\ldots,N \qquad \text{(A.2)}$$

$$\sum_{t=1}^{T}(1/2)\left[\boldsymbol{\Sigma}-(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})(\mathbf{y}_t-\mathbf{A}\mathbf{x}_{1,t-1}-\mathbf{B}_{s_t}\mathbf{x}_{2,t-1})'\right]=\mathbf{0} \qquad \text{(A.3)}$$

where $\delta(s_t = i)$ denotes unity if $s_t = i$ and zero otherwise. Stacking (A.1)–(A.2) horizontally gives

$$\sum_{t=1}^{T}(\mathbf{y}_t - \mathbf{A}\mathbf{x}_{1,t-1} - \mathbf{B}_{s_t}\mathbf{x}_{2,t-1})\mathbf{z}'_{t-1} = \sum_{t=1}^{T}(\mathbf{y}_t - [\mathbf{A}\ \ \mathbf{B}_1\ \ \mathbf{B}_2\ \ \cdots\ \ \mathbf{B}_N]\mathbf{z}_{t-1})\mathbf{z}'_{t-1} = \mathbf{0} \tag{A.4}$$

for

$$\underset{[1\times(k_1+Nk_2)]}{\mathbf{z}'_{t-1}} = \left[\mathbf{x}'_{1,t-1}\ \ \mathbf{x}'_{2,t-1}\delta(s_t=1)\ \ \mathbf{x}'_{2,t-1}\delta(s_t=2)\ \ \cdots\ \ \mathbf{x}'_{2,t-1}\delta(s_t=N)\right].$$

Multiplying the tth term within the sums in (A.4) and (A.3) by $\text{Prob}(s_t = i|\boldsymbol{\Omega}_T;\hat{\boldsymbol{\lambda}}^{(\ell)})$, summing over $i = 1,\ldots,N$, and rearranging gives Eqs. (29) and (30).

CHAPTER 4

The Macroeconomics of Time Allocation

Contents

Abstract

In this chapter we explore the macroeconomics of time allocation. We begin with an overview of the trends in market hours in the United States, both in the aggregate and for key subsamples. After introducing a Beckerian theoretical framework, the chapter then discusses key empirical patterns of time allocation, both in the time series (including business cycle properties) and over the life cycle. We focus on several core nonmarket activities, including home production, child care, and leisure. The chapter concludes with a discussion of why these patterns are important to macroeconomics and spells out directions for future research.

1. INTRODUCTION

What drives the time series variation in labor supply? During the last decade, the employment to population ratio of prime-age workers has fallen sharply—particularly for lower skilled workers. As market work falls, how do households allocate their time? Why does labor supply vary so much at business cycle frequencies? Can the ability to produce at home make labor supply more elastic? Can innovations in home production technology explain the rise in female employment and the convergence of male and female labor supply elasticities? Why does consumption vary over the life cycle? As market work falls after middle age, how do household individuals allocate their time? As individuals age, do they allocate more time to home production and shopping reducing their observed market expenditure for a constant consumption basket?

In this chapter, we introduce readers to the importance of time allocation for life cycle, business cycle, and long-run time series movements in labor supply and market consumption. Becker's Presidential Address (1989) provides a nice argument in favor of linking micro time allocation and associated expenditure decisions to key macroeconomic outcomes. The goal of the chapter is to provide an introduction to the literature that examines these issues. In doing so, we highlight differences by both gender and years of accumulated schooling. As we show, the time series and life cycle patterns in time use differ markedly between men and women. Likewise, the time series and life cycle patterns also differ across skill groups. For example, the time women allocate to market work has risen sharply over the last five decades relative to men. Simultaneously, the time women allocate to home production has fallen sharply over the last five decades relative to men. However, the trends in leisure time are nearly identical between men and women. Yet, less-skilled men and women experienced a much larger increase in leisure than higher skilled men and women over the same period.

The chapter begins by exploring patterns in market work over time. We illustrate these patterns over time for different age, sex, and skill groups. These patterns set the stage for the work that follows. In Section 2, we outline a Beckerian model of consumption with multiple goods. The model illustrates the key forces illustrating how changes in the way time is allocated outside of the market sector can explain time series, life cycle, and business cycle movements in both the time allocated to market work and market consumption. This model while simple is quite powerful. Individuals are endowed with a given amount of time and, with said endowment, make choices on how it is allocated across activities given the prices and technologies they face.

In Sections 3–5, we document the time series, business cycle, and life cycle variation in individual time use, respectively. We primarily focus on three uses of time aside from market work. First, we look at home production broadly. These activities include activities like cooking, cleaning, shopping, doing laundry, moving the lawn, and caring for older adults. Second, we look at child care. In doing so, we discuss why the literature treats child care as a distinct activity relative to home production. Lastly, we look at the time individuals spend in leisure activities. This category includes time spent watching television, socializing, going to the movies, playing video games, exercising, and sleeping. On occasion, we discuss the trends in the remaining time-use categories like job search, accumulating human capital, and participating in civic organizations. Throughout all of these sections, we also set these facts in the broader macroeconomics literature. In the final section, we close with a few comments on a future research agenda.

2. TRENDS IN MARKET WORK

In this section we set the stage by reviewing and updating some familiar trends in market labor. In the remainder of the chapter, we discuss how trends in market hours are complemented by trends in other time-intensive activities. The next section provides a theoretical framework which highlights why measuring time allocation across multiple activities may be useful in understanding market hours.

Fig. 1 shows the trends in male hours worked per week allocated to market work (left axis) and employment propensity (right axis) from 1967 through 2014. To compute this

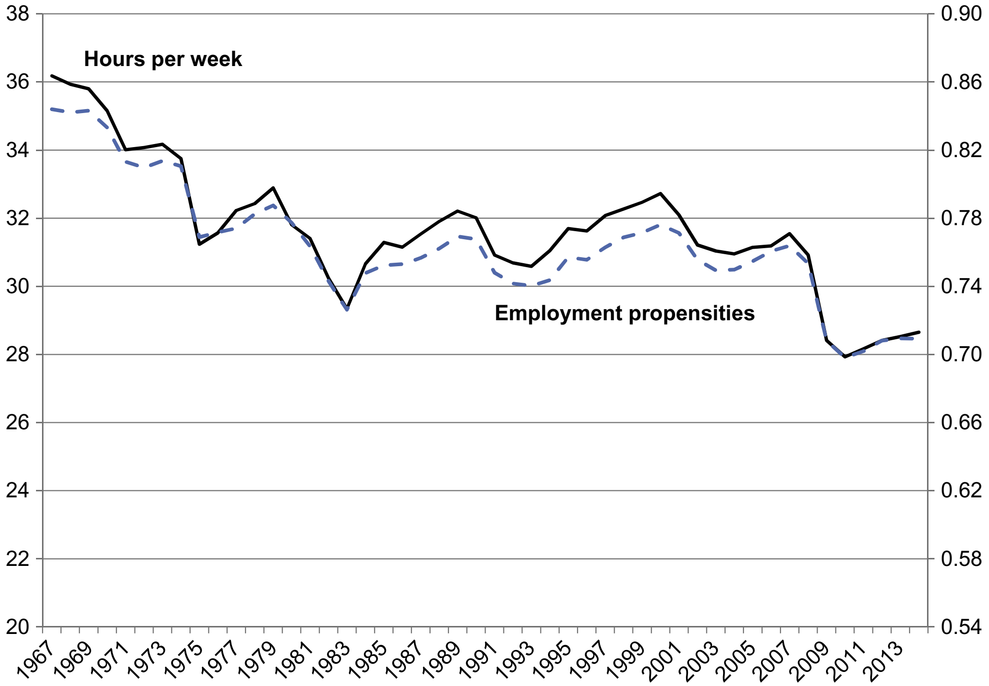

Fig. 1 CPS trends in market hours and employment rates: all men (21–75). Note: Figure shows the trends in market hours per week worked (*solid line—left axis*) and employment propensities (*dashed line—right axis*) between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all men between the ages of 21 and 75 (inclusive) within the survey. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week. Employment propensities are based on the amount of people who report being employed in a given week.

figure (and all figures within this section), we use data from the March Current Population Survey (CPS).[a] The only restriction we placed on the data was to restrict the sample to include men between the ages of 21 and 75 (inclusive). Hours per week is measured as the individual's self-reported hours worked on all jobs during the prior week. For those that did not work last week, hours per week is measured as zero. The employment propensity is a dummy variable that takes the value of 1 if the individual reported having a job (regardless of whether or not they worked any hours last week).

As seen from Fig. 1, male hours per week have fallen sharply since the late 1960s. In 1967, the typical male between the ages of 21 and 75 worked roughly 36 h per week. That number fell steadily to the 1980s where, on average, men worked about 31 h per week. During the 2008 recession, male hours fell to only about 28 h per week. That number has not rebounded as of 2014. The movement in hours per week is almost entirely driven by movements on the extensive margin of labor supply. As seen from Fig. 1, employment propensities moved in lock step with the hours movement over this time period. Put another way, hours per week worked conditional on being employed remained roughly constant over this 47-year period. Prior to the 2008 recession, roughly 77% of men in the 21–75 age range were employed. That number fell to 70% during the recession and it has only rebounded to 71% by 2014.

Fig. 2 shows hours per week, conditional on working, for men during the 1967–2014 period. Hours worked per week, conditional on working, have remained roughly constant over the last 50 years. Since 1970, hours worked per week, conditional on working, have bounced around between 40 and 42 h per week. Since the early 2000s, there has been a persistent decline in hours worked per week, conditional on working, from 42 h per week to roughly 40 h per week in 2009. The low hours per week, conditional on working, has remained roughly constant since 2009.

Fig. 3 shows the similar patterns for women. Between the late 1960s and the late 1990s, female time allocated to market work increased sharply. Both hours per week and employment propensities increased continuously during this period. Starting in 2000, however, female hours worked per week and employment propensities fell. The trends in female hours and employment propensities matched their male counterparts. Fig. 4 shows hours per week, conditional on working, for women during the 1967–2014 period. Like men, hours worked per week, conditional on working, have remained roughly constant over the last 50 years. Since 1980, hours worked per week, conditional on working, have remained roughly constant at about 35 h per week. This shows that for women essentially all the change in total hours since 1980 is due to changes in the extensive margin of employment.

Figs. 5 and 6 show the same patterns by educational attainment for men (Fig. 5) and women (Fig. 6). We define higher educated as individuals who completed a bachelor's

[a] We downloaded the data directly from the Integrated Public Use Microdat Series (IPUMS) website: https://www.ipums.org.

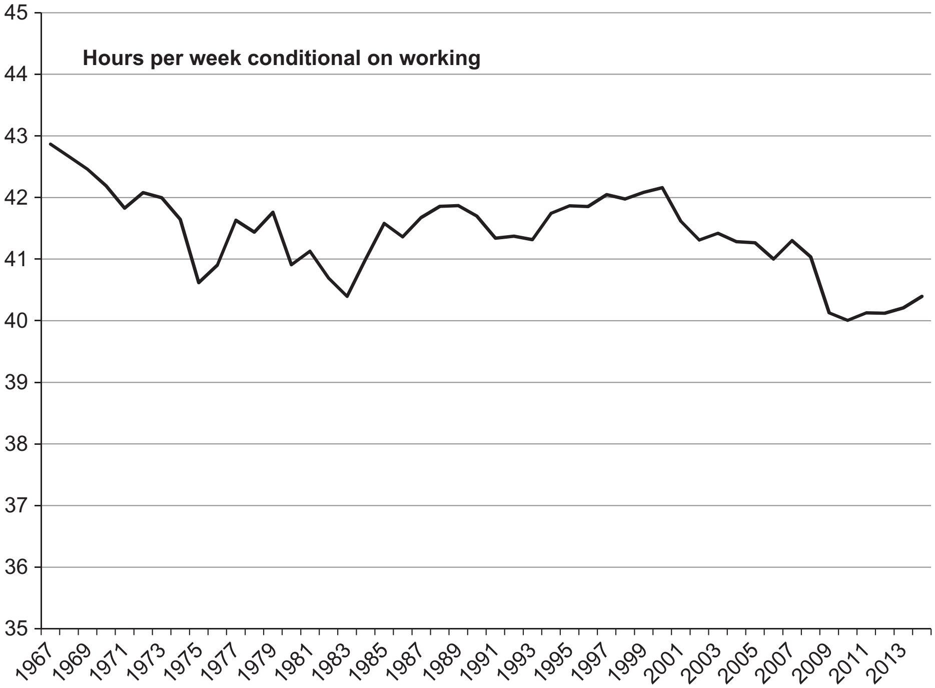

Fig. 2 CPS trends in market hours and employment rates: employed men. Note: Figure shows the trends in market hours per week worked for men, conditional on working. The sample is the same as Fig. 1.

degree or higher. Lower educated individuals include anyone with less than a bachelor's degree. Given that the population has been aging during this time period, Figs. 7 and 8 show the trends in hours work by sex, skill, and age. Fig. 7A shows the patterns for four age groups for higher skilled men. The age groups are 21–40, 41–55, 56–65, and 66–75. Figs. 7B and 8A and B show the analogous age breakdown for lower skilled men, higher skilled women, and lower skilled women, respectively.

The patterns in Figs. 5–8 highlight many of the questions that frame our subsequent analysis. First, hours allocated to market work is falling for men of both skill levels since the late 1960s. Higher educated men experienced a decline in market work hours from about 43 h a week in 1967 to about 34 h a week in 2008. Much of this decline was concentrated prior to 1980 and after 1999. As the population aged during this time, a greater fraction of individuals became retired. In Fig. 7A, we see that hours worked declined for every age group of higher skilled men during the last 47 years. Higher skilled men aged 56–65 saw the largest decline. In 1967, these men worked on average 40 h a week. That number fell to about 30 h a week in 1990 has been relatively constant throughout—even during the 2008 recession. High-skilled men aged 41–55 experienced a steady decline in

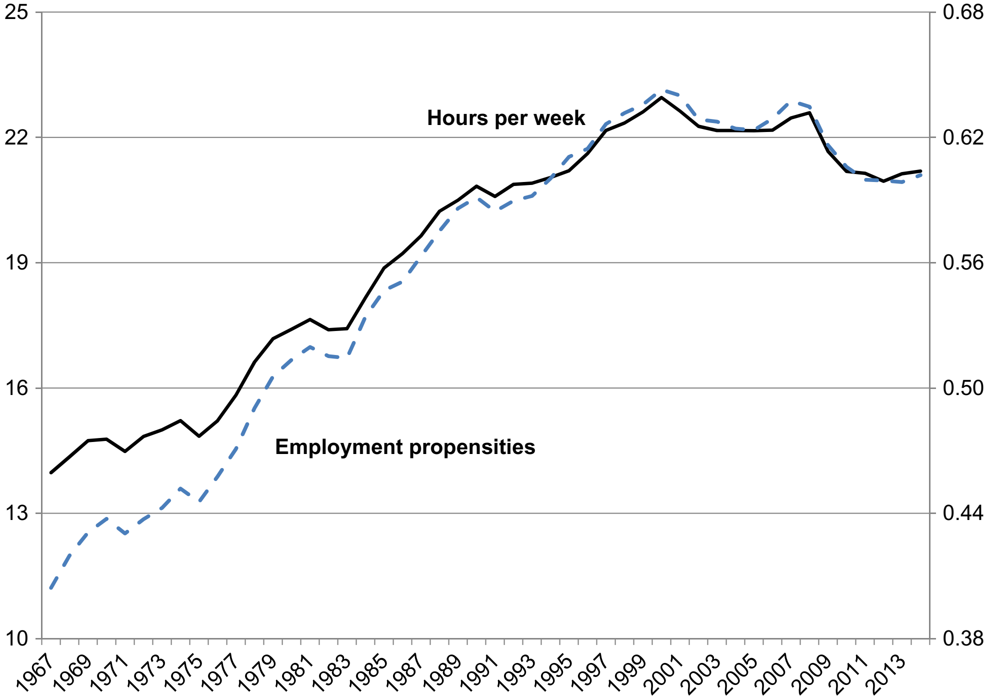

Fig. 3 CPS trends in market hours and employment rates: all women (21–75). Note: Figure shows the trends in market hours per week worked (*solid line—left axis*) and employment propensities (*dashed line—right axis*) between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all women between the ages of 21 and 75 (inclusive) within the survey. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week. Employment propensities are based on the amount of people who report being employed in a given week.

hours worked since the late 1960s from 45 h per week in 1967 to 40 h a week in 2014. Like the trend for all high-skilled men regardless of age, much of the decline took place prior to 1980 and after 1999. Younger high-skilled men (those aged 21–40) had relative flat hours through 1999. But, since the late 1990s, younger higher skilled men have reduced their hours from 41 h per week to about 37 h per week in 2014. Conversely, higher skilled men aged 66–75 have increased their hours worked by about 3–4 h.

The qualitative decline in market hours is roughly similar for lower skilled men within each age group. The main quantitative difference, however, is that the declines were much more dramatic for low-skilled men between the ages of 21 and 40 and between the ages of 41 and 55. For this group of relatively young men, there was a marked decline in hours worked relative to their higher educated counterparts. In 1967, younger lower skilled men worked roughly 40 h per week. Yet, by 2014, lower educated men between the ages of 21–40 are only working just over 28 h per week. This 12 h per week decline

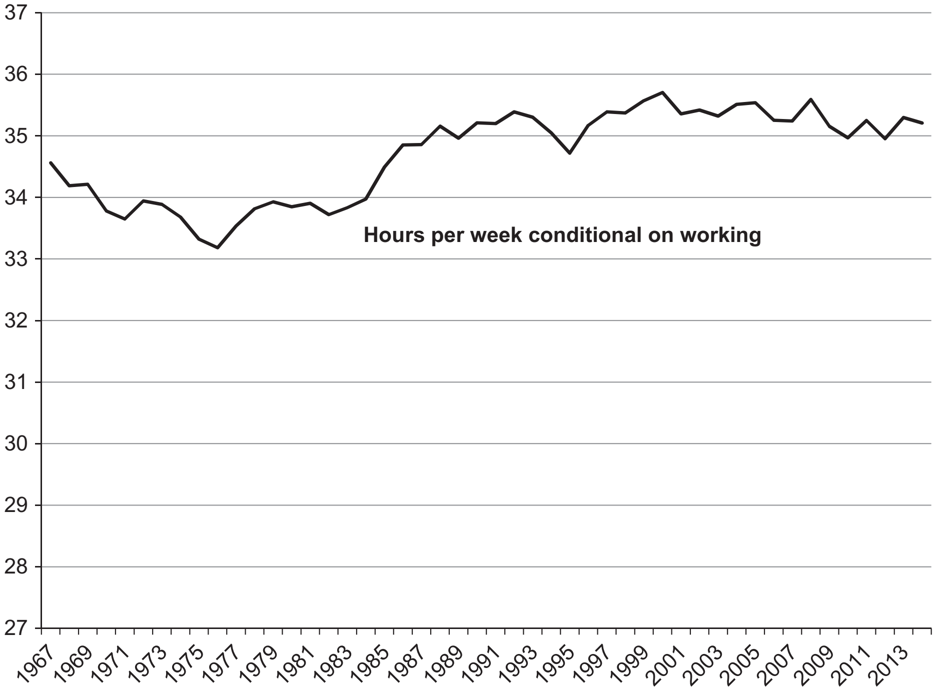

Fig. 4 CPS trends in market hours: employed women. Note: Figure shows the trends in market hours per week worked for women, conditional on working. The sample is the same as Fig. 3.

dwarfs 5-h decline for higher educated men in the same age range. Lower skilled men aged 41–55 decreased their market work hours by 8 h per week on average. This is larger than the 5-h decline experienced by the higher skilled men of the same age. Much of this divergence occurred starting after 1999. Young lower skilled men have dramatically reduced their hours during the last 15 years. As with the patterns in Fig. 1, essentially all of the action is on the extensive margin of employment. There was relatively little movement in hours worked per week conditional on being employed. The increase in inequality in employment propensities between higher and lower prime-aged men is a defining feature of time use since 2000.

Like with men, higher skilled women consistently work more in the market sector than lower skilled women. Like their male counterparts, higher skilled prime-aged women (those 21–40 and those 41–55) reduced their market work hours slightly during the 2000s. This comes as a reversal of trends during the prior decades. From 1967 through 1990, prime-aged higher skilled women increased their market hours by roughly 6–9 h per week. Again, like their male counterparts, prime-aged lower skilled women saw a dramatic reduction in market work hours during the 2000s. For example, younger low-skilled women (those aged 21–40) reduced their market work hours by roughly

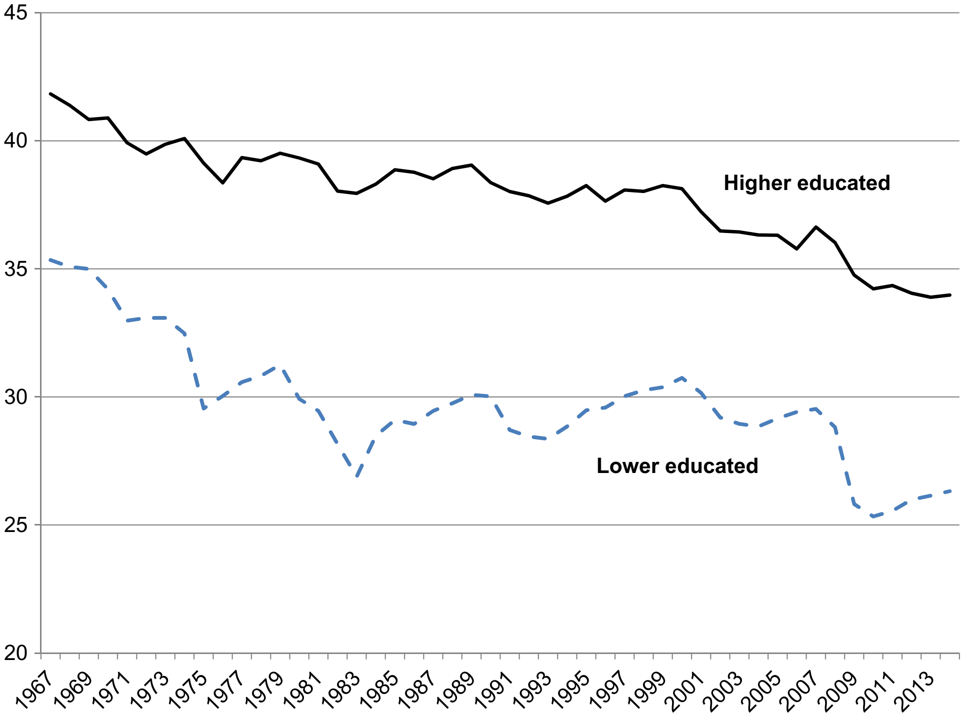

Fig. 5 CPS trends in market hours: men by skill (21–75). Note: Figure shows the trends in market hours per week worked for higher skilled men (*solid line*) and lower skilled men (*dashed line*) between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all men between the ages of 21 and 75 (inclusive) within the survey. Higher educated men are defined as those men with a bachelor's degree or higher. Lower educated men have years of schooling less than 16 years. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week.

4 h per week between 1999 and 2014. The combination of these patterns caused inequality market work hours to also increase during the 2000s for lower skilled prime-aged women relative to higher skilled prime-aged women.

Given these large fluctuations in market work hours over time, across genders, across skill groups within gender and across age groups within a gender * skill group, it is interesting to understand how time allocated to activities other than market work have been changing as well. We turn to that analysis now.

3. A THEORY OF TIME USE

The modern theory of time allocation was first laid out in the seminal Becker (1965). The Beckerian approach recognizes the consumption "commodities" produced using both

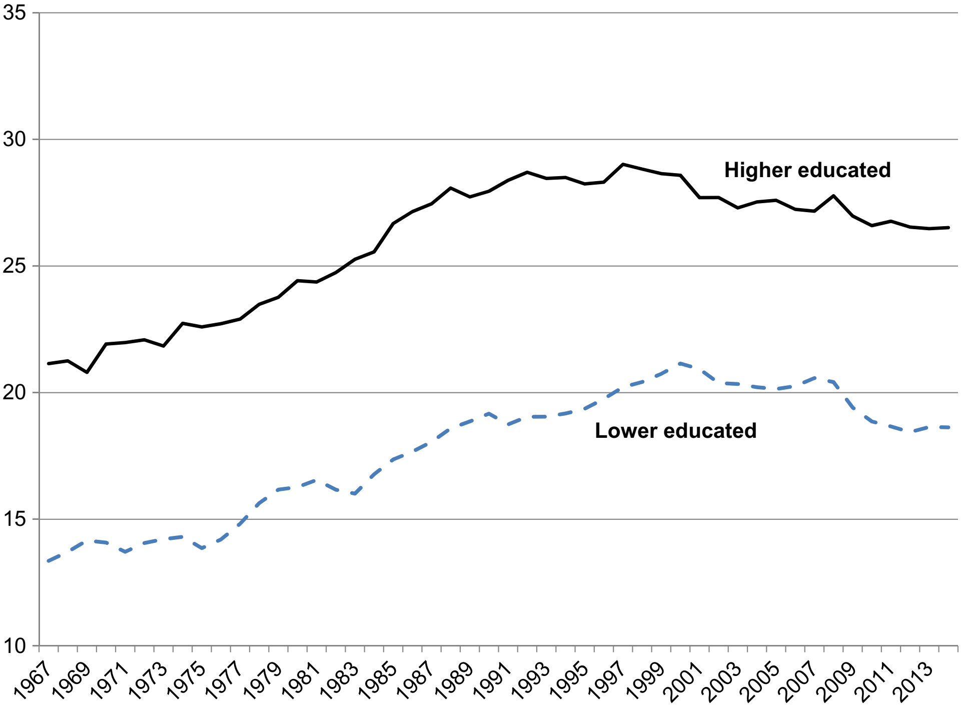

Fig. 6 CPS trends in market hours: women by skill (21–75). Note: Figure shows the trends in market hours per week worked for higher skilled women (*solid line*) and lower skilled women (*dashed line*) between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all women between the ages of 21 and 75 (inclusive) within the survey. Higher educated women are defined as those women with a bachelor's degree or higher. Lower educated women have years of schooling less than 16 years. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week.

market goods and one's time. In this section, we highlight a few implications of the Beckerian model that have proved useful in understanding empirical time allocation and associated market expenditures. The version of Becker's model presented below draws on Aguiar and Hurst (2007b) and Aguiar et al. (2012). For expositional reasons, we make a number of simplifying assumptions which can easily be relaxed in order to highlight the key mechanisms.

Consider an agent which enjoys utility over I different consumption commodities, $c_1, \ldots, c_i, \ldots, c_I$. Commodity i is produced using market input x_i and time input h_i according to the technology:

$$c_i = f^i(x_i, h_i).$$

We assume that there is no joint production, so x_i and h_i are used only to produce commodity i.

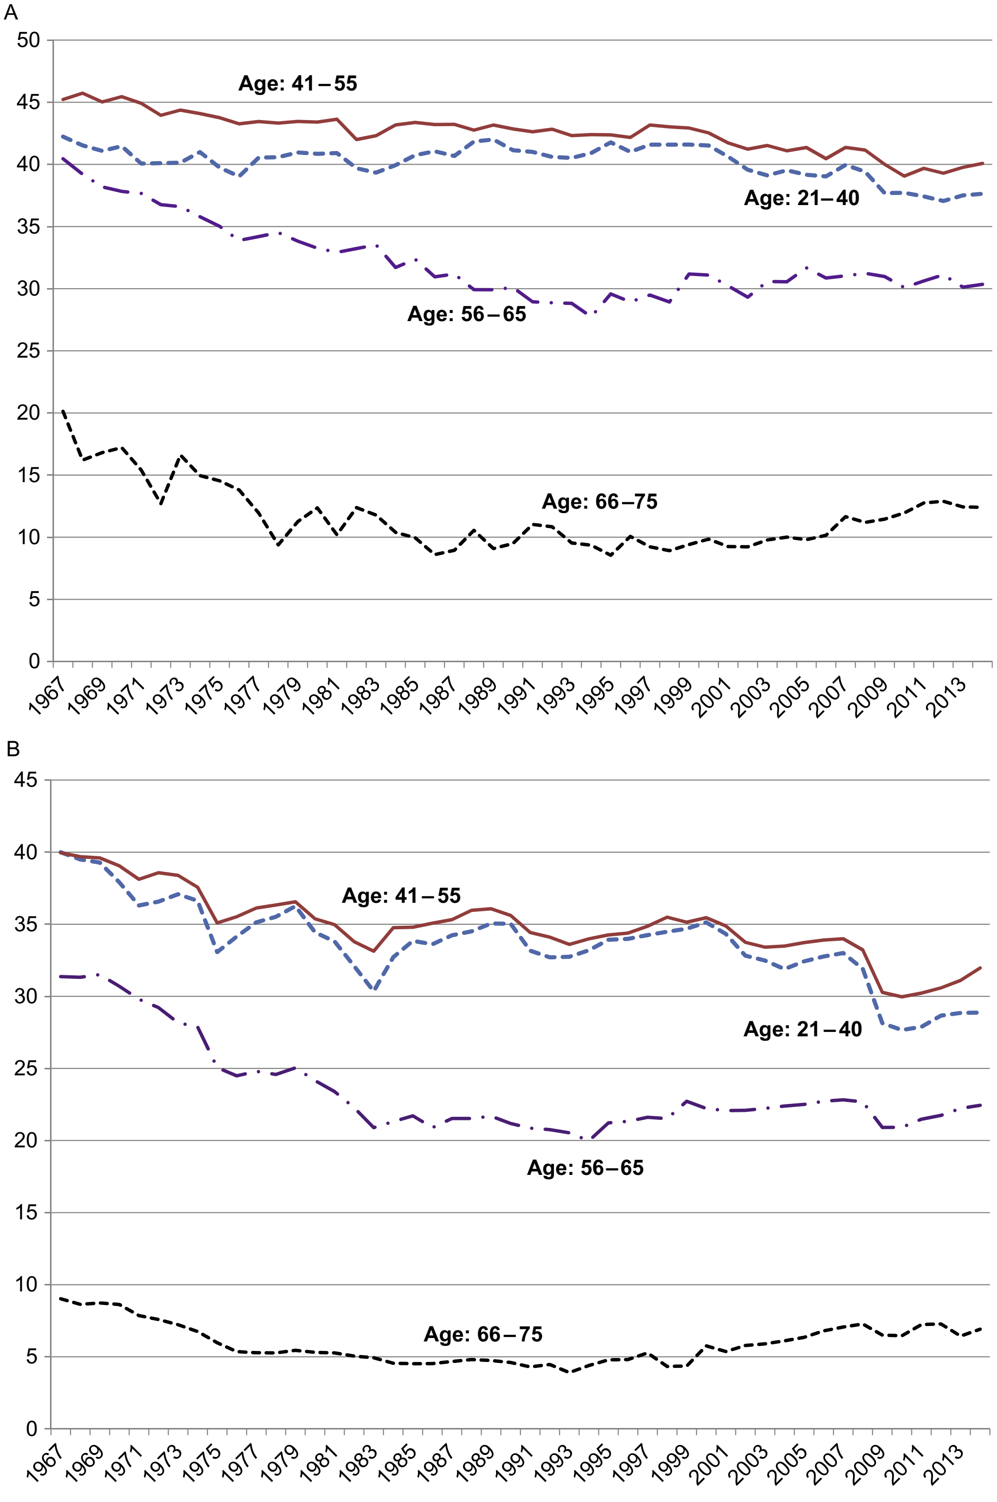

Fig. 7 See legend on opposite page.

To motivate the framework, a commodity could be a meal, which is produced using ingredients (a market good) as well as cooking time. In this example, time and goods are substitutes, as one could purchase the meal partially or completely prepared at a higher goods price but a lower time cost. Another example, in which time and goods are complements, is watching TV. For this commodity, the ability to substitute market expenditures for time inputs is limited; however, the purchase of additional inputs (like a premium channel) raises the value of time spent in the production of the commodity.

The agent lives for T periods and has preferences over sequences of consumption given by:

$$\sum_{t=0}^{T-1} \beta^t u(c_1(t), \ldots, c_I(t)).$$

There is no uncertainty and utility is separable across periods.

We assume that the agent can borrow and lend freely at a an interest rate $R = \beta^{-1}$ and in period t chooses to supply labor $n(t)$ at a market wage $w(t)$. Starting from some initial assets a_0, the budget set is therefore:

$$\sum_{t=0}^{T-1} \beta^t \left(\sum_{i=1}^{I} p_i(t) x_i(t) - w(t) n(t) \right) \leq a_0.$$

We normalize the time endowment to one each period. The time allocation budget constraint is:

$$\sum_i h_i + n \leq 1, h_i, n \geq 0.$$

We shall assume that labor is interior, and so the wage is the opportunity cost of time inputs into home production. We also assume that $h_i \geq 0$ is never binding as well.

If we assume that f^i has constant returns to scale, then the implied price index for a unit of consumption commodity c_i can be expressed by $q^i(p_i, w)$, where q^i solves:

$$q^i(p_i, w) = \min_{x_i, h_i} p_i x_i + w h_i$$

subject to

$$f^i(x_i, h_i) \geq 1.$$

Fig. 7 CPS trends in market hours: men by education and age. Note: Figure shows the trends in market hours per week worked for more educated (A) and less educated (B) men by age between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all men between the ages of 21 and 75 (inclusive) within the survey. More educated men are defined as those men with a bachelor's degree or higher. Less educated men have years of schooling less than 16 years. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week.

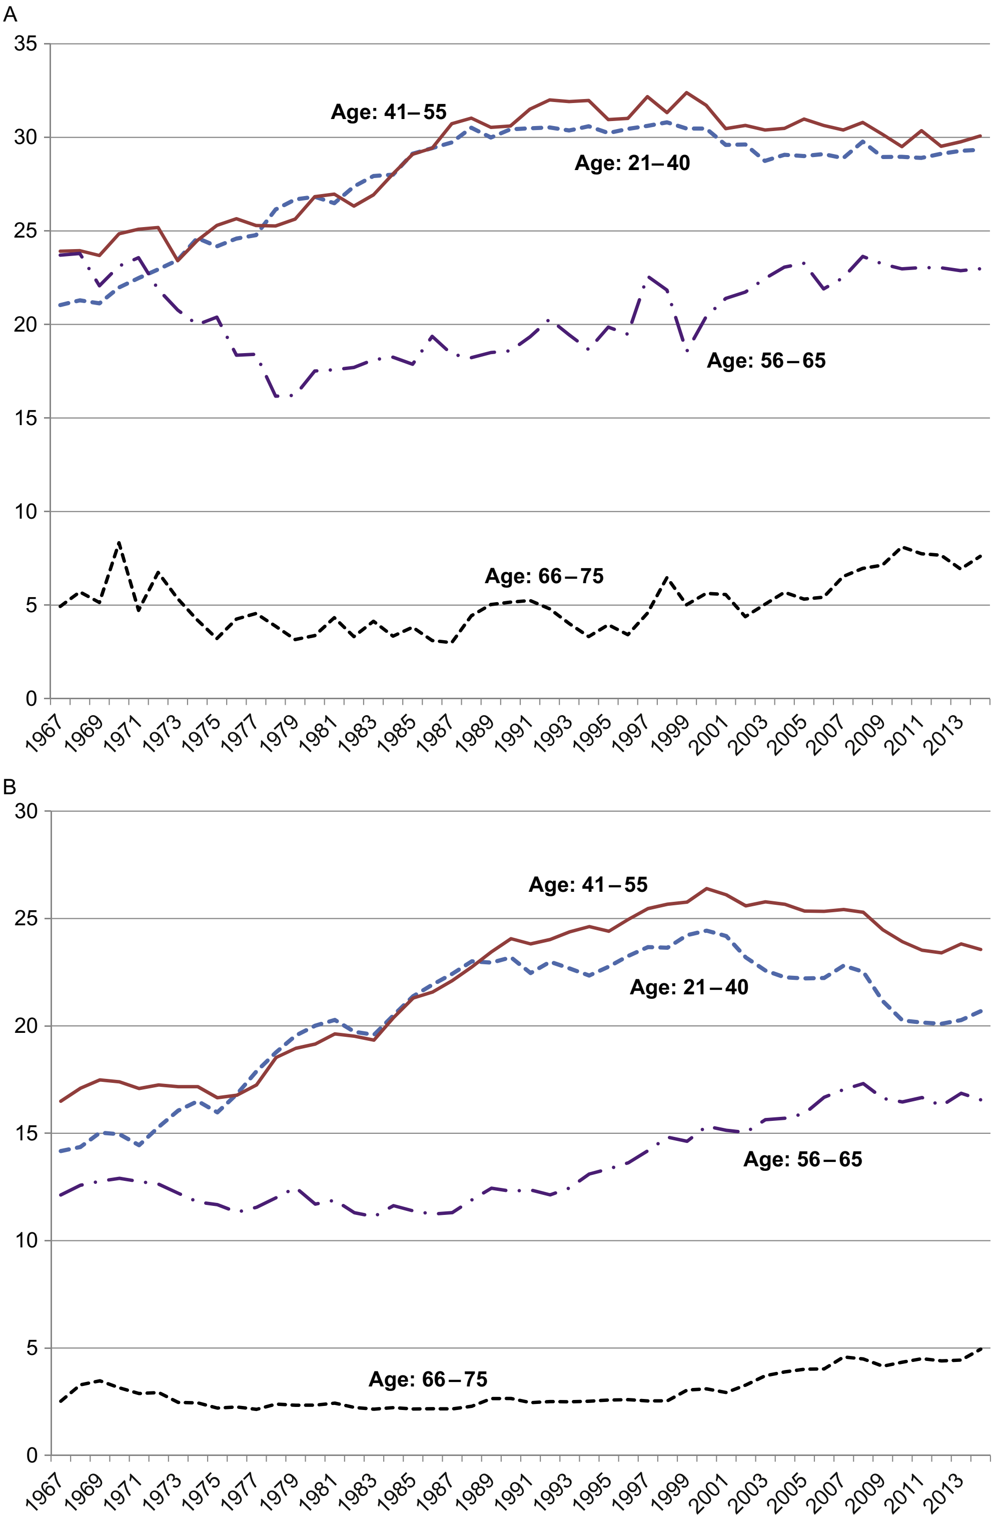

Fig. 8 See legend on opposite page.

Home production implies that the price of a consumption commodity depends on the price of the market input as well as the opportunity cost of time.

It is straightforward from the cost-minimization problem that:

$$\frac{f_h^i}{f_x^i}=\frac{w}{p_i},$$

that is, the marginal rate of technical substitution is set equal to the relative price of inputs. Denote the elasticity of substitution between x_i and h_i associated with the technology f^i by σ_i. As the relative cost of time increases, the agent will reduce the ratio of time to market inputs $\left(\frac{h_i}{x_i}\right)$ in production, the extent of this substitution being governed by σ_i. Again, for notational simplicity, we take σ_i to be constant.

The agent's problem can be rewritten as:

$$\max_{\{c_i(t)\}}\sum_{t=0}^{T-1}\beta^t u(c_1(t),\ldots,c_I(t))$$

subject to

$$\sum_{t=0}^{T-1}\beta^t\left(\sum_i q_i(p_i(t),w(t))x_i(t)-w(t)\right)\le a_0.$$

Letting λ be the multiplier on the budget constraint, the first-order condition is:

$$u_i\ =q^i\lambda.$$

An interesting question is how does time and market inputs vary with the wage holding constant λ. A little algebra leads us to:

$$\left.\frac{d\ \ln x_i}{d\ \ln w}\right|_\lambda\ =s_h^i\left(\sigma_i-\frac{1}{\gamma_i}\right), \tag{1}$$

where:

$$s_h^i=\frac{\partial\ \ln q^i}{\partial\ \ln w}=\frac{wh}{q_i c_i}$$

is the cost share of time input into commodity i and

Fig. 8 CPS trends in market hours: women by education and age. Note: Figure shows the trends in market hours per week worked for more educated (A) and less educated (B) women by age between 1967 and 2014. Data come from the March Current Population Survey. The sample includes all women between the ages of 21 and 75 (inclusive) within the survey. More educated women are defined as those women with a bachelor's degree or higher. Less educated women have years of schooling less than 16 years. Hours worked per week in the market are based on the self-reported response to a question of how many hours the individual worked last week.

$$\frac{1}{\gamma_i} = -\frac{u_i}{u_{ii}c_i}$$

is the intertemporal elasticity of substitution for commodity i.

Eq. (1) states that if the intratemporal elasticity of substitution is greater than the intertemporal elasticity of substitution, an increase in the cost of time (holding λ constant) will lead to an increase in market expenditure, and vice versa if $\sigma_i < \frac{1}{\gamma_i}$. The intuition is the following. An increase in the price of time induces substitution away from h_i and toward x_i for a given level of production. This substitution is governed by σ_i. However, an increase in the price of time raises the cost of consuming today relative to other periods, as $q^i(p_i, w)$ is increasing in both arguments. This induces a shift in consumption away from the high-wage period, and both expenditure and time inputs correspondingly decline. The size of this effect is governed by the intertemporal elasticity of substitution, $1/\gamma_i$. Whether expenditure goes up or down in response to variation in w depends on which effect dominates. Moreover, the effect is scaled by the share of time input into production of the commodity, s_h^i.

Similarly, the agent's first-order conditions imply:

$$\left.\frac{d\ \ln h_i}{d\ \ln w}\right|_{\lambda} = -\sigma_i(1 - s_h^i) - \frac{1}{\gamma_i} s_h^i. \tag{2}$$

This elasticity is unambiguously negative, as both intra- and intertemporal considerations imply reducing time inputs when the wage is high. The total effect is a weighted average of the two elasticities.

Using the time constraint, which implies $\sum_i h_i = 1 - n$, we can express the Frisch elasticity of nonmarket time $1 - n$ as:

$$\left.\frac{d\ \ln n}{d\ \ln w}\right|_{\lambda} = \sum_{i=1}^{I}\left(\frac{h_i}{n}\right)\left(\sigma_i(1 - s_h^i) + \frac{1}{\gamma_i} s_h^i\right), \tag{3}$$

which is a weighted average of the elasticity of each commodity's time input from Eq. (2). Eq. (3) implies that the elasticity of market labor depends on how time is allocated away from the market, and how elastic those activities are with respect to the wage. This insight goes back at least to Mincer (1962), who argued that women have a higher elasticity of market labor as their nonmarket time was concentrated in activities with close market substitutes, which would be high σ_i in our framework. As we shall see, women have been substituting nonmarket time away from home production and toward leisure in recent decades. In the Beckerian framework, this implies a corresponding evolution in the elasticity of labor supply. An interesting question for future research is whether this is reflected in the data.

4. TIME-USE DATA

Before proceeding, it is worth discussing how we measure time away from market work. For our primary data source, we use data from the 2003 to 2013 waves of the American Time-Use Survey (ATUS). The ATUS is conducted by the US Bureau of Labor Statistics (BLS) and individuals in the sample are drawn from the exiting sample of the CPS. On average, individuals are sampled approximately 3 months after completion of their final CPS survey. Given this, we can link each respondent to their labor market conditions when they were in the CPS. The ATUS is a highly detailed and easy-to-use survey, and the link to the CPS makes it straightforward to link time diaries to a long list of covariates.

At the time of the ATUS survey, the BLS updates the respondent's employment and demographic information. Each wave is based on 24-h time diaries where respondents report the activities from the previous day in detailed time intervals. Survey personnel then assign the activities reported by the individual to a specific category in the ATUS's set classification scheme which is comprised of over 400 detailed time-use categories. For more information on the types of activities that are recorded in the ATUS, see Hammermesh et al. (2005). The 2003 wave of the survey includes over 20,000 respondents, while each of the remaining waves includes roughly 13,000 respondents.

We segment the allocation of time into six broad time-use categories. We construct the categories to be mutually exclusive and to sum to the individual's entire time endowment. The six categories we look at are described in detail below and are based on the response for the primary time-use activity. These categories are defined similar to Aguiar et al. (2013).

Market work includes all time spent working in the market sector on main jobs, second jobs, and overtime, including any time spent commuting to or from work and time spent on work-related meals and activities. We separate from total market work the time spent on job search and the time spent on other income-generating activities outside the formal sector. This allows us to study the extent to which households spend time looking for employment or substitute time from the formal to the informal sector.

Job search includes all time spent by the individual searching for a job. As with all time-use categories, we include the time spent commuting associated with job search as part of time spent on job search. Job search includes, among others, activities such as sending out resumes, going on job interviews, researching details about a job, asking about job openings, or looking for jobs in the paper or the Internet.

Child care measures all time spent by the individual caring for, educating, or playing with their children. Guryan et al. (2008) show that the time series and life cycle patterns of time spent on child care differ markedly from the patterns of time spent on home production. In particular, the income elasticity of time spent on child care is large and positive, while the income elasticity of time spent on home production is large and negative. Additionally, some components of child care have a direct leisure component. For example, according to Juster (1985), individuals report spending time playing with their children as among their most enjoyable activities. On the other hand, there is a well-developed market for child care services that parents are willing to pay for to reduce their time spent with their children. Given these dichotomies, we treat child care as a separate category.

Nonmarket work (home production) consists of four subcategories: core home production, activities related to home ownership, obtaining goods and services, and care of other adults. Core home production includes any time spent on meal preparation and cleanup, doing laundry, ironing, dusting, vacuuming, indoor household cleaning, cleaning or repairing vehicles and furniture, and activities related to the management and the organization of the household. Home ownership activities include time spent on household repairs, time spent on exterior cleaning and improvements, time spent on the garden, and lawn care.[b] Time spent obtaining goods and services includes all time spent acquiring any goods or services (excluding medical care, education, and restaurant meals). Examples include grocery shopping, shopping for other household items, comparison shopping, coupon clipping, going to the bank, going to a barber, going to the post office, obtaining government services, and buying goods online. Finally, care of other adults includes any time supervising and caring for other adults, preparing meals and shopping for other adults, helping other adults around the house with cleaning and maintenance, and transporting other adults to doctors offices and grocery stores.

Leisure includes most of the remaining time individuals spend that is not on market work, nonmarket work, job search, or child care. Specifically, we follow Aguiar and Hurst (2007c, 2009) and try to isolate goods for which time and expenditure are complements. The time spent on activities which comprise leisure includes time spent watching television, time spent socializing (relaxing with friends and family, playing games with friends and family, talking on the telephone, attending and hosting social events, etc.), time spent exercising and on sports (playing sports, attending sporting events, exercising, running, etc.), time spent reading (reading books and magazines, reading personal mail and email, etc.), time spent on entertainment and hobbies that do not generate income (going to the movies or theater, listening to music, using the computer for leisure, doing arts and crafts, playing a musical instrument, etc.), time spent with pets, and all other similar activities. We also include in our leisure measure activities that provide direct utility but may also be viewed as intermediate inputs such as time spent sleeping, eating, and

[b] With respect to the long-run trends in time use, there is a debate about whether time spent gardening or spending time with one's pets should be considered as home production or leisure. See, for example, Ramey (2007). Given that the ATUS time-use categories can be disaggregated into finer subcategories, in this paper we include gardening and lawn care in nonmarket work and we include pet care into leisure.

personal care. While we exclude own medical care, we include activities such as grooming, having sex, and eating at home or in restaurants.

Other includes all the remaining time spent on one's education, time spent on civic and religious activities, and time spent on one's own medical and health care. Some of this time can be considered home production as well, as they represent time investments into the stock of health and human capital.[c]

For our main sample, we include all ATUS respondents between the ages of 21 and 75 (inclusive) who had complete time-use record. Specifically, we exclude any respondent who had any time allocation that was not able to be classified by the ATUS staff. In total, we have 107,768 individuals in our base sample. We use the sample weights provided by the ATUS to aggregate responses by age or by year. Throughout our analysis, we also look at subsamples by age, gender, and accumulated schooling.

We also bring in results from Aguiar and Hurst (2007c, 2009) when exploring historical trends in time use. For these historical trends, data are used from the *1965–1966 America's Use of Time* and the *1985 Americans' Use of Time*. The 1965–1966 Americans' Use of Time was conducted by the Survey Research Center at the University of Michigan. The survey sampled one individual per household in 2001 households in which at least one adult person between the ages of 19 and 65 was employed in a nonfarm occupation during the previous year. This survey does not contain sampling weights, so we weight each respondent equally (before adjusting for the day of week of each diary). Of the 2001 individuals, 776 came from Jackson, Michigan. The time-use data were obtained by having respondents keep a complete diary of their activities for a single 24-h period between November 15 and December 15, 1965, or between March 7 and April 29, 1966. When recounting historical trends in Aguiar and Hurst (2007c, 2009), the Jackson, Michigan sample was included. The 1985 Americans' Use of Time survey was conducted by the Survey Research Center at the University of Maryland. The sample of 4939 individuals was nationally representative with respect to adults over the age of 18 living in homes with at least one telephone. The survey sampled its respondents from January 1985 through December 1985. Again, weights were used to ensure that each day of the week was represented equally. The classification scheme for the time-use data used in Aguiar and Hurst (2007c, 2009) was nearly identical to the classification outlined above.[d]

[c] The "other" category also includes any time spent engaging in activities that generate income outside the formal market sector. These include time spent preparing hobbies, crafts, or food for sale through informal channels. Additionally, activities like informal babysitting are included in this category. As shown in Aguiar et al. (2013), this subcategory of time spent on income-generating activities outside the formal market sector is close to zero on average, suggesting that it is not worth analyzing as a separate category.

[d] While nearly identical, there were some differences. In particular, Aguiar and Hurst (2007c, 2009) included lawn care and gardening as a component of "leisure." In the classification using the 2003–3013 ATUS discussed above, lawn and gardening was included as a component of home production.

5. LONG-RUN TRENDS IN TIME USE

5.1 Historical Trends in Time Use

As show above, time spent on market work for men has been falling within the United States since the late 1960s, while time spent on market work for women has been increasing steadily during this time period. Using the detailed time diaries, we can measure the trends in three other time-use categories: nonmarket work, child care, and leisure. For much of the historical trends we document in this section, we draw on the work of Aguiar and Hurst (2007c, 2009). In those papers, Aguiar and Hurst restrict their attention to individuals between the ages of 18 and 65 who are nonretired. The nonretired restriction is necessitated by the restrictions to the 1965 survey which only sampled people who were nonretired. Likewise, the restriction excluding individuals over the age of 65 was necessitated by the 1965 survey not interviewing individuals above the age of 65. While these restrictions are slightly narrower than the restrictions, we impose on the ATUS data in subsequent sections, the restrictions do not alter the main take aways for the time series trends in any meaningful way.

Fig. 9 shows the time series patterns in nonmarket work, child care, and leisure for the full sample, men and women in 1965, 1985, and 2003 as documented by Aguiar and Hurst (2007c). Fig. 9A shows the trends in nonmarket work. Between 1965 and 2003, women dramatically decreased the time they allocated to home production by roughly 10 h per week. Men, conversely, increased their home production between 1965 and 1985 by roughly 3 h per week. Between 1985 and 2003, male home

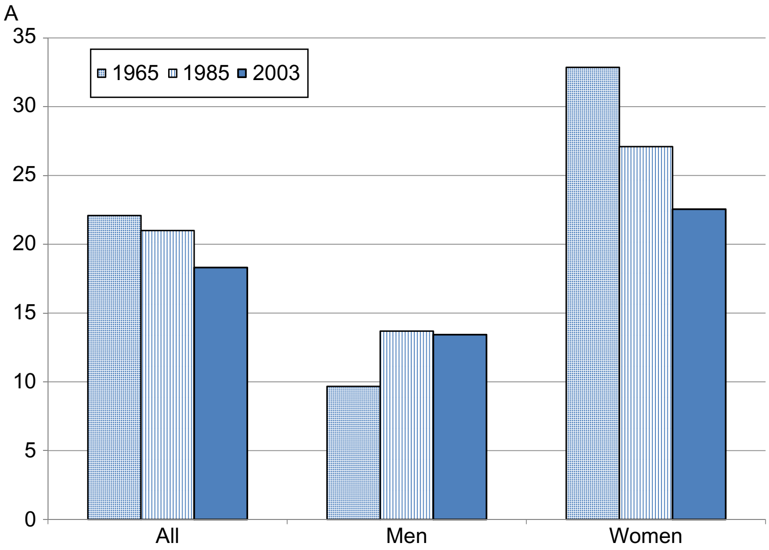

Fig. 9 Trends in time allocation: all men and women. Note: Figure shows the amount of time allocated to nonmarket work (A), child care (B), and leisure (C), in 1965, 1985, and 2003. Results in the figure come from tables II and III of Aguiar and Hurst (2007c). See text for additional details.

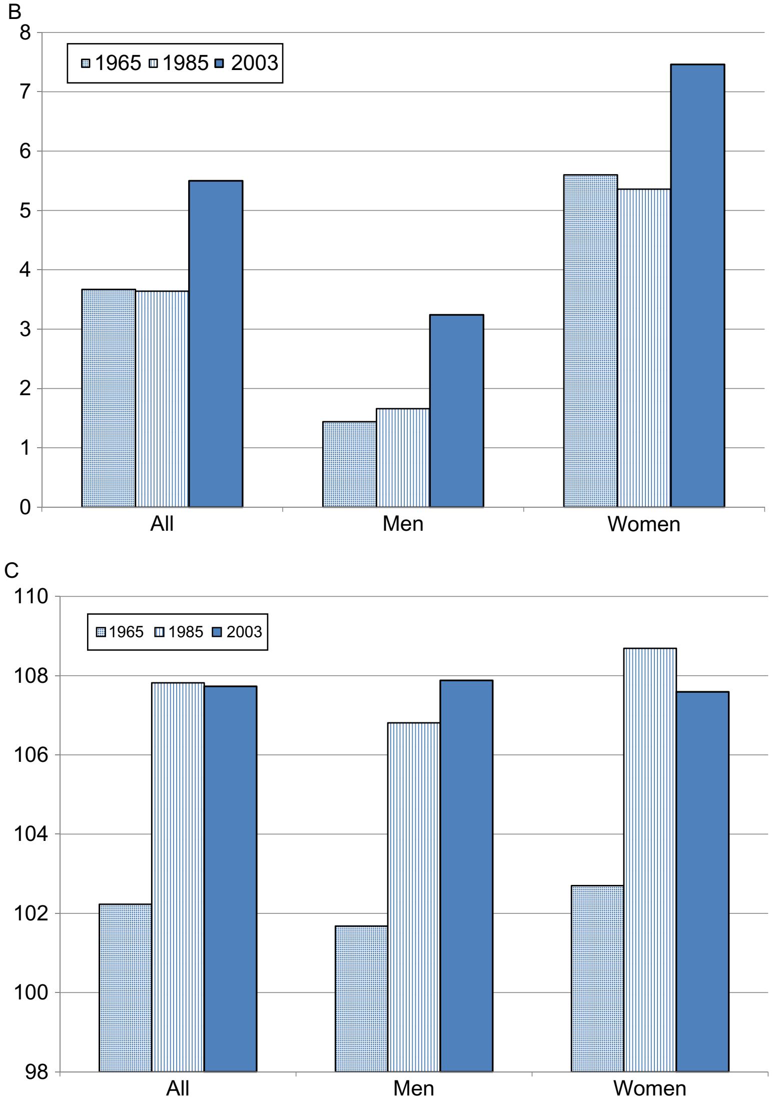

Fig. 9—Cont'd

production hours have been roughly constant. Not only has nonmarket work become less prevalent within the United States during the last 40 years, but also men and women are converging in their nonmarket work levels. Existing work has emphasized that innovations in the nonmarket sector caused women's increase in market work. For example, Greenwood et al. (2005) have shown that innovations in labor-saving devices used in home production allowed women to increase their labor supply in a model where home production is an active margin of substitution.

In Fig. 9B, we see time spent on child care has increased in recent years as well for both men and women. All of the increase took place after 1985. It is hard to tell how much of that increase is real or an artifact of the different survey designs between the 2003 ATUS and the earlier surveys. In particular, the ATUS had as a goal to measure parental time inputs into children. Ramey and Ramey (2010) document that the increase in time spent with children has increased more for high educated parents relative to low educated parents. The increasing gap in time spent with children by education has occurred in all categories of child care time: time spent on basic child care, time spent on educational child care, and time spent on recreational child care. They suggest that the increase in time spent on child care is real and a result of increased competition to get children into elite universities.

In Fig. 9C, the time series trends in leisure are shown. The large declines in market work for men during the 1960s, 1970s, and 1980s led to a large increase in leisure time for males between 1965 and 1985. Likewise, the large declines in home production for women during the 1960s, 1970s, and 1980s led to a large increase in leisure time for females between 1965 and 1975. For both men and women, leisure was roughly constant between 1985 and 2003. Men's leisure increase by roughly 1 h and women's leisure declined by roughly 1 h over the two decades between 1895 and 2003. It is interesting to note, however, that despite very different levels of market work, home production, and child care, men and women's leisure time is nearly identical in each decade. For example, in 2003, both men and women allocated roughly 107 h per week to leisure time activities. The 107 h includes time spent sleeping. Removing sleep from the leisure activities does not change any of the cross-sectional or time series patterns given that sleeping time is roughly constant over the decades and roughly constant between men and women.

Figs. 10 and 11 show the trends in home production and leisure by sex-skill groupings. The take aways from these figures are twofold. First, the trends in home production are nearly identical across educational attainment, conditional on sex. Second, the trends in leisure have diverged sharply between higher skilled and lower skilled individuals. Higher skilled individuals only experienced modest increases in leisure between 1965 and 2003. After experiencing large increases between 1965 and 1985, the leisure gains reversed between 1985 and 2003. Conversely, lower skilled individuals tracked their higher educated counterparts in terms of increased leisure time between 1965 and 1985 but continued to increase their leisure time between 1985 and 2003. The increase in leisure inequality has matched the well-documented increase in income and consumption inequality during the last 30 years documented by many in the literature.[e]

The above facts are drawn from the work of Aguiar and Hurst (2007c, 2009). However, Aguiar and Hurst (2007c, 2009) were not the only papers to harmonize historical

[e] See, for example, Aguiar and Bils (2015).

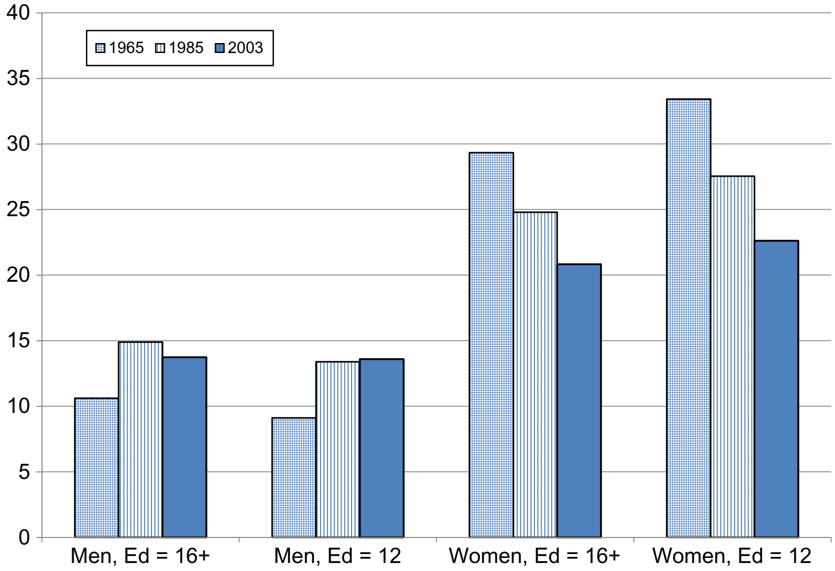

Fig. 10 Trends in nonmarket work hours: all, men, and women, by skill. Note: Figure shows the amount of time allocated to home production activities in 1965, 1985, and 2003 by sex and skill. The figure focuses on those with schooling levels of a bachelor's degree or more (Ed = 16+) and schooling levels of exactly a high school degree (ED = 12). Results in the figure come from tables V of Aguiar and Hurst (2007c). See text for additional details. Unlike the results in Fig. 7A–C, the results in this figure also adjust for the changing demographic composition over time within each sex-skill group. The demographic adjustment accounts for changing age distribution and family composition. The demographic adjustments made little difference to the broad time trends.

US time-use surveys to examine trends in nonmarket work and leisure over time. In classic books, Juster and Stafford (1985) and Robinson and Godbey (1999) harmonized the subset of the time-use data sets used by Aguiar and Hurst to explore trends in leisure and nonmarket work time during the 1960s, 1970s, and 1980s. Like Aguiar and Hurst (2007c, 2009), they also find large increases in leisure time for men and women during the 20-year period between 1965 and 1985. Contemporaneous to Aguiar and Hurst, Ramey and Francis (2009) harmonized the US time-use data and documented trends in leisure and home production for the population as a whole and for men and women separately. Like Aguiar and Hurst (2007c), Ramey and Francis (2009) also found a large decline in aggregate home production time for prime-age individuals between 1960 and the early 2000s. Ramey and Francis (2009), however, find that there was very little increase in leisure for either prime-age men or women during this time period.[f]

[f] See Ramey (2007) and Aguiar and Hurst (2007a) for a reconciliation of the differences in leisure trends between the two papers. A large part of the debate is whether eating while at market work is considered market work (Aguiar and Hurst) or leisure (Ramey and Francis).

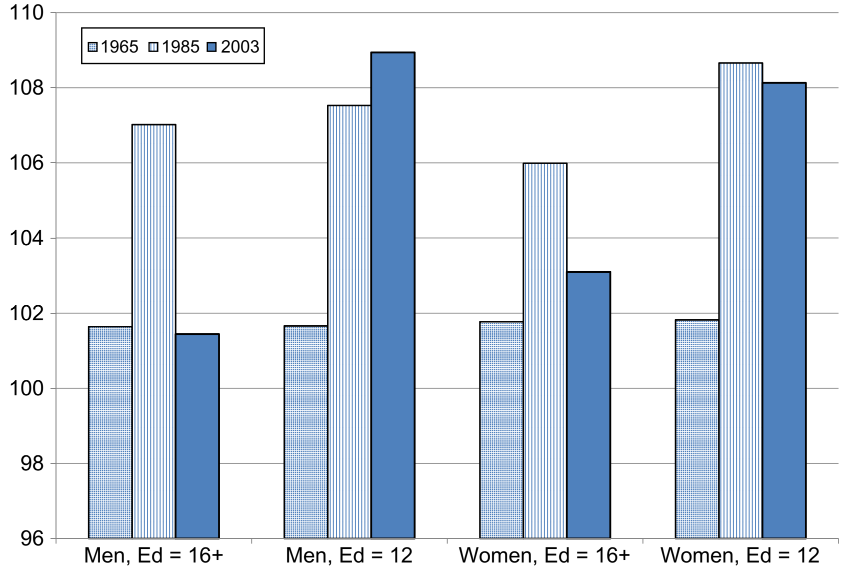

Fig. 11 Trends in leisure hours: all, men, and women, by skill. Note: Figure shows the amount of time allocated to leisure activities in 1965, 1985, and 2003 by sex and skill. The figure focuses on those with schooling levels of a bachelor's degree or more (Ed = 16+) and schooling levels of exactly a high school degree (ED = 12). Results in the figure come from tables V of Aguiar and Hurst (2007c). See text for additional details. Unlike the results in Fig. 7A–C, the results in this figure also adjust for the changing demographic composition over time within each sex-skill group. The demographic adjustment accounts for changing age distribution and family composition. The demographic adjustments made little difference to the broad time trends.

Additionally, Ramey and Francis (2009) incorporate the findings of Ramey (2009) into their analysis which allows them to compute trends in nonmarket work and leisure prior to 1965. This is a very ambitious task given that there are no nationally representative time diaries within the United States prior to 1965. The goal of Ramey (2009) is to use nonrepresentative time-use surveys conducted within the United States prior to 1965 to compute the amount of home production done in the United States for an average individual by weighting the nonrepresentative samples appropriately. Using this methodology, Ramey (2009) concludes that between 1900 and 1965, nonmarket work time for women fell by about 6 h per week, while nonmarket work time for men increased by about 7 h per week. Given the Ramey (2009) estimates, Ramey and Francis (2009) state that aggregate leisure increased by an additional 2 h per week for prime-aged individuals between 1900 and 1965.

In summary, there is ample evidence that home production has been declining in the aggregate and leisure has been increasing in the aggregate over long time periods.

5.2 Recent Trends in Time Use

One of the prominent downsides to harmonizing the different time-use surveys to compute long-run trends is that there is no guarantee that the data collection methods, sample frame, and time-use categorization remained constant over time. Changes in collection methods, sample frames, and categorization may cause the trends highlighted above to be mismeasured. The recent advent of the American Time-Use Survey (ATUS) helps to mitigate such issues. Since 2003, a nationally representative sample of individuals have been asked to record their time use using a consistently defined method and categorization procedure. Given the data have been in existence for 11 years now, it is possible to create time series trends using only within ATUS variation.

Using the sample described in the preceding section, Fig. 12 shows the trends in market work, nonmarket work, child care, and leisure over the 2003–2013 period. Each panel focuses on a different time-use category. Within each panel, four lines are shown.

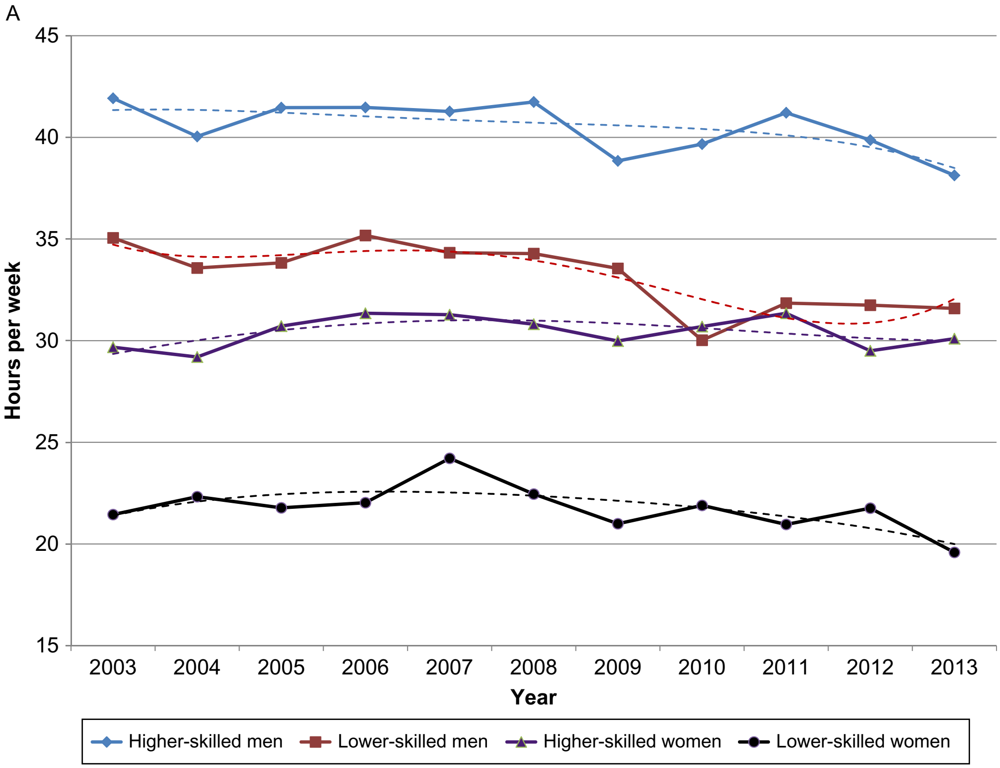

Fig. 12 ATUS trends by education and age. Note: Figure shows the trends in market hours (A), nonmarket work (B), child care (C), and leisure (D), per week worked for higher skilled men (*diamonds*), lower skilled men (*squares*), higher skilled women (*triangles*), and lower skilled women (*circles*) between 2003 and 2013. Data come from the American Time-Use Survey. The sample includes all individuals between the ages of 21 and 75 (inclusive) within the survey who had complete time diaries. Market work includes all time working on jobs for pay as well as any time commuting to work and any time spent at work associated with work meals and breaks. Nonmarket work includes activities such as cooking, cleaning, doing laundry, and shopping for groceries. Higher educated men are defined as those men with a bachelor's degree or higher. Lower educated men have years of schooling less than 16 years.

Fig. 12—Cont'd

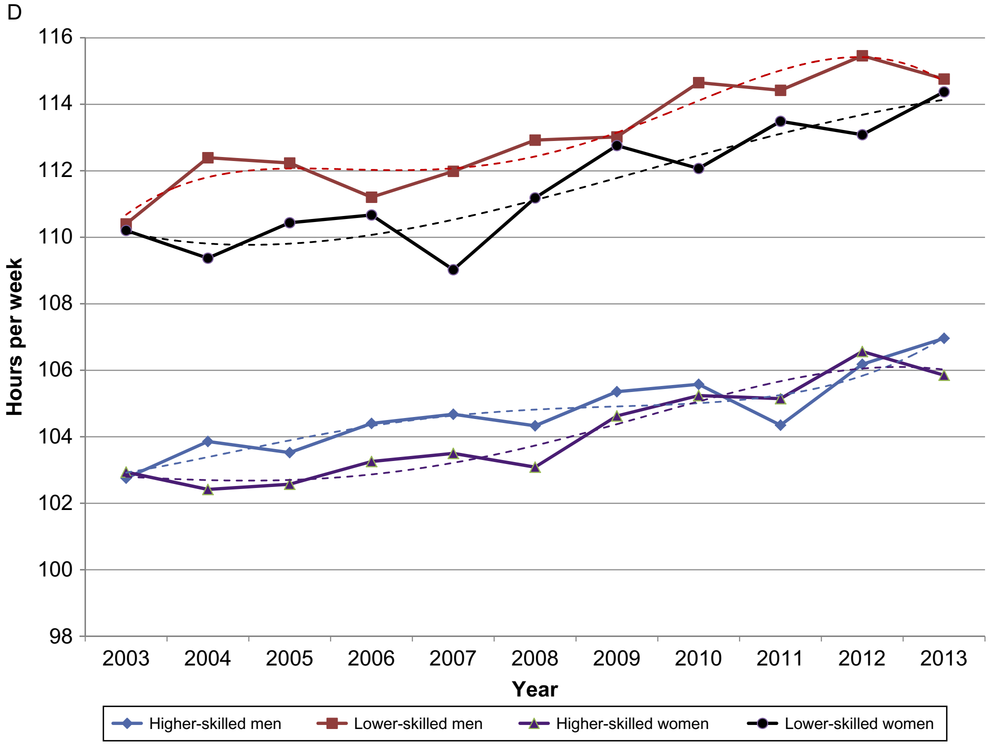

Fig. 12—Cont'd

Each line represents a sex-skill group pair. The data include all individuals between the ages of 21 and 75 who have all of their time use categorized by the ATUS. Fig. 13 is analogous to Fig. 12 except that the sample is restricted to individuals between the ages of 21 and 55.

Fig. 12A shows patterns similar to Figs. 5 and 6. During the last decade, all workers reduced the amount of time spent in market work with the declines being greater for those with less than at least a bachelors degree. Notice that the amount of time allocated to market work is higher in the ATUS relative to CPS totals documented in Figs. 5 and 6. The reason for this is that we are including time commuting to work and time spent at work during breaks and meals as being part of our market work measure. If we restrict our analysis to just time spent engaged in market work, the totals in the ATUS would be much closer to the market work totals reported in the CPS. Fig. 11A shows that the broad patterns are similar even restricting our analysis to those workers between the ages of 21 and 55 (as opposed to 21–75).

Figs. 12B and 13B show that home production has declined for all groups during the 2003–2013 period. For women, this just represents a continuation of the home production decline during the prior four decades. Notice that even within the ATUS, higher skilled women reduced their home production hours per week from about 22 h per week to about 19 h per week during the 2002–2013 period. This was made possible despite an overall decline in market work. As we show in the next section, a decline in market work is almost always associated with an increase in home production. What is also noticeable from Figs. 12B and 13B is that men actually reduced their nonmarket hours during this period as well. Again, this occurred despite their declines in market work hours. This

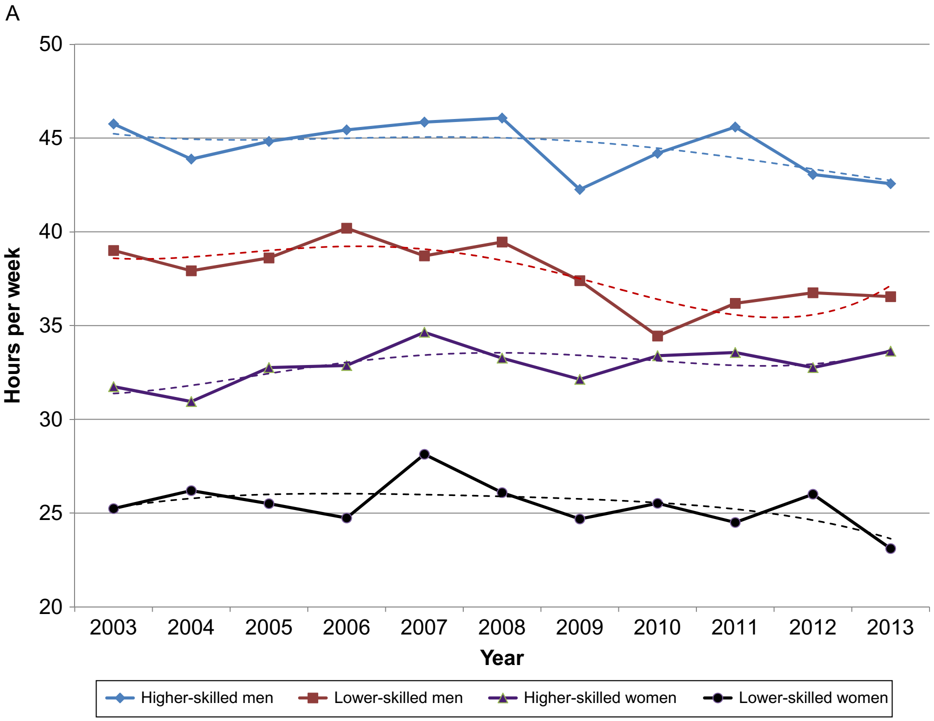

Fig. 13 ATUS trends by education and age: prime age. Note: Figure shows the trends in market hours (A), nonmarket work (B), child care (C), and leisure (D), per week worked for higher skilled men (*diamonds*), lower skilled men (*squares*), higher skilled women (*triangles*), and lower skilled women (*circles*) between 2003 and 2013. Data come from the American Time-Use Survey. The sample includes all individuals between the ages of 21 and 55 (inclusive) within the survey who had complete time diaries. Fig. 13—Cont'd

recent trend is a slight reversal of the near constant nonmarket hours between 1985 and 2003 highlighted in the prior section.

Figs. 12C and 13C show that trends in child care also reversed slightly relevant to the trends over the prior 20 years. Both higher and lower skilled women reduced their child care time by about 1 h per week between 2003 and 2013. This increase reduced much of the gains in child care time that occurred between 1985 and 2003. For men, child care time was essentially flat during the last decade.

Figs. 12D and 13D show the trends in leisure for higher and lower skilled men and women between 2003 and 2013. All groups experienced an increase in time allocated to leisure during this period. What is noticeable is that the trends are nearly identical in terms of both levels and growth rates within a skill category. For example, high-skilled men and women again have nearly identical times allocated to leisure despite having dramatically different time allocated to market work, home production, and child care. Likewise, low-skilled men and women have nearly identical time allocated to leisure. Prime-aged lower skilled individuals increased their time allocated to leisure by roughly 3 h per week over the last decade. Prime-aged higher skilled individuals increased their leisure time by about 2 h per week during the last decade. Again, the recent time series results suggest a continuation of the increased leisure inequality trends that have been occurring during the prior few decades.

5.3 Business Cycle Variation in Time Use

In the prior section, we showed that leisure time increased while market work and home production time fell for all sex-skill groups during the last decade. However, it is hard to tease out the time series trends from the potential effects of the recent business cycle using time series data alone. As described in Aguiar et al. (2013), business cycle effects can be estimated using cross-region data.

We begin this section by documenting the business cycle effects on time use by exploiting cross-region variation in employment changes during the recent recession. Specifically, we estimate the following specification:

$$\Delta Time_{kt}^{j} = \alpha_0^j + \alpha_1^j \Delta Time_{kt}^{market} + \epsilon_{kt}^{j},$$

where $\Delta Time_{kt}^{market}$ is the average hour per week change in market hours across individuals in state k between period t and $t + s$ and $\Delta Time_{kt}^{j}$ is the average hour per week change in time spent on category j across individuals in state k between period t and $t + s$. To estimate these relationships, we use data for all individuals between the ages of 21 and 75 in the ATUS samples between 2007 and 2013. To increase power when computing means at the state level, we collapse the underlying data into multiyear samples. In particular, we create state level means for each time-use category in 2007–2008, 2009–2010, and 2011–2013. For each state, we compute $\Delta Time_{kt}^{j}$ by taking the difference in average time spent in category j in state k between the two adjacent time periods (2009–2010 vs 2007–2008 and 2011–2013 vs 2009–2010). As a result, we have 102 observations in the regression (two observations each for the 50 states plus the District of Columbia). The identification restriction for this exercise is that the underlying trends in time use for each category are similar across states. Therefore, the state variation is isolating only the business cycle variation in time use.[g]

Fig. 14 shows the cross-state relationship between market work changes and home production changes (A), child care changes (B), leisure changes (C), and job search (D). The change in market work within each state during the adjacent time periods (measured in hours per week) is on the x-axis. This stays the same across each of the four panels. On the y-axis of each panel is the respective change in the relevant activity, also measured in hours per week. According to Fig. 14A, as market work hours fall at business cycle frequencies, 36% is reallocated to home production ($\alpha_1^{nonmarket} = -0.36$ with a standard error = 0.04). As seen in Fig. 14C, a fall in market work of 1 h at business cycle frequencies leads to an increase in leisure of 0.44 h ($\alpha_1^{leisure} = -0.44$ with a standard error = 0.04). Taking the two together, 80% of the foregone time from a decline in

[g] See Aguiar et al. (2013) for a more complete discussion of the identification issues.

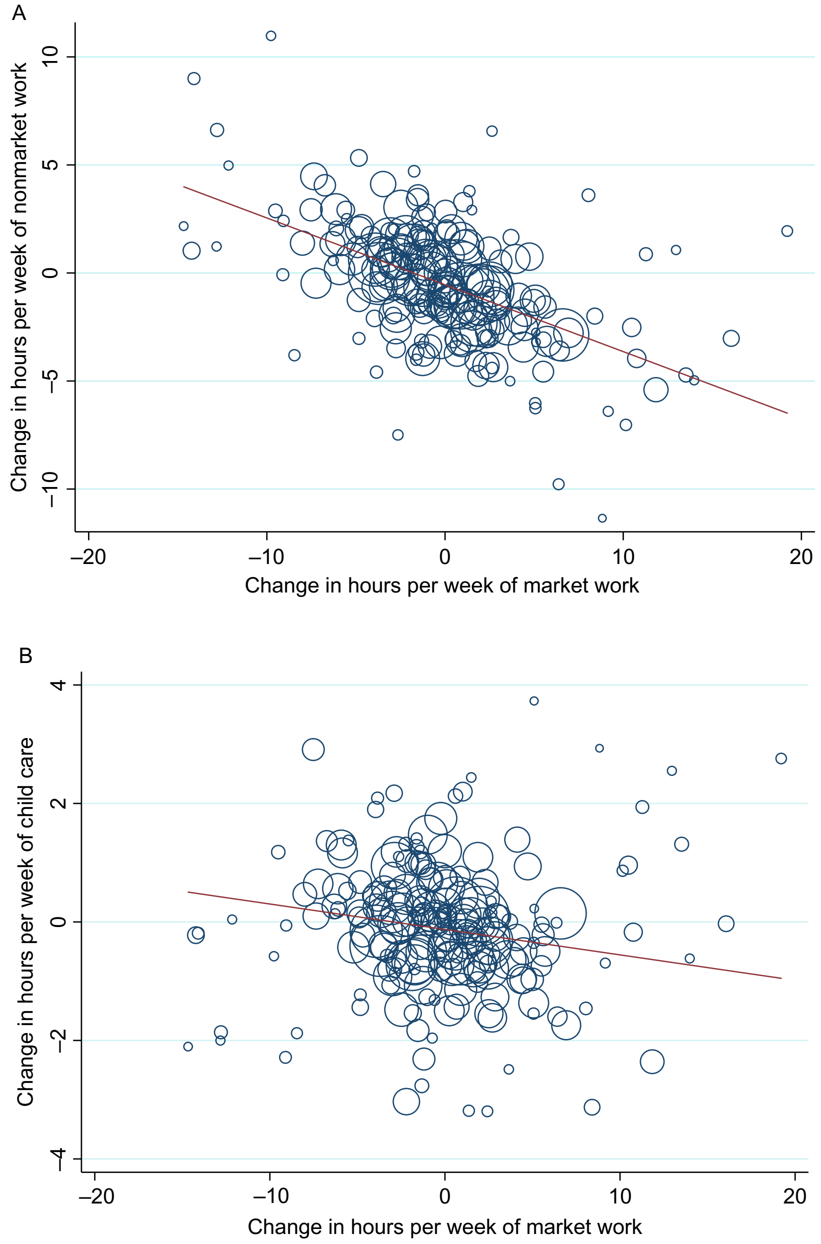

Fig. 14 Time allocation during the Great Recession. (A) Nonmarket hours, (B) child care, (C) leisure, and (D) job search. Note: Each panel shows change in market hours per week at the state level vs change in the indicated activity at the state level during the 2007–2013 period. For each state, three time-use observations are computed for each category: average time use in a given category pooled over years 2007 and 2008 (period 1), average time use in a given category pooled over years 2009 and 2010 (period 2), and average time use in a given category between 2011, 2012, and 2013 (period 3). The figure plots the change in time use between the first and the second period as well as the change in time use between the second and third time period. As a result, each state plus the District of Columbia is in the figure twice (for a total of 102 observations). The size of the *circle* represents the number of ATUS respondents within the state in the initial period from which the change is computed. The *line* is a weighted regression line through the scatter plots where the weights are the number of ATUS respondents within the state in the initial period from which the change is computed. The slope of the line is −0.31 with a standard error of 0.03 where the standard error is clustered by state.

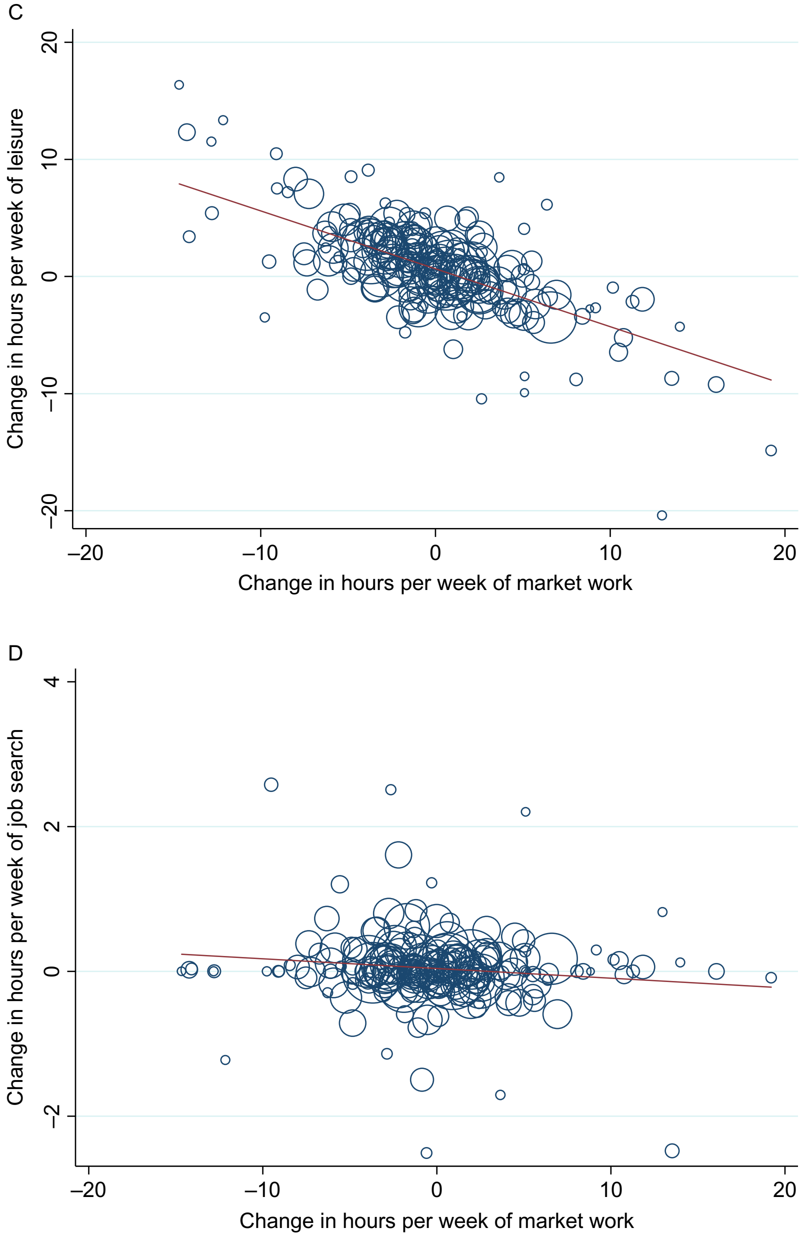

Fig. 14—Cont'd

market work is allocated to either leisure or home production. However, these findings complicate the interpretation of the time series trends shown in the prior sections. The fact that home production times fell for both high- and low-skilled men and women from the mid-2000s through 2013 despite the fact that the economy was in a recession may seem puzzling. If there were only business cycle factors driving the time series patterns, we would have expected home production times to increase as market work hours fell. The fact that home production times fell suggests that there was a large secular decline in home production time above and beyond the business cycle. This is not surprising given that home production times have been declining for decades.

Fig. 14B shows that child care time also increases in states as market work fell during the recession. Again, the time series patterns of time use suggest that during the recession child care time in the aggregate actually fell. The fact that aggregate time spent on child care activities fell despite the aggregate recession again suggests that there may have been a secular decline in child care time during the 2000s. If true, this would represent a reversal of the trends documented in Ramey and Ramey (2010), showing that time spent with children was increasing particularly among higher skilled parents.

While not formally extended in this chapter, Aguiar et al. (2013) show that investments in education, civic activities, and health care also absorb an important fraction of the decrease in market work hours (more than 10%), whereas job search absorbs around 1% of the decrease in market work hours (Fig. 14D). The latter finding is not surprising, given how little time unemployed spent searching for a job (Krueger and Mueller, 2010). The results suggest whether the job search measures in time-use surveys are designed to measure actual job search efforts of individuals looking for a job.

5.4 Time Use of the Unemployed

Another way to look at the effects of business cycle conditions on time use is to compare the time use of the unemployed relative to the employed. Such a comparison may suffer from composition differences across individuals. For example, individuals with a higher taste for leisure may be more likely to end up in the unemployment pool. Despite that limitation, we feel it is still informative to document the time use of individuals with different labor market status.

Table 1 shows the allocation of time in market work, nonmarket work, child care, leisure and other for men with at least 16 years of schooling (top panel) and men with less than 16 years of schooling. Each column represents a distinct labor market status. The first and second columns include men employed in the formal market sector (column 1) and men who are unemployment (column 2). The unemployed men are those individuals who are currently not working but who are actively seeking employment. Columns 3 and 4 include men who are out of the labor force. This category includes those who are disabled, retired, students, or who are otherwise not working and not seeking employment. We segment those out of the labor force into those under 63 and those 63 and over. The reason for this bifurcation is to identify potentially retired households. Most households over the age of 63 who are not attached to the labor force are retired.

Table 1 Time allocation by employment status: men

	More educated			
Activity	**Employed**	**Unemployed**	**NILF (age $<$ 63)**	**NILF (age $\geq$ 63)**
Leisure	100.27	121.47	127.80	134.11
Market work	47.70	1.98	0.47	0.11
Job search	0.09	9.37	0.58	0.00
Home production	12.73	23.64	21.42	25.26
Child care	3.59	4.25	2.70	1.71
Other	3.45	6.86	14.70	6.55
Observations	13,746	412	783	1,054

	Less educated			
Activity	**Employed**	**Unemployed**	**NILF (age $<$ 63)**	**NILF (age $\geq$ 63)**
Leisure	103.36	131.58	139.14	140.42
Market work	46.15	0.76	0.38	0.20
Job search	0.11	4.90	0.22	0.00
Home production	12.91	21.89	16.85	20.62
Child care	2.63	3.74	2.49	1.21
Other	2.72	4.59	8.71	5.31
Observations	22,319	1625	3603	3399

A few things are noticeable from Table 1. First, higher (lower) educated men who are unemployed still allocate roughly 2 (1) h per week to market work. All of this work, however, is outside the formal sector. This work includes side jobs for pay outside the formal sector. Second, higher educated unemployed men spend roughly 9 h per week in job search. The comparable number for lower educated men is 5 h per week. The number is essentially zero for employed men and men out of the labor force regardless of years of schooling. Third, like with the business cycle analysis discussed above, roughly 47% of the foregone difference in market work hours for higher skilled men (21/45) and 62% of foregone difference in market work hours for lower skilled men (28/45) are allocated to leisure. About 20–25% of the difference in work hours between unemployed and employed men—regardless of skill—is allocated to nonmarket work. The increase in leisure for lower skilled unemployed relative to the higher skilled unemployed is primarily due to differences in job search.

Table 2 shows similar patterns for women. The main difference between men and women is that lower educated women and higher educated women both have an increase in leisure time that represents roughly 45% of foregone differences in market work between the employed and unemployed. That is much smaller than the 62% of foregone work hours for lower educated men. Again, regardless of the analysis we perform—time series, life cycle, or business cycle—lower educated men take the most leisure.

Table 2 Time allocation by employment status: women

	More educated			
Activity	**Employed**	**Unemployed**	**NILF (age $<$ 63)**	**NILF (age $\geq$ 63)**
Leisure	99.56	115.96	112.79	128.24

Other	3.90	7.07	7.32	6.23
Observations	22,665	2068	8878	5671

One final question we want to address is whether the long-term unemployed have different allocation of time relative to shorter term unemployed. If differences exist, it could represent either selection or potential duration dependence on time use. However, as seen in Table 3, there does not appear to be any differential time-use patterns between the short- and long-term unemployed. To measure the duration of unemployment, we bring in data from the individual's labor market status in their last interview of the CPS. As discussed above, the ATUS sample is drawn from the exiting rotation of the CPS. In the last interview of the CPS, an individual's current employment status is measured. If the individual is unemployed, it asks the duration of their unemployment spell. While the ATUS asks respondents of their current employment status, it does not ask them the duration of their unemployment spell if they were unemployed. By linking individuals across the two samples, we can get an imperfect measure of current unemployment duration.[h]

In Table 3, we restrict our sample to those individuals who are unemployed (not working and currently looking for job) in the ATUS who were either employed or unemployed in the CPS 3 months earlier.[i] We then estimate the following regression:

[h] There is no information on employment spells between the CPS and ATUS interviews.

[i] We restrict observations to having a 3-month gap between the ATUS and CPS. This was the overwhelming majority of ATUS respondents.

Table 3 Time use of the unemployed: duration dependence

Duration (weeks)	Leisure	Search	Home production	Child care
0–9	0.23	−0.70	0.34	0.37
	(1.57)	(0.77)	(1.29)	(0.69)
10–19	0.43	0.48	−0.80	−0.23
	(1.95)	(0.96)	(1.61)	(0.86)
20–29	−0.97	−2.16	2.23	1.95
	(2.51)	(1.23)	(2.08)	(1.10)
30–39	−1.53	1.83	0.04	0.59
	(2.61)	(1.29)	(2.16)	(1.15)
40–49	−5.64	2.86	−0.10	1.53
	(3.58)	(1.76)	(2.95)	(1.57)
50+	3.14	−1.23	1.11	−0.20
	(1.76)	(0.87)	(1.45)	(0.77)

Note: The sample consists of ATUS respondents between the ages of 21 and 62 who report being unemployed at time of ATUS interview and whose interview is 3 months after last CPS interview. The sample size is 2164. The omitted group consists of respondents who were employed at the time of the last CPS interview. The rows of the table report coefficients on dummy variables for being unemployed at the time of the CPS interview for a duration of 0–9 weeks, 10–19 weeks, etc. Other controls include age, age squared, marital status, a dummy indicating having a child, and a dummy indicate race=white.

$$Time^j_{it} = \beta^j_0 + \beta^j_1 UnempDur_{it} + \beta_2 X_{it} + \beta_4 D_t + \eta^j_{kt},$$

where $Time^j_{it}$ is the time use of individual i in time t on category j, $UnempDur_{it}$ is the duration of the respondent's unemployment spell as measured in the CPS 3 months earlier, X_{it} is a vector of individual-level controls, and D_t is a vector of 1-year time dummies. The X_{it} vector includes age, age squared, a marital status dummy, a dummy for whether the individual had a child, and a race dummy. The unemployment duration measure is a series of dummy variable indicating the length of the CPS unemployment spell: 0–9, 10–19, 20–29, 30–39, 40–49, and 50+ weeks. The omitted dummy in the regression is those individuals who were employed in their last CPS interview but are currently unemployed. As a result, the regression estimates how time use among the current unemployed differs by the duration of their CPS unemployment spell relative to the current unemployed who were working in their last CPS interview. If unemployment spells are persistent, those unemployed in the ATUS working in their last CPS interview will have shorter unemployment durations than those unemployed in the ATUS who were also unemployed in the CPS. It should be stressed that this is an imperfect measure of unemployment duration because we do not observe the individual's employment status in 3 months in between the CPS and ATUS.

The results in Table 3 show that there is no statistically significant relationship between time use and the duration of the unemployment spell in the CPS. However, standard errors of our estimates are large. As a result, we cannot rule out that time use evolves with the duration of unemployment. Additionally, as discussed above, there is some noise in the unemployment duration measure. Just because an individual was unemployed for 10 weeks in their last CPS interview does not mean they were unemployed for 22 weeks when we measure them in the ATUS. There is, on average, 12 weeks between an individual's CPS and ATUS interview. The individual could have found employment in that interval but because unemployed again by the start of the ATUS. We view this as suggestive evidence at best about the relationship between unemployment duration and time use.

5.5 Macro Implications of Time Use over the Business Cycle

One of the most important contributions of the economics of time is in improving our understanding of aggregate fluctuations. The first wave of dynamic general equilibrium models, pioneered by Kydland and Prescott (1982), assumed that total time is allocated into only two activities, market work and leisure. There are good reasons why introducing a third activity, time spent on home production, can make a difference for these models. First, when individuals derive utility both from market-produced goods and from home-produced goods, volatility in goods and labor markets can arise because of relative productivity differences between the two sectors, and not just because of productivity shocks in the market sector. Second, relative price changes cause households to substitute goods and time not only intertemporally between periods but also intratemporally between the market and the home sector. Intratemporal substitution introduces a powerful amplification channel which is absent from the standard real business cycle model. In fact, in his review of the home production literature Gronau (1997) writes that "…the greatest contribution of the theory of home production in the past decade was in its service to the better understanding of consumption behavior and changes in labor supply over the business cycle."

The first papers to introduce home production into the stochastic neoclassical growth model were Benhabib et al. (1991) and Greenwood and Hercowitz (1991). Benhabib et al. (1991) show that the real business cycle model with home production performs better than the standard real business cycle model along a number of dimensions. Specifically, in a calibrated version of their model, one of the main findings is that home production increases the volatility of labor and consumption relative to output. This is because home production introduces an additional margin of substitution toward which market work and market consumption can be directed following exogenous technology shocks. Second, the introduction of technology shocks in the home sector lowers significantly the correlation of productivity with labor hours. This is because technology shocks in the home sector shift the labor supply schedule and tend to generate a negative correlation between productivity and hours. This tends to offset the positive correlation induced by technology shocks in the market sector which shift the labor demand schedule.

However, the model also produces some notable discrepancies relative to the data. As Greenwood and Hercowitz (1991) show, the model produces a counterfactual negative correlation between investment in the market sector and investment in the home sector. This is because in a two-sector frictionless model, resources tend to flow to the most productive sector. In general, this implies that investment does not increase in both sectors simultaneously following a technology shock in one of the sectors. Greenwood and Hercowitz (1991) show that introducing highly correlated technology shocks between the home and the market sector and increasing the complementarity of time and capital in the production of home goods help address this discrepancy. Chang (2000) shows that adjustment costs in the accumulation of capital help resolve the investment anomaly when time and capital are substitutes in the production of home goods.

6. LIFE CYCLE VARIATION IN TIME USE

The economics literature typically analyzes life cycle patterns of consumption and work by appealing to models that emphasize only the intertemporal substitution of goods and time. However, as discussed above, intratemporal substitution between time and goods could be important for explaining the life cycle patterns of both time use and expenditures. In this section, we begin by documenting life cycle patterns in time use for both men and women of different schooling levels. We then briefly highlight recent research that has found evidence on the importance of intratemporal substitution in explaining life cycle profiles of expenditure.

6.1 Life Cycle Profiles of Time Use

When estimating the life cycle profiles of time use, one has to consider the potential that either time or cohort effects are driving the results. However, as is well known, colinearity prevents the inclusion of a full vector of time dummies, cohort dummies, and age dummies when estimating life cycle profiles. In particular, as discussed in Hall (1968), age, year, and cohort effects are identified in repeated cross sections up to a log-linear trend that can be arbitrarily allocated across the three effects. To isolate age profiles, additional assumptions are required.

In the remainder of this section, we proceed in two steps. First, we assess the extent to which cohort effects alter the life cycle profiles of market work using repeated cross-sectional data from the CPS between 1967 and 2013. Second, we then document the life cycle profiles of market work, home production, child care, and leisure using repeated cross sections from the ATUS between 2003 and 2007. For the latter analysis, we stop in 2007 to isolate periods before the Great Recession took place.

Fig. 13A–D uses the CPS data to show the life cycle patterns for market work for higher educated men, lower educated men, higher educated women, and lower educated women, respectively. As above, "higher educated" means having at least 16 years of schooling. Specifically, each figure shows the age coefficients (relative to age 25) from the following regression:

$$market\_hours^g_{it} = \beta^g_0 + \beta^g_{age} Age_{it} + \beta^g_c Cohort_{it} + \beta^g_t D^{norm}_t + \varepsilon^g_{it}, \tag{4}$$

where $market\_hours^g_{it}$ is market hours of household i during year t from group g, Age_{it} is a vector of 50 1-year age dummies (for ages 26–75) referring to the age of the household head, $Cohort_{it}$ is a vector of 1-year birth cohort dummies, and D^{norm}_t is a vector of normalized year dummies. Our approach is to attribute hours differences across households to age and cohort effects and use year dummies to capture cyclical fluctuations. Specifically, we restrict the year effects to average zero over the sample period. Henceforth, we refer to the year dummies with this restriction on their coefficients as normalized year dummies.

Each of the four panels in Fig. 15 contains three lines. The first line estimates the above equation as is using the CPS data from 1967 through 2013. These lines are represented with triangles on each of the four figures. The second line drops the cohort effects and does not restrict the year effects to sum to zero. Formally, we report the age coefficients from the following specification:

$$market\_hours^g_{it} = \beta^g_0 + \beta^g_{age} Age_{it} + \beta^g_t D_t + \varepsilon^g_{it}.$$

This specification is also estimated on the CPS data from 1967 through 2013. The second line is designated with squares on each of the figures. By comparing the first line to the second line, we can provide an assessment of the importance of omitting cohort effects when estimating life cycle profiles in market work off repeated cross sections. The third line on each figure—designated with the triangles—is the same as the second regression except restricted to the 2003–2007 period. By comparing the third line to the second, we can see the extent to which the life cycle profiles with no cohort effects and unrestricted time effects differ in the 2003–2007 period relative to the longer 1967–2013 period. This is important given that for the ATUS data, we will only be estimating life cycle profiles using the 2003–2007 period.

There are three interesting take aways from Fig. 15. First, the life cycle profiles of market work differ across sex-skill groups. For higher skilled men, market work hours per week increase by about 6–7 h between the ages of 25 and 31. Between 31 and 51, hours worked per week were roughly constant for these men. After the age of 51, market work hours declined steadily toward zero by age 75. For lower skilled men, market work hours did not increase as much between the ages of 25 and 31 (2–3 h per week). For these men, peak market hours worked per week occurred around 40 h per week. So lower skilled men start decreasing their hours worked per week much earlier than higher skilled men. The life cycle patterns for market work for higher skilled women is dramatically different relative to either lower or higher skilled men. Higher skilled women reduce their work hours per week by about 5 h between the ages of 25 and 35. These are the ages when higher skilled women leave the labor force to start families. However, by the early 40s, their market work hours per week are back to the levels in their mid-20s. Their hours remain high through their mid-50s before declining toward zero by age 75. Lower skilled women

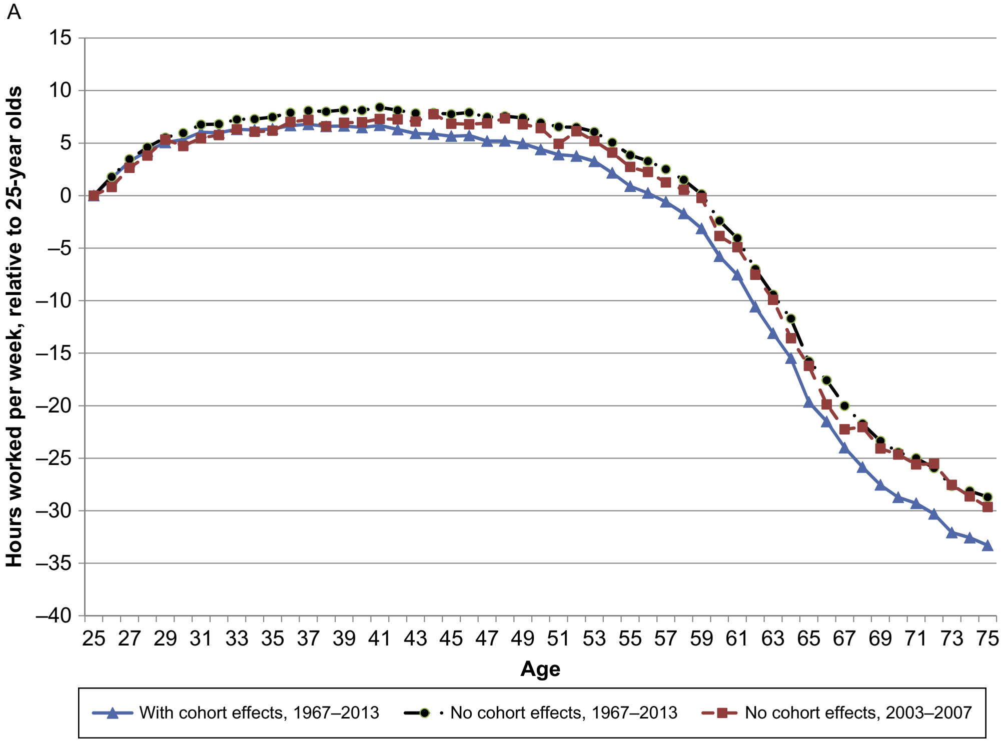

Fig. 15 Market hours over the life cycle. (A) More educated men, (B) less educated men, (C) more educated women, and (D) less educated women. Note: Figure shows the life cycle profile of market hours worked in the Current Population Survey (CPS) for men with at least 16 years of schooling (A), men with less than 16 years of schooling (B), women with at least 16 years of schooling (C), and women with less than 16 years of schooling (D). The *solid line with triangles* shows the life cycle profile using data from 1967 to 2013 controlling for 1-year cohort effects and normalized year effects. The normalized year effects are constrained to sum to zero across all years. The *dashed line with circles* shows the life cycle profile using data from 1967 to 2013 with no cohort effects but instead including year effects for each year separately. The *dashed–dotted line with squares* shows the life cycle profile using only data from 2003 to 2007 including year effects for each year separately.

have relatively low labor supply through their early 30s before increasing by roughly 3–5 h per week in their mid-40s.

The second thing to notice from Fig. 15 is that not controlling for cohort effects has only trivial effects on the life cycle profiles of market work for higher skilled men and women. This can be seen from the fact that the coefficients controlling for cohort effects (triangles) are nearly identical to the coefficients omitting the cohort effects (circles). When deviations exist, the differences are small. For example, controlling for cohort effects, higher educated men increase their hours worked per week by about 7 h per week between the ages of 25 and 40 and then decrease hours worked per week by about 41 h between 40 and 75. Without controlling explicitly for cohort effects, higher educated men increase their hours worked per week by about 8 h per week between ages 25 and 40 and then reduce hours worked per week by about 38 h between 40 and 75. The differences are slightly more pronounced for lower educated men and women. However, the life cycle patterns are for the most part quite similar regardless of whether or not one controls explicitly for cohort effects.

The final thing to notice from Fig. 15 is that life cycle profiles estimated from 1967 to 2013 with no cohort effects are again nearly identical as life cycle profiles estimated from 2003 to 2007 with no cohort effects. This fact holds for all sex-skill groups. This result gives us confidence that even though the ATUS data only start in 2003, the life cycle patterns we get from this period should be broadly consistent with the life cycle patterns over the past half century.

Fig. 16A plots the life cycle profiles of market work for higher educated men (diamonds), lower educated men (squares), higher educated women (triangles), and lower educated women (circles) using the 2003–2007 ATUS data. Instead of using 1-year age dummies, we regress hours per week in a given time-use category on a fourth-order polynomial in age. Using the coefficients from the fourth-order polynomial, we fit the predicted life cycle patterns for each time-use category. We use the fourth-order polynomial to smooth out some of the fluctuations over the life cycle in the 1-year age dummies given that the sample size of the ATUS is much smaller than the CPS. We then anchor the plots by taking the mean time use in each category for each sex-skill group at age 25.[j] This allows us to measure both the level and changes over the life cycle in hours per week allocated to a given activity.

Fig. 16A shows that the life cycle patterns in market work estimated of the cross section in the ATUS using 2003–2007 data are nearly identical to the patterns in Fig. 15A using CPS data. Higher educated men increase hours slightly from 25 to 40 before experiencing decline hours in their early 50s. Higher educated women decline their hours in market work between their mid-20s and mid-30s before increasing hours in market work through their early 50s. We view it as comforting that the life cycle patterns in market work in the ATUS are broadly similar with the life cycle patterns in the CPS.

Fig. 16B–D shows the life cycle patterns of time allocated to home production, child care, and leisure, respectively. Among younger individuals, lower educated women spend the most hours per week in nonmarket work. However, by the early 40s and throughout the remainder of the life cycle, the hours spent on home production for higher educated and lower educated women is nearly identical. All women, regardless of skill level, spend roughly 25 h per week in nonmarket work in their mid-40s. This number rises to about 30 h per week by age 65. Likewise, men spend nearly identical amounts in home production regardless of skill. As seen from Fig. 16B, the higher educated men and lower educated men lines are nearly on top of each other throughout most of the life cycle. Men spend about 12 h per week in home production in their mid-20s, about 15 h per week in their mid-40s, and about 20 h per week in their mid-60s. Between the ages of 40 and 70, the difference in home production hours per week between men and women narrows considerably. For all groups, as households age their time spent on home production increases.

Fig. 16C shows the life cycle patterns of time spent on child care for each group. A few things are noticeable from this figure. First, higher educated women have their peak in child care time around the age of 35. This is much later than the peak for lower

[j] When we report age 25 values, we actually take the mean for each sex-skill group for each category for ages 23–27. Again, we do this to help mitigate the measurement error given the smaller sample sizes within the ATUS.

educated women (around age 29). This reflects the fact that higher educated women have children later. Second, after the age of 29, higher educated women spend considerably more time in child care than lower educated women at every age. For example, at age 35, higher educated women allocate 17 h per week to child care. The comparable number is only about 10 h per week for lower educated women. Third, conditional on skill, men spend much less time on child care than do their female counterparts. Fourth, after the age of around 35, higher educated men spend much more hours per week in child care than lower educated women. Finally, higher educated men spend more time in child care at essentially every age. The uptick in time spent in child care in the 60s for higher educated men and women likely represents time spent with grandchildren.

Fig. 16D shows the life cycle patterns in leisure for all groups. Like the results above, lower skilled men experience the most leisure at every age of the life cycle. Higher educated men and women experience the least leisure at every age of the life cycle. However,

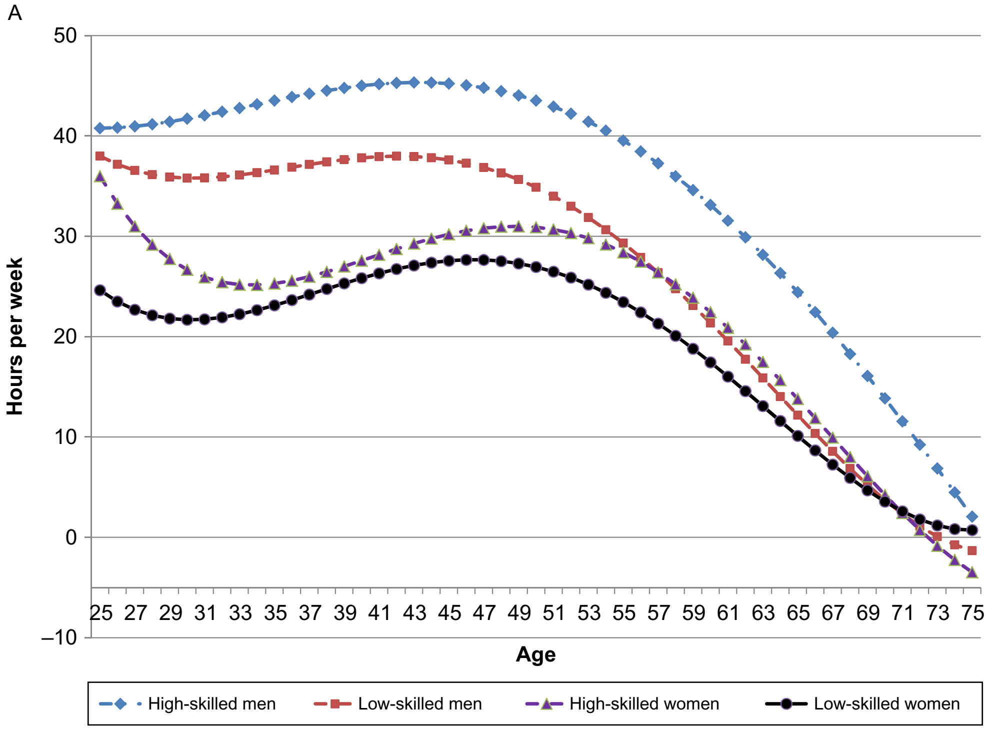

Fig. 16 Time allocation over the life cycle: ATUS data. (A) Market work, (B) nonmarket work, (C) child care, and (D) leisure. Note: Figure shows the life cycle profile of time allocation in the American Time-Use Survey (ATUS) by sex and skill group. The *line marked with diamonds* shows the pattern for men with at least 16 years of schooling. The *line marked with squares* shows the pattern for men with less than 16 years of schooling. The *line marked with triangles* shows the patterns for women with at least 16 years of schooling. The *line marked with circles* shows the patterns for women with less than 16 years of schooling. The profiles do not control for cohort effects but do include year effects for each year separately.

Fig. 16—Cont'd

one of the most striking facts from Fig. 16D is that despite the dramatic differences in market work, home production, and child care over the life cycle between higher educated men and women, their leisure times are nearly identical at every age. So, while the composition of work activities may differ between higher educated men and women, they are taking nearly identical amounts of leisure times. This is consistent with the time series evidence discussed above. Additionally, all households increase their leisure time dramatically after middle age. For example, higher educated men and women increase their weekly leisure time by about 35 h per week between the ages of 41 and 75. The increase is about 30 h per week for lower educated men and women.

6.2 The Importance of Intratemporal Substitution Between Time and Goods

The workhorse model of consumption over the life cycle, the permanent income hypothesis, posits that individuals allocate their resources in order to smooth their marginal utility of consumption across time (see, eg, Attanasio, 1999 for a review). If the marginal utility of consumption depends only on measured consumption, this implies that individuals will save early in their life cycle in order to maintain a smooth level of expenditures at retirement. During the last decade, there was a large amount of research that has showed that the substitution between time and expenditures is a first-order explanation as to why consumption varies over the life cycle.

The typical finding in the literature has been that consumption follows a hump-shaped pattern over the life cycle with consumption being low early in the life cycle, peaking at middle age and falling sharply at retirement. Some authors have argued that this life cycle profile represents evidence against the forward-looking consumption smoothing behavior implied by permanent income models, particularly since the hump in expenditures tracks the hump in labor income (as documented by Carroll and Summers, 1991). This view interprets expenditure declines in the latter half of the life cycle as evidence of poor planning. Other authors argue that the hump-shaped profile of consumption reflects optimal behavior if households face liquidity constraints combined with a need to self-insure against idiosyncratic income risks (see, for example, Zeldes, 1989; Deaton, 1991; Carroll, 1997; Gourinchas and Parker, 2002). Households build up a buffer stock of assets early in the life cycle, generating the increasing expenditure profile found during the first half of the life cycle. The decline in the latter half of the life cycle is then attributed to impatience once households accumulate a sufficient stock of precautionary savings.

In a recent paper, Aguiar and Hurst (2013) demonstrate that there is tremendous heterogeneity in the life cycle patterns of expenditures across different spending categories. In particular, some categories (eg, food and transportation) display the familiar hump-shaped profile over the life cycle, but other categories display an increasing (eg, entertainment) or decreasing (eg, clothing and personal care) profile over the life cycle. This heterogeneity cannot be captured by the standard life cycle model of consumption that emphasizes only the intertemporal substitution of goods and time. They show that home-produced goods (food) and work-related expenditures (clothing and nondurable transportation) account for the entire decline in total expenditures after middle age. Additionally, these same goods explain the overwhelming majority of the increase in the cross-individual dispersion in expenditures after middle age. The paper shows that failure to account for home-produced and work-related goods leads one to overestimate the amount of income risk faced by individuals.

A separate literature focused on the "retirement consumption puzzle." The literature found that that household expenditure falls discontinuously upon retirement. Banks et al. (1998) look at the consumption smoothing of British households around the time of retirement. Controlling for factors that may influence the marginal utility of consumption (such as family composition and age, mortality risk, labor force participation), they find that consumption falls significantly at retirement. Bernheim et al. (2001) find that total food expenditure declines by 6–10% between the preretirement and the postretirement period, which leads them to conclude that households do not use savings to smooth consumption with respect to predictable income shocks. Haider and Stephens (2007) use subjective retirement expectations as an instrument to distinguish between expected and unexpected retirements and find a decline in food expenditures ranging from 7% to 11% at retirement.

Aguiar and Hurst (2005) argue that tests of the life cycle model typically equate consumption with expenditure. However, as stressed by the model above, consumption is the output of a home production process which uses as inputs both market expenditures and time. As the above model highlights, individuals will substitute away from expenditures toward time spent on home production when the market price of time falls. Since retirees have a lower opportunity cost of time than their preretired counterparts, time spent on the production of commodities should increase during retirement. If this is the case, then the drop in expenditure does not necessarily imply a large decrease of actual consumption at retirement.

To test this hypothesis, Aguiar and Hurst (2005) explore how actual food consumption changes during retirement. Using data from the Continuing Survey of Food Intake of Individuals, a data set conducted by the US Department of Agriculture which tracks the dollar value, the quantity, and the quality of food consumed within US households, they find no actual deterioration of a household's diet as they transition into retirement. To test the hypothesis that retirees maintain their food consumption relatively constant despite the declining food expenditures, Aguiar and Hurst (2005) use detailed time diaries from the National Human Activity Pattern Survey and from the American Time-Use Survey and show that retirees dramatically increase their time spent on food production relative to otherwise similar nonretired households. That retirees allocate more time to nonmarket production has been also shown by Hurd and Rohwedder (2006) and Schwerdt (2005).

In light of these evidence, Hurst (2008) concludes that the retirement puzzle "has retired." That is, even though it is a robust fact that certain types of expenditures fall sharply as households enter into retirement, standard life cycle models with home production are able to explain this sharp fall because retirees spent more time producing goods.[k] Additionally, as we discuss in the next section, declines in expenditures are mostly limited to two types of consumption categories: work-related items (such as clothing and transportation expenditures) and food (both at home and away from home). When expenditures exclude food and work-related expenses, the measured declines in spending at retirement are either close to zero or even increasing.

A key parameter in whether household expenditures on a given good will increase or decrease as the household's opportunity cost of time falls is the elasticity of substitution between time and expenditures (σ from the theoretical discussion above) is greater than

[k] Hurst (2008) also discusses how health shocks that lead to early retirement can help reconcile the fact that actual consumption falls for a small fraction of households upon retirement.

or less than 1. In Aguiar and Hurst (2005) leisure goods are defined as goods for which the intratemporal elasticity between time and expenditures is less than 1. For these goods, spending increases when the opportunity cost of time falls (holding the marginal utility of wealth constant). For example, suppose that as individuals retire they play more golf. If the marginal utility of wealth was held constant during the retirement transition, golf would then be considered a leisure good. Conversely, Aguiar and Hurst argue that home-produced goods are goods for which the intratemporal elasticity between time and expenditure is great than 1 (holding the marginal utility of wealth constant). These goods may include groceries and cleaning services.

A large literature has developed to estimate the exact value of σ_i. Rupert et al. (1995) use home production time and food expenditure data from the Panel Study of Income Dynamics (PSID) to estimate σ for food. Most of their estimates point out for an elasticity that exceeds 1. Aguiar and Hurst (2007b) use data from the American Time-Use Survey. Assuming that the relevant opportunity cost of time is the marginal rate of technical substitution between time and goods in the shopping technology, they find a value of σ of around 1.8 for home-produced goods. Using PSID data, Gelber and Mitchell (2012) find that, in response to tax shocks, the elasticity of substitution between market- and home-produced goods is around 1.2 for single men and as high as 2.6 for single women. Finally, using consumer-level data on hours, wages, and consumption expenditure from the PSID and metro-level data on price indices p_i from the US BLS, Gonzalez Chapela (2011) estimates a life cycle model with home production and finds a value of σ in the production of food of around 2.

7. CONCLUSION AND DISCUSSION

The wealth of new data on measuring time use enable researchers to empirically investigate a variety of substantive questions in macroeconomics. Detailed diaries, linked to larger surveys, allow us to gain a better understanding of time series trends in market work, life cycle movements in household expenditures, and business cycle fluctuations in consumption and employment. This advances the agenda set forth in Gary Becker's Presidential Address. We conclude this chapter by highlighting some of the limitations of the existing time-use data and then discuss some directions for future research.

There are four major limitations to existing time-use surveys: (i) individual time-use data are not linked to individual data on expenditures; (ii) the data are from repeated cross sections, and do not contain a panel component; (iii) the data do not include measures of time use from multiple members of the same household; and (iv) the data do not measure detailed activities while at market work.

Researchers have worked around the lack of panel data by creating synthetic cohort data. Twenty-five-year-old white male high school graduates in year t of a time-use survey are, on average, the same individuals who are 26-year-old white male high school graduates in survey year $t + 1$. By tracking demographic groups across different years of cross-sectional data, synthetic panel data can be constructed. The synthetic cohort method also allows for a solution to the problem that time-use data and consumption data are measured in different surveys. If the samples are nationally representative, the consumption of 25-year-old white male high school graduates in year t from expenditure surveys can be merged with data for this same group in year t of the time-use surveys. The variation from the synthetic cohort method comes from variation across these demographic groups. Often this variation is enough to identify the questions of interest. But, the limitation is that lots of individual variation within a demographic group are thrown away when the synthetic panel method is used. Having panel data of time use—ideally in a survey which also measures expenditure—would allow researchers to exploit more variation to identify questions of interest. It would allow to compute changes in time allocation in response to, for example, demographic or employment status, while controlling for an individual's fixed characteristics. Moreover, multiple surveys would provide a better sense of how frequently an activity is undertaken.

Another major limitation of current time-use measurement is that we do not collect time-use information for multiple members of the same household. Many of the key questions that can be answered with time-use data can benefit from measuring the time use of multiple household members. If women start working more in the market, do their husbands work more at home? If one family member starts caring for an elderly parent, how is time use reallocated among additional family members? How do parents invest their time into their children? To really get a sense of the role of the family in explaining time series, life cycle, and business cycle variation in expenditure and labor supply, it is necessary to have time-use data that span multiple members of the same household.

Finally, no current nationally representative survey within the United States tracks in detail how individuals spend their time while at work. For example, within the American Time-Use Survey, time spent at market work is just one category. There is no additional detail provided about the tasks individuals perform while at work. It may be informative, for example, to know how much time individuals spend on the computer while at work vs in meetings. Or, alternatively, how much time an individual spends interacting with customers vs stocking shelves. How much time is spent in manual labor relative to time spent in cognitive activities? Making progress measuring how individuals allocate their time at work can help us to understand how the nature of work changes over time, over an individual's life cycle, and over the business cycle. As time-use surveys evolve, the type of questions researchers can answer will expand.

Nevertheless, the time-use data we now have available enable researchers to address many interesting macroeconomic questions. One line of research is obtaining a better understanding of labor supply, including how technological advances in nonmarket sectors shift labor force participation. Business cycle research can also benefit from incorporating data on time allocation. Particularly of interest is the time spent searching for employment, and the cyclical returns to job search. Time spent investing in children's human capital (viewed broadly) is also an active area of study. Time allocation is a key determinant of human capital accumulation, and it is important to quantify the return to time spent acquiring skills, on and off the job. More broadly, time-use surveys can shed light on how differences in the parental time allocated to child care influence the economic prospects of the next generation.

ACKNOWLEDGMENTS

We thank our discussant, Thibaut Lamadon, as well as the editors, John Taylor and Harald Uhlig, for helpful comments. The chapter also owes a debt to our collaborations with Loukas Karabarbounis. We thank Hilary Shi for excellent research assistance.

Abstract

This chapter reviews empirical estimates of differential income and consumption growth across individuals during recessions. Most existing studies examine the variation in income and consumption growth across individuals by sorting on ex ante or contemporaneous income or consumption levels. We build on this literature by showing that differential shocks to household net worth coming from elevated household debt and the collapse in house prices play an underappreciated role.

Handbook of Macroeconomics, Volume 2A
ISSN 1574-0048, http://dx.doi.org/10.1016/bs.hesmac.2016.03.005

Using zip codes in the United States as the unit of analysis, we show that the decline in numerous measures of consumption during the Great Recession was much larger in zip codes that experienced a sharp decline in housing net worth. In the years prior to the recession, these same zip codes saw high house price growth, a substantial expansion of debt by homeowners, and high consumption growth. We discuss what models seem most consistent with this striking pattern in the data, and we highlight the increasing body of macroeconomic evidence on the link between household debt and business cycles. Our main conclusion is that housing and household debt should play a larger role in models exploring the importance of household heterogeneity on macroeconomic outcomes and policies.

1. INTRODUCTION

Severe recessions are characterized by a large decline in household consumption. Consumption in real terms in the United States fell by almost 3% from the second quarter of 2008 to the second quarter of 2009. Consumption fell from 1929 to 1933 of the Great Depression by 18%. From 2008 to 2011, consumption fell by more than 5% in seven countries in the European Union, and by just less than 5% in Ireland and the United Kingdom.

Given the importance of consumption in household welfare, these sharp declines help explain why the study of recessions is a central pursuit of macroeconomics. One approach is to focus on the causes and implications of the aggregate decline in consumption. We believe, however, that an important pursuit of macroeconomic research should be to understand the *distribution* of the consumption decline across individuals. As the title of our chapter suggests, we want to focus on the question: who bears the cost of recessions? More specifically, which households see the largest drop in consumption during economic downturns?

This is an important question for several reasons. First, there has been an ongoing discussion within macroeconomics on the welfare cost of aggregate fluctuations, a debate instigated by the provocative exercise in Lucas (1987). Research since Lucas (1987) has shown that the distribution of income and consumption losses across individuals during recessions is an important factor in whether business cycles have large welfare consequences. For example, both Krebs (2007) and Krusell et al. (2009) use models with heterogeneity across households to argue that the welfare consequences of aggregate fluctuations are an order of magnitude larger than those calculated by Lucas (1987). Understanding both the distribution of consumption losses and their persistence helps reveal how harmful economic downturns are.

Another important reason to study the distribution of consumption growth during recessions is to evaluate the financial system. One of the central roles of the financial system is to efficiently allocate risk. A large body of research has focused on whether the data are consistent with full consumption risk sharing, when an individual consumption is not a direct function of idiosyncratic shocks received by the individual (eg, Cochrane, 1991). A focus on recessions is useful because it helps us evaluate whether risk sharing is present during times of steep declines in aggregate consumption. If it is not, then further analysis of the financial system and government insurance provision is warranted.

There are also important asset pricing implications from examining the distribution of consumption growth during recessions. Recessions tend to be times when asset prices decline. In representative agent consumption-based asset pricing models, a security's payments during recessions (ie, periods when marginal utility of consumption is high) is a central determinant of the value of the security. But as many researchers have noted, financial securities such as corporate equity are held disproportionately by high-income, wealthy individuals. Fluctuations in aggregate consumption may not be as useful in pricing financial assets as the fluctuations in consumption of individuals that tend to hold financial assets (eg, Malloy et al., 2009; Mankiw and Zeldes, 1991). Therefore, a central question in valuing financial assets is whether the consumption of individuals that hold financial assets is more or less cyclical than the rest of the population.

This review is split into three main parts. In the first part, we review the empirical literature on the cyclicality of income and consumption across individuals. We detail the exact time periods studied, data used, and conclusions of each study. Our primary focus is on research examining the cross-sectional differences in income growth and consumption growth across individuals during recessions. But we also cover ancillary empirical studies on consumption risk sharing and the evolution of consumption and income inequality over time. These latter two areas of research are related both from a theoretical and methodological perspective.

It becomes clear in our review of the literature that the role of wealth shocks, and in particular wealth shocks associated with housing, is largely absent. In Sections 3 and 4 of this chapter, we present empirical evidence on the importance of shocks to household net worth in explaining cross-sectional differences across US zip codes in consumption growth during the Great Recession. We begin this section by discussing both the advantages and disadvantages of zip code-level data. As a preview, the main advantage of zip code-level data is the ability to match high-quality administrative data on income, consumption, wealth, and demographics that naturally add up to aggregates used by most macroeconomists. The main disadvantage is that we can only estimate key parameters such as the elasticity of consumption with respect to net worth shocks at a slightly aggregated level.

Using zip code-level data, we show that variation in the decline in net worth coming from the collapse in house prices from 2006 to 2009, what we call the housing net worth shock, is a powerful predictor of consumption growth across zip codes. We utilize zip code-level administrative data on car ownership, new car purchases, and boat ownership, in addition to survey-based measures of the number of individuals living in a housing unit. By all of these measures, zip codes with a more negative housing net worth shock saw substantially lower consumption growth during the Great Recession. We also show that births declined by substantially more in zip codes hit harder by the housing crash.

The housing net worth shock in a zip code can be decomposed into the decline in house prices in the zip code, and the ex ante exposure of the zip code's wealth to a decline in house prices. We find that both matter. Prior to the recession, zip codes with a large exposure to the housing collapse saw a larger increase in house prices, homeowner borrowing, and consumption.

Motivated by these empirical results, we then review models of aggregate economic fluctuations that can best explain the link between house price shocks and the cross-sectional differences in consumption growth. While our empirical results focus mostly on the Great Recession, we also highlight macroeconomic evidence showing a strong link between household debt, house prices, and business cycles across many countries and time periods.

It is important also to note what this review chapter does not cover. Probably the biggest absence is a detailed review of quantitative macroeconomic models with heterogeneity across households (eg, the literature started by Bewley (1977) and Huggett (1993) among others). We cover some of this research as it has an important component, but we do not review it comprehensively. This literature has shaped our thinking in important ways, and our exclusion of this excellent body of research reflects the fact that there is already a must-read review of this literature by Heathcote et al. (2009). We highly recommend reading their review as a complement to this one.

2. WHO BEARS RECESSION RISK? EXISTING RESEARCH

2.1 Categorizing the Literature

As noted in Section 1, the cyclicality of consumption and income across the distribution of households in the economy plays a crucial role in important questions in macroeconomics. A critical input into any model of cross-sectional heterogeneity in risk exposure is a set of basic facts. As Guvenen et al. (2014) put it:

> *What is common to all of these theoretical and quantitative investigations is that they need to rely on empirical studies to first establish the basic facts regarding the cyclical nature of income risk. Unfortunately, apart from a few important exceptions discussed below, there is little empirical work on this question, largely because of data limitation.*

Our goal in this section is to review the empirical evidence on the cyclical nature of both income and consumption risk. While Guvenen et al. (2014) are correct that the evidence is limited, there are a number of important studies that can be used as a launching pad for further research.

There are five dimensions on which the extant literature can be categorized. First, does the study examine the cyclicality of *income* growth or *consumption* growth? Second, what data set is employed? Third, what time period is examined, and more specifically, does the study focus on one recession or a longer time series of cycles? Fourth, on what dimension are households sorted in the cross section when examining income growth or consumption growth across the distribution? And finally, does the study sort households based on ex ante characteristics, contemporaneous placement in the income or consumption distribution, or shocks received during the recession?

It is this last dimension around which we organize the rest of this section. In our view, the ideal empirical setting is one in which households can be sorted on some ex ante characteristic, and then tracked across cycles. More formally, define some period $\tau = 0$ to $\tau = T$ as an aggregate episode such as an expansion or recession. Following Guvenen et al. (2014), the empirical object of interest is:

$$f(H_{-1}^i) \equiv E[y_T^i - y_0^i | H_{-1}^i] \tag{1}$$

where H_{-1}^i is a characteristic of individual or group i measured before the episode in question and y_τ^i is log consumption or log income for individual or group i at τ.[a] The empirical object $f(H_{-1}^i)$ can be estimated in a flexible manner based on the number of groups.

For example, Guvenen et al. (2014) examine four recession periods between 1978 and 2013, and their primary specification uses average income over the five years prior to the recession as H_{-1}^i. They sort individuals into percentile bins based on this measure of H_{-1}^i, and they plot $y_T^i - y_0^i$ during each recession for each bin, where y is a measure of income. Such a plot allows us to see whether individuals with higher ex ante income levels see larger or smaller declines in income growth during recessions. As Guvenen et al. (2014) note, researchers must be cautious in estimating object (1) when H_{-1}^i is income or consumption. It is likely that income and consumption have mean-reverting properties. As a result, an estimation strategy that sorts on ex ante income and looks at subsequent income growth will tend to find negative effects of ex ante income on income growth. For example, one is likely to find that high-income individuals see larger declines in income growth. But in the presence of a mean-reverting income process, such a result would be partially mechanical.

Notice that availability of *panel* data is crucial for such an exercise. It is only possible if one can track the same households over time. We refer to the literature that estimates the object in (1) as sorting on ex ante characteristics.

[a] To minimize notation, y_τ^i represents log average consumption or log average income in the group whenever i is a group instead of an individual.

A related technique exploits panel data but sorts not on ex ante household characteristics but instead on shocks received during the recession. For example, a common assumption in quantitative models of heterogeneity is that some households become unemployed, and the probability of becoming unemployed is higher in recessions (eg, Krusell and Smith, 1999). A natural empirical object of interest in such a model is the decline in consumption among those individuals becoming unemployed during the recession:

$$f(S_T^i) \equiv E[y_T^i - y_0^i | S_T^i] \tag{2}$$

where S_T^i is a shock received during the recession such as unemployment or a decline in wealth. Once again, panel data are required to estimate this object. We refer to the literature that estimates the object in (2) as sorting on *contemporaneous shocks*.

Unfortunately, estimation of the objects in (1) and (2) requires panel data which are not widely available, especially on consumption. As a result, a third technique is to rely on repeated cross sections, where households in each cross section are sorted into percentiles of either the income or consumption distribution. This is common in studies, for example, that rely on income data from the Internal Revenue Service. Letting p be a percentile group of the distribution, these studies typically follow the object y_τ^p across time.

The drawback of this approach is that the evolution of y_τ^p over time depends both on changes in y for households that stay within group p, and changes in the composition of households in group p. Following Perri and Steinberg (2012), the change from any period $\tau = 0$ to $\tau = T$ in group p is:

$$y_T^p - y_0^p = \alpha\left(y_T^{p-stay} - y_0^{p-stay}\right) + (1-\alpha)\left(y_T^{p-in} - y_0^{p-out}\right) \tag{3}$$

The growth in an outcome for the p percentile of the distribution is a weighted average of the growth in the outcome for households that stay in the percentile group $\left(y_T^{p-stay} - y_0^{p-stay}\right)$ and the compositional change in the percentile group $p\left(y_T^{p-in} - y_0^{p-out}\right)$. Notice that the first term of this expression is almost identical to the object of interest in (1) where the sorting variable is the percentile of the distribution ex ante. We refer to research following (3) as following a *repeated cross-section* approach.

One obvious question is how good a proxy for object (1) is object (3). This depends primarily on movements across the distribution during episode being examined. To our knowledge, there is no comprehensive evaluation of this technique in the literature. The closest we could find is Perri and Steinberg (2012), who highlight different patterns in consumption growth depending on whether individuals or percentiles are tracked over time. We will discuss Perri and Steinberg (2012) in more detail below.

A final group of studies we discuss below are those that use empirical moments from data to calibrate quantitative macroeconomic models of household heterogeneity. As mentioned in Section 1, we do not do a comprehensive review of this literature.

But many of these studies contain significant empirical work that is related to the core questions of this review.

2.2 Sorting on Ex Ante Characteristics

The gold standard for evaluating the cross-sectional implications of recessions for earnings is the study by Guvenen et al. (2014). Using a very large data set from the US Social Security Administration, they are able to track the earnings of individuals from 1978 to 2011, which allows analysis of four recessions. Their main data set focuses on US working-age males over this time period. Given the panel structure of the data, they are able to estimate object (1) explicitly by sorting individuals into income bins prior to each recession and expansion.

The exact dates they use for the four recession periods are 1979–83, 1990–92, 2000–02, and 2007–10. They estimate a slight variation of object (1) above in order to avoid problems associated with those with zero earnings. The actual function they estimate is:

$$\log\left(E[y_T^i|H_{-1}^i]\right) - \log\left(E[y_0^i|H_{-1}^i]\right)$$

Figure 13 in their study reveals the central finding with respect to recessions. In all four recessions, there is a positive relation between ex ante income and income growth from the 10th percentile of the distribution to the 70th percentile. For all recessions except for 2000 to 2002, the positive relation continues to the 90th percentile. That is, for the majority of the income distribution and for all recessions, lower income individuals suffer more during recessions as measured by income growth. Notice this effect is probably understated given that mean-reversion would bias the coefficient in the opposite direction.

The pattern is less consistent at the upper tail of the distribution. The two latest recessions look remarkably similar at the very top of the income distribution. Individuals in the top 10% of the ex ante income distribution see the largest decline in income in the entire population. At the 99th percentile, income drops by a stunning 30%. This pattern is not present in the two earlier recessions. In sum, from the 10th percentile to 90th percentile of the ex ante income distribution, lower income individuals see a bigger decline in income during recessions. The results are less definitive above the 90th percentile, with the last two recessions showing the biggest decline among the very rich.

Perri and Steinberg (2012) use panel data from the Panel Study of Income Dynamics (PSID) to study disposable income growth during the 2007 to 2009 recession across the income distribution. They first show that the bottom 20% of the income distribution saw a sharp decline in earnings, falling by 30% relative to the median over the course of the recession. However, they also show that redistribution through taxes and transfer programs helped offset the decline in earnings. Disposable income, after taking into account taxes and transfers, declined the same amount for the rest of the population and households in the bottom 20% of the income distribution.

The above findings are based on comparing income for the bottom 20% of the income distribution in 2006 and 2008. But as mentioned above, a problem with such a methodology is that there may be significant compositional changes in the households in the bottom 20%. The study by Perri and Steinberg (2012) is one of the few that discusses this problem, and compares estimates when taking into account the compositional change. They show that 75% of the individuals in the bottom 20% of the income distribution in 2008 were in the bottom 20% in 2006. They also show that the households that enter the bottom 20% of the income distribution from 2006 to 2008 see a dramatic 53.4% decline in disposable income. Households that stayed in the bottom 20% saw a decline of 2% in disposable income. Households that left the bottom 20% from 2006 to 2008 saw a 110% rise in disposable income.

Heathcote and Perri (2015) utilize data from the Consumer Expenditure Survey (CEX) and the PSID to study the relation between ex ante household wealth and the change in consumption rates, or the consumption to income ratio, during the recession of 2007–09. The primary focus is on the PSID, and they sort households in year t based on the ratio of wealth to average consumption in years t and $t + 2$. Because the denominator includes future consumption, the analysis does not strictly sort on ex ante characteristics. Nonetheless, the spirit of the exercise is to sort on individuals on their wealth to consumption ratio prior to the recession.

Heathcote and Perri (2015) find a larger drop in the consumption rate for poor households from 2006 to 2008. The consumption rate out of income drops by almost 10 percentage points for the lower half of the wealth distribution, and only 4 percentage points for the upper half. The authors interpret the larger drop in consumption rates of the poor as evidence consistent with a larger rise in a precautionary savings motive. They conduct tests showing that the wealth shock from 2006 to 2008 was larger for rich households, and income prospects deteriorated equally for the rich and poor. Both of these factors strengthen the conclusion that the larger drop in consumption rates for poor households was due to precautionary savings.

Another strand of research focuses on variation in the cyclicality of consumption growth across households based on whether the household holds financial assets. The motivation behind this research is a canonical model of consumption-based asset pricing, where the key determinant of asset prices is consumption risk. Isolating who bears risk during recessions is not the central question of this literature. Nonetheless, it offers insight by showing how consumption growth is correlated with stock returns across households that own and do not own stocks.

Mankiw and Zeldes (1991) use the PSID from 1970 to 1984 and sort households based on whether they report a positive market value of stock holdings in 1984. Unfortunately, the PSID first asked this question in 1984, and so the authors must use an ex post measure of stock holding rather than an ex ante measure. They find that stockholders' consumption is more volatile and more highly correlated with the stock market than households that do not hold stock. They argue that this higher correlation "may be crucial to an ultimate resolution of this puzzle and other asset pricing anomalies." Households that hold stocks tend to have higher income and higher wealth than those that do not; therefore, this finding suggests that the cyclicality of consumption is highest for richer households.

A more recent paper by Malloy et al. (2009) uses the CEX from 1982 to 2004 to test whether long-run consumption growth of households who hold financial assets is more sensitive to asset price fluctuations. The CEX is typically used in the literature as a repeated cross section of respondents. However, there is a panel element because households are surveyed for four consecutive quarters. Malloy et al. (2009) utilize the panel dimension by calculating consumption growth for a group of households from period t to $t + 1$ as the average over each household's consumption growth from t to $t + 1$. The resulting group-level consumption growth rates have both a panel and repeated cross-sectional dimension, because households in the sample leave after four quarters.

Using consumption growth of stockholders vs nonstockholders, the authors first show that stockholder consumption growth has a higher sensitivity (or "beta") to aggregate consumption growth, especially at long horizons. They conclude based on this finding that "stockholders bear a disproportionate amount of aggregate consumption risk relative to nonstockholders and this burden increases in the long run …." Further, the authors find that the consumption growth of stockholders is more correlated with asset returns. Malloy et al. (2009) estimate Euler equations using asset returns and the consumption growth of stockholders, and they find that estimated risk aversion is much lower compared to using aggregate consumption growth.

2.3 Repeated Cross-Section Approach

Only a few of the existing data sets on income and consumption cover a panel of individuals that one can track over an extended period of time. As a result, many researchers use a "percentile-sorting" methodology, as described in Section 2.1. A classic example of this technique is the series of studies by Piketty, Saez, and Zucman using IRS tax returns to measure the evolution of income and wealth inequality in the United States (Piketty and Saez, 2003, 2006; Piketty and Zucman, 2014; Saez, 2015; Saez and Zucman, 2014). The primary focus of these studies is long-run trends in income and wealth inequality, not isolating who bears the cost of recessions.

However, Saez (2015) uses the same data to try to address the cyclicality of income across different groups. For example, he shows that average real income growth from 1993 to 2013 was 15.1%, and 62.4% for the top 1% of the distribution. Recall that this latter figure takes the income of the top 1% in 2013 and compares it to the income of the top 1% in 1993—it is not based on the same individuals. Saez then shows that the income of the top 1% falls considerably more in recessions, and increases significantly more during expansions. For example, the top 1% saw a decline in income of 31% and 36% during the 2001 recession and the Great Recession, respectively. The corresponding growth rates for average income are −12% and −17%. These figures include capital gains income, but the pattern is also present excluding capital gains, albeit less pronounced. This finding using repeated cross-sectional analysis confirms the panel data analysis of earnings in Guvenen et al. (2014): income fell the most for very high income individuals during the 2001 and the 2007–09 recessions.

Parker and Vissing-Jorgensen (2010) use the IRS data to show that more cyclical income growth of high income individuals is a recent phenomenon. They measure income as real pre-tax, pre-transfer income excluding capital gains. They examine the cross-sectional variation in income growth across the income distribution during recessions and expansions, and they find that the top 1% of the income distributions saw sharp declines during the last three recessions. However, the five recessions prior to the last three did now show this pattern. The authors also calculate an income "beta," which comes from the estimation of the following equation:

$$\Delta \ln Y_{i,t+1} = \alpha_i + \beta_i \Delta \ln Y_{t+1} + \epsilon_{i,t+1}$$

This specification tells us whether income of group i loads more heavily on changes in aggregate income. Parker and Vissing-Jorgensen (2010) show that the top 1% of the income distribution has a much higher β from 1982 to 2008 than in previous years. Further, the higher cyclicality of income of the very rich is robust to alternative measures of income from the Census.

Parker and Vissing-Jorgensen (2010) also examine the cyclicality of consumption across the ex ante expenditure distribution. They utilize the CEX and a methodology that is similar to Malloy et al. (2009). More specifically, they first sort households into groups based on expenditure level in quarter q, and they calculate the quarterly consumption growth for the group as the average of the quarterly growth rates of the households within the group. Recall that the CEX allows for such a calculation because households are surveyed for four consecutive quarters. They then calculate annual consumption growth for each group as the sum of the four quarterly growth rate figures. In this manner, the consumption growth measure has both a repeated cross section and panel dimension.

The authors estimate a similar equation as the income specification above to find a consumption β of each group on aggregate consumption and aggregate income. They find that the top 5% of the expenditure distribution has more cyclical consumption than the rest of the population. They find higher cyclicality using a number of measures including aggregate pre- and post-tax income from NIPA or aggregate consumption from NIPA. As with Malloy et al. (2009), the measures of consumption used by Parker and Vissing-Jorgensen (2010) are primarily expenditures on nondurable goods and services. Expenditures on durable goods, for example, are not included.

Meyer and Sullivan (2013a) focus on consumption inequality from 2000 to 2011 using the CEX. They convert expenditures into consumption for vehicles using a service flow equivalent, and they exclude housing outlays and spending on education. Their analysis is a pure repeated cross section; they do not take advantage of the panel element of the data. For each year, they sort households into percentiles based on the level of consumption, and they plot the log difference for each group relative to 2000. They find more cyclical consumption in the high consumption groups. For example, for the 90th percentile, consumption increased by 20% from 2000 to 2007 and then subsequently fell by 6% from 2007 to 2009. In contrast, consumption at the median increased by 16% from 2000 to 2007 before dropping by 4% from 2007 to 2009.

Most of the extant research on consumption growth variation across households relies on either the CEX or the PSID. Cynamon and Fazzari (2014) is an exception. They focus on consumption of the bottom 95% and top 5% of the income distribution, and they track these two groups over time. They estimate consumption by each of these two groups by estimating income and saving rates, and using the difference as the consumption rate. Their methodology takes aggregate savings and uses microeconomic estimates of savings rates to distribute savings to each of the two groups. Similarly, they distribute income to the two groups based on information from the Congressional Budget Office and the Piketty and Saez IRS data sets. By construction, total income, saving, and consumption add up to the aggregates from NIPA.

Cynamon and Fazzari (2014) show that the consumption to income ratio of the bottom 95% of the income distribution fell sharply during the Great Recession from 92% in 2007 to 87% in 2010. The consumption to income ratio rose sharply for the top 5% of the income distribution, which the authors argue is evidence that the top 5% smoothed consumption (income fell but consumption remained constant). The consumption to income ratio of the top 5% also increased substantially during the 2001 recession. Looking at the level of consumption, the authors show that consumption during the Great Recession deviated sharply from trend for both groups, with the magnitude of the decline being slightly larger for the bottom 95% of the income distribution.

2.4 Sorting on Shocks Received in the Recession

Unemployment increases sharply in recessions. For example, Davis and von Wachter (2011) show that the quarterly layoff rate rises by 129 basis points from 1990Q2 to 1991Q2, 85 basis points from 2000Q2 to 2001Q4, and 208 basis points from 2007Q3 to 2009Q1. Rather than sorting on ex ante characteristics, Davis and von Wachter (2011) sort individuals based on exposure to a mass layoff wave during recessions.

More specifically, the authors regard a worker as "displaced" in year y if he separates from his employer in y and the employer experiences a mass layoff in y. A mass layoff event is one where the employer meets the following criteria: 50 or more employees in year $y-2$, a contraction of employment between 30% and 99% from $y-2$ to y, employment in $y-2$ is no more than 130% of employment in year $y-3$, and employment in $y+1$ is less than 90% of employment in $y-2$. They utilize longitudinal SSA records from 1974 to 2008 to measure earnings, which is the same data used by Guvenen et al. (2014). Given the sample period, there are three main recession periods they analyze: the early 1980s, the early 1990s, and the early 2000s.

The central finding is that individuals losing a job during a mass layoff in a high unemployment environment (greater than 8%) lose 2.8 years of predisplacement earnings in present value terms. The loss is 1.4 year of predisplacement earnings if an individual loses a job in a mass layoff event when the unemployment rate is below 6%. The large loss of income when losing a job during a high unemployment rate environment is supported by a number of other studies. For example, Jacobson et al. (1993) show that job displacement in Pennsylvania in the early 1980s led on average to a near-term earnings loss of more than 50%. Losses persist for at least 10 years (Sullivan and Von Wachter, 2009). Topel (1991) finds that workers displaced from 1979 to 1984 who can find a new job face a 14% reduction in earnings. Davis and von Wachter (2011) have data only through 2008 and are therefore unable to measure the long-term consequences of the Great Recession. However, as they note, the existing research "suggests that workers who have experienced job displacement events since 2008 are likely to suffer severe and persistent earnings losses."

A related line of research examines the effects of graduating from college during a recession. Kahn (2010) uses data from the National Longitudinal Survey of Youth on students that graduated from college between 1979 and 1989. She uses both variation in the national unemployment rate and the state unemployment rates to identify the effect of graduation in a weak economy on wages. She finds "large, negative wage effects of graduating in a worse economy which persist for the entire period studied." More specifically, she finds an initial wage loss of 6–7% for a 1 percentage point increase in the unemployment rate. The wage loss dissipates over time, but wages remain 2.5% lower even 15 years after graduation. A related study by Oreopoulos et al. (2012) examines Canadian data. They find that a rise in unemployment rates by 5 percentage point implies an initial loss in earnings of about 9% that halves within 5 years and finally fades to 0 by 10 years.

Recessions are also times when there are substantial shocks to both housing and financial wealth. Such shocks typically have a strong cross-sectional component, given substantial cross-sectional variation across households in exposure to such shocks. Mian et al. (2013) exploit cross-sectional variation across US geographic units—counties or zip codes—in the exposure to housing net worth shocks during the Great Recession. The authors define the housing net worth as the decline in household net worth coming from the collapse in house prices. The variation across the country is large: the housing net worth shock was almost -50% in the bottom decile of county distribution, but

0% in the top. They show that the decline in consumer spending was larger in counties with a more negative housing net worth shock. Using zip code-level data on auto purchases, they also show that the marginal propensity to spend out of housing wealth is substantially larger for lower income and higher household leverage zip codes. Kaplan et al. (2015) and Stroebel and Vavra (2014) use a different data source and find results similar to Mian et al. (2013); consumption growth during the Great Recession is strongly correlated with house price growth across US cities. In the analysis below, we show a strong state-level correlation between house price growth and personal consumption growth during the Great Recession using new data from the Bureau of Economic Analysis.

Mian and Sufi (2010) sort counties by the change in the household debt to income ratio from 2002 to 2006, and then examine how the decline in new auto purchases and residential investment during the Great Recession is related to the previous increase in household debt. They find a negative relation: counties with large increases in the household debt to income ratio from 2002 to 2006 saw the largest decline in new auto purchases and residential investment during the Great Recession. Mian and Sufi (2010) also show that there is a strong relation between house price growth from 2006 to 2009 and the previous increase in household debt. As a result, while Mian and Sufi (2010) technically sort on an ex ante variable, it is best to view both the increase in ex ante household debt and ex post house price decline as reflecting similar underlying shocks. Bunn and Rostom (2014) use microeconomic data on British households and find that individuals with higher debt had lower subsequent consumption growth after 2007. Andersen et al. (2014) use individual data on Danish households and find a strong negative correlation between precrisis leverage and the change in nonhousing consumption during the crisis. Baker (2014) uses data from an online financial services firm and finds that highly indebted households in the United States during the Great Recession displayed a larger elasticity of consumption with respect to negative income shocks. All of these studies imply a close connection between consumption growth during recession and household balance sheets.

One concern with sorting individuals based on a shock received in the recession is that the decline in income of consumption could be related an omitted variable driving both the shock and the outcome of interest. For example, in Davis and von Wachter (2011), one worry is that the individuals laid off during a recession are lower quality workers, which partially explains the high earnings displacement. Or in Mian et al. (2013), the worry is that some omitted variable drives both the collapse in house prices and the collapse in consumption in a given county. In the section below, we will extend the results in Mian et al. (2013) and discuss why we believe this is unlikely to be the case. The studies examining college graduation are less exposed to this criticism given that the timing of college graduation is less likely to be driven by an omitted variable correlated with a recession occurring.

2.5 Results from Quantitative Models

As mentioned in Section 1, we focus in this review chapter on studies focusing on the cross-sectional variation across individuals in consumption growth and income growth during recessions. There is a large body of research employing quantitative models and calibration to assess the importance of business cycle fluctuations, and the review chapter by Heathcote et al. (2009) covers these studies in detail. We did, however, want to highlight some of the empirical findings from this literature, as they are related to the core question of who bears the cost of recessions.

Storesletten et al. (2001, 2004) use the PSID to make two main points. First, they argue that innovations to the idiosyncratic component of an individual's income process is highly persistent. And second, they argue that idiosyncratic earnings risk is counter-cyclical. They support these arguments with a number of results. For example, they show that the cross-sectional standard deviation of earnings increases substantially during recessions just as the cross-sectional mean of earnings falls. Further, they show that an age cohort of individuals who have lived through more contractionary periods have higher cross-sectional dispersion in earnings even as they age.[b] The authors use these facts to motivate a quantitative model where the welfare losses associated with business cycle fluctuations are substantially larger than those implied by Lucas (1987).

2.6 Summarizing the Literature

A few points emerge when looking at the research as a whole.

First, there remains a need for more panel data, especially when it comes to consumption. Of the studies reviewed, only two sort on ex ante characteristics, and then track consumption through a recession for the same units. One of these is based on county-level data, not individual-level data. On this same point, we need more research detailing whether sorts on contemporaneous placement within the distribution biases results in a meaningful way. This related to the discussion in Section 2.1 about people moving into and out of groups.

Second, the results on consumption growth in recessions are mixed. Researchers using the CEX tend to find that consumption of the rich is more cyclical and falls more in the Great Recession. Researchers using the PSID find that the poor see substantial declines in consumption, and one study shows that the decline in the consumption rate is much larger for the poor than the rich. It is difficult to reconcile the different findings because different data are used and different points in the distribution are analyzed. It may be that the perfect consumption data (the analogous data of the SSA on income)

[b] Guvenen et al. (2014) use SSA data to argue that variance of idiosyncratic earnings shocks is not counter-cyclical. Instead, it is the left skewness of shocks that is strongly counter-cyclical.

would show the same nonmonotonicity shown in Guvenen et al. (2014) where the very rich see the largest decline in consumption, but the moderate rich see less of a decline than the poor.

Third, researchers that sort on shocks received in the recession find long-lasting effects. This is especially true when sorting on whether one loses a job in a recession.

2.7 Related Areas of Research

There are two areas of research that are related to the core question of this chapter: consumption risk sharing and consumption inequality. We do not present a comprehensive review of these areas here, but we want to mention a few studies that are related to the issue of who bears recession risk. Full consumption risk sharing is the idea that an individual's consumption is insured against idiosyncratic shocks. Cochrane (1991) is one of the earliest contributions. He uses the PSID to test whether idiosyncratic shocks such as illness, unemployment, or forced moving affect consumption. He finds that involuntary job loss in particular has a large effect on consumption growth. However, given a limited sample, he concludes that "many of the variables examined here do not yield a robust rejection of the theory."

Attanasio and Davis (1996) examine how consumption responds across groups in response to changes in the hourly wage structure of US workers in the 1980s. They note the "extreme scarcity of longitudinal data sources with high-quality information on both earnings and consumption …." Given this problem, they instead construct synthetic panels of individuals based on earnings information from the Current Population Survey and consumption data from CEX. They form groups of men based on age and education, and they examine how relative movements in wages for each group affects consumption growth during the 1980s. Their core finding, best illustrated in their Fig. 2, shows a strong relation between relative wage movements and consumption growth. They conclude that their findings represent "a spectacular failure of between-group consumption insurance, a failure not explained by existing theories of informationally constrained optimal consumption behavior."

Schulhofer-Wohl (2011) argues that it is crucial to take into account heterogeneity in risk preferences when conducting tests of consumption risk sharing. For example, he shows that if less risk-averse households have more procyclical incomes (as would be expected if individuals sort into occupations based in part on risk tolerance), standard tests of consumption risk sharing will tend to reject full risk sharing even if it is present. He uses the PSID to show that accounting for such heterogeneity leads to a failure to reject full consumption risk sharing.

Another related area of research is on the evolution of consumption inequality over the past 50 years in the United States. There is an enormous literature on this subject, which includes contributions by Aguiar and Bils (2015), Attanasio et al. (2004, 2012), Heathcote et al. (2010), Krueger and Perri (2006), Slesnick (2001), and Meyer and Sullivan (2013b). For the purposes of this chapter, we want to highlight the data used and controversy regarding whether there in fact has been an increase in consumption inequality. The earlier studies in this literature found that consumption inequality measured using the CEX does not track the increase in income inequality. However, later studies argued that this may be due to reporting biases associated with the CEX. Attanasio et al. (2012) in particular make adjustments in the use of the CEX and look also at evidence from the PSID to find that consumption inequality did in fact rise over the past 30 years.

This debate was particularly fruitful because it helped researchers understand better the advantages and disadvantages of the CEX, which is the main data set on consumption used in the literature. Our approach in our own research has been to rely on administrative data collected by private companies. We will return to some of the issues associated with the CEX in the next section.

3. ZIP CODE-LEVEL CONSUMPTION MEASURES

3.1 Toward Administrative Measures of Consumption

Following the discussion in Section 2.1, a key goal of empirical research in macroeconomic fluctuations is to estimate loadings on ex ante factors that predict the decline in consumption across individuals during economic downturns. Substantial progress has been made on the factors that predict a decline in *income* during recessions, in large part due to advances in the administrative data on earnings that have become recently available. But less progress has been made on *consumption*. The key limitation is the lack of individual-level panel data that very accurately measure consumption.

As noted above, researchers have primarily used data from two surveys: the CEX and the PSID. However, these two data sets have important limitations. First, neither data set is an ideal panel. The CEX data set only tracks the same individuals for four quarters, and the PSID is only conducted once every two years. This makes a comprehensive analysis of consumption growth during a recession difficult.

Second, both data sets are based on surveys rather than administrative data. The CEX in particular has been criticized as a method for studying cross-sectional variation in consumption across individuals (Attanasio et al., 2004; Cantor et al., 2011). Studies have outlined many problems with the CEX, such as underreporting by high-income households and a low response rate. Further, according to Cantor et al. (2011), these problems are becoming worse over time.[c] More generally, there is an extensive body of research

[c] The debate on the quality of CEX data is not settled. For example, Bee et al. (2012) argue that the CEX performs well once adjustments are taken into account. Attanasio et al. (2012) argue that adjustments can be done to the CEX which makes cross-sectional comparisons across individuals more accurate. We do not wish to wade too deep into this debate; our goal is to point out that alternative measures of consumption can help.

showing nonclassical error in measures of consumption using survey data.[d] One of the most striking examples from the literature comes from Sweden. Koijen et al. (2014) measure actual car purchases from registry data vs responses to a survey. They find underreporting in the survey of 30%—that is, 30% of the households that actually buy a car do not report the purchase to the survey. This underreporting is worse for low income, poor, and older households.

To be clear, we are not saying we should never use survey-based measures of consumption. Adjustments to the measures can be made, or measurement errors may be less relevant for certain questions. However, we believe a promising avenue is to follow the income literature which increasingly relies on administrative data, such as the Social Security Administration data used in Guvenen et al. (2014).

Some progress on this front has been made very recently. For example, Baker (2014) uses data from a large online personal finance website that connects users' financial accounts. Because the website has bank and credit card accounts, Baker (2014) can measure consumption using administrative data on transactions and withdrawals. Using these data, he finds that highly indebted households are more sensitive to income fluctuations. In particular, a one-standard deviation increase in the debt to asset ratio increases the elasticity of consumption by approximately 25%. Two studies use administrative data from personal finance websites to study the effect of the 2013 government shutdown on consumption and borrowing (Baker and Yannelis, 2015; Gelman et al., 2015).

3.2 Zip Code-Level Data on Consumption

The approach we have used in our own research is to use administrative data that are aggregated by some geographical unit (Mian et al. (2013)). We have utilized two measures: new auto sales at the zip code level from R.L. Polk, and purchases from debit card and credit card transactions at the county level from MasterCard Advisers. The county identified in the latter data set reflects the county of the store where items are purchased, not the county of residence of the buyer. Both of these data sets are based on actual transactions as opposed to survey responses. The R.L. Polk data are based on the universe of new vehicle registrations. The MasterCard data are limited to transactions where MasterCard is the servicer, but Mian et al. (2013) show that aggregate spending using the MasterCard data closely tracks aggregate spending from Census retail sales.

In the work that follows we introduce three new measures of consumption. The first is also from R.L. Polk, and reflects the total number of vehicles registered to individuals living in a zip code. We have the total number of vehicles broken down by model year, which we use to depreciate the older vehicles using average used car prices reported in Jacobsen and van Benthem (2015). The final zip code-level variable is the total number of vehicles in units of the current year (where older vehicles are depreciated before adding up to the total).

[d] See for example the cites in Koijen et al. (2014).

The second measure of consumption is registered recreational boats. The boat data come from Merchant Vessels of the United States, a data file of merchant and recreational vessels documented by the US Coast Guard. Code of Federal Regulations (2001) requires any vessel of at least five net tons which engages in the fisheries on the navigable waters of the United States or in the Exclusive Economic Zone, or coastwise trade to be registered each year, with some minor exemptions. Most vessels longer than 25 ft measure five net tons.

The data contain variables for the general service type of the vessel and the registration status. We take the number of all boats with recreational service type and valid registration to calculate the amount of boat consumption. Roughly 70% of vessels with valid registrations are recreational vessels in the data. We use the postal code of the managing owner's address to allocate boats to zip codes.

The third measure of consumption comes from the American Community Survey. The ACS provides zip code-level statistics for every five-year wave of surveys conducted. We use the 2005–09 wave and the 2008–12 wave. Two of the five years overlap (2008 and 2009), which will mechanically bias us away from finding large changes in a zip code. We refer to each wave by their midpoint year: the earlier wave is the 2007 wave and the later wave is the 2010 wave. The specific measure of consumption we use from this survey is the number of individuals over 16 per housing unit. We calculate the change in the number of adults living per housing unit from 2007 to 2010 as a measure of per capita consumption of housing services.

There is an additional measure we use that is better interpreted as a measure of welfare than consumption: the number of child births. We have this data set only for the state of California, which collects information on the number of births for residents of zip codes.

3.3 Advantages and Disadvantages of Zip Code-Level Data

The main advantage of administrative zip code-level data on consumption is that it is measured very well and therefore closely tracks aggregates. For example, total new purchases of vehicles according to R.L. Polk almost perfectly match total purchases according to Census retail sales. In an ideal world, we would be able to decompose aggregate macroeconomic consumption data into each individual. The zip code-level administrative data sets are the closest we have at this point to this ideal.[e]

Relative to the ideal individual-level panel data set, what are the disadvantages of using data at the zip code level? The first major disadvantage is that any aggregation procedure smooths differences across the population. If we are interested in how differences in ex ante factors or ex post shocks affect consumption growth during recessions, we must have sufficient variation across zip codes to estimate parameters. The extent of this

[e] Baker (2014) shows that data he employs from a personal finance website closely track aggregates once weights are taken into account to adjust for differences in the characteristics of individuals who use the website.

problem depends crucially on how people sort across zip codes. If, for example, there is a large degree of heterogeneity across individuals but no heterogeneity across zip code averages, then analysis using zip code-level data has no variation to exploit. This would be the case if people randomly sorted across zip codes.

How big of a problem is this in the United States? As of 2000, there were 220 million individuals living in the United States over the age of 16, and approximately 31,000 zip codes, which gives an average number of adults per zip code of about 7000. However, the zip code-level population is heavily skewed to the right. The median number of adults per zip codes is 2225 and there are 21,732 at the 90th percentile. There are 43,377 at the 99th percentile.

How much variation do we lose by using zip code-level data? To answer this question, we need data for some variable at both the individual level and zip code level. One important sorting variable in the literature is income. IRS data are available at both the individual level (in the public use file) and the zip code level. Fig. 1 plots the distribution of the individual- and zip code-level data. For the zip code-level data, we calculate the adjusted gross income per return, and then we look at points in the distribution when weighting by the total number of returns. As Fig. 1 shows, the zip code-level distribution is smoothed, especially at the tails of the distribution. The 99th percentile in the individual-level data is almost $400,000. The 99th percentile zip code has an average AGI of $250,000. But even with this smoothing, there is substantial variation in average income across zip codes.

The second potential problem is movers. This is the same criticism that applies to repeated cross-sectional analysis based on percentiles already discussed in Section 2.1, Eq. (3). Over long periods, people moving across zip codes present a serious problem. It is not obvious how large a problem moving is when studying a two- to three-year window such as the Great Recession.

We are unaware of estimates that document the likelihood of people moving across zip codes during a two- to three-year period. The Census provides information on annual mover rates, which averaged 12.5% from 2006 to 2009. However, most of these movers stayed within the same county. From 2006 to 2009, annual moving rate to another county was 3.9%.

We do not yet have sufficient evidence to assess how moving across zip codes affects the cross-sectional variation of consumption growth using zip code-level data. For example, if movers tend to move to other zip codes that are similar based on the sorting variable in question, such movement may not be a concern.[f]

[f] The closest study we could find to answering this question is Yagan (2014) who examines whether workers bore the incidence of local labor demand shocks during the Great Recession even after they move to less affected areas. He finds that even workers that migrate to less impacted areas see "unusually small employment gains." This does not answer the key question we have in mind: do individuals that move end up in zip codes with a similar shock as the one they left.

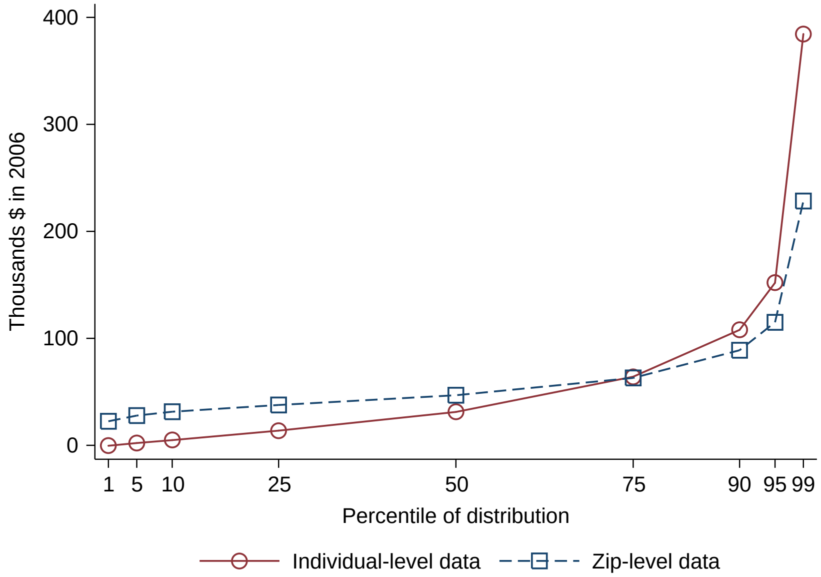

Fig. 1 Zip code vs individual data: distribution of 2006 income. This figure compares zip code-level and individual-level data on 2006 adjusted gross income from the IRS. For the zip code-level distribution, we calculate the AGI per return for each zip code, and then we look at points on the distribution when weighting by the total number of returns in the zip code. As the figure shows, zip code-level data smooth the distribution, and the smoothing is substantial at the tails of the distribution.

4. HOUSING NET WORTH SHOCK AND THE GREAT RECESSION

In this section, we review and build on evidence on the importance of shocks to net worth coming from the collapse in house prices during the Great Recession. In particular, Mian et al. (2013) show that variation across US counties in the housing net worth shock—or the percentage decline in household net worth coming from the collapse in house prices—is correlated strongly with consumption growth. Using new measures of consumption at the zip code level, we build on this study and discuss possible interpretations of the results.

4.1 Housing Net Worth Shock: Definition

Following Mian et al. (2013), we define the housing net worth shock in a zip code as:

$$\text{HNW shock}_z \equiv \frac{p_{z,2009} - p_{z,2006}}{p_{z,2006}} * \frac{H_{z,2006}}{F_{z,2006} + H_{z,2006} - D_{z,2006}} \tag{4}$$

where $p_{z,t}$ is the median price of an owner-occupied unit in zip code z at time t, $H_{z,2006}$ is the value of housing assets owned by residents in zip code z in 2006, $F_{z,2006}$ is the value of financial assets held by residents in zip code z in 2006, and $D_{z,2006}$ is the book value of debt outstanding for residents of zip code z in 2006. This definition follows from the decomposition of the percentage change in net worth from 2006 to 2009, where we isolate the percentage change in net worth coming from the collapse in house prices.[g]

As definition (4) illustrates, the cross-sectional variation across zip codes in the housing net worth shock during the Great Recession is driven by two factors: house price growth in zip code z during the Great Recession and the ex ante housing wealth to net worth ratio. The latter captures the effect of leverage. All else equal, zip codes that have more leverage have a higher housing wealth to net worth ratio. This amplifies the effect of house price growth on total net worth. Throughout, we define the housing wealth to total net worth ratio as the second term:

$$\text{Housing wealth to net worth ratio}_z \equiv \frac{H_{z,2006}}{F_{z,2006} + H_{z,2006} - D_{z,2006}} \tag{5}$$

As we show below, the housing wealth to net worth ratio is a strong predictor of consumption growth across zip codes during the Great Recession, with high housing wealth to net worth ratio zip codes seeing a larger decline in consumption.

The main sample restriction we must make is due to the fact that not all zip codes have accurate house price indices available. In particular, we use CoreLogic data on house prices, which cover approximately 6600 of the 31,000 zip codes in the United States. These zip codes account for 65% of the adult population of the United States as of 2000. The main difference between zip codes with and without house price data is population density. The zip codes not in the sample are much more likely to be in rural areas. Rural areas do not have a sufficient number of housing transactions to construct house price indices.

In Fig. 2, we sort zip codes into five quintiles based on the housing net worth shock during the Great Recession. The quintiles are population weighted, so each quintile contains the same number of people. We then plot the housing net worth shock across the distribution. By construction, the housing net worth shock is more negative in the lower quintiles.

Fig. 2 shows a large degree of heterogeneity across zip codes in the United States in the housing net worth shock. In the first quintile, the collapse in house prices reduced household net worth by almost 30%. In the fifth quintile, there is almost no change in household net worth coming from the collapse in house prices.

Table 1 shows summary statistics for the sample of zip codes. The summary statistics weight zip codes by total adult population as of 2000. As mentioned above, the housing net worth shock can be decomposed into house price growth from 2006 to 2009 and the housing wealth to net worth ratio as of 2006. As the summary statistics show, there

[g] The exact methodology used to construct all variables in definition (4) is in Mian et al. (2013).

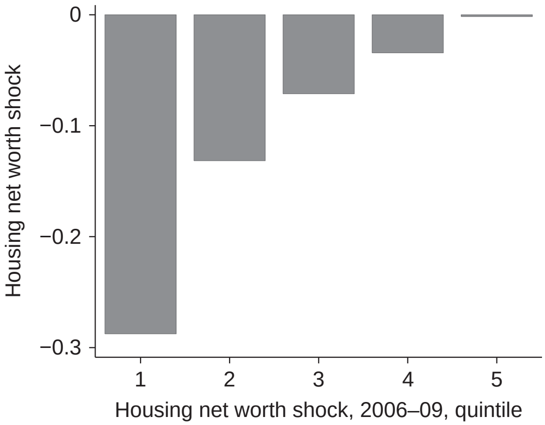

Fig. 2 Housing net worth shock from 2006 to 2009 across zip codes. This figure plots the housing net worth shock across the housing net worth shock distribution. Each quintile contains 20% of the adult population.

Table 1 Summary statistics

	N	Mean	SD	10th	90th
Housing net worth shock

Outcomes					
Growth in autos registered, 2006–10	6689	−0.135	0.084	−0.234	−0.036
Growth in new auto sales, 2006–09	6689	−0.382	0.149	−0.582	−0.199
Change in adults per housing unit, 2007–10	6686	−0.016	0.095	−0.125	0.091
Growth in boats registered, 2006–10	3204	−0.102	0.196	−0.348	0.150
Growth in number of births, 2006–10	855	−0.087	0.106	−0.202	0.038
Fraction of homeowners underwater, 2011	6300	0.337	0.158	0.143	0.565
Ex ante patterns					
House price growth, 2002–06	6689	0.456	0.318	0.090	0.910
Change in cash-out refinancing share	6689	0.022	0.047	−0.025	0.081
Median household income, 2000	6689	48.705	16.657	31.031	70.821
Wage growth, per tax return, 2002–06	6689	0.106	0.068	0.030	0.189
AGI growth, per tax return, 2002–06	6689	0.186	0.124	0.064	0.345

This table presents summary statistics for zip codes in our sample. The sample is restricted to zip codes for which CoreLogic house price growth data are available. The housing net worth shock is the decline in net worth driven by the decline in house prices, or the product of house price growth from 2006 to 2009 and the 2006 housing wealth to net worth ratio. Registered autos reflect the total number of autos registered to residents of a zip code, where autos are depreciated according to their model year. Data on births are available only for California. For registered recreational boats, only zip codes with at least 10 registered boats in 2006 are included.

is substantial variation across zip codes in both measures. The average housing wealth to net worth ratio is 0.46, but it is 0.21 at the 10th percentile and 0.77 at the 90th percentile.

Table 1 also shows summary statistics for measures of consumption growth. There is a sharp decline in both new auto purchases and in the stock of vehicles during the Great Recession. Recall that our measure of registered autos depreciates older cars so that the units are in terms of new cars. The average number of adults per housing units declined by 0.016 from 2007 to 2010. The number of births fell sharply during the Great Recession.[h]

4.2 Housing Net Worth Shock and Consumption Growth

Figs. 3 and 4 show the strong correlation between consumption growth and the housing net worth shock across zip codes. Zip codes with the most negative housing net worth shock from 2006 to 2009 see a 20% decline in registered autos from 2006 to 2010 and a 50% decline in new auto purchases. For zip codes in the top quintile, the respective growth was −10% and −25%.

Similar results are found in Fig. 4. Registered recreational boats fall more in zip codes with the most negative housing net worth shock. The number of adults living per housing unit increases the most in these same zip codes. The number of births also falls more in zip codes with the most negative housing net worth shock.

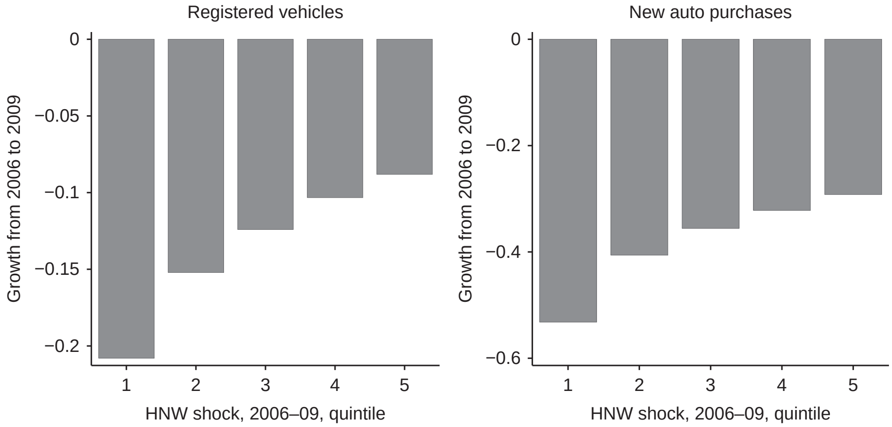

Fig. 3 Housing net worth shock from 2006 to 2009 and consumption growth. This figure plots measures of consumption growth across the housing net worth shock distribution. Each quintile contains 20% of the adult population.

[h] For auto and boat registrations, we use 2006–10 as the time period of examination. We do so because the registration data are not updated immediately, especially when registrations expire. For births, we use 2006 to 2010 under the assumption that parental decisions on births that are made in 2009 are realized in 2010.

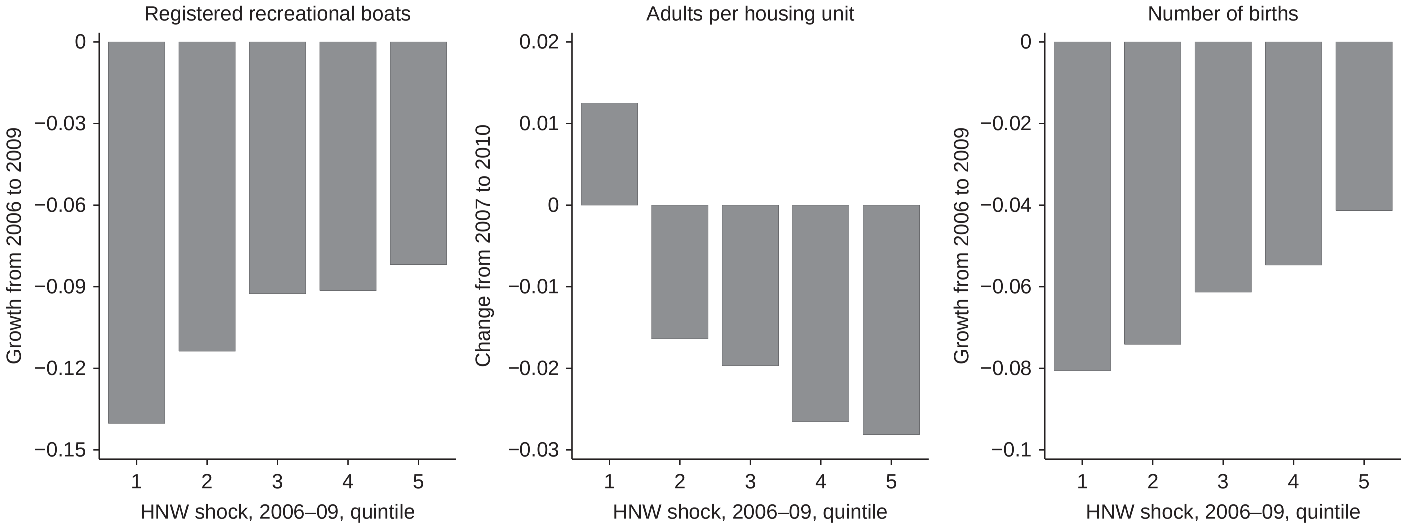

Fig. 4 Housing net worth shock from 2006 to 2009 and other measures of consumption growth. This figure plots recreational boats registered, the number of adults per housing unit, and births across the housing net worth shock distribution. Each quintile contains 20% of the adult population. Births are only available for California, and as a result we resort zip codes into quintiles based on California only for the right panel.

Table 2 presents estimates of the elasticity of consumption growth with respect to the housing net worth shock. Recall that the housing net worth shock is defined as the percentage decline in net worth coming from the collapse in house prices. The estimated elasticities are on the order of 0.2–0.8 depending on the measure of consumption. For births, the estimated elasticity is 0.12.

The magnitude in column 5 requires additional information to interpret. Moving from the 90th to 10th percentile of the distribution of housing net worth shocks is a −0.25 movement. The coefficient estimate in column 5 implies such a move leads to a 0.04 increase in the number of adults living per housing unit. This may sound small, but the variation in the number of adults living per housing unit is also small—the standard deviation in the change in number of adults living per unit is only 0.095, and so this effect is almost 1/2 a standard deviation.

In Table 3, we decompose the housing net worth shock from 2006 to 2009 into its two components: house price growth from 2006 to 2009 and the housing wealth to net worth ratio as of 2006. Panel A presents OLS estimates. The first column shows that the two components are strongly correlated: zip codes with a high housing wealth to net worth ratio in 2006 experienced a larger decline in house prices during the Great Recession. The powerful correlation makes it difficult to separate the independent effects on consumption. The OLS estimates in columns 2 through 6 show that both components matter, especially for registered autos and new autos.

In panel B, we include county fixed effects in the estimation. This is useful because the majority of the variation in house price growth across zip codes is driven by county-level

Table 2 Housing net worth shock from 2006 to 2009 and consumption growth

This table presents zip code-level regressions relating measures of consumption growth during the Great Recession to the components of the housing net worth shock: the 2006 house wealth to net worth ratio and house price growth from 2006 to 2009. Births are only available for California. Panel B includes county fixed effects. Standard errors are clustered by county.

**,* Coefficient statistically different than zero at the 1% and 5% confidence level, respectively.

variation.[i] For example, the across-county standard deviation in house price growth from 2006 to 2009 is 0.13, whereas the within-county standard deviation is only 0.05. This is a robust feature of house price variation in the United States—the majority of the variation is across county (or across city) as opposed to within county. In contrast, more of the variation in the housing wealth to net worth ratio as of 2006 is driven by within-county differences. The within-county standard deviation in the housing wealth to net worth ratio is 0.16, whereas the across county standard deviation is 0.12.

In an ideal setting, we could test whether the ex ante housing wealth to net worth ratio as of 2006 in a zip code predicts a stronger decline in consumption, given an identical decline in zip code-level house prices. In other words, we could hold the asset price shock constant and estimate whether larger exposure to the shock has a strong effect on consumption growth.

Unfortunately, even with county fixed effects, house price growth and the housing wealth to net worth ratio are correlated. As column 1 of panel B shows, the regression coefficient remains negative and statistically significant when including county fixed effects, but the coefficient is smaller with a smaller *t* statistic. In columns 2 through 6 we include county fixed effects, and the results indicate a much stronger loading of consumption growth on the housing wealth to total net worth ratio as of 2006. That is, controlling for house price growth, zip codes with a larger share of net worth in housing see a bigger decline in consumption.

Fig. 5 plots the fraction of homeowners underwater on their mortgage as of 2011 across the 2006 housing wealth to net worth ratio. As it shows, homeowners in zip codes

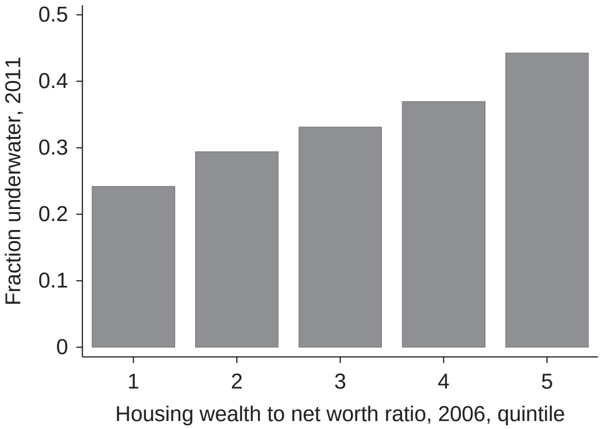

Fig. 5 Housing wealth to net worth ratio and underwater homeowners. This figure plots the fraction of homeowners underwater in 2011 (total mortgage balance greater than the value of the home) across the distribution of the 2006 housing wealth to net worth ratio. Each quintile contains 20% of the population.

[i] There are 1021 counties in our sample, so an average of about 7 zip codes per county.

with a higher housing wealth to net worth ratio as of 2006 were almost twice as likely to find themselves underwater on their mortgage when house prices fell.

4.3 Exploring Zip Codes with High 2006 Housing Wealth to Net Worth Ratio

We have so far kept silent on the underlying economic mechanism connecting the 2006 housing wealth to net worth ratio to consumption growth during the Great Recession. Table 4 begins our discussion. Each cell in Table 4 is a regression coefficient from a separate regression of the 2006 housing wealth to net worth ratio on factors leading up to the Great Recession. The first column presents OLS estimates, and the second column presents county fixed effects specifications.

Zip codes with a higher housing wealth to net worth ratio as of 2006 experienced higher house price growth from 2002 to 2006. The second row uses as a dependent variable the change in the cash-out refinancing share. This variable is defined as the average share of mortgages refinanced with cash taken out (ie, the mortgage balance was increased) from 2003 to 2006 minus the average share from 2000 to 2002. As the coefficient estimates show, households with a high housing wealth to total net worth ratio as of 2006 saw a large increase in the share of mortgages refinanced with cash taken out from 2003 to 2006.

Fig. 6 shows the result over time. We split the sample into five population-weighted quintiles based on the 2006 housing wealth to net worth ratio, and then plot the share of

Table 4 Understanding variation in 2006 housing wealth to net worth ratio

	Housing wealth to net worth ratio, 2006	
	(1)	(2)
House price growth, 2002–06	0.313** (0.041)	0.499** (0.106)
Δ Cash-out refinancing share	2.495** (0.271)	3.894** (0.205)
Wage growth, 2002–06	−0.626** (0.071)	−1.179** (0.090)
AGI growth, 2002–06	−0.825** (0.038)	−1.078** (0.051)
ln(Adjusted gross income, 2002)	−0.244** (0.025)	−0.339** (0.014)
Fraction subprime, 2002	0.702** (0.075)	0.957** (0.057)
County fixed effects	No	Yes

This table presents coefficients from zip code-level univariate regressions of the housing wealth to net worth ratio in 2006 on various zip code-level characteristics. Each cell is from a separate regression. The regression specifications in column 2 include county-fixed effects. Standard errors are clustered by county.
**,* Coefficient statistically different than zero at the 1% and 5% confidence level, respectively.

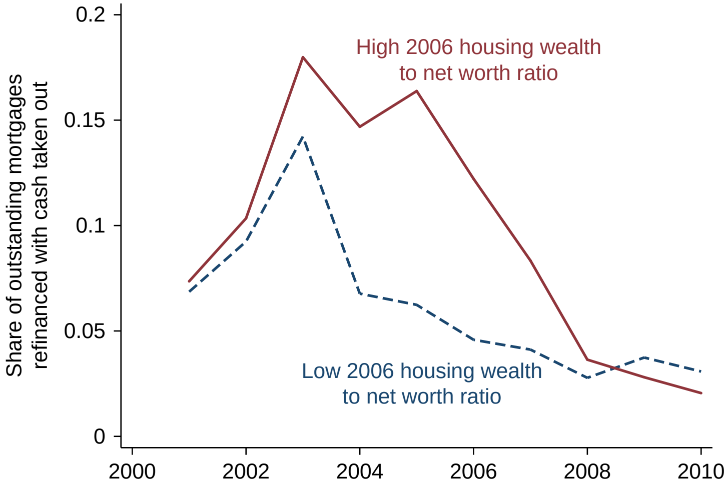

Fig. 6 Cash out refinancing share, by 2006 housing wealth to net worth ratio. For this figure, we sort zip codes into population-weighted quartiles based on the 2006 housing wealth to net worth ratio. We plot the highest and lowest quartile below. The cash out refinancing share is the share of outstanding mortgages refinanced where cash is taken out in a given year.

mortgages refinanced with cash out for the top and bottom quintile. There is a spike in cash-out refinancing in 2003 for both quintiles. But the share drops sharply for low ratio zip codes but remains elevated for high ratio zip codes through 2006. Starting in 2007, the cash-out refinancing share drops sharply for high ratio zip codes.

In Fig. 7, we utilize individual-level data from Equifax (described in detail in Mian and Sufi, 2011) to plot debt growth of existing homeowners. More specifically, we condition the sample on people who already owned their home in 1998, and then we plot total debt for the high and low 2006 housing net wealth to net worth ratio zip codes. It shows evidence consistent with Fig. 6: existing homeowners borrowed much more aggressively against their homes during the housing boom, especially in 2005, 2006, and 2007.

Taken together, the evidence in Table 4 and Figs. 5 and 7 supports the following narrative. Zip codes with a high 2006 housing wealth to net worth ratio in 2006 saw a large relative increase in house prices from 2002 to 2006, and a large increase in borrowing by homeowners. Fig. 8 shows evidence that consumption growth was also higher from 2002 to 2006, which builds on evidence in Mian and Sufi (2014). New auto sales and registered autos increased by more in high housing wealth ratio zip codes during the housing boom, and then fell sharply during the recession.[j]

[j] McCully et al. (2015) use survey data on home equity withdrawal and car purchases, and they argue that cash extracted through home equity withdrawal was not directly used for car purchases. They investigate other channels for the correlation between cash-out refinancing and auto purchases.

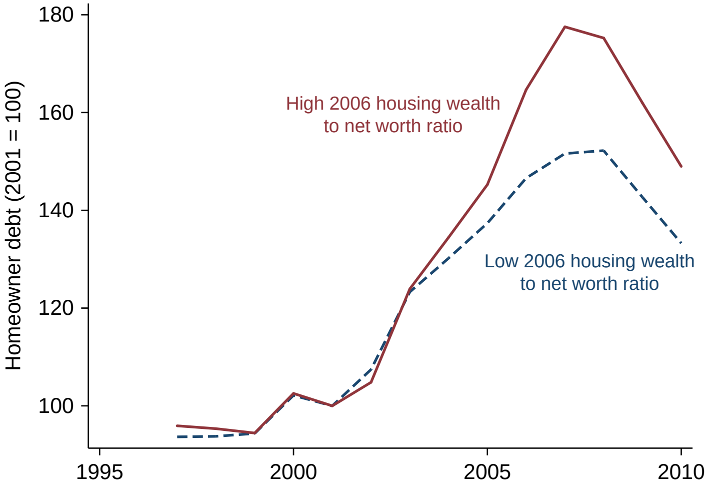

Fig. 7 Total debt of homeowners, by 2006 housing wealth to net worth ratio. This figure uses individual-level data on people who were homeowners as of 1998. We sort individuals into groups based on the housing net worth to total net worth ratio of the zip code they live in 2006. We then track total debt of homeowners in the top and bottom quartile.

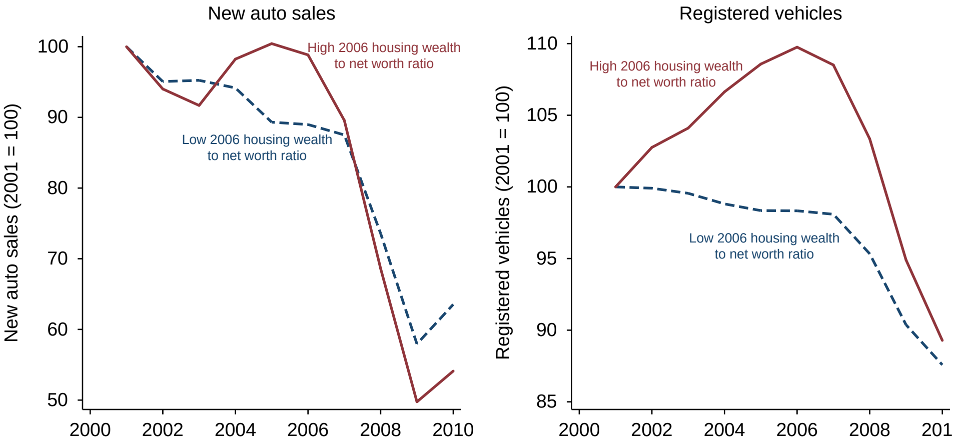

Fig. 8 Consumption of car services, by 2006 housing wealth to net worth ratio. For this figure, we sort zip codes into population-weighted quartiles based on the 2006 housing wealth to net worth ratio. We plot the highest and lowest quartile below.

4.4 Identification of House Price Effects

Our preferred interpretation of the evidence is that cross-sectional variation in exogenous house price growth from 2002 to 2006 across zip codes drove the cross-sectional variation in debt growth and consumption growth by existing homeowners across zip codes. When house prices fell, households in these same zip codes were forced to cut back sharply on consumption. The cut back in consumption was likely due to both an increase in desired savings and a tighter constraints on borrowing. This is the essence of the argument we have built in a series of studies (Mian et al., 2013; Mian and Sufi, 2011, 2014).

It is crucial to note that the causal channel we have highlighted in our previous research is related to zip codes that saw both a *boom* and *bust* in house prices. A zip code-level regression of house price growth from 2006 to 2009 on house price growth from 2002 to 2006 yields a negative coefficient with a t-statistic of 57 and an R^2 of 0.33. In our view, it is difficult to exploit exogenous variation across zip codes in the collapse in house prices independent of the boom in house prices. The boom and bust should be considered together.

The primary concern with an interpretation in which house price movements were the causal factor is that the cross-sectional variation across zip codes in the house price boom and bust was due to omitted factors that may have simultaneously driven house prices, borrowing, and consumption patterns. The most worrisome alternative explanation in our view is a shock to permanent income or productivity during the early part of the 2000s differentially affecting zip codes where house prices rose the most that subsequently reversed during the Great Recession.

In an attempt to rule out such alternative explanations for the patterns we have shown above, our previous work has relied on instruments for cross-sectional variation in house price growth. In Mian and Sufi (2011), we use two instruments: one based on across-MSA variation and the other on within-MSA variation. The across-MSA instrument is housing supply elasticity of a city according to Saiz (2010). The logic behind this instrument is that there was a national shock to housing demand from 2002 to 2006 (driven by increased credit availability or stronger preferences for housing services). This national shock translated into higher house price growth in inelastic housing supply MSAs. The within-MSA instrument is based on the interaction of MSA housing supply elasticity and zip code-level credit scores. Mortgage originations for home purchase pushed up house prices disproportionately in low credit score neighborhoods, even though these neighborhoods saw no evidence of stronger wage or income growth.

The third and fourth rows of Table 4 examine the regression coefficients of zip code-level housing wealth to total net worth ratio as of 2006 on income growth from 2002 to 2006. Echoing results from our previous research, there is no evidence of a contemporaneous positive income shock in these zip codes. In fact, income fell in relative terms in zip codes that saw the most house price growth and borrowing.[k]

The across-city housing supply elasticity instrument has been criticized by Davidoff (2013) and Davidoff (2014). In particular, Davidoff (2014) argues that supply constraints are correlated with demand growth. One implication of this argument is that perhaps the

[k] In Mian and Sufi (2014), we also utilize an instrument proposed by Charles et al. (2014) which is based on how quickly house prices accelerated in some cities during the 2000–05 period.

relative increase in borrowing and spending in inelastic housing supply cities during the 2002–06 period was driven by differential demand shocks. Davidoff (2014) does not address the evidence in Mian and Sufi (2011) and Mian and Sufi (2014) that contemporaneous measures of permanent income shocks are uncorrelated with housing supply elasticity. Further, he does not address the within-city or within-county evidence that shows that borrowing and spending growth were strongest among zip codes within inelastic cities seeing a relative *decline* in observable measures of income growth. The results described in Table 4 confirm this evidence: zip codes with the highest housing wealth to net worth ratio as of 2006 saw a relative *decline* in adjusted gross income and wage growth from 2002 to 2006, at the same time they were seeing the largest increase in borrowing and consumption of car services.

There are additional facts about high housing wealth to net worth ratio zip codes: they are poorer and have lower credit scores. The final two rows of Table 4 show that 2006 average adjusted gross income is lower in high housing wealth to net worth zip codes, and the fraction of individuals with a credit score below 660 was higher. These results are similar with or without county fixed effects. Fig. 9 shows the relation between income and the housing wealth to net worth ratio. In zip codes in the highest quintile of the housing wealth to net worth ratio as of 2006, adjusted gross income was on average $40,000. It was almost $90,000 in the lowest quintile.

This is important because many researchers sort on ex ante income or wealth when examining cross-sectional variation in consumption growth during the Great Recession. Lower consumption growth among low income individuals will reflect partially the differential effect of house price declines on low-income individuals.

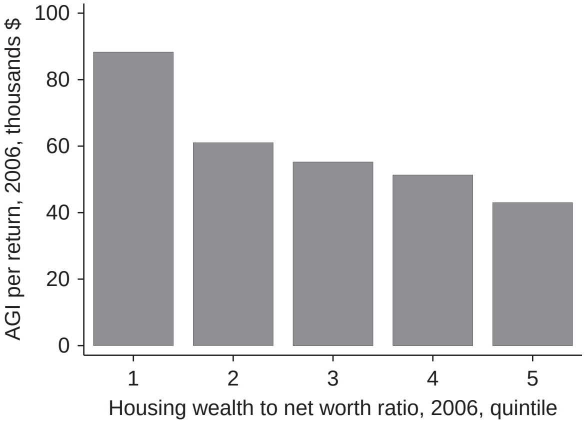

Fig. 9 Average 2006 income by 2006 housing wealth to net worth ratio. This figure plots the average 2006 adjusted gross income across the housing wealth to net worth ratio distribution. Each quintile contains 20% of the adult population.

5. MODELS MOST CLOSELY RELATED TO THESE FACTS

The importance of housing and household debt in the Great Recession has spurred a large body of theoretical research exploring the interaction of household balance sheets and consumption. The first wave of macroeconomic models that most closely match the facts presented above are Eggertsson and Krugman (2012), Guerrieri and Lorenzoni (2015), Midrigan and Philippon (2011), and Huo and Ríos-Rull (2016).

In Guerrieri and Lorenzoni (2015), agents receive idiosyncratic uninsurable productivity shocks that generate a wealth distribution. There is a borrowing constraint households face, and households that have received the worst realization of productivity shocks end up closest to the constraint. The aggregate shock that precipitates a recession in the model is an exogenous tightening of the borrowing constraint. Such a tightening generates a decline in consumption across much of the distribution. Even unconstrained agents cut back on consumption when the constraint tightens due to a precautionary savings motive.

However, the drop in consumption is largest among households closest to the constraint. Guerrieri and Lorenzoni (2015) provide a figure showing heterogeneity in the consumption response depending on proximity to the constraint (Fig. 6 in the current version). The most constrained agents cut consumption by more than 10%, whereas the least constrained agents do not adjust consumption.

In Eggertsson and Krugman (2012), there are only two types of agents where an assumption on preferences generates the variation. Constrained agents have a low discount factor and consume up to their borrowing limit every year. Their consumption is therefore pinned down by the borrowing limit. Unconstrained agents lend to the constrained agents, and the interest rate governs their intertemporal consumption allocation decision.

As in Guerrieri and Lorenzoni (2015), the shock that generates the recession is a tightening of the borrowing constraint. In response to the tightening, the constrained agents cut back on consumption. If the interest rate is free to adjust, the unconstrained agents boost consumption as the interest rate falls. However, in the presence of nominal rigidities and the zero lower bound on nominal interest rates, the sharp decline in consumption of the constrained agents pushes the economy into recession. Once again, the key cross-sectional pattern in the model is that the decline in consumption is largest for the constrained agents.

How do these models relate to the empirical findings above? One interpretation is that the tightened borrowing constraint in the model reflects collapsing house prices during the Great Recession. Indeed, as Eggertsson and Krugman (2012) put it: "there are many reasons to expect the borrowing limit to depend to some extent on current condition, for example if the collateral value of the borrowers assets depend on current market conditions (such as the price of houses)…." Under this interpretation, the model prediction that the cut-back in consumption is largest in zip codes hardest hit by the house price collapse fits well with the data. Mian et al. (2013) show that counties hit hard by the housing crash saw a larger decline in home equity loan availability, credit card limits, and mortgage refinancing volume.

In Midrigan and Philippon (2011), the key friction is a cash-in-advance constraint where both government-issued cash and private credit can be used by households to spend. Private credit for consumption must be collateralized by housing wealth, and the key parameter of interest is the fraction of housing wealth that can be borrowed against, which the authors call θ. The authors introduce heterogeneity by having islands that start identical, but then receive differential positive shocks to their own θ. The positive differential shocks to θ are meant to explain the differential rise in household debt during the housing boom. But then, θ reverts back to its preboom level, which generates a boom and bust on islands that saw the biggest rise and fall in the collateral constraint.

Midrigan and Philippon (2011) calibrate the model with assumptions on nominal rigidities, labor market rigidities, and collateral constraints that come from cross-sectional analysis of US states during the Great Recession. Their key result is that states with a larger run-up in household debt see a bigger decline in consumption during the Great Recession.

Huo and Ríos-Rull (2016) build a model in which the fundamental shock is a tightening of financial conditions facing households. A key contribution of their study is a more serious consideration of housing wealth. In their model, the reduction in credit availability to households triggers a large drop in house prices, which then in turn depresses consumption. The model contains additional frictions such as difficulty in expanding production of tradable goods and labor market frictions preventing a dramatic decline in wages. In their model, the households that see the most negative consumption growth are those with most of their wealth tied up in housing. This is consistent with the patterns we have shown above, where the decline in consumption is largest in zip codes where housing wealth was a large fraction of total net worth prior to the recession.

A second wave of studies extends the above models to explain more broadly how excessive borrowing may lead to economic downturns. Korinek and Simsek (2014) begin with a framework similar to Eggertsson and Krugman (2012), with preference differences generating a set of borrowers and lenders. Borrowers can choose any level of debt in the initial period of the model, but then a borrowing constraint is imposed in the second period of the model. If the imposed borrowing constraint is sufficiently tight, borrowers must cut spending considerably, generating a similar cross-sectional relation as in Eggertsson and Krugman (2012). Korinek and Simsek (2014) show that in the presence of nominal rigidities that generate aggregate demand externalities, borrowing in the initial period may be excessive relative to the optimum a social planner would choose.

The reasoning is that the severe cutback in consumption by borrowers in the second period generates a reduction in consumption by other individuals in the economy (the "aggregate demand externality"), given the presence of nominal rigidities such as the zero lower bound on interest rates. Borrowers do not take into account their effect on the consumption of other individuals if the borrowing constraint is binding, which implies that they borrow more than is socially optimal in the initial period.

Farhi and Werning (2015) explore economies in which nominal rigidities are present in both goods and labor markets, and the economies are subject to the zero lower bound on nominal interest rates or fixed exchange rate regimes. They show in this setting that the distribution of wealth affects aggregate demand and output, and agents may borrow too much ex ante. They apply this framework to a number of situations including credit booms and capital flows into an open economy.

Justiniano et al. (2014) build a quantitative model to show that an expansion in credit supply, as opposed to a loosening of borrowing constraints, is more consistent with house price and mortgage debt patterns witnessed from 2000 to 2006. In particular, an expansion in credit supply predicts an increase in house prices, an increase in mortgage debt to GDP ratios, a decline in interest rates, and a flat debt to collateral value ratio. However, Justiniano et al. (2014) do not explore how the expansion in credit supply affects consumption. Favilukis et al. (2015) build a quantitative model to explore dynamics in house price movements, and find that the housing boom from 2000 to 2006 was due to the relaxation of financing constraints and a decline in the risk premium associated with housing assets.

The models described utilize as exogenous shocks an expansion or contraction in borrowing limits or credit supply, and then explore the effects of these shocks on consumption and the aggregate economy. They generate cross-sectional predictions in who should experience the biggest drop in consumption during recessions. However, their primary focus is explaining the decline in aggregate economic activity. In contrast, the recent study by Berger et al. (2015) is focused on what governs the individual consumption response to a change in house prices. The build a model in which households derive utility from both the consumption of nonhousing goods and housing services and from bequeathing wealth to their children. They also face borrowing constraints and income uncertainty. Their main analytical result is to show that the individual elasticity of nondurable consumption to an unexpected and permanent change in house prices can be characterized by the following sufficient statistic:

$$\eta_{it} = \frac{\frac{dC_{it}}{C_{it}}}{\frac{dP}{P}} = MPC_{it} * (1-\delta) * \frac{P * H_{i,t-1}}{C_{it}} \tag{6}$$

where MPC_{it} is the marginal propensity to consume out of transitory income shocks for individual i at time t, δ is the depreciation rate of housing assets, P is the price of housing (assumed to be constant prior to the shock), $H_{i,t-1}$ is the amount of housing assets held by individual i at time $t-1$, and C_{it} is consumption of individual i at time t. The authors provide evidence from the PSID that the marginal propensity to consume out of transitory shocks and housing asset holdings are not strongly correlated.

Eq. (6) is derived in a partial equilibrium framework, and both sides of the equation depend on endogenous variables such as house price growth and the marginal propensity to consume. Nonetheless, it is a useful statistic for understanding the cross-sectional variation across individuals in consumption growth in response to the same decline in house prices. If one can isolate exogenous shocks to house price growth, then Eq. (6) implies that the effect on consumption growth will be larger for individuals with a larger marginal propensity to consume out of temporary income shocks and a higher housing wealth to consumption ratio.

Our zip code-level data described above is insufficient to test this equation explicitly, because we cannot measure either the marginal propensity to consume out of housing wealth or total consumption for households living in a zip code. Nonetheless, the results shown in Tables 3 and 4 are broadly supportive of Eq. (6). Panel B of Table 3 shows that consumption growth during the Great Recession was lower in zip codes with a high housing wealth to net worth ratio after controlling for house price growth. In other words, for the same decline in house prices, high housing wealth to net worth zip codes saw lower consumption growth.

While we cannot know for sure, it seems likely that zip codes with a high housing wealth to net worth ratio also have a high housing wealth to consumption ratio. Further, as Table 4 shows, high housing wealth to net worth ratio zip codes have lower income and lower credit scores. We know from a large body of research that lower income and lower credit score individuals have higher marginal propensities to consume and borrow out of income, borrowing availability, or house price shocks.

We look forward to more empirical research that explicitly tests the elasticity of consumption growth with respect to house price growth using the sufficient statistic approach of Berger et al. (2015). As a final note, while Berger et al. (2015) use a fully rational framework to derive Eq. (6), it is useful to note that marginal propensities to consume may vary across the population due to behavioral biases such as hyperbolic discounting in addition to borrowing constraints (see Harris and Laibson, 2001).

6. AGGREGATE EVIDENCE ON HOUSEHOLD DEBT

The primary focus of this review chapter is on who bears the cost of aggregate economic downturns. However, the theoretical studies discussed above—in particular, Eggertsson and Krugman (2012), Guerrieri and Lorenzoni (2015), Farhi and Werning (2015), Huo and Ríos-Rull (2016), and Korinek and Simsek (2014)—have the additional implication that elevated household debt combined with a credit supply shock and nominal rigidities may precipitate recessions. That is, these studies have both *cross-sectional* and *aggregate* implications.

Testing whether elevated household debt and a collapse in house prices cause aggregate economic downturns is a difficult exercise. For example, Beraja et al. (2015) argue that inferences about the determinants of aggregate business cycles using cross-region variation is potentially misleading because aggregate shocks cannot always be identified in the cross section. However, there is an increasing body of evidence that suggests a robust correlation between increases in household debt and subsequent economic growth. One approach is to look at cross-sectional variation across more aggregated geographical units, such as countries or states within a country. Fig. 10 utilizes new state-level personal consumption expenditure data from the BEA, and it shows a very strong relation between house price growth and consumption growth across states during the Great Recession. The estimated elasticity is 0.21 and has a *t* statistic of 7. There may be skepticism of whether we can interpret this relation as a causal effect. But previous research has attempted to isolate exogenous variation in the boom and bust in house prices, and it robustly predicts a boom and bust in household spending.

Similar analyses have been conducted across countries for the Great Recession. Glick and Lansing (2010) look across countries and find that "countries with the largest increases in household leverage tended to experience the fastest rises in house prices over the same period. These same countries tended to experience the biggest declines in household consumption once house prices started falling." An analysis by Leigh et al. (2012) confirms these findings. They find that countries with a larger run-up in household debt fueled by house price growth from 2002 to 2006 see the largest decline in

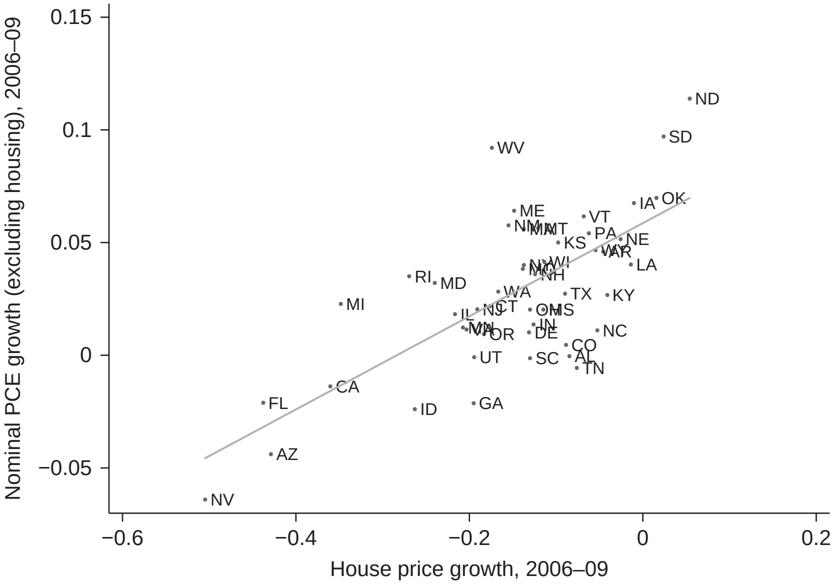

Fig. 10 Consumption growth and house price growth across states, 2006–09. This figure plots consumption growth from 2006 to 2009 against house price growth from 2006 to 2009 for states. We use BEA state-level data on personal consumption growth and house price growth data from CoreLogic.

consumption during the bust. Further, they do a more systematic analysis of past episodes from 1980 to 2011, and they find that housing busts lead to a larger decline in consumption when a large run-up in private debt precedes the bust.

The evidence goes beyond the Great Recession. In a series of studies, Jordà et al. (2013, 2014a); Jordà et al. (2014b) and Schularick and Taylor (2012) examine how growth in credit predicts financial crises and recession severity in a long historical panel of advanced countries. Schularick and Taylor (2012) estimate regressions showing that credit growth predicts financial crises, whereas Jordà et al. (2013) show that recessions preceded by a large run-up in credit tend to be more severe. Jordà et al. (2014b) extend the work in these previous two studies using novel data splitting credit into household and firm debt. They find that mortgage debt and real-estate booms predict financial crises in the post-World War II era, and they find that recessions preceded by rapid growth in mortgage debt tend to be deeper with slower recoveries. Dell'Ariccia et al. (2012) examine the characteristics of sharp increases in the bank credit to GDP ratio across a panel of countries from 1970 to 2009, and present descriptive evidence on the nature of booms and whether they lead to busts or financial crises.

Perhaps the strongest evidence in support of the aggregate implications of the theoretical frameworks by Eggertsson and Krugman (2012), Guerrieri and Lorenzoni (2015), Farhi and Werning (2015), Huo and Ríos-Rull (2016), and Korinek and Simsek (2014) comes from Mian et al. (2015). They show robust predictive power of increases in the household debt to GDP ratio on subsequent economic growth in a panel of 30 mostly advanced economies over the last 40 years. Further, they attempt to isolate *credit supply*-driven increases in household debt, and show these credit supply-driven booms predict lower subsequent economic growth. The predictive power of household debt increases is strongest in economies with fixed exchange rate regimes, supporting the importance of nominal rigidities. They also show evidence of a global household debt cycle: increases in the global household debt to GDP ratio predict subsequent lower global output growth.[1]

7. CONCLUSION

Shocks to household net worth coming from the collapse in house prices was an important determinant of consumption growth during the Great Recession. Further analysis of this pattern reveals that exposure to the housing crash as of 2006, which we measure as the 2006 housing wealth to total net worth ratio, was an important driver of this relation. Our review of the existing literature shows that very few studies focus on exposure to housing

[1] In contrast, Cecchetti et al. (2011) estimate country-level panel regressions relating economic growth from t to $t+5$ to the *level* of government, firm, and household debt in year t. They use a longer window of five years because it "reduces the potential effects of cyclical movements and allows [them] to focus on the medium-term growth rate." They do not find strong evidence that the *level* of private debt forecasts growth.

shocks when discussing the cross-sectional variation across households in consumption growth over the business cycle. We believe that more work is needed. Studies using macroeconomic data at the country level over longer time horizons find a robust relation between increases in household debt and subsequent economic downturns, which suggests that the strong relation between household balance sheets and output growth is present even outside the Great Recession.

We now have a solid body of theoretical work that can be used to motivate further empirical analysis of the effects of house prices and household debt on consumption. We believe the most important leap forward on these questions will be made if researchers are able to obtain administrative panel data on consumer spending that mirrors the high-quality panel income data from the Social Security Administration. As discussed in Mian et al. (2013), estimating differences in the marginal propensity to consume out of income and wealth shocks requires high-quality microeconomic data on consumption. Obtaining such high-quality data is even more important given the increasing focus of research on differences in the population in the marginal propensity to consume.

ACKNOWLEDGMENTS

Abstract

Modern monetary business-cycle models rely heavily on price and wage rigidity. While there is substantial evidence that prices do not adjust frequently, there is much less evidence on whether wage rigidity is an important feature of real world labor markets. While real average hourly earnings are not particularly cyclical, and do not react significantly to monetary policy shocks, systematic changes in the composition of employed workers and implicit contracts within employment arrangements make it difficult to draw strong conclusions about the importance of wage rigidity. We augment a workhorse monetary DSGE model by allowing for endogenous changes in the composition of workers and also by explicitly allowing for a difference between allocative wages and remitted wages. Using both individual-level and aggregate data, we study and extend the available evidence on the cyclicality of wages and we pay particular attention to the response of wages to identified monetary policy shocks. Our analysis suggests several broad conclusions: (i) in the data, composition bias plays a modest but noticeable role in cyclical compensation patterns; (ii) empirically, both the wages for newly hired workers and the "user cost of labor" respond strongly to identified monetary policy innovations; and (iii) a model with implicit contracts between workers and firms and a flexible allocative wage replicates these patterns well. We conclude that price rigidity likely plays a substantially more important role than wage rigidity in governing economic fluctuations.

1. INTRODUCTION

Since at least Hume ((1742), sluggish adjustment of wages and prices has been thought to be central for understanding the monetary transmission mechanism. This is certainly true in modern New Keynesian models, of either the textbook variety or in medium-scale models that attempt to match economic data.[a] Loosely speaking, models with nominal rigidities reproduce many of the patterns featured in partial-equilibrium settings, and can make demand-determined output fluctuations consistent with both basic business cycle facts and observed reactions to changes in monetary policy. Beyond monetary nonneutrality, it is now understood that models with nominal rigidities also behave differently in response to real shocks. For example, models with nominal rigidities can

[a] For a classic textbook treatment, see Woodford (2003). The canonical medium-scale models are due to Christiano et al. (2005) and Smets and Wouters (2007).

create business-cycle comovements in response to intertemporal shocks (such as news about future technology, uncertainty, or financial frictions that change expected capital returns), even when flexible-price models would not display such comovements.[b]

It is thus important to understand the extent and importance of nominal price and wage rigidities. While we discuss both wage and price rigidities in this survey, we focus mostly on wage rigidity, for several reasons. First, Christiano et al. (2005, CEE henceforth) and many successors have found that wage rigidity is quantitatively more important than price rigidity for explaining the effects of monetary shocks and for explaining cyclical fluctuations more generally. Second, attempts to decompose the cyclical behavior of the "labor wedge"—the gap between the marginal product of labor and the marginal rate of substitution between consumption and leisure—typically find that sluggish wage adjustment accounts for a large fraction of the observed cyclical behavior of the total wedge. That is, the wage markup appears more cyclical than the price markup.[c] Third, there is broad agreement among researchers on the basic empirical facts regarding price rigidity, but there is no such consensus regarding the nature of wage rigidity. Following the initial work of Bils and Klenow (2004), a large number of recent papers have investigated the frequency and magnitude of price changes and the pass-through from costs to prices. By contrast, there are fewer studies of wage rigidity, and the ones that exist often do not relate their results to macroeconomic models. Part of the reason for the greater uncertainty regarding wage behavior is that wages are harder to measure, and it is difficult to know whether observed wages are allocative.

While there is a tendency to discuss price and wage rigidity as independent phenomena, this is incorrect at the macroeconomic level. In some cases, one might be able to take the *microeconomic* rates of wage and price rigidity—for example, exogenous Poisson hazard rates for adjusting wages or prices—as independent parameters. But as macroeconomic models make clear, the inertia of the aggregate price level—the extent of *macroeconomic* price rigidity—depends heavily on the rigidity of wages. Since most models assume that target prices are set as a constant markup on nominal marginal costs, the inertia of the price level depends on sluggish adjustment of marginal cost. Wages are the largest component of the marginal cost of producing real value added, and thus wage stickiness naturally reinforces price stickiness. Indeed, in most medium-scale models, wage stickiness is essential for obtaining price level inertia and thus, for example, persistent real effects of nominal shocks. Similarly, wage setting, for example by monopoly unions, will also be influenced by expectations of future price inflation. In another chapter in this *Handbook*, Taylor (2016) discusses microeconomic evidence on staggered wage and price setting and its implications for macroeconomic models.

[b] See, for example, Basu and Bundick (2012). The basic issues were pointed out by Barro and King (1984).

[c] See, for example, Galí et al. (2007). However, their conclusion depends sensitively on the wage measure used. See, for example, Bils et al. (2014).

Our main purpose in this survey is to discuss several definitions and measures of wage stickiness and cyclical wage adjustment and then ask what they imply for wage and price rigidity in a prototypical medium-scale macroeconomic model. Although this survey concentrates on wage measurement, we believe that it is difficult to assess the implications of data without reference to theory. Thus, we construct a medium-scale DSGE model based on CEE, but with more extensive modeling of different concepts of wages. The model distinguishes between four concepts that we discuss later: average earnings, average earnings adjusted for labor force composition, wages of new hires, and the user cost of labor. These distinct wage concepts behave in different ways in response to the monetary shock we study, so we can use the model to predict the behavior of these different concepts of wages to a monetary policy shock, which is our measure of an archetypal nominal aggregate shock.

Our use of a model to motivate the measurement has the effect of focusing attention on the wage and price statistics that we believe are most relevant for macroeconomics. These are the responses of prices and wages to identified aggregate shocks—that is, conditional correlations—rather than average business-cycle correlations or the average frequency of wage or price change. When there are both idiosyncratic and aggregate shocks, micro wages and prices may change frequently for reasons unrelated to aggregate fluctuations, but they may change only slowly in response to aggregate shocks. To concentrate attention on the statistics that matter most for macroeconomics, we focus on the responses of nominal wages and prices to a monetary shock, which is the standard example of a nominal aggregate shock. Our focus on monetary shocks does not reflect a judgment that these shocks cause a significant fraction of business-cycle fluctuations. On the contrary, most of the available evidence suggests that monetary shocks account for a relatively small fraction of output volatility. But because they are identified using a consensus set of restrictions, and because these shocks would be neutral absent some nominal rigidities, they provide a valuable opportunity for assessing the performance of macroeconomic models.

To preview our findings, we argue that recent research provides suggestive evidence that the conceptually correct measure of the allocative wage is strongly procyclical. This finding contrasts sharply with typical estimates in the macro literature, which often claim that the real wage is roughly acyclical. We then discuss the implications of the new facts about wages for models with nominal rigidities, and find that these models struggle to explain the empirical facts regarding the effects of monetary policy shocks. We show that standard DSGE models can be augmented with realistic features to reproduce many of the wage patterns found in the recent literature but that these features typically pose serious problems for the ability of DSGE models of the monetary business cycle to match estimated reactions of other variables to monetary shocks. We argue that additional evidence on measured adjustment for allocative wages and on propagation mechanisms for monetary models is needed to reconcile the micro data with our understanding of the monetary transmission mechanism. The search for this evidence should be a high priority for future research.

This survey is structured as follows. After an initial overview of different concepts of "the wage" and a survey of the relevant literature, we take the workhorse model of CEE and extend it along several dimensions. The model enables us to define several different concepts of wages in a precise manner, and to derive predictions for their behavior in response to a monetary policy shock. Importantly, the model produces output corresponding to each wage concept, even though only one is perceived by workers and firms as the allocative wage. Thus, we are able to use the model to predict the behavior of both allocative and nonallocative wages in response to a monetary shock. We then relate the model implications to existing micro data studies on wages and prices, and indicate points where further evidence is needed.

With the concepts from the model in mind, we discuss evidence on wage cyclicality, drawing mostly on research using US micro data. We focus on three issues that are crucial for interpreting the data but are generally not incorporated into macroeconomic models: composition bias in aggregate wage measures, the distinction between wages of new hires and wages of workers in continuing employment, and the distinction between spot wages and the expected time path of wages. In order to draw our statistics from a common source and ensure that they are comparable to one another, we construct the composition-corrected wages, the wages of new hires and the user cost of labor using micro data from the National Longitudinal Survey of Youth 1979 (henceforth NLSY). We then show how the different measures of real wages respond to a monetary policy shock. Our main conclusion is that real wages, correctly defined and measured, are quite procyclical, in contrast to average hourly earnings, which are basically acyclical.

We conclude by confronting the model we have developed with the empirical evidence based on micro data. We find that the allocative wage needs to be quite flexible in order to match the behavior of the real wage we estimate from the micro data. However, in order to match the behavior of average hourly earnings, it is useful to combine the flexible allocative wage with a remitted (observed) wage that changes only infrequently, also in line with evidence from micro data. A model with sticky prices, flexible wages, and implicit labor contracts comes closest to matching the impulse responses of key variables to a monetary policy shock. However, a standard medium-scale DSGE model with flexible wages struggles to match the estimated high persistence of the output response to a monetary shock. Many recent models have used wage stickiness, justified in a variety of ways, as an important propagation mechanism for shocks. With the micro data indicating that wage flexibility is a better assumption than wage stickiness, macroeconomists need to search for new propagation mechanisms in order to match the observed persistence of output fluctuations, especially to monetary shocks.

2. DEFINING "THE WAGE"

Macroeconomic models are typically populated by a large number of identical worker-consumers, who supply labor along the intensive margin in a spot market. In this setting, it is easy to define the wage: it is the current payment at time *t* for an extra unit of labor supplied in the same period. If the world were as simple as the model, "the wage" would be easy to measure. Unfortunately, nearly all of the assumptions about the labor market noted above are violated in important ways in the data, making the effort to measure wage behavior far more complicated.

First, workers are not homogeneous. This obvious fact would not necessarily create a problem for measuring wage cyclicality if the hours of workers of different types increased and decreased in synchronized fashion. Then one could define a representative worker as a worker with human capital equal to the weighted average of the human capital of all workers in the population, and show that the average wage we observe in the data is also the wage commanded by the representative worker's fixed bundle of human capital characteristics. Unfortunately, the composition of the labor force changes over the cycle. Stockman (1983) conjectured and Solon et al. (1994) confirmed that the hours of low-paid workers are more cyclical than average. Hence, low-paid workers account for a larger share of labor payments in booms than in recessions. Thus, the cyclical behavior of the aggregate (average) real wage is not the cyclicality of the wage paid to a representative worker with fixed human capital characteristics, which is the implicit or explicit concept in almost all business-cycle models. As we shall see, correcting for this composition bias shows that the wage paid to a representative worker with fixed characteristics is considerably more procyclical than the average wage in the data. This is also the conclusion of an important early paper by Bils (1985).

Second, since most workers are in long-term relationships with their employers, the labor market is not a spot market. Thus, their spot wages are not necessarily what the firm perceives as the marginal cost of labor, which is the key concept for most macroeconomic purposes. Barro (1977) used the idea of an implicit contract to criticize the "right to hire" model of wage stickiness, where workers propose a fixed, possibly nominal, wage, and firms choose employment (or hours) along their labor demand curves. He showed that other contracts would increase the payoff to both parties in the bargain, and suggested that an efficient contract would equate workers' marginal rates of substitution between consumption and leisure to firms' marginal products of labor in every period, with the total compensation for labor paid out to workers in "installment payments" over the lifetime of the worker-firm association. This reasoning follows the classic work of Becker (1962), who showed in a neoclassical setting that only the present discounted value of the wages paid by firms to workers over the length their association is allocative for employment. Holding the present value of wage payments constant, the time path of *remitted* wages can have any shape without affecting real outcomes.

Thus, one needs to know how the annuity value of the expected present value of wages, which one might conceptually regard as the "permanent wage," changes in response to changing economic conditions. By analogy to the permanent income hypothesis, the behavior of the permanent wage, not the current wage, is what matters to an optimizing worker or firm. Much of the search literature implicitly ties the behavior of the permanent wage to that of the wage for new hires, but to the extent the two differ, the permanent wage matters more. If workers and firms are in long-term associations and the permanent wage is the correct measure of the cost of labor input, then it is possible for the observed average wage to appear insensitive to cyclical fluctuations (sticky) even if the correct allocative wage is flexible. This conclusion was anticipated by Barro (1977, p. 316), who wrote, "In fact, the principal contribution of the contracting approach to short-run macro-analysis may turn out to be its implication that some frequently discussed aspects of labor markets are a facade with respect to employment fluctuations. In this category one can list sticky wages …."

3. BACKGROUND AND RELATED LITERATURE

We survey the history of research on wage cyclicality, with an eye to distilling and interpreting the evidence on the cyclicality of the marginal cost of an efficiency unit of labor to the average firm. Given the central importance of this subject for macroeconomics and the vast number of papers written about it over several decades, we can only touch on the key ideas that are most closely related to our investigation of the topic. Fortunately, a number of fine surveys of wage cyclicality have been written over the years, and we refer the reader to those for more in-depth discussions of particular issues.[d]

Our survey ranges over estimates of both nominal wage rigidity and real wage cyclicality. Both are important for assessing modern "medium-scale" macroeconomic models, and especially the ability of these models to reproduce the real effects of monetary policy shocks as observed in the data.[e] Ultimately what matters is the behavior of the "shadow" real wage facing firms. The shadow wage is the marginal cost of a unit of labor to the firm, which may or may not be what economists can readily observe in the data. To the extent that the shadow real wage is insensitive to changes in labor demand, it may be due to either real features of the economy (eg, elastic labor supply) or to wage rigidity (even if notional labor supply is inelastic), or both. From the

[d] For example, see Abraham and Haltiwanger (1995).

[e] The "narrative" approach to documenting monetary nonneutrality is exemplified by Friedman and Schwartz (1963) and is developed further by Romer and Romer (1989). The modern VAR literature on estimating the effects of monetary policy shocks originates with Bernanke and Blinder (1992). See Christiano et al. (1999) for a survey of the VAR approach. For an alternative to both the narrative and VAR approaches to identification, see Romer and Romer (2004).

standpoint of a firm, both rationales can explain why total hours fluctuate nearly as much as GDP over the business cycle.[f] However, one generally needs nominal rigidity somewhere in the model to explain why a nominal shock has real effects. But even if nominal wages can adjust freely, acyclical real wages combined with nominal price rigidity can explain why monetary shocks are generally estimated to have sizable and persistent effects on output but little effect on nominal wages.[g]

In keeping with our focus on the cost of labor to a firm, we ignore a number of related and important topics on the behavior of wages. In particular, we do not survey the literature on the *reasons* for wage rigidity, such as efficiency-wage models or insider–outsider models. We also touch only briefly on search models of the labor market, although there is an important literature combining search models with New Keynesian macroeconomics.[h]

3.1 Wage Rigidity in Historical Data

In the *General Theory*, Keynes (1936) made nominal wage rigidity the centerpiece of his theory of aggregate supply. His framework predicted that procyclical changes in prices, combined with money wage inertia, would result in countercyclical real wages. Since money wages and prices should move in the same direction, the *General Theory* predicted that nominal and real wage changes should be negatively correlated. This prediction was tested but not confirmed by Dunlop (1938) and Tarshis (1939), who took their findings as *prima facie* evidence against the hypothesis of nominal wage rigidity.[i]

On the other hand, a variety of papers have examined the historical data and find clear evidence of nominal wage rigidity in the late nineteenth and early twentieth centuries. In a classic paper, Eichengreen and Sachs (1985) used cross-sectional data for 10 countries to show that over the Great Depression period there was a negative relationship between output and real wages. They also show that countries which remained on the gold standard had low output and high real wages, while countries that left gold early experienced high output and low real wages. Bernanke and Carey (1996) extended the Eichengreen–Sachs sample to 22 countries, examined dynamics by using panel data, and performed a number of other econometric and economic robustness tests, all of which supported the basic hypothesis of nominal wage rigidity. As Bernanke and Carey emphasized, they were studying the consequences of a purely nominal shock—the transition from the Gold Standard to a fiat money regime—which took place at different times in different countries. The fact that, when countries left the Gold Standard, real wages systematically fell

[g] For a development of this argument, see Ball and Romer (1990), Kimball (1995), and Woodford (2003, chapter 3).

[h] See Walsh (2003), Ravenna and Walsh (2008), and Gertler and Trigari (2009).

[i] Pencavel (2015) discusses the early Keynesian literature on wages. Galí (2013) relates the controversies of the 1930s to modern New Keynesian analysis.

while output rose suggests, first, that purely monetary shocks can have significant real effects, and second, that expansions in nominal aggregate demand raise output by lowering real wages, giving firms an incentive to employ more labor.

Evidence suggests, however, that nominal wage rigidity is not a universal feature of labor markets. Hanes (1993) argues that wages became inflexible around the time of widespread large-scale industrial production and episodes of labor unrest, which he dates to 1890. Hanes argues that nominal wages appear to stay rigid at least through World War I, although there is some weak evidence that they become somewhat more flexible starting in the 1970s. Basu and Taylor (1999) use both time-series and cross-country data to investigate wage cyclicality. They concentrate on real wages, and interpret their results in light of the prediction of countercyclical real wages in the *General Theory*. They find that there is no definite sign of the relation of real wage movements to the business cycle. For their sample of 13 countries, real wages were slightly procyclical in the period before World War I and somewhat countercyclical in the interwar period, before becoming decidedly more procyclical after World War II. Thus, their evidence supports the idea that real wages have become more procyclical over time.

Hanes (1996) and Huang et al. (2004) seek to explain the changing cyclicality of real wages over a long historical period of more than 100 years. Both papers propose an explanation that relies on *prices* becoming more sticky over time—due to a larger number of stages of processing for goods in Hanes's case, and due to a larger output elasticity of intermediate inputs in the work of Huang *et al.* (Both papers also include mechanisms that deliver countercyclical price markups, which are important for the result.) Thus, in these works the change in real wage cyclicality over time emerges from changes that take place in the *product* market rather than the labor market. Whether or not this hypothesis is ultimately adjudged to be plausible, it is a sobering reminder that general-equilibrium effects complicate the interpretation of simple business-cycle correlations, especially in a macroeconomic setting.

3.2 Wage Rigidity in Modern Data

In a benchmark survey of business-cycle facts, Stock and Watson (1999) find an almost zero correlation between detrended real average hourly earnings and detrended GDP in postwar US data.[j] This and similar findings (for example, that labor productivity is also approximately acyclical in US data), has led modelers to emphasize preferences or institutions leading to effective labor supply functions that are nearly infinitely elastic with respect to the wage.[k] Of course, a setting in which both nominal wages and prices are

[j] Stock and Watson detrend both series using the band-pass filter, set to isolate fluctuations lasting between 6 and 32 quarters.

[k] For models in which the wage is insensitive to output fluctuations, see Hansen (1985), Rogerson (1988), Greenwood et al. (1988) and, in nonneoclassical settings, Solow (1979) and Hall (2005).

slow to adjust can also produce a real wage that is approximately acyclical regardless of preferences; this is the path taken by Christiano et al. (2005) and Smets and Wouters (2007), among others.

A near-zero average correlation between output and real wages of course admits another interpretation. It might be the case that real wages fall in response to some shocks (perhaps expansionary monetary shocks) and rise with others (perhaps positive technology shocks). If the two types of shocks are roughly equally important in the data, then on average the real wage may be acyclical. Of course, this small average correlation could hide important conditional correlations that might be far from zero. The "multiple shocks" hypothesis could also explain the instability of the correlation between output and real wages in the historical data discussed earlier. The change in the correlation between the cyclical component of wages and the cyclical component of output might just reflect the changing contributions of the two types of shocks over different subperiods.[l]

Sumner and Silver (1989) present evidence in favor of this hypothesis. They classify periods dominated by "demand shocks" as those in which output and the price level move in the same direction, while periods where the two variables move in opposite directions are classified as being dominated by "supply shocks." They find that wages move countercylically in response to demand shocks but procyclically in response to supply shocks, a finding that is consistent with an augmented version of the "Old Keynesian" model.[m]

Huang et al. (2004) argue against the "multiple shocks" interpretation of the changing correlation between output and real wages over the business cycle. Their main argument is that the observed change in cyclicality applies to conditional correlations and not just simple correlations. For example, they cite the evidence of Eichengreen and Sachs (1985) and Bernanke and Carey (1996) discussed earlier to establish that real wages decline in response to expansionary monetary shocks during the interwar period, but then refer to evidence from structural VARs run on post-war data to show that real wages rise modestly in response to expansionary monetary shocks in the recent period. The empirical results in CEE, for example, show the real wage rising slightly several quarters after a monetary expansion and then declining slightly after 10 quarters, although at no horizon is the real wage response statistically significant in either direction. In their data, one can reject the hypothesis that real wages fall significantly in response to an expansionary monetary policy shock.

[l] Geary and Kennan (1982) present evidence from the manufacturing sectors of 12 OECD countries suggesting that wage cyclicality changes significantly depending on the time period studied. They also find that the choice of deflator (a consumer price or a product price index) can make a noticeable difference. Presumably a product price index is more appropriate for testing the hypothesis that employment and wages move along a stable labor demand curve.

[m] Fleischman (1999) comes to similar conclusions using a structural VAR with long-run restrictions to identify various categories of shocks.

3.3 "The Wage" in Aggregate and Micro Data

Most papers in the historical and macro literatures examining the behavior of wages use aggregate wage data.[n] Unfortunately, aggregate data are subject to a composition bias that makes aggregate (average) wage rates less procyclical than the wages of individual workers. Stockman (1983) conjectured that low-productivity (and hence low-wage) workers would have the most cyclical employment—they would be the most likely to be fired in recessions, but also the most likely to be hired in booms. If true, then the aggregate wage (either approximately or exactly the labor-income-weighted average of the individual wage rates) would be less procyclical than the wages of individual workers, since low-wage workers would earn a larger share of labor income in booms.

Bils (1985) used individual panel data from the National Longitudinal Survey of Young Men covering the period 1966–1980, and found that wages in micro data appear extremely procyclical: a one percentage point decline in the unemployment rate is associated with a rise in real wages of 1.5–2%. While Bils finds a countercyclical composition bias in aggregate wage measures, consistent with Stockman's conjecture, he argues that this bias does not contribute significantly to his finding of a procyclical wage, since aggregate wage data also show a very procyclical real wage over this sample period. Other than the sample period, Bils attributes his finding of a procyclical wage to his inclusion of overtime earnings into his wage measure.

Solon et al. (1994) also investigate Stockman's hypothesis of composition bias in aggregate wage data using longitudinal microdata, in their case from the Panel Study of Income Dynamics (PSID) for the years 1967–87. Unlike Bils, they find that composition bias played a substantial part in reducing the apparent cyclicality of the aggregate real wage over their sample period.[o] Controlling for composition bias, they find that wages are about twice as procyclical as they appear in aggregate data. Solon, Barsky and Parker interpret their finding as consistent with movements of wages and employment along a stable aggregate labor supply curve with a labor supply elasticity between 1.0 and 1.4. They suggest that their finding is more consistent with models that predict procyclical real wages than is the usual stylized "fact" of acyclical wages, and note that both neoclassical and New Keynesian theories of the business cycle tend to predict that wages should be quite procyclical.

It may appear that the finding of strongly procyclical real wages is at odds with the finding, discussed earlier, that US labor productivity is roughly acyclical. In fact, there

[n] Ironically, the historical literature is more likely to use disaggregated data, even though high-quality data are scarce for earlier periods. For example, Hanes (1993) and Hanes and James (2003) use fixed-weight indexes of wages in narrowly-defined occupations, a wage concept akin to the Employment Cost Index (ECI) produced by the Bureau of Labor Statistics.

[o] Solon et al. (1994) argue that the estimates in Bils (1985) apply to composition bias within narrowly defined categories of workers but do not fully reflect compositional changes across groups, and thus understate the aggregate effects of compositional changes.

is no inconsistency. Once one admits that labor is heterogeneous, labor productivity needs to be measured in terms of output per efficiency unit of labor rather than output per raw labor hour. Since the lower-wage workers added in a boom contribute less in efficiency units of labor than their contribution of work hours would suggest, labor productivity correctly measured is also more procyclical than it appears in aggregate data. In fact, when it comes to measuring unit labor cost (the hourly wage divided by output per hour worked), the composition corrections for wages and labor productivity exactly offset. Thus, in the Cobb–Douglas case, the unadjusted unit labor cost measures used in the literature as a straightforward measure of the markup of price over marginal cost are not biased by cyclical changes in composition.[p]

Using data from the CPS, Daly and Hobijn (2016) come to similar conclusions regarding the "intensive" and "extensive" margins of wages. Along the intensive margin—wage changes of continuously employed individuals—wages are clearly procyclical. The extensive margin consists of cyclical changes in employment, which are concentrated among workers with lower-than-average earnings. The extensive margin makes the aggregate wage appear countercyclical. The two effects combine to make the aggregate real wage appear acyclical on average, although Daly and Hobijn note that the relative strength of the two margins varies over time, and so does the cyclicality of the aggregate wage.

Elsby et al. (2016) revisit the issues of wage cyclicality and composition bias, focusing on the experience of the United States and the United Kingdom during the Great Recession of the 2000s. They use longitudinal microdata for both countries, but note that in many respects the UK data are preferable, first because of the larger sample size, and second because the data on earnings and work hours come from the payroll data of employers, which are generally thought to be significantly more accurate than workers' recollections.

Elsby et al. report somewhat nuanced findings. They confirm the earlier microdata-based result for the United States, that men's real wages are significantly procyclical, but find that their wages were less cyclical in the Great Recession than the experience of previous large recessions would suggest. Women's real wages, which had been rising sharply in the period since 1979, stagnated during the Great Recession. However, Elsby et al. find some hints that women's wage growth was declining prior to the last recession, and thus conclude that it is too early to tell whether the lack of wage growth in the most recent recession is due to women's wages being highly procyclical or whether it is due to a shift to a new trend of slow wage growth. In one respect, the findings for the United Kingdom for both men and women are similar to those of the US men: real wages fell significantly in the Great Recession. But the variation in wage cyclicality across recessions is more or less the opposite in the two countries: wages in the United Kingdom were much more procyclical in the Great Recession than in previous recessions, while the

[p] For measures of unit labor costs interpreted as the markup, see Rotemberg and Woodford (1991, 1999), Galí and Gertler (1999), Sbordone (2002) and Nekarda and Ramey (2013).

opposite was true in the United States, at least for men. Another major difference is that composition bias appears to matter much less for measuring wage cyclicality in the United Kingdom than it does in the United States. These differences are important to bear in mind when drawing lessons from the empirical results we report in this chapter, which are based exclusively on US data.

3.4 Downward Nominal Wage Rigidity

A long strand of Keynesian analysis is based on the hypothesis that wages are more rigid downward than upward. For example, Tobin's (1972) Presidential Address suggested that workers care about relative wages, implying that they would tend to resist asynchronized wage cuts but might tolerate a neutral mechanism like inflation that cuts all real wages proportionally. This hypothesis of an asymmetry between wage increases and decreases has been the focus of a substantial literature in labor economics. One of the first researchers to address this question using micro data is McLaughlin (1994), who failed to find much evidence of asymmetry. Later work by Card and Hyslop (1997), Kahn (1997), and Lebow et al. (1999) found evidence of downward nominal wage rigidity (DNWR), including a large spike in the observed wage change distribution at zero (unchanged nominal wages), and a smaller number of small wage declines than small wage increases. Gottschalk (2005) performed an analysis of micro data on wage changes using an econometric procedure to correct for measurement error in self-reported wages, and found substantial downward nominal rigidity. The more recent papers thus suggest significant downward rigidity of nominal wages and, given the low-inflation environment that has prevailed since the mid-1990s, of real wages as well.

Hanes and James (2003) examine historical data on individual wage changes in another low-inflation period, the years 1841–91. Applying the tests for asymmetry in wage changes developed in the literature analyzing modern wage data, they find no evidence of DNWR. They interpret their results as suggesting that an aversion to nominal wage cuts is not a fundamental feature of worker preferences. They note, however, that their results do not contradict the hypothesis that institutions may have changed in such a way as to make DNWR desirable in the modern era, perhaps as a boost to worker morale and hence productivity, as suggested by Bewley (1999). Another cautionary note in interpreting the consequences of DNWR comes from Elsby (2009). Elsby begins by assuming that an aversion to nominal wage cuts is indeed a feature of workers' preferences, but then shows that preferences of this unusual form often have only a small effect on equilibrium outcomes. The reason is that dynamically optimizing firms, when confronted with a workforce that exhibits DNWR preferences, will delay nominal wage increases, thus keeping a cushion that allows real wages to rise without causing substantial employment declines if the constraint on nominal wage declines comes into play. Elsby's model suggests that it is possible to find substantial evidence of DNWR in micro data while observing few macro consequences of such asymmetric behavior. (Indeed, the evidence supporting the macroeconomic implications of DNWR does not seem to be overwhelming: see, for example, Akerlof et al. (1996).)

A number of observers have suggested that DNWR is a good explanation for the recent observation that inflation has been slow to decline during protracted and severe recessions (for example, in Japan starting in the 1990s and the Great Recession in the Untied States and other countries in the 2000s). To our knowledge, no formal evidence of this connection has been offered. However, Schmitt-Grohé and Uribe (2013) suggest that if DNWR exists, then there is a strong case for higher inflation in the Eurozone to lower real wages and stimulate employment.

3.5 Wage Change Frequency in Micro Data

Canonical New Keynesian models, such as CEE and Smets and Wouters (2007), follow Blanchard and Kiyotaki (1987) in assuming that wages for each type of worker are set by a monopoly union. Like the monopolists in the product market, the monopoly unions are subject to the Calvo friction when changing nominal wages. Thus, just as the frequency of price adjustment is important for quantifying the significance of nominal price rigidities, the frequency of wage changes in micro data is important for assessing the plausible degree of inertia in nominal wage rates. However, unlike the large literature on the rigidity of micro-level prices, there are few studies of the frequency of change of individual wages.

Barattieri et al. (2014) provide one such study using micro data from the US Survey of Income and Program Participation (SIPP). One advantage of the SIPP is that participants are surveyed three times a year, unlike participants in the PSID, who are surveyed annually. SIPP data are thus more suitable for high-frequency analysis of individual wages.[q] Because all large surveys of US micro data on individual wages use self-reported wages, a substantial fraction of the paper of Barattieri et al. (2014) is devoted to proposing a method to correct for measurement error in such a way that one can recover a consistent estimate of the frequency of individual wage adjustment. Such studies can be carried out more easily in countries where one can obtain access to administrative data, which presumably have less measurement error. Individual wage change probabilities have been analyzed for France by Le Bihan et al. (2012), for Luxembourg by Lünnemann and Wintr (2009), and for Iceland by Sigurdsson and Sigurdardottir (2016). (Researchers can access confidential administrative data sets for the United States as well, but these generally provide information on total earnings rather than hourly wage rates, which were the focus of Barattieri et al.)

As we shall see in the model of the next section, the frequency of changes in the observed wage at the individual level is an important parameter for calibrating

[q] Other well-known sources of micro wage data, the Current Population Survey (CPS) and the Employment Cost Index (ECI), do not provide sufficiently long time-series data on the wages of individual workers to be useful for this purpose.

Table 1 Wage change frequency in SIPP data

	Hourly workers[a]	Salaried workers
Reported	0.565	0.721
Adjusted	0.120	0.061
Adjusted + correction[b]	0.211	0.209
Number of obs.	17,148	21,947

[a]Based on data and calculations in Barattieri et al. (2014).
[b]Based on calculations from Gottschalk and Huynh (2010).

implicit-contracting models of the labor market. (This is true even if, as in the model we present below, the observed wage need not be the allocative wage.) The estimate reported by Barattieri et al. is not directly applicable to the full US labor market, since these authors restricted their sample to hourly paid workers. Here, we present new estimates for the frequency of wage changes for salaried workers using the methodology of Barattieri et al.[r] The results are in Table 1.

The results for hourly paid workers, the first column, reproduce the first three lines of results for the "Overall" sample in Barattieri et al. (2014, table 6). The new results for salaried workers are in the second column. Earnings per hour change even more frequently for salaried workers in the raw, self-reported data than they do for hourly paid workers. Nearly three-quarters of hourly earnings for salaried workers change each quarter. However, applying the iterative procedure of Gottschalk (2005) to correct for measurement error in wages reduces the estimate of the quarterly probability of actual wage changes for salaried workers to 6.1%. Unfortunately, this is not a consistent estimate of the desired probability due to the presence of Type I and Type II errors. Using the adjustment for the signal-to-noise ratio based on the work of Gottschalk and Huynh (2010), as presented in Barattieri et al. (2014), the final estimate of the quarterly probability of a change in earnings per hour of salaried workers is 20.9%. This figure is remarkably close to the probability of 21.1% for hourly paid workers in Table 1. In our model calibrations below, we generally set the quarterly frequency of an observed change in the remitted wage to 21%.

3.6 Implicit Contracts, Adjustment Costs, and Real Wage Cyclicality

In a classic paper, Becker (1962) showed in a neoclassical setting that only the present discounted value of the wages paid by firms to workers over the length their association is allocative for employment. Holding the present value of wage payments constant, the time path of *remitted* (observed) wages could have any shape without affecting real outcomes. For example, firms and workers might agree to an implicit contract in which remitted wage payments are smoothed relative to changes in the allocative present value

[r] We are greatly indebted to Alessandro Barattieri for these estimates.

of wages, but the fact that the observed wage is smooth would not affect real outcomes. Barro (1977) used the idea of an implicit contract to criticize the "right to hire" model of wage stickiness, where workers propose a fixed wage, and firms choose employment (or hours) along their labor demand curves. He showed that other contracts would increase the payoff to both parties in the bargain, and suggested that an efficient contract would equate workers' marginal rates of substitution between consumption and leisure to firms' marginal products of labor in every period, with the total compensation for labor paid out to workers in "installment payments" over the lifetime of the worker-firm association.

Models where workers and firms have an implicit contract over the present value of wages clearly require some assumptions about the ability of the parties to commit. In some models, such as the one we present later, one simply assumes that commitment is feasible. An alternative is to assume adjustment costs to dissolving the match for one or both parties. Absent such costs, the party that is "ahead" in the installment payments would dissolve the match. The most popular current model of labor adjustment costs is based on search. Hall (2005) addressed Barro's (1977) critique of allocative wage stickiness by showing that the allocative wage could be history dependent and hence sticky within the Diamond–Mortensen–Pissarides model of search in the labor market, as long as the preset wage remains within the Nash bargaining set generated by that model. (This argument addressed the critique of the DMP model due to Shimer (2005), who identified the sharp procyclicality of the wage as the central reason why this canonical model fails to match the volatility of the unemployment and vacancy rates.) Hall and Milgrom (2008) showed that some wage stickiness could emerge from alternative-offer bargaining. Pissarides (2009) and Gertler and Trigari (2009) showed that in the search setting, the key allocative wage is that of new hires. Haefke et al. (2013) examine data from the Current Population Survey and conclude that the wages of newly hired workers are in fact much more procyclical than average hourly earnings of all employed workers.

Relative to the literature on composition bias, the main contribution of the search-based papers is to concentrate attention on a subset of wages, namely the wages of new hires. Thus, for example, Gertler and Trigari (2009) argue that the key statistic is whether new hires receive the same wages as workers currently employed by the firm they are joining, or whether they can be hired at different wages that better reflect current economic conditions.

Assuming that newly-hired workers expect to stay with their current employer for a significant length of time, it is intuitive that their expected labor compensation consists of the expected present value of the wages they will receive over the length of the association. In this case, what matters is actually not even the cyclicality of the spot wage of new hires *per se*, but the cyclicality of the expected present value of wage payments to new hires.

In an important recent paper, Kudlyak (2014) uses such a framework to observe that one way to measure the opportunity cost of hiring a worker this period is, apart from discounting, the cost of hiring the same worker in the next period. If the labor market is a spot market, then this difference is just the current-period wage. But if there are implicit contracts, the difference of present values can differ significantly from the wage. Kudlyak observes that the object of interest, which she terms the "user cost of labor" can be constructed by using panel data on workers to estimate the present discounted value of wages at time t and $t + 1$, correcting for both observed differences in human capital characteristics and for unobserved differences by estimating a worker fixed effect. Using data from the NLSY, she presents such estimates for the period 1978–97. Kudlyak finds that the user cost is significantly more procyclical than average hourly earnings, and more procyclical than even the wage for new hires. In the empirical component of the paper, we also construct the user cost of labor using NLSY data and a procedure much like Kudlyak's, and find very similar results.

Kudlyak shows that her user cost of labor is the right measure of the allocative wage in a large range of search models of the labor market. Thus, she calls into question search models based on sticky allocative wages, as in many of the papers discussed earlier. We embed Kudlyak's insight into a standard New Keynesian model, and find that the user cost is also the allocative wage in that framework.

Kudlyak's empirical finding was foreshadowed in two important earlier papers by Beaudry and DiNardo (1991, 1995), who found that the " permanent" wage might be significantly more procyclical than the wage at a point in time. They found that workers hired when the unemployment rate was high received persistently lower wages, even after the economy recovered. Thus, while the spot wage was cyclical, the present value of the wage fluctuated even more. Beaudry and DiNardo interpreted their finding as support for the Becker–Barro hypothesis of implicit contracts with costly worker mobility. In a sense, Beaudry and DiNardo approached the problem from the workers' side, asking why a worker would take a job in a recession, since the effective (permanent) wage that he or she receives is so low. Our approach (like Kudlyak's) examines the same facts from the firms' side, asking why firms do not hire more in recessions, since the effective cost of hiring a worker in a downturn appears to be low. (Beaudry and DiNardo also argue that the data favor a model where workers cannot commit fully to a time path of future wages since, in addition to the unemployment rate that prevailed when the worker was hired, wages seem to depend positively on the minimum unemployment rate observed since the hiring date.)

Hagedorn and Manovskii (2013) argue that much of the observed history dependence of current wages can be understood by appealing to labor search when workers face a job ladder. In Hagedorn and Manovskii's search model, wages are completely determined by current labor market conditions but because workers gradually "climb" the job ladder, wages appear to be history dependent. To see this, define an employment cycle as the length of time between spells of involuntary unemployment (Wolpin, 1992). *Ceteris paribus*, the longer an employment cycle, the more job offers the worker has received.

Consequently, the current wage must be relatively high to outbid the other competing offers. An individual who enters a period of involuntary employment (thus breaking an employment cycle) falls off the job ladder, and thus his reservation wage falls. Moreover, when a worker begins a new employment cycle, his initial wage offer is determined by current labor market conditions. Workers who start an employment cycle during an expansion, start relatively high up on the job ladder because they receive relatively more offers initially. Workers who start an employment cycle during a recession receive relatively fewer offers and thus accept a lower wage initially.

In Hagedorn and Manovskii's model, the match quality of a job can be proxied by including the cumulative labor market "tightness" during the employment cycle in the wage regression. Labor market tightness is the ratio of vacancies to unemployment. Intuitively, during an employment cycle, a worker gradually climbs up the match-quality ladder. How fast he or she climbs is determined by current aggregate labor-market tightness. Ultimately, how high the person gets is given by *cumulative* labor-market tightness over the employment cycle. Hagedorn and Manovskii use empirical work based on their model to criticize the conclusions of Beaudry and DiNardo (1991, 1995). They find that when they augment wage regressions with empirical proxies for match quality based on the job ladders model, they no longer find a significant role for lagged unemployment in explaining current wages. In our empirical work using NLSY data, we investigate whether Kudlyak's finding of implicit wage contracts is sensitive to Hagedorn and Manovskii's critique.

4. THE BENCHMARK MODEL

We begin by extending a standard business cycle model to allow for several real-world features of wage setting. Our benchmark model is a standard New Keynesian DSGE system built on the basic framework analyzed in CEE. We build on the baseline model by allowing for (i) endogenous variation in the composition of the workforce and (ii) differences between the allocative wage and the measured remitted payments to workers. We will spend more time describing our treatment of labor supply and wage setting and the mapping between the model variables and data because these are the nonstandard features of the model. Many of the other mechanisms in the model are now common in the DSGE literature and the quantitative New Keynesian literature and so we present them with relatively less detailed discussion.

4.1 Households

Consumers get utility from consumption and real money balances and get disutility from working. Let C_t be consumption of a nondurable good, let N_t be labor supplied at date-t and let M_t/P_t be real money balances held at date-t. Households act to maximize

$$E_t\left[\sum_{j=0}^{\infty}\beta^j\left\{\frac{\sigma}{\sigma-1}\left[C_{t+j}-hC_{t+j-1}\right]^{\frac{\sigma-1}{\sigma}}-\phi\frac{\eta}{\eta+1}N_{t+j}^{\frac{\eta+1}{\eta}}+\Lambda\left(\frac{M_{t+j}}{P_{t+j}}\right)\right\}\right] \tag{1}$$

subject to the nominal budget constraint

$$P_t(C_t+I_t+b(u_t)K_t)+S_t+M_t=W_tN_t+R_tK_tu_t+S_{t-1}(1+i_{t-1})+\Pi_t+M_{t-1} \tag{2}$$

and the capital accumulation equation

$$K_{t+1}=K_t(1-\delta)+F(I_t,I_{t-1}) \tag{3}$$

Here, P_t is the nominal prices of the durable and the nondurable, W_t is the nominal wage rate and R_t is the nominal rental price of capital services, which is the product K_tu_t. Π_t denotes profits returned to the household through dividends. M_t is the supply of nominal money balances held at time t, S_t is nominal savings and i_t is the nominal interest rate. σ is the intertemporal elasticity of substitution, η is the Frisch labor supply elasticity, $\Lambda(.)$ expresses the household's valuation for real money balances and $h \geq 0$ is a habit persistence term ($h > 0$ implies habit persistence in utility). The function $F(.)$ is an investment adjustment cost function and $b(u_t)$ gives the resource cost of additional utilization per unit of physical capital. Following CEE, we assume that

$$F(I_t,I_{t-1})=\left[1-f\left(\frac{I_t}{I_{t-1}}\right)\right]I_t$$

with $f(1)=1, f'(1)=0$ and $f''(1)=\kappa$.

Households choose C_t, I_t, M_t, u_t and K_{t+1} to maximize (1) subject to (2) and (3). The determination of labor supply N_t is the key object of interest for this paper and we discuss this in greater detail below.

4.2 Firms and Price Setting

Following much of the New Keynesian literature we model the production and pricing component of the model as a two-stage process. Final goods are produced from a combination of intermediate goods. Final goods producers are competitive and have flexible prices. Intermediate goods firms are monopolistically competitive and change prices infrequently according to the Calvo mechanism.

4.2.1 Final Goods Producers

Final goods are produced from intermediates. Specifically, final output is given by the standard Dixit–Stiglitz aggregator

$$Y_t=\left[\int_0^1 y_t(s)^{\frac{\varepsilon-1}{\varepsilon}}ds\right]^{\frac{\varepsilon}{\varepsilon-1}}, \tag{4}$$

where $\varepsilon > 1$. Final goods producers are perfectly competitive and take the final goods price P_t and intermediate goods prices $p_t(s)$ as given. It is straightforward to show that demand for each intermediate good has the standard isoelastic form

$$y_t(s) = Y_t\left(\frac{p_t(s)}{P_t}\right)^{-\varepsilon}. \tag{5}$$

Competition among final goods producers ensures that the nominal price of the final good is a simple combination of the nominal prices of the intermediate goods used in production. Specifically,

$$P_t = \left[\int_0^1 p_t(s)^{1-\varepsilon} ds\right]^{\frac{1}{1-\varepsilon}}. \tag{6}$$

4.2.2 Intermediate Goods Producers

Intermediate goods are produced by monopolistically competitive firms who take the demand curve (5) as given when they set their prices. Each intermediate goods firm has a constant returns to scale production function

$$y_t(s) = Z_t k_t(s)^{\alpha} l_t(s)^{1-\alpha},$$

where $k_t(s)$, $l_t(s)$ and $y_t(s)$ denote capital, labor and output for intermediate producer s at time t. k_t is the quantity of capital services *inclusive of utilization*, and thus is not the firm-level equivalent of K_t, which is the stock of physical capital. Similarly, l_t is number of standardized units of labor employed by the firm. That is, it is an index of the total labor input the firm derives from the potentially heterogenous workers it employs, expressed in a common numeraire, such as the number of high-school-educated workers. This concept of labor, which is relevant for productivity, should be distinguished from N_t, which is akin to total employment or the total number of hours worked by all persons, and is the object relevant for utility. Here, Z_t is an aggregate productivity shock common to all firms. While the intermediate goods firms have some monopoly power in their output markets, they are competitive in the input markets, and take the nominal input prices W_t and R_t as given when making their decisions. Each period, firms choose their inputs to minimize costs. For any given level of production $\bar{y}$, the firm's cost-minimization problem is $\min_{l,k} Wl + Rk$ subject to $Zk^{\alpha}l^{1-\alpha} \geq \bar{y}$.

Because the production functions have constant returns to scale, and because capital and labor can flow freely across firms, firms choose the same capital-to-labor ratios. That is, for each intermediate producer s,

$$\frac{k_t(s)}{l_t(s)} = \frac{K_t u_t}{L_t},$$

where we have used the market clearing conditions $\int k_t(s)ds = u_t K_t$ and $\int l_t(s)ds = L_t$. The nominal marginal cost of production, MC_t, for the intermediate goods producers is common to all firms (because the firms have constant returns to scale production functions). It can be shown that the date-t nominal marginal cost is

$$MC_t = \left(\frac{1}{\alpha}\right)^{\alpha}\left(\frac{1}{1-\alpha}\right)^{1-\alpha}\frac{W_t^{1-\alpha}R_t^{\alpha}}{Z_t}. \tag{7}$$

Price setting for each intermediate good producer is governed by a Calvo mechanism. Let θ_p be the probability that an intermediate goods producing firm cannot reset its price in a given period. Thus, each period, $1-\theta_p$ firms reset their prices as they see fit. In many DSGE models, the firms that cannot reset their prices (ie, those that don't get the Calvo draw) are assumed to reset their prices according to a backward-looking rule. CEE refer to this modeling device as "lagged inflation indexation" in the DSGE literature. To allow for inflation indexing, we would assume that the remaining θ_p firms set their prices according to the backward-looking rule $p_t(s) = p_{t-1}(s)(1+\pi_{t-1})$ where

$$1+\pi_t = \frac{P_t}{P_{t-1}}$$

is the gross nominal inflation rate. Without inflation indexing, firms that do not get the Calvo draw simply continue to charge the same nominal price they had at the beginning of the period.

Intermediate goods firms maximize the discounted value of profits for their shareholders (the households) and thus discount future nominal profits in period $t+j$ by the stochastic discount factor $\beta^j\lambda_{t+j}$ (technically, λ_t is the Lagrange multiplier associated with the nominal constraint (2)). The optimization problem for an intermediate goods firm is to choose a reset price p_t^* to maximize the objective

$$E_t\left[\sum_{j=0}^{\infty}(\theta_p)^j\left[\beta^j\lambda_{t+j}\left(p_t^*\prod\nolimits_{s=0}^{j-1}(1+\pi_{t+s}) - MC_{t+j}\right)\left(\left[\frac{p_t^*\prod_{s=0}^{j-1}(1+\pi_{t+s})}{P_{t+j}}\right]^{-\varepsilon}Y_{t+j}\right)\right]\right]$$

where is it understood that $\prod_{s=0}^{-1}(1+\pi_{t+s}) \equiv 1$. (The expression above, and those that follow, are written under the assumption that firms index their prices to lagged inflation as discussed earlier. The equations corresponding to the model without inflation indexing are the same except that the terms $(1+\pi_{t+s})$ are all simply 1.)

Given the reset price p_t^*, and using (6), the price of the final good evolves according to

$$P_t = \left[\theta_p([1+\pi_{t-1}]P_{t-1})^{1-\varepsilon} + (1-\theta_p)(p_t^*)^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}.$$

Well-known methods show that the optimal reset price together with the dynamic evolution of the aggregate price level imply that the model satisfies a hybrid New Keynesian Phillips curve of the form

$$\widetilde{\pi}_t - \widetilde{\pi}_{t-1} = \gamma^p \widetilde{mc}_t + \beta E_t\left[\widetilde{\pi}_{t+1} - \widetilde{\pi}_t\right],$$

where $\gamma^p = \dfrac{(1-\theta_p\beta)(1-\theta_p)}{\theta_p}$ is the microeconomic rate of price adjustment.[s] We use the notation $\widetilde{v}_t$ to denote the percent deviation of the variable v_t from its steady-state value $\bar{v}$. That is, $\widetilde{v}_t = dv_t/\bar{v}$.

4.3 Labor Supply and Wage Setting

The supply of labor features several mechanisms that are prominent in the empirical literature on labor supply and the measurement of wages. As in Erceg et al. (2000) and CEE, we allow for nominal wage rigidity in the model. In addition to nominal wage stickiness, we augment the model to include two new features: (i) endogenous composition bias and (ii) a difference between allocative wages and remitted wages. Both mechanisms influence the mapping between model predictions on the one hand and empirical measures of wages and labor supply on the other. To accommodate these mechanisms, we treat the supply of labor as occurring in two separate stages within a period. We refer to these simply as stage 1 and stage 2.

In the first stage, the composition bias mechanism allocates workers with differential productivity to the market. This stage results in a single nominal wage paid for units of productivity-adjusted labor and an average wage for employed workers. We denote the wage for productivity-adjusted labor as W_t^1, the average hourly wage for employed workers as $\bar{W}_t^1$ and the total supply of effective (productivity-adjusted) labor as L_t^1 where the superscript indicates that these variables are determined in stage 1.

In the second stage, an allocative wage is determined. The allocative wage is sticky and evolves according to a Calvo mechanism taking the stage 1 wage W_t^1 as the effective marginal cost of supplying units of effective labor. In addition to the allocative wage, which governs actual employment, the second stage also produces two separate observed wages: a new-hire wage W_t^{New} and a wage for all employed workers that corresponds to average hourly earnings W_t^{AHE}.

[s] We can also allow for the possibility for *partial* inflation indexing $p_t(s) = p_{t-1}(s)(1+\pi_{t-1})^{\omega}$ with $\omega \in [0,1]$. In this case, the implied Phillips curve is

$$\widetilde{\pi}_t - \omega\widetilde{\pi}_{t-1} = \gamma^p \widetilde{mc}_t + \beta E_t\left[\widetilde{\pi}_{t+1} - \omega\widetilde{\pi}_t\right].$$

4.3.1 Composition Bias

It is well understood that the composition of the workforce changes systematically over the course of the business cycle. Typically, the labor force has a higher fraction of low-wage workers in booms than in recessions, making the average wage somewhat more countercyclical than the wage for a representative worker with fixed human capital characteristics, which is the concept of the wage in most macroeconomic models. To the extent that composition fluctuates over the cycle, the changing characteristics of the workforce automatically makes output per person appear more counter-cyclical than otherwise.

To introduce composition bias into the model, we imagine that labor varies by productivity. Specifically, we assume that total actual *hours* of labor (the argument in the utility function (1)) is given by

$$N_t = \int_0^A n_t(a)\varphi(a)da. \tag{8}$$

Here, a is an index of productivity and A is the maximum productivity of any individual in society. $\varphi(a)$ is the measure of the population with labor productivity a and $n_t(a)$ denotes hours worked per person with productivity a. For each type, $n_t(a) \in [0,1]$. The total population is $\bar{N} = \int_0^A \varphi(a)da$. Each type is paid a nominal wage $w_t^1(a)$.

Workers supply labor to labor aggregating firms who in turn sell an effective labor aggregate at a wage W_t^1. The labor aggregating firms' maximization problem is to hire different types of labor to maximize nominal profits.

$$\max_{n_t(a)} \left\{ W_t^1 \int a n_t(a)da - \int w_t^1(a)n_t(a)da \right\}$$

The labor aggregating firms' first order conditions for the choice of $n_t(a)$ requires

$$w_t^1(a) = W_t^1 a$$

for all a. That is, the individual's wage is a direct reflection of the worker's individual productivity.

Consider an increase in $n_t(a)$ from the perspective of the representative household. The utility impact of this increase is

$$\left[-\phi N_t^{\frac{1}{\eta}} + \lambda_t w_t^1(a) \right] \varphi(a) \times dn_t(a)$$

where λ_t is the shadow value of money payments to the representative household (ie, λ_t is the Lagrange multiplier on the nominal budget constraint). If the term in brackets is positive, then it is optimal to set $n_t(a) = 1$. If the term in brackets is negative, then it is optimal to set $n_t(a) = 0$. Using $w_t^1(a) = W_t^1 a$ we can express the critical productivity cutoff $\hat{a}_t$ as

$$\frac{\phi N_t^{\frac{1}{\eta}}}{\lambda_t W_t^1} = \hat{a}_t. \tag{9}$$

For any type $a > \hat{a}_t$ it is optimal to work full-time. Types $a < \hat{a}_t$ are out of the labor force. Total employment is $N_t = \int_{\hat{a}_t}^{A} \varphi(a)da$ and total effective-productivity-adjusted labor is

$$L_t^1 = \int_{\hat{a}_t}^{A} a\varphi(a)da.$$

Except for two important differences, (9) is essentially a standard labor supply condition. First, $\hat{a}_t$ is endogenous and covaries negatively with aggregate employment N_t. Second, there is a difference between effective labor L_t^1 and measured hours of employment N_t.

The *average* wage $\bar{W}_t^1$ of employed workers in the first stage is simply the ratio of total wage payments to total hours of work, that is,

$$\bar{W}_t^1 = \frac{\int_0^A w_t^1(a)n_t(a)\varphi(a)da}{N_t} = \frac{L_t^1 W_t^1}{N_t}.$$

In contrast, the composition-adjusted wage from stage 1 is simply W_t^1. Notice that the ratio of total hours worked to effective labor is equal to the ratio of the composition-adjusted wage to the average wage, $\frac{N}{L} = \frac{W}{\bar{W}}$. Using log-linear expressions for N_t and L_t, one can show that composition bias (the log difference between $\bar{W}_t$ and W_t) satisfies

$$\widetilde{\bar{W}}_t - \tilde{W}_t^1 = -\left[\frac{LN-1}{LN}\right]\tilde{N}_t \tag{10}$$

where we use the notation LN to denote the ratio of effective labor to measured hours worked L/N. Since the average wage exceeds the wage for the marginal worker (ie, since $LN > 1$), composition bias imparts a negative comovement between the average wage and aggregate hours. In US data, the cyclical variation in average real wages is negligible, while the composition-corrected wage is procyclical.

4.3.2 Allocative Wage Rigidity

In addition to the composition-bias mechanism presented above, the model features nominal wage rigidity, as in CEE. The wage block of their model is from Erceg et al. (2000). Like these earlier papers, we assume that wage rigidity applies directly to an "allocative wage," by which we mean, the relevant wage for determining employment and work effort. Unlike these earlier papers, we allow the allocative wage to differ from the remitted wage that is readily observed in data. In addition to this allocative wage, the model produces a measured remitted wage that we discuss later.

We denote the allocative wage by X_t. The allocative wage adjusts sluggishly according to a Calvo mechanism. As we did in our treatment of composition bias, we assume that there is a labor aggregating firm that assembles an aggregate of labor "types." This aggregating firm supplies effective labor to the productive firms at flow allocative wage X_t, but hires labor by type according to the type-specific allocative wages $x_t(s)$. The labor aggregate is given by a CES aggregate of labor types s,

$$L_t^2 = \left[\int_0^1 l_t(s)^{\frac{\psi-1}{\psi}} ds\right]^{\frac{\psi}{\psi-1}},$$

where the superscript 2 refers to the fact that this labor supply is determined in stage 2. (Note, this treatment is essentially identical to our treatment of prices. As we did earlier, we let s be an index of different types though in this context s refers to a type of labor while before s was a type of intermediate good.) If the aggregating firm chooses to supply labor force L_t^2, its demand for type s work is given by the isoelastic function,

$$l_t^2(s) = L_t^2 \left(\frac{x_t(s)}{X_t}\right)^{-\psi}.$$

The allocative wages $x_t(s)$ for each type s of labor are set by a monopolist in that type (similar to a union). The aggregate allocative wage X_t for units of the labor aggregate is a reflection of the type-specific allocative wages $x_{i,t}$

$$X_t = \left[\int_0^1 x_t(s)^{1-\psi} ds\right]^{\frac{1}{1-\psi}}.$$

Note that the labor market clearing condition implies that, up to a first-order approximation, the labor aggregate from stage 1 is equal to the resulting labor aggregate from stage 2 (ie, $\tilde{L}_t^1 \approx \tilde{L}_t^2$).

As we did with the price setters, we assume that the type-specific wages are set according to a Calvo mechanism. The probability of adjusting a type-specific wage is $1 - \theta_w$ and the probability of not adjusting is θ_w. As we did with the price setters, we allow for the possibility of wage inflation indexing. In this case, wage setters who do not get the Calvo draw, instead follow the wage inflation indexing rule $x_t(s) = x_{t-1}(s)(1 + \pi_{t-1})$. Without wage inflation indexing, these wage setters would simply maintain the constant nominal allocative wage they had at the start of the period. The union tries to maximize the present discounted value of wage markups $x_t(s) - W_t^1$. An extra dollar in period $t+j$ is worth $\beta^j \lambda_{t+j}$ to the household. Thus, a monopolist who has the option to set his wage at time t should choose a reset wage w_t^* to maximize

$$\max_{x_t^*} \left\{ E_t \left[\sum_{j=0}^{\infty} (\beta\theta_w)^j \lambda_{t+j} \left(x_t^* \prod_{s=0}^{j-1} (1 + \pi_{t+s}) - W_{t+j}^1 \right) L_{t+j}^2 \left(\frac{x_t^* \prod_{s=0}^{j-1} (1 + \pi_{t+s})}{X_{t+j}} \right)^{-\psi} \right] \right\}$$

where again is it understood that $\prod_{s=0}^{-1}(1+\pi_{t+s})=1$. Given the reset wage x_t^*, the aggregate allocative wage evolves according to

$$X_t=\left[\theta_w\{(1+\pi_{t-1})X_{t-1}\}^{1-\psi}+(1-\theta_w)\left(x_t^*\right)^{1-\psi}\right]^{\frac{1}{1-\psi}}.$$

4.3.3 Remitted Wages

Our discussion highlights the difference between the *allocative* wage—the shadow wage X_t that governs work effort and employment—and the *measured* wage that governs the periodic payments from the employer to the workers. We assume that the remitted wage is a smoothed function of the allocative wage. Specifically, we assume that workers periodically renegotiate their contract terms (or separate from their current jobs and get new jobs with new terms). When wage contracts are renegotiated, the workers are given a new remitted wage. Let PDV_t be the expected present discounted value of future nominal allocative wages for a newly employed worker that resets the remitted wage with probability $s\in(0,1]$. That is,

$$PDV_t=X_t+\beta(1-s)E_t\left[\frac{\lambda_{t+1}}{\lambda_t}PDV_{t+1}\right]=E_t\left[\sum_{j=0}^{\infty}[\beta(1-s)]^j\frac{\lambda_{t+j+1}}{\lambda_t}X_{t+j}\right].$$

Clearly PDV_t depends on the reset rate s (even though the reset rate plays no role in allocations). The measured remitted wage for new hires (or workers who newly renegotiated their contract) at date-t will be a smoothed version of the PDV. Specifically, we assume that the measured wage for new hires will solve

$$PDV_t=W_t^{New}E_t\left[\sum_{j=0}^{\infty}[\beta(1-s)]^j\frac{\lambda_{t+j+1}}{\lambda_t}\right].$$

That is, W_t^{New} is a constant wage that will transfer the same expected amount to the workers given the reset rate s as they would receive by getting the time-varying aggregate allocative wage, X_t. For purposes of comparison with the data, W_t^{New} is the new-hire wage.

We can also track the average outstanding wage for all workers in the model. Let W_t^{AHE} be the average hourly earnings of all employed workers. By construction, the average outstanding wage at time t is the average wage for all workers that did not renegotiate together with the new-hire wage

$$W_t^{AHE}=W_{t-1}^{AHE}(1-s)+H_tW_t^{New}$$

where $H_t=L_t-L_{t-1}(1-s)$ denotes "new hires" which we interpret as all workers who are newly hired plus those who remain employed but receive new contract terms for their remitted wage.

It is worth mentioning some of the difference between the different wage concepts W_t^1, $\bar{W}_t^1$, W_t^{AHE}, W_t^{New} and X_t. One key difference between the wages in the first stage (W_t^1 and $\bar{W}_t^1$) and the wages in the second stage (W_t^{AHE}, W_t^{New} and X_t) is that the wages in the second stage have a (potentially, time varying) wage markup. That is, in the nonstochastic steady state, $W^{AHE} = W^{New} = X = \frac{\psi}{\psi - 1} W^1$. If the allocative wage is flexible, then the markup $\frac{\psi}{\psi - 1}$ is constant even away from the steady state and in this case the dynamic behavior of the allocative wage and the stage 1 wage is the same (ie, $\widetilde{X}_t = \widetilde{W}^1_t$). If there is no composition bias, then the two stage 1 wages are the same, $W^1_t = \bar{W}^1_t$. If the renegotiation rate $s = 1$, then all of the stage 2 wages are identical, $W^{AHE}_t = W^{New}_t = X_t$. In general all of the wages will differ.

4.4 Aggregate Conditions and the Steady State

The goods market clearing condition is

$$Y_t = C_t + I_t + K_t a(u_t).$$

Although in principle there can be many different sources of uncertainty in the model, we focus our attention here on monetary shocks. We assume that monetary policy is described by a Taylor rule

$$\widetilde{\imath}_t = \left(1 - \rho^i\right)\left[\phi_Y \frac{\widetilde{Y}_t}{4} + \phi_\pi \widetilde{\pi}_t\right] + \rho^i \widetilde{\imath}_{t-1} + \varepsilon^i_t$$

Here, ϕ_Y and ϕ_π give the relative reaction of the monetary authority to output and inflation while ρ^i is an interest rate "smoothing" parameter. Here, ε^i_t is a shock to the monetary authorities policy rule. We assume that ε^i_t is mean zero and i.i.d. over time.

4.4.1 Nonstochastic Steady State

We choose parameters to ensure that in the nonstochastic steady state, $L = P = u = 1$. The steady-state markups are $\mu^p = \frac{\varepsilon}{\varepsilon - 1}$ and $\mu^w = \frac{\psi}{\psi - 1}$. We normalize the steady-state productivity cutoff to $\hat{a} = 1$. The steady-state nominal marginal cost is $MC = 1/\mu^p$. Since there is no inflation and no economic growth in the steady state, $1 + r = 1 + i = \frac{1}{\beta}$. It is straightforward to show that the nominal rental price is $R = r + \delta$ and we must have $R = b'(1)$. Steady-state capital is

$$K = \left(\frac{\alpha MC}{R}\right)^{\frac{1}{1-\alpha}}.$$

The remaining details of the steady state are standard and are therefore omitted.

4.4.2 Calibration

To compare the model to the data, as we do in Section 6, we will need to calibrate the parameters in the model. When possible, we adopt calibration settings based on conventional parameter values used for medium scale DSGE models. The discount factor β is set to 0.97 which implies a steady-state annual real interest rate of 3%. We set both the Frisch elasticity η and the intertemporal elasticity of substitution σ to 1.00. Capital's share, α, is set to 0.36. We set the type-specific elasticity of labor demand ψ to 21 which implies a 5% markup of the allocative wage over the base wage. We set the type-specific elasticity of product demand ε to 6 which implies a 20% markup of nominal price over nominal marginal cost. We set the Calvo parameters for wage and price adjustment, θ_w and θ_p, to 0.90 (quarterly). This implies that both wages and prices have an average duration of roughly 10 quarters. These durations are somewhat longer than most studies of microeconomic price adjustment data but are comparable to estimates from DSGE models.

Following Basu and Kimball (1997), we set the utilization elasticity $\frac{b''(1)}{b'(1)} = 1.00$. We set the investment adjustment cost parameter is set at $\kappa = 4.00$ and the habit persistence parameter $h = 0.65$. We allow firms to index their prices to past inflation as in CEE.

In addition to the standard parameters discussed earlier, the model also requires values for the parameters that govern composition bias and the remitted wage. There are three key parameters that govern these mechanisms: the renegotiation hazard s, the steady-state ratio of effective labor to total hours worked LN and the density of types at the steady-state productivity cutoff $\varphi(1)$. For our baseline setting, we assume that neither of these mechanisms is operative and thus we set $s = 1.00$ (so the remitted wage is equal to the allocative wage), $LN = 1.00$ (so there is no difference in average productivity per hour) and $\varphi(1) = \infty$ (so hours can be varied without changing the productivity of the marginal worker). This baseline specification is thus essentially equivalent to a standard medium-scale sticky-price/sticky-wage DSGE model. When we introduce composition bias and infrequent resetting of remitted wages we set $s = 0.21$ following Barattieri et al. (2014), $LN = 2.0$ and $\varphi(1) = 2$.

5. EMPIRICAL MEASURES OF REAL WAGES

Empirically, the cyclicality of the real wage is potentially influenced by several different features. Cyclical variations in the composition of employed workers has been emphasized as an important component of variation in real wages (see, Solon et al. (1994) and Elsby et al. (2016)). Even after correcting for compositional changes, however, it is difficult to speak unambiguously about a single concept of "the real wage." As emphasized by Haefke et al. (2013), wages of newly hired workers appear to be much more cyclical than the wages of workers who are continually employed. Beaudry and DiNardo (1991, 1995) argue that wage payments are shaped by implicit agreements between employers and employees and thus the remitted wage at a given point in time provides at best an incomplete measure of the worker's compensation. Similarly, Kudlyak (2014) finds that wage paths of workers hired at various points of the business cycle exhibit great differences in present value suggesting that the theoretical concerns articulated by Becker (1962) and Barro (1977) regarding implicit long-term contracts have empirical as well as theoretical merit.

In this section, we will examine micro data on real wages to attempt to assess whether available evidence can provide insight into how various measures of real wage payments move over the business cycle and also whether these wage measures react to monetary policy shocks. We empirically quantify the separate contributions of composition bias, variations in the new-hire wage, and variations in the present value of wage commitments.

5.1 Background

In the model in the previous section, there are several objects that map to measured wages, but only one, which we have called X_t, is allocative. Unfortunately this allocative wage is not directly measured in the data. In principle, this allocative wage can be uncovered by differencing measures of the present value at two points in time. This difference is what Kudlyak (2014) calls the *user cost of labor* (UCL).[t] Specifically,

$$UCL_t = PDV_t - \beta(1-s)PDV_{t+1} \approx X_t. \tag{11}$$

The UCL_t is only approximately equal to the allocative wage since the calculation above ignores the expectations operator and the stochastic discount factor. Kudlyak finds that unlike the average wage, the UCL is highly procyclical, even more so than the wage of new hires.

Below we will construct measures of both the UCL and the new-hire wage. Both the UCL and the new-hire wage are difficult objects to measure, since one needs to observe individual workers over time. The two panel data sets for the United States, the NLSY and the PSID, both have relatively small samples and limited sample periods. Furthermore, the data are annual, which is not ideal for business-cycle analysis. A benefit of using individual level panel data is that such data can correct for composition bias. Thus, in their early analyses of composition bias over the business cycle, Bils (1985) uses the NLSY and Solon et al. (1994) use the PSID. The recent papers by Haefke et al. (2013) and Elsby et al. (2016) instead use CPS data. The drawback to using the CPS is that since it is not a true panel, one cannot remove the effects of *unobserved* individual effects from the wages. On the other hand, the CPS has the advantage that it provides a large and nationally-representative sample, and continuous monthly data going through the Great Recession period and its aftermath.

[t] The term is used as an analogy to the "user cost of capital" under adjustment costs, in which case the decision to add an extra unit of capital is a dynamic decision with long-term consequences.

5.2 NLSY

For the purposes of the analysis in this chapter, we focus on wage data from the National Longitudinal Survey of Youth 1979 (NLSY). The NLSY is an unbalanced panel of workers initially interviewed in 1979 and then, if possible, interviewed every subsequent year until 1994 and every second year after 1994 (see below). The initial sample included 12,686 individuals born between 1957 and 1964. The birth years of the individuals in the data are distributed roughly uniformly over the years between 1957 and 1964. At the time of the initial survey in 1979 these individuals were all between 14 and 21 years of age. The initial respondents consisted of 6403 males and 6283 females.

While there are many advantages to using NLSY data, there are some disadvantages as well. Chief among these disadvantages is the fact that, due to the nature of the survey's construction, the sample in the NLSY "ages" systematically with the passage of time. This immediately means that the average wage of employed workers in the NLSY should not be directly compared to the average hourly earnings wage series constructed from NIPA data which presumably reflects wage payments to all individuals employed at any given point in time. Moreover, there is only a small amount of age variation in any single year. Thus, while we can in principle control for age in our wage regressions, the age (or more accurately "experience") coefficients will be difficult to distinguish from the growth of average wages over time.

Our data includes all data from the first interview in 1979 up to 2013. Because the NLSY was modified to a biennial survey starting in 1994, we drop all of the odd years between 1994 and 2012.[u] For our analysis here, we focus exclusively on men. Thus our sample consists of the 6403 men interviewed initially in 1979 and then followed until 2012. Although the NLSY is not a representative sample of the US population, the survey provides a yearly cross-sectional weight variable that can be used to make the sample comparable to that year's population.[v]

[u] While the NLSY does ask the respondent to remember information for the previous years after it made the transition to biennial surveys, the wage series and responses appear to be systematically different for the odd years.

[v] Of the whole initial interview sample, roughly half (6111) comprised what the NLSY refers to as a "representative sample" of the noninstitutionalized working-age population born between 1957 and 1964. In addition to the representative sample, the NLSY also collected data on a "disadvantaged sample" consisting of 5295 individuals who identified as Hispanic, Latino, Black and economically disadvantaged respondents. Finally, the NLSY includes 1280 respondents who are representative of the population serving in the armed forces. This latter sample is referred to as the "military" sample. Both the disadvantaged sample and the military sample were severely cut back or eliminated entirely from the NLSY in 1984 and again in 1990. We keep all males in each of the three subgroups (the representative sample, the military sample and the disadvantaged sample). We then use the cross-sectional weights to convert the NLSY data to an overall representative sample. Note, we do not use the longitudinal weights that are included in the NLSY. The longitudinal weights are intended to produce a representative panel over the entire period.

The NLSY reports wage information for up to five jobs each year. Our sample technically includes data from jobs in 1978 even though the first interviews were done in 1979. (The 1978 data come from interviews that were done early in 1979 and so pertained to jobs in 1978.) We focus on the "hourly rate of pay" variable that is constructed by the NLSY. Respondents are asked for the most convenient way to report their total earnings.[w] They could report pay per hour, per day, per week, per month, or per year. In every case, the reported statistic is then converted to an hourly pay rate based on a measure of the respondents typical hours worked. The resulting hourly rate of pay includes tips, overtime pay, and bonuses but is computed before any deductions. To construct real wages, we deflate the hourly rate of pay with a price index. We considered two separate price deflators in our analysis: the consumer price index and the implicit price deflator for the nonfarm business sector.[x,y] The analysis for the two separate price indices were quite similar overall. Since our focus is on intertemporal labor demand from the firms' perspective (ie, the real product wage), we focus on the real wage measures using the deflator for the nonfarm business sector in the discussion later.

In addition to the information on wages, the NLSY includes information on the industry of the jobs and whether the jobs are covered by a union. We do not include union status in our analysis because the union variables included in the Employer History Roster exhibit an unusual change following the 1994 change from annual to biennial coverage in the NLSY.

5.2.1 Wage Regressions

We begin by describing how we construct the various measures of real wage series from the NLSY data. Given the available data, as described above, we run regressions of the following form:

$$\ln w_{t,\tau}^{i} = c + \alpha^{i} + \zeta t + \Psi X_{t}^{i} + \sum_{d_0=1}^{T} \sum_{d=d_0}^{T} \chi_{d_0,d} D_{d_0,d}^{i} + \varepsilon_{t}^{i}. \tag{12}$$

This is the basic empirical specification considered in Kudlyak (2014). Here, $w_{t,\tau}^{i}$ is the real wage for individual i at time t who was hired at time τ. This regression provides a best linear prediction of the log real wage at time t of a worker i, who started his job in period τ. In its most general form, this wage regression allows for a time trend, demographic and

[w] QES-71A in the 2012 survey.

[x] We used the consumer price index for all urban consumers: All items and the nonfarm business sector implicit price deflator. Both variables are seasonally adjusted and are available from the FRED database as CPIAUCSL and IPDNBS.

[y] We exclude wage rates less than 1 dollar per hour and above 100 dollars per hour measured in 1979 dollars. This restriction led to the elimination of 2894 wage-year observations. This censoring at 1 dollar and 100 dollars is the same censoring used by the BLS when it uses NLSY data.

industry controls (included in X_t^i), individual fixed effects (the α^i coefficients), and time effects that depend on two periods: when the individual began work at his current job and the current date. The additional covariates in the X_t^i matrix are the individual's experience at time t (and experience squared), tenure at time t (and tenure squared), schooling completed, and industry fixed effects. Experience is defined as the maximum of (Age − 6 − years of schooling) and 0. The dummy variables $D_{d_0,d}^i$ take the value 1 if $d_0 = \tau$ and $d = t$ and 0 otherwise.

The χ coefficients are particularly important for interpretation of the new-hire wage series and the user-cost series that we emphasize below. At time t, all workers who began work at their current job at date-τ get an additional adjustment to their predicted wage given by the coefficient $\chi_{\tau,t}$. These adjustments imply that workers who begin at date-τ experience an expected strip of log wage realizations given by $\{\hat{\chi}_{\tau,\tau}, \hat{\chi}_{\tau+1,\tau}, \hat{\chi}_{\tau+2,\tau}, \ldots \hat{\chi}_{\tau+j,\tau}, \ldots \text{etc}\}$. These dummy variables thus adjust for vintages of hired workers, where the vintage is defined by when the worker was hired in addition to the current calendar date. Notice that the variable $\hat{\chi}_{\tau,\tau}$ reflects the wages of a newly hired worker (ie, the date-τ wage of a worker hired at date-τ). In the estimation, we truncate the χ strips at 7 years (including year 0).[z]

This specification can also be used to calculate composition adjusted wages. For instance, if we restrict the $\chi_{\tau+j,\tau}$ coefficients to be zero then the resulting specification gives a predicted wage that adjusts for both observed changes in workforce composition (by including the X_t^i variables) and unobserved workforce composition (by including the individual fixed effects α^i), but does not allow for vintage effects on the wage. Adding the χ dummy variables allows us to recover composition-adjusted wages with vintage effects. For example, the coefficient on $\chi_{\tau,\tau}$ tells us whether a newly hired worker receives a wage increase or reduction relative to workers hired in previous years, controlling for any differences in human capital between new hires and other workers.

5.2.2 Average Hourly Earnings and New-Hire Wages

Before we consider our measures of the user cost of labor, we first examine average hourly earnings. We consider two measures. The first is a measure taken from the BLS. The BLS reports a measure of compensation per hour for the nonfarm business sector. We then deflate this measure by the implicit price deflator.[aa] We refer to this measure as AHE-BLS.

[z] More precisely, we include all of the dummy variables in the estimation of (12); however, following Kudlyak (2014), we use only seven χ estimates when we calculate the user cost of labor.

[aa] The variables used in this calculation are from the FRED database. We use nonfarm business sector: Compensation Per Hour (COMPNFB) and the Nonfarm Business Sector: Implicit Price Deflator (IPBNBS).

Our second measure of average hourly earnings is constructed from the NLSY data. We refer to this measure as AHE-NLSY. This wage series is constructed by first running the simplified version of regression (12)

$$\ln w_t^i = c + \Psi X_t^i + \sum_{d=1}^{T} \omega_d D_d^i + \varepsilon_t^i,$$

where D_d^i is a time dummy variable (D_d^i takes the value 1 if $d = t$ and zero otherwise). For the NLSY measure of average hourly earnings, the controls X_t^i include only experience and experience squared. Because the experience variable is defined as $\max\{\text{age} - 6 - \text{schooling}\}$ this is close to being a control for age and age squared. The estimated time fixed effects $\hat{\omega}_t$ are then an estimated time series of average hourly earnings. Note that, because the NLSY is based on a fixed set of individuals who were entering the workforce in the late 1970s, it is crucially important to include controls for age in this measure. If we did not include experience and experience squared, then the sample would systematically age and this would impart a systematic aging component to the wage measures.

To construct the new-hire wage, we return to the original regression specification (12). As noted, the new-hire wage series corresponds to the estimated coefficients $\hat{\chi}_{t,t}$. We include all of the available demographic controls in X_t^i and we also include individual fixed effects in the regression.[ab]

5.2.3 Calculating the User Cost of Labor

We base our calculation of the user cost of labor (UCL) on equation (11). To calculate the user cost, we need to calculate a forecast of the present value of wage payments for a worker hired at date-t and the present value of wage payments for a worker hired at date-$t + 1$. For an individual hired at date-t and still employed at date-$t + j$, we construct the predicted value of the log real wage $\widehat{\ln w_{t,t+j}}$. We can then calculate the implied present value of compensation as

$$\widehat{PDV}_t = \sum_{j=0}^{\infty} \beta^j (1-s)^j \exp\left\{\widehat{\ln w_{t,t+j}}\right\}.$$

Note that in addition to requiring a sequence of predicted log wages $\{\widehat{\ln w_{t,t+j}}\}_{j=0}^{\infty}$, this calculation requires a separation rate s and a discount factor β.

To construct the projected wage payments $\widehat{\ln w_{t,\tau}}$, we consider the anticipated wage payments for a firm that hires an "average worker" at date-t. As the employment

[ab] Our method for constructing the new-hire wage differs from that in Kudlyak (2014), who simply examines the wages for workers hired in the current year. Our procedure creates a wage series for new hires correcting for composition, in parallel with our construction of the user cost of labor.

relationship continues, our measure of the worker's experience and our measure of the worker's tenure both increase. We assume that the initial experience is fixed at the sample average of 11.72 years and we set the initial tenure variable to 0.5 years (this implicitly assumes that a worker who reports being newly hired at his current job at the time of the interview was hired 6 months earlier). We set the worker's schooling to 12.57 years, again the sample average in the NLSY. Then, based on (12), at date-τ, a worker hired at date-$t \leq \tau$ has a projected log wage

$$\widehat{\ln w_{t,\tau}} = \hat{c} + \hat{\zeta}\tau + \hat{\Psi}\bar{X}_{\tau-t} + \hat{\chi}_{\tau,t} \tag{13}$$

where $\bar{X}_{\tau-t}$ are demographic controls for the "average worker" (ie, schooling = 12.57, experience = 11.72 + $\tau - t$ and tenure = 0.5 + $\tau - t$).

For the separation rate s, we follow Kudlyak (2014) who uses a monthly separation rate of 0.0295. This figure is based on calculations of the average separation rate in the NLSY. We then convert this monthly separation rate into an annual separation rate by setting $s = 1 - (1-0.0295)^{12} = 0.3019$. The NLSY figure might be somewhat low relative to other datasets. The separation rate from the JOLTS dataset is closer to 0.035. The annual discount factor is set to 0.97. Note that our calculation of the present value of wage payments is truncated at 7 years (including the initial year). Given the high observed separation rates in the data, this truncation has a relatively small effect on the present value.

5.3 The Cyclicality of Real Labor Compensation

We are now in a position to examine the cyclical behavior of real wages. Tables 2 and 3 report cyclicality estimates for six different measures of log real wages. For each measure of real wages, we regress the calculated wage series on an indicator of the business cycle (and a time trend and a constant). Table 2 examines the cyclicality of real wages with respect to the HP filtered unemployment rate. We use HP filtered unemployment rather than the unemployment rate in levels because the average unemployment rate changes substantially over the time period for the NLSY.[ac] Thus, the coefficients reported are semielasticities: the percent change in a real wage measure in response to a one percentage-point deviation of unemployment relative to its trend. The sample for columns 1–5 consists of 25 data points from 1979 to 2012, dropping the odd years between 1994 and 2012 (see Section 3.2). To construct the UCL, we need to impute values of wages for the odd years between 1994 and 2012. The final user cost series itself ends

[ac] The HP filtered unemployment rate is taken from monthly data from 1985 to 2016. To avoid the well-known endpoint problem in HP filtering, we add 120 months of predicted unemployment rates taken from an estimated AR(6) to the end of the sample. We then HP filter the padded series using a smoothing parameter of 500,000. The regression uses annual averages of the monthly HP deviations.

Table 2 Real wage cyclicality: Unemployment rate

	AHE–BLS	AHE–NLSY			New hire	UCL
	(1)	Base (2)	Controls (3)	Controls, FEs (4)	(5)	(6)
HP-filtered unemployment rate	−0.507 (0.471)	−0.976 (1.530)	−1.185 (1.507)	−1.328 (1.623)	−0.698 (1.822)	−5.818 (2.079)
Observations	34	25	25	25	25	27

Notes: OLS standard errors are in parentheses. Coefficients are multiplied by 100.

Table 3 Real wage cyclicality: GDP

	AHE–BLS	AHE–NLSY			New hire	UCL
	(1)	Base (2)	Controls (3)	Controls, FEs (4)	(5)	(6)
HP-filtered GDP	0.311 (0.353)	0.984 (1.093)	0.960 (1.082)	1.165 (1.161)	1.325 (1.287)	3.122 (1.351)
Observations	34	25	25	25	25	27

Notes: OLS standard errors are in parentheses.

in 2007 because we require seven subsequent wage observations to calculate the value of the UCL in year *t* (again see Section 3.2 for details).

Columns 1–4 report results for average hourly earnings. For the BLS wage series, AHE-BLS, the coefficient on the unemployment rate is −0.507: real average hourly earnings fall by roughly 0.5% for each percentage point increase in the cyclical component of the unemployment rate. Columns 2–4 report results for our constructed measure of average hourly earnings from the NLSY data, AHE-NLSY. As noted in our discussion earlier, the dependent variables in Columns 2–4 are estimated time fixed effects from regressions of individual wages on the listed set of controls. The columns differ according to the number of controls included in the regression. Column 2 includes only experience and experience squared; column 3 adds industry fixed effects, job tenure and schooling; column 4 includes all of the aforementioned controls and adds individual fixed effects. The NLSY sample exhibits greater cyclicality for all of the measures of average hourly earnings, and the cyclicality rises with the number of controls for worker characteristics. We interpret this finding as being supportive of the basic composition-bias effect emphasized by Bils (1985) and Solon et al. (1994). Typically, as we add more controls for worker heterogeneity, the point estimate of the cyclicality rises (though note, the standard errors are high enough that we cannot say with any certainty that any one of these measures is clearly more or less cyclical than any other).

Column 5 reports results for the new-hire wage. The point estimate for the cyclicality coefficient is − 0.698, so a one percentage point increase in the cyclical component of unemployment corresponds to a 0.7% reduction in the real new-hire wage. By itself, the point estimate seems to be at odds with the findings in Haefke et al. (2013) who reported that in CPS data, the wages of newly hired workers appeared substantially more cyclical than average hourly earnings. We should note that while our point estimates do not indicate greater cyclicality of the new-hire wage, the estimates are quite noisy and admit a range of interpretations.

Column 6 reports results for the user cost of labor (UCL). Our measure of the UCL exhibits *much* greater cyclicality than either the composition-adjusted wage or the new-hire wage series. In Table 2, the cyclicality estimate is − 5.818 indicating that for every one percentage-point increase in the cyclical component of unemployment, the real user cost of labor falls by almost 6% (!).

The estimates in Table 2 are robust to alternate measures of the business cycle. Table 3 reports estimates for the same dependent variables as those in Table 2, but uses HP filtered GDP as the indicator of the business cycle instead of the unemployment rate. Again, average hourly earnings seem to be only moderately cyclical. When HP filtered GDP is above trend by 1%, AHE-BLS is above trend by only 0.311%. By contrast, holding the set of workers fixed in the NLSY and controlling for observed and unobserved heterogeneity increases this estimate to 1.165%. The point estimate of the cyclicality of the new-hire wage is more cyclical. The point estimate is a rise of roughly 1.3% for every 1% change in the cyclical component of GDP. Finally, as before, the UCL is the most cyclical wage measure. For each percent increase in GDP above trend, the UCL rises by approximately 3.1%.

What these results seem to suggest is that both composition bias and implicit contracting play important roles in shaping the wage payments made to workers over the business cycle. Quantitatively, controlling for composition (by including individual fixed effects and controls for observed worker differences in the wage regressions) increases wage cyclicality by perhaps as much as a factor of two relative to a group of workers without such controls. The effects of implicit contracting and wage-smoothing seem to be even greater than the effects of composition bias. According to our calculations, the user cost of labor has a cyclicality that is, in some cases, about six times greater than the log real wages of the base group. Since average payments are less cyclical than the user cost, workers hired in bad times are paid a wage greater than their user cost. In return, the workers expect to receive fewer and smaller wage increases over their employment spell.

Our findings (which are consistent with the results in Kudlyak, 2014) seem to corroborate the results in Beaudry and DiNardo (1991, 1995), who argued that current wage payments seem to be tied to past labor market conditions. In that paper, the authors showed that the maximum unemployment rate during a job spell and the unemployment rate that prevailed when the worker was hired both have a significant influence on current wage payments. The specification above, which we have adapted from Kudlyak's work, is a more general econometric specification than the one in Beaudry and DiNardo, but implicit contracts still appear to play an important role in shaping wage payments.

5.4 Wage Responses to Monetary Shocks

Almost all of the literature on wage cyclicality examines the response of real wages to a cyclical indicator, typically the unemployment rate. However, the monetary business-cycle literature has also emphasized the importance of replicating estimated impulse response functions to identified shocks—most often monetary shocks. The modern literature on estimating the effects of monetary policy shocks using VARs began with Bernanke and Blinder (1992). Here we follow the approach in CEE, since we ultimately want to make comparisons between empirical and theoretical impulse responses to monetary shocks.

To implement the VAR procedure, we first extend our annual real wage measures from the NLSY to a longer quarterly series using the Chow–Lin procedure. The extension to quarterly data is important for the validity of the identifying assumptions commonly used in the VAR literature. The identification assumptions invoked are plausible in quarterly observations but this plausibility becomes strained if the data are sampled at an annual frequency. The Chow–Lin method uses the annual data to estimate the relationship between the annual wage measures constructed above and other variables that are available at a quarterly frequency. The variables used in the Chow–Lin procedure are Real Gross Domestic Product, Real Hourly Compensation in the nonfarm business sector, the Civilian Unemployment Rate, and Total Nonfarm Payrolls for All Employees.[ad] The resulting interpolated series distributes the annual measure to the corresponding quarters (thus, the annual averages of the constructed quarterly series equal the original annual measures). We then extend the series by projecting the missing data to periods outside the years 1979–2012 covered by the NLSY. We first regress the interpolated quarterly wage measures on the variables in the Chow–Lin procedure above. We then use the OLS estimates to form estimates $\hat{w}_t$ for time periods earlier than 1979 and later than 2012. Fig. 1 plots quarterly average hourly earnings, the new-hire wage, and the user cost of labor for the period 1965:1 to 2015:3. For each series, a separate linear trend was removed prior to plotting. Each series is in log points and is plotted so that the mean of each series is centered at 1.00.

The impulse response functions to monetary policy shocks are constructed following the approach recommended by CEE. We include the same variables, in the same

[ad] All variables are in logs except for the unemployment rate which is entered in levels.

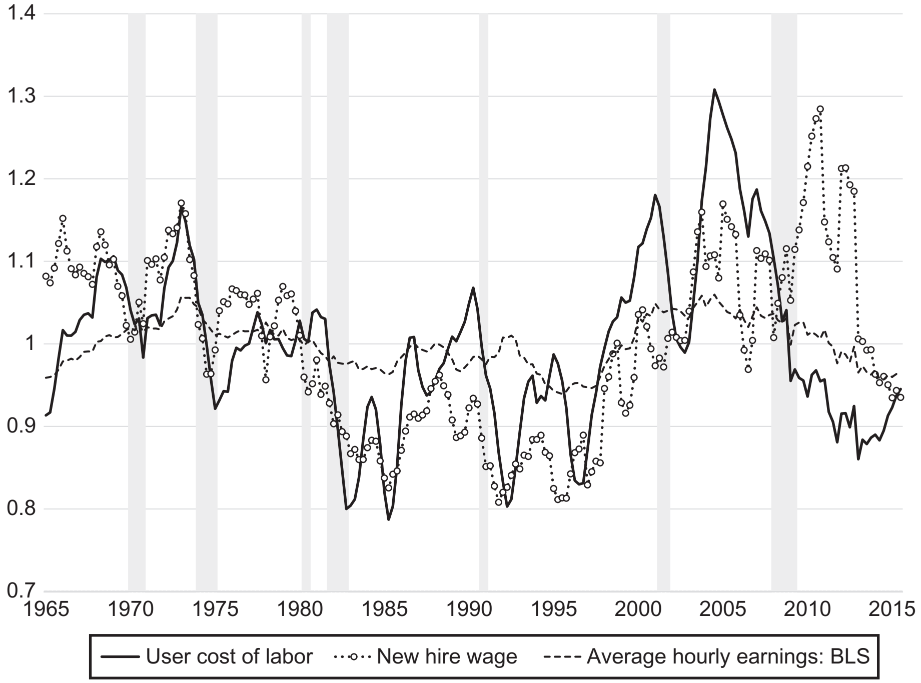

Fig. 1 Measures of the real wage.

Choleski ordering as in the original CEE specification. In order, the variables are real output, real consumption expenditure, the price level, real investment spending, real average hourly compensation, average labor productivity, the federal funds rate, real corporate profits, and the growth rate of the money supply (M2). Following Bernanke and Blinder (1992), the innovation to the funds rate is identified as a structural shock to monetary policy. Notice that by assumption, none of the variables in the first block (output, consumption, the price level, investment, compensation and labor productivity) responds contemporaneously to a shock to monetary policy. In contrast, both corporate profits and the growth rate of M2 respond contemporaneously to monetary shocks. Our approach is to extend the CEE specification by appending a single additional variable—an additional wage measure—to the second block of variables. Thus, our augmented VAR introduces a wage which is allowed to respond contemporaneously to monetary shocks. However, we add the restriction that monetary policy does not respond contemporaneously to shocks to the new wage measure. This restriction is sufficient to identify the impulse response of the wage measure to a monetary policy shock.

We do not want to allow the new wage measures to influence the identified monetary policy shocks. That is, we wish to ensure that the identified shocks remain the same as we change our measure of wages in the VAR. This first consideration implies that the new wage measures should be excluded from the dynamic equations governing the variables originally included in the CEE specification. It also suggests that we should order the new wage series last so that these new measures will respond to the other variables but the other variables—in particular the federal funds rate—will not respond to the alternate wage measures.[ae] One consequence of ordering the new wage measures last is that they respond contemporaneously to a monetary policy shock. In CEE's original specification their measure of the wage, average hourly earnings, comes before the federal funds rate, and may respond to monetary policy shocks only with a one-quarter lag. Thus, our procedure treats the new wage measures differently from average hourly earnings, but only for the first quarter after a monetary policy shock.[af]

As in CEE, consumption, investment and corporate profits come from the BEA's NIPA tables. Unlike CEE, our measures of output, the price level, employee compensation and labor productivity are only for the nonfarm business sector. Our decision to use the nonfarm business sector is motivated primarily by our belief that the nonfarm business sector is a better match to models of infrequent price adjustment by firms that are trying to maximize profits. Excluded industries (such as utilities and government production) likely do not set prices optimally the way most macroeconomic models posit. All variables are in log levels, except for the federal funds rate which is in levels and M2 which is in log differences. All variables were downloaded from the Federal Reserve Bank of St. Louis FRED web database.

To estimate the VAR, we use the same sample used by CEE, namely 1965:3 to 1995:3. We do so in order to make it easy to compare our results to the ones in this benchmark paper.[ag] We experimented with other sample periods, including extending the sample forward to 2007. The extended sample would allow us to estimate the VAR using a larger data set, while stopping short of the zero-lower-bound period in which the identifying assumptions do not apply. Unfortunately, we found that the impulse responses reported by CEE change significantly when the later data are added, in ways that are difficult to interpret in light of the underlying theory. (For example, the well-known "price puzzle" is clearly apparent in the extended sample.) Since our main objective is to explore how our novel real wage measures responded to a well-known identified shock, we chose to estimate the VAR over the original CEE sample. However, we believe that the instability of the impulse responses to monetary shocks over different

[ae] As in CEE, the federal funds rate is assumed to respond to average hourly compensation. Thus, we *always* include real hourly compensation in the VAR. This ensures that our identification assumptions match those in CEE.

[af] We experimented with other identification schemes, including ones that constrain the contemporaneous responses of the new wage measures to zero, symmetrically with average hourly earnings. The results we report below are qualitatively robust to all the variants we tried.

[ag] Even though our sample is identical with the sample in CEE, differences will arise because of data revisions and also because we use NFB output and prices rather than GDP and the GDP deflator.

sample periods—reminiscent of the results in Hanson (2004)—is worthy of investigation in its own right.[ah]

Our focus in this chapter is on the responses of the various wage measures constructed above. For each "new" measure of the real wage, we estimate a different VAR system to recover the response of the wage to the monetary shock. For example, we estimate the system separately for the new-hire wage and for the user cost. Given the VAR structure discussed later, the new variable does not affect the responses of the original CEE variables in any way. As a result, we report the impulse responses of the baseline set of variables to a monetary policy shock in one block, since these do not change as we change the additional wage variable added to the CEE specification.

Fig. 2 shows the reaction of the standard macroeconomic variables included in the CEE system to an identified increase in the federal funds rate of 50 basis points. (To save space, the figure omits the responses for corporate profits and for the growth rate of M2.) Each panel reports the impulse response of a single variable. The units of all variables are reported in percentage points (ie, 1.00 corresponds to 1%). The dotted lines correspond to 1 standard deviation error bands. The shock leads to a reduction in output of roughly 0.25%, a reduction in nondurable consumption of slightly less than 0.2% and a reduction

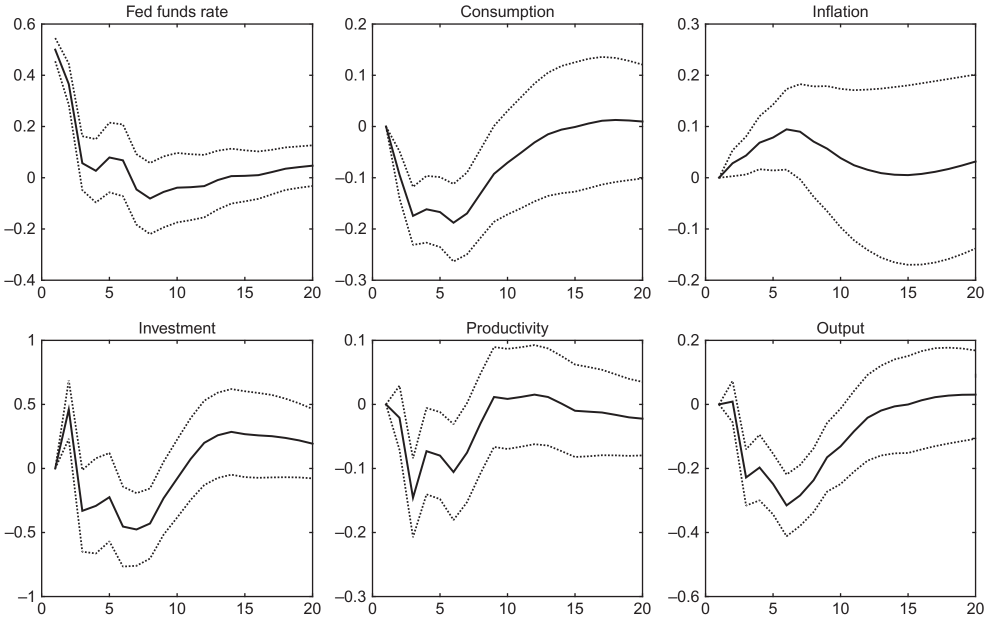

Fig. 2 Impulse responses to an identified monetary contraction: Standard variables.

[ah] In line with our findings, in her chapter in this *Handbook*, Ramey (2016) also emphasizes that the original CEE estimates "do not hold up well in later samples." She concludes that "the most likely reason for the breakdown [...] in the later sample is simply that we can no longer identify monetary policy shocks well."

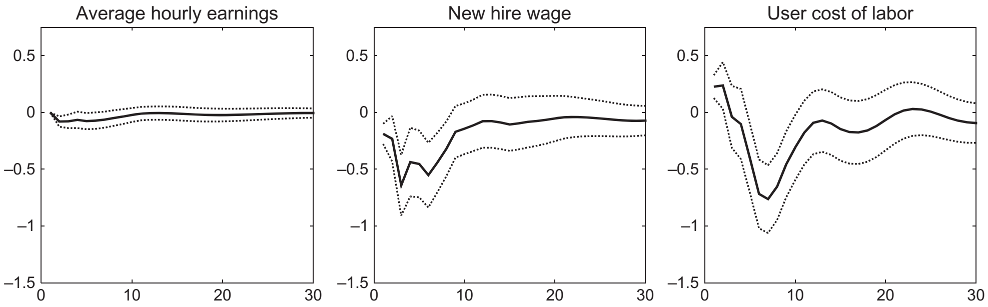

Fig. 3 Impulse responses to an identified monetary contraction: Real wage measures.

in investment of nearly 0.5%. Note that measured productivity also declines, suggesting that unobserved factor utilization contributes to the decline in production.

Fig. 3 reports the impulse responses for the three wage measures we constructed above. The left side panel reports the reaction of average hourly earnings (AHE-BLS). This wage measure barely reacts to the shock. In the center panel, the new-hire wage falls by substantially more. After roughly a year and a half, the new-hire wage has fallen by more than 0.5%. The right side panel shows the user cost of labor. The UCL falls even more than the new-hire wage and remains relatively low even more than 2 years after the shock.

We found similar results when estimating impulse response functions over the time period 1979:4–2007:4. The beginning of this alternative sample corresponds to the beginning of Paul Volcker's chairmanship of the Federal Reserve, but also has the benefit of excluding any backward projection of the user cost series. In general, the impulse responses from the main block of variables are more muted but take longer to return to trend. Despite this difference, the user cost series still has a peak response near 0.75%. The new-hire wages oscillate rapidly, but reach a similar peak response after a similar lag. We conclude that the results are qualitatively unchanged over this shorter sample period that overlaps significantly with Kudlyak's data sample and is also the period when the "modern" era of US monetary policy may be said to have begun.

5.5 Extension: Controlling for Match Quality

As discussed in Section 3, Hagedorn and Manovskii (2013) argue that much of the observed history dependence of current wages can be understood by appealing to labor search when workers face a job ladder. In Hagedorn and Manovskii's model, the match quality of a job can be proxied by including the cumulative labor market "tightness" during the employment cycle in the wage regression. Labor market tightness is the ratio of vacancies to unemployment. Intuitively, during an employment cycle, a worker gradually climbs up the match-quality ladder. How fast he or she climbs is determined by current aggregate labor-market tightness. Ultimately, how high the person gets is given by *cumulative* labor-market tightness over the employment cycle. In this section, we extend the results above to include Hagedorn and Manovskii's proposed measure of labor market tightness, to see whether the results we have reported are robust to the inclusion of this variable.

To implement Hagedorn and Manovskii's proposed correction, we use the NLSY's weekly arrays to classify each respondent's work history into employment cycles. An employment cycle begins when a person finds a job and exits involuntary unemployment. The employment cycle spans the full length of time employed, even if a worker switches employers, as well as *voluntary* spells of unemployment. The employment cycle ends through involuntary unemployment or voluntary unemployment that turns involuntary if the person cannot find a job within 2 months of voluntarily entering unemployment. The NLSY survey asks individuals why they left their last job, and we use this information to determine whether unemployment is voluntary or involuntary.[ai]

We then calculate the sum of labor market tightness for each job cycle for each individual and include the resulting variable in the individual wage regression (12) as an additional control.[aj,ak] Formally, let $\xi_t = \frac{v_t}{u_t}$ denote labor market tightness at date t. Then, for an individual i, currently in an employment spell that began at date $J(i)$, we calculate the sum of the individual's labor market tightness as $\omega_t^i = \sum_{s=t-J(i)}^{t} \xi_s$. We then reestimate (12) and include ω_t^i in the vector of controls X_t^i.

Finally, we modify the prediction equation by assuming that firms hire an individual with average characteristics (as before) and with a fixed average duration of an employment cycle in the NLSY, $\bar{J} = 3.24$ years. That is, we form the projections $\widehat{\ln w_{t,\tau}}$ by including the variable $\bar{x}_t = \sum_{s=t-\bar{J}}^{t} \xi_s$ in the estimated equation (13). Unlike the variable x_t^i, which varies across workers depending on when their employment spell began, the variable $\bar{x}_t$ exhibits no cross-sectional variation. However, since aggregate labor market tightness ξ_t changes over time, $\bar{x}_t$ has time-series variation which is included in the forecasts of $\widehat{\ln w_{t,\tau}}$.

[ai] A person leaves a job involuntarily if he or she is fired, laid off or if the plant closes. If the person voluntarily quits to look for a new job (etc.) and finds a new job within 2 months, the employment cycle is assumed to continue. If the person voluntarily leaves but it takes longer than 2 months to find a job, the employment cycle ends and the person falls off the job ladder.

[aj] To construct our measure of labor market tightness, we use the help wanted index calculated by Barnichon (2010).

[ak] Hagedorn and Manovskii actually use two separate controls. They control for cumulative labor market tightness both during a job spell (the variable q^{HM} in their 2013 paper) and also prior to starting a job if the worker either makes a job-to-job transition or starts from a period of voluntary unemployment (the variable q^{EH}). Because (12) includes an arbitrary set of fixed effects $\chi_{\tau,t}$ for the current job spell, the first adjustment (the q^{HM} variable) is already included in our baseline specification. Thus in our analysis we confine our attention to the second adjustment, which controls only for cumulative labor market tightness *prior* to the start of a job.

Table 4 Real wage cyclicality controlling for match quality: Unemployment rate

	AHE–BLS	AHE–NLSY			New hire	UCL
	(1)	Base (2)	Controls (3)	Controls, FEs (4)	(5)	(6)

Observations	34	25	25	25	25	27

Notes: OLS standard errors are in parentheses.

Tables 4 and 5 report results for the cyclicality of the various wage measures after we control for unobserved idiosyncratic match quality. Notice that the cyclicality estimates do decline somewhat, though the overall cyclicality of the wage series is only moderately changed. In particular, the high cyclicality of the new-hire wage and the user cost of labor remain. Similar results are found in response to monetary shocks. Repeating the steps above for the wage measures including the control for match quality gives impulse response functions that are close to the response functions we saw earlier. Fig. 4 compares the impulse response of the new-hire wage and the user cost of labor with and without the control for match quality. As shown in the figure, the impulse responses are almost indistinguishable.

6. COMPARING THE MODEL AND THE DATA

We now relate the empirical evidence we have presented regarding the cyclicality of real wages to the predictions of New Keynesian models of the class developed in Section 4. To build intuition, we begin by examining the models without either composition bias or infrequent renegotiation of wage remittances. This requires that we set the renegotiation rate s and the ratio of effective labor to total hours L/N both to 1.00, and the inverse

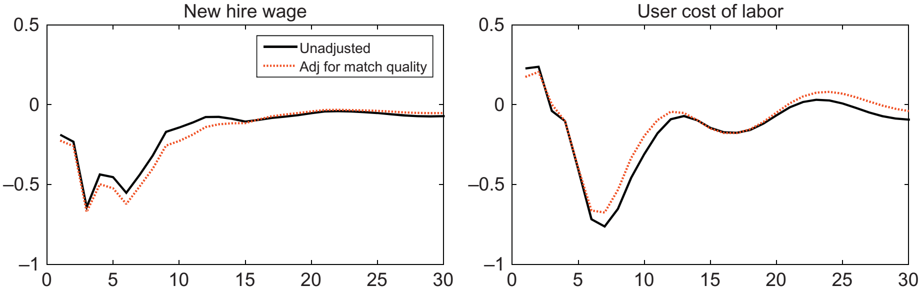

Fig. 4 Impulse responses controlling for match quality.

density of types $\varphi(1)^{-1} = 0$. Since s is the renegotiation rate of long-term wage contracts, $s = 1$ implies that remitted wages are changed in every period and thus move in lock step with changes in the (sticky) allocative wage. Since the remitted wage is equal to the allocative wage in this specification, there are no implicit wage contracts in the economy. The assumption of no composition bias implies that the marginal and average worker supplies the same number of efficiency units of labor per observed hour of work. We examine the responses of this baseline New Keynesian model to a monetary shock under the assumption of sticky prices only, sticky wages only, and both sticky prices and wages. The results will guide us regarding the features to add to the model in order to bring the model's predictions closer to the observed wage data.

We set the Calvo parameter for price adjustment to $\theta_p = 0.90$ (quarterly) implying that prices adjust on average once every 10 quarters, or once every two and a half years. We do the same for the initial sticky wage specification, so $\theta_w = 0.90$. While these calibrations are somewhat high relative to the micro data on the average frequency of price and wage changes, they are in line with many DSGE estimates and the implied model impulse response functions have enough persistence for their computed trajectories to be comparable with the empirical impulse responses. The DSGE model also features traditional mechanisms considered by business cycle analysts to better match the dynamic effects of monetary shocks on output. Specifically, the model features investment adjustment costs, habit persistence in consumption, variable capital utilization, price and wage indexation, and increasing returns to scale in production. The parameter values used are reported in Table 6, and are roughly in line with prevailing estimates in the literature.

Fig. 5 shows impulse responses of this baseline model to a 25 basis point shock to the central bank's policy rate (a shock to the Taylor rule). Since our main interest is in comparing the model responses of different wage measures to the corresponding empirical responses, we show the model and data responses of average hourly earnings (AHE), the new-hire wage (NHW) and the user cost of labor (UCL), as well as output. We reproduce the data responses that appeared in Fig. 3 together with responses from the baseline model with only price rigidity, only wage rigidity, and with both types of nominal inertia. We find that, as one might expect, following the increase in the interest rate,

Table 6 Parameters for New Keynesian DSGE model

Parameter	**Value**
Discount factor, annual (β)	0.97
Intertemporal elasticity of substitution (σ)	1.00
Frisch labor supply elasticity (η)	1.00
Depreciation rate, annual (δ)	0.10
Capital's share (α)	0.36
Type-specific labor elasticity (ψ)	21.00
Type-specific product elasticity (ε)	6.00
Average duration of prices, quarterly ($(1-\theta_p)^{-1}$)	10.00
Average duration of wages, quarterly ($(1-\theta_w)^{-1}$)	10.00
Inflation indexing	Yes
Marginal cost of capital utilization ($b''(1)/b'(1)$)	1.00
Investment adjustment cost (κ)	4.00
Habit weight (h)	0.65
Ratio of effective labor to total hours (LN)	2.00
Inverse density at unit productivity ($\varphi(1)^{-1}$)	2.00
Renegotiation rate, quarterly (s)	0.21

all three types of nominal rigidity cause output to decline. Output falls significantly more in the model with only sticky prices than in the model with just sticky wages; of course, it falls further in the model with both nominal fractions. Although the baseline models reproduce the hump-shaped output response observed in the data, the trough of output comes 2–3 quarters earlier in the models than in the data. That is, the models need additional persistence mechanisms or stronger persistence mechanisms to match the estimates.

One of the main findings in the empirical section is that different wage measures behave differently over the business cycle and in response to monetary shocks. In the baseline model, since there is just a single wage (or more precisely, since the average wage, the new-hire wage, and the allocative wage are all identical), the model is completely incapable of matching the differential patterns of wages in the data. We see that the impulse responses for the three concepts of the wage are identical in each model. As usual, the UCL in the model is the allocative wage, but with constant wage negotiation and no composition bias, AHE and the NHW are identical to the UCL. Thus, in this set of models there is a single unambiguous wage response to a monetary shock.

In the sticky-price model with flexible wages, the wage declines sharply (thus, it is "procyclical" in the sense that it moves in the same direction as output does following the monetary shock). The wage decline qualitatively matches the responses of the NHW and UCL, but does not match the fact that AHE responds much less. On the other hand, the model with sticky wages and flexible prices shows a mild *countercyclical* response of the wage to a monetary shock, for the same reasons that Keynes's (1936) model in the *General Theory* predicted high real wages in recessions. Finally, note that the model with equal

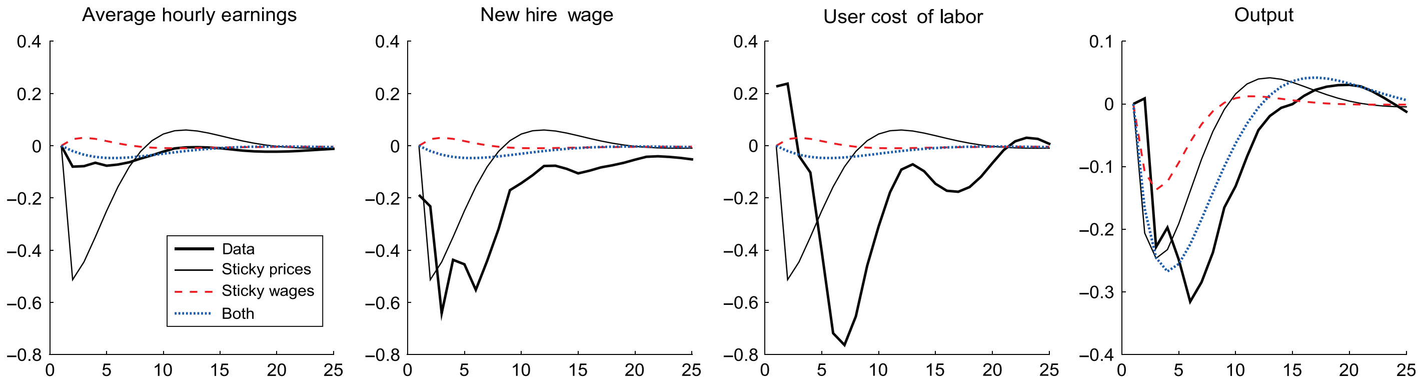

Fig. 5 Wage dynamics in baseline New Keynesian models. *Notes:* Each panel reports the estimated impulse responses (heavy line) and model impulse responses to a 25 basis point shock to the federal funds rate. The thin solid line displays the response of the baseline New Keynesian model with sticky prices but flexible wages. The dashed line displays the response of the model with sticky wages but flexible prices, and the dotted line displays the responses of the model with both sticky prices and sticky wages.

(and high) price and wage rigidity shows that the real wage is basically acyclical in the wake of a monetary policy shock. One might summarize the three models by saying that in the model with price rigidity firms are off their labor demand curves but workers are on their labor supply curves, so real wages are procyclical. The situation is reversed in the model with sticky wages, so real wages are countercyclical. (However, the assumption of variable capital utilization flattens the labor demand curve significantly, so the degree of countercyclicality is modest.) Finally, with both sticky wages and prices, both workers and firms are off their notional supply and demand curves in the labor market, and the real wage has no clear cyclical pattern. Note that the wage response in this variant of the model is qualitatively consistent with the empirical response of AHE. Hence, it is clear why modelers who interpret AHE as the allocative wage have been led towards models with both wage and price rigidity, as in CEE.

Starting from the baseline model above, we now consider the effects of implicit contracting and composition bias on model predictions for our three wage measures. In the following discussion, we consider models with sticky prices and flexible wages only. We do this both to conserve space and also because the sticky-wage models typically have simulated wage paths that are either sharply counterfactual (ie, there are sharp increases in wage payments following a negative monetary shock) or wage paths that are acyclical which, while matching the observed behavior of average hourly earnings, fail to match the responses of new-hire wages and the UCL.

We begin by examining the role of implicit contracting. Starting with the baseline model above, we consider the effects of gradually reducing the parameter s from its initial value of 1.00. When $s < 1$, the *remitted* wage is changed infrequently even though the allocative wage (the UCL) is fully flexible, since in this model we assume no wage rigidity. While the UCL is free to react to changing economic conditions, other measures of the wage—AHE and the NHW—change by substantially less than the UCL. The results are shown in Fig. 6. Note that the results for $s = 1$ reproduce the sticky-price impulse responses of the previous figure. As discussed in Section 3, Barattieri et al. (2014) find that $s = 0.21$ is the approximate frequency of changes in remitted wages observed in micro wage data. We include $s = 0.50$ as an intermediate case. Note that the three impulse responses are identical for the UCL—the allocative wage is unaffected by the value of s. However, $s < 0$ implies the existence of implicit contracts, which makes the three wage measures differ in their responses to monetary policy shocks. Particularly interesting is the result for the measured value of $s = 0.21$. For this value of s, the allocative wage falls sharply, the wage for new hires falls less, and average hourly earnings fall only slightly. The pattern of wage responses for the three wage measures relative to the output response bears a strong qualitative resemblance to the empirical impulse responses. This observation leads us to conclude tentatively that the evidence suggests that a model with sticky prices, flexible wages, and a significant role for implicit wage contracts has the best chance of matching the data.

Fig. 7 shows the impulse response function for the model with composition bias effects. Endogenous composition adjustment has two separate effects on the responses

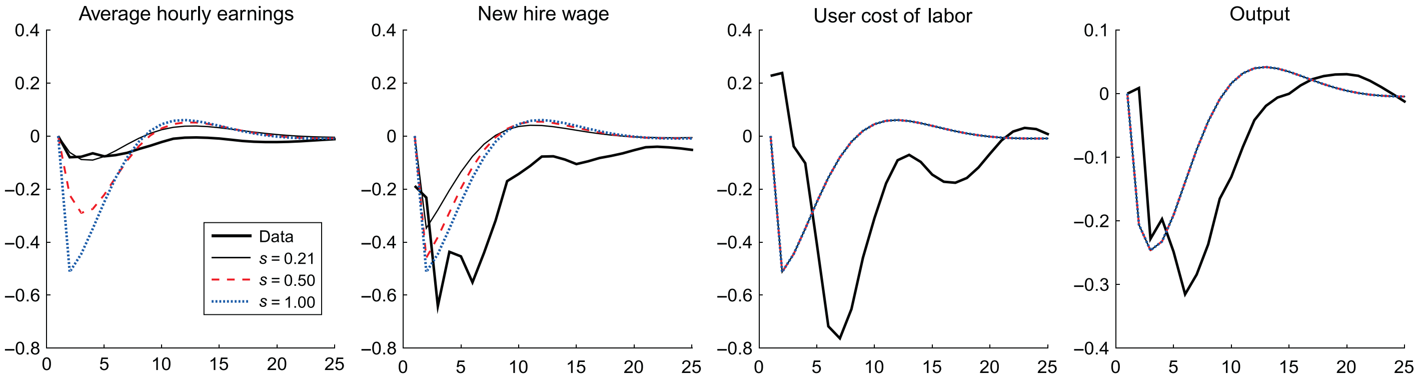

Fig. 6 Implicit contracts in sticky price models. *Notes:* Each panel reports the estimated impulse responses and model impulse responses to a 25 basis point shock to the federal funds rate. The different lines correspond to different parameter values. In all cases, prices are sticky but wages are flexible. The thin solid line displays the responses of the baseline model when remitted wages are reset with a quarterly probability (s) of 0.21 (roughly every 15 months). The dashed line displays results for the model with $s = 0.50$ and the dotted line displays results when $s = 1.00$ (continual adjustment of the remitted wage).

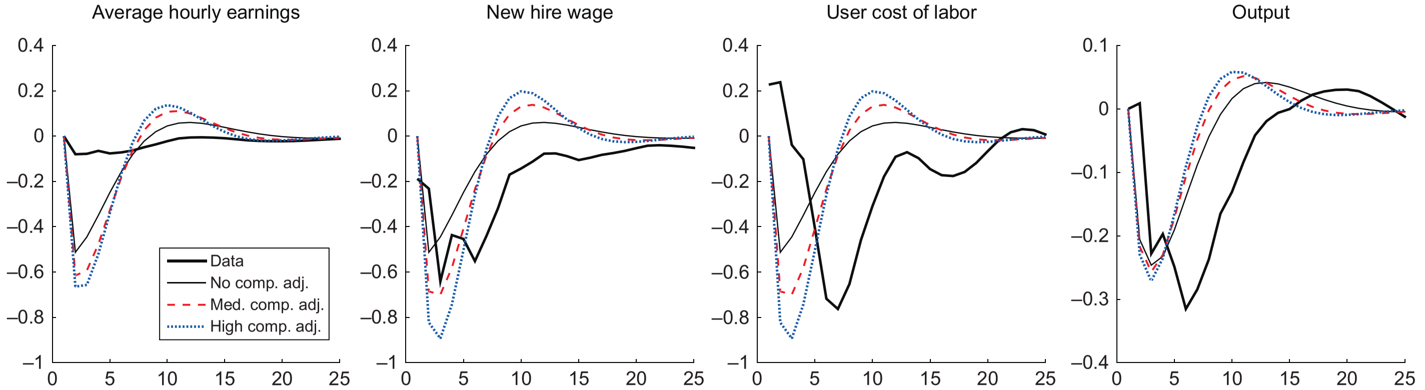

Fig. 7 Wage dynamics and composition bias in sticky price models. *Notes:* Each panel reports the estimated impulse responses and model impulse responses to a 25 basis point shock to the federal funds rate. The different lines correspond to different parameter values. In all cases, prices are sticky but wages are flexible. The thin solid line displays the responses of the model with no composition bias ($LN = 1.00$ and $\varphi^{-1}(1) = 0.0001$). The dashed line displays results for an intermediate level composition bias ($LN = 2.00$ and $\varphi^{-1}(1) = 2.00$). The dotted line displays results for high composition bias ($LN = 4.00$ and $\varphi^{-1}(1) = 4.00$).

of wages to monetary (and nonmonetary) shocks. First, by introducing a difference between the average labor compensation of employed workers and the labor compensation for the "marginal" workers, composition adjustments cause average hourly earnings to be less responsive than the user cost of labor which holds labor force composition fixed. The magnitude of this differential is given by the ratio $(LN-1)/LN$ in equation (10) where $LN \geq 1$ is the steady-state ratio of the effective labor supply to hours worked or equivalently, LN is the ratio of average labor compensation to wages paid to marginal workers. In a model without endogenous composition adjustment, this ratio is 1 and there are no effects of composition bias on measured wages. If $LN > 1$ then average wages move by less than the user cost.

The second effect of compositional changes is that the effective labor supply elasticity in such an environment is strictly less than the individual labor supply elasticities. The reason for this is that expanding employment means hiring workers who are increasingly less productive. The magnitude of this effect is governed by the inverse density of types at the productivity cutoff $\varphi(1)^{-1}$. In a typical model in which all workers are the same, $\varphi(1)=\infty$ (ie, there is a mass point at the common productivity 1) and thus $\varphi(1)^{-1}=0$. If the density of types at the cutoff is smooth, however, $\varphi(1)^{-1}$ is greater than 0 indicating that hiring more workers requires lowering the marginal productivity. If $\varphi(1)^{-1}$ is large then expanding the workforce requires tolerating much lower productivity workers and thus the effective labor supply elasticity is substantially lower.

We consider three different model specifications in Fig. 7. First we report the response for the standard model (the thin solid line) without composition bias. The dashed line reports the impulse responses for a model with an "intermediate" degree of composition bias. For this specification we consider a case with $LN=2.0$ (so the average worker is paid twice as much as the marginal worker) and $\varphi^{-1}(1)=2.00$. The dotted line reports the responses for a "high" degree of composition bias in which $LN=\varphi^{-1}(1)=4.00$. The figure displays both of the effects mentioned above. Notice in particular that the specifications with composition bias feature notably sharper reductions in wages. This is because, in the sticky-price environment, output, and thus labor, is effectively demand determined. Given demand, the firms simply hire or fire as many workers as necessary to increase or decrease production. Since the effective labor supply elasticity is reduced by the compositional adjustments, the wages must fall by more. Also, notice that the reduction in average hourly earnings is less than the decline in the user cost. This is a direct consequence of $LN > 1$: exactly the effect highlighted in Solon et al. (1994).

Fig. 8 considers the baseline model with both implicit wage smoothing contracts and a modest amount of composition bias. For this simulation, we set $s=0.21$ as suggested by Barattieri et al. (2014) and we adopt the intermediate composition bias specification, $LN=\varphi(1)^{-1}=2.0$.

As we did in Fig. 5, Fig. 8 shows the impulse responses under the assumption of pure sticky prices (solid line), pure sticky wages (dashed line) and a specification with both

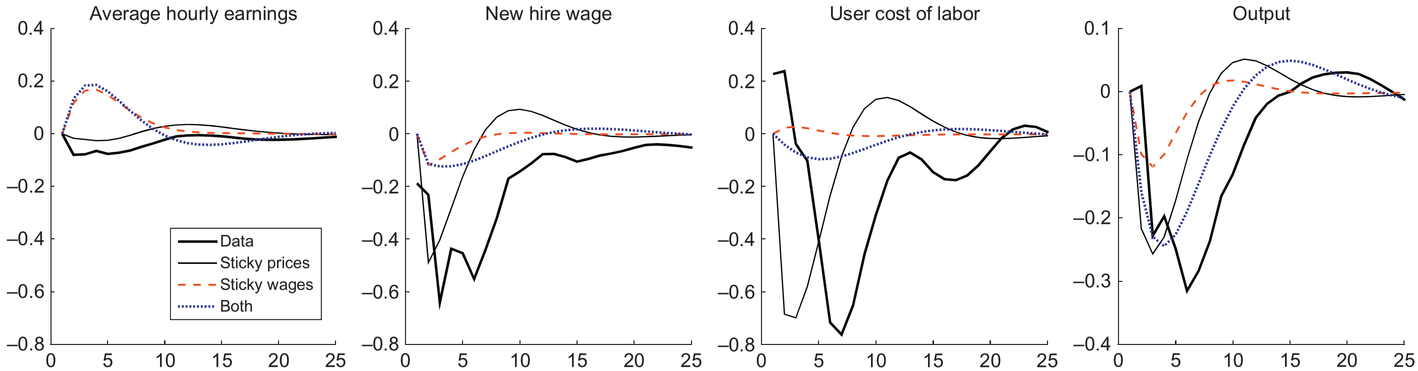

Fig. 8 Real wage dynamics in the modified model. *Notes:* Each panel reports the estimated impulse responses (heavy line) and model impulse responses to a 25 basis point shock to the federal funds rate. The parameter values for the model are set according to Table 6. We use $s = 0.21$ and the intermediate level of composition adjustment ($LN = 2.00$ and $\varphi^{-1}(1) = 2.00$). The thin solid line displays the response of a model with sticky prices but flexible wages. The dashed line displays the response of a model with sticky wages but flexible prices, and the dotted line displays the responses of a model with both sticky prices and sticky wages.

sticky prices and sticky wages (dotted line). Based on this simulation, the sticky price specification seems to outperform both of the other cases. In the sticky-wage case and the specification with both types of nominal rigidities, average hourly earnings rise noticeably following the monetary contraction, while the sticky price model is surprisingly close to the actual point estimates from the SVAR impulse response, which show a slight decline. While still not matching the shape of the dynamic responses to the new-hire wage or the user cost of labor, the model responses are quantitatively close. The model predicts a maximum decline in the new-hire wage of roughly 0.50% and a maximum decline in the user cost of labor of 0.70%. In comparison, the SVAR estimates a decline in the new-hire wage of roughly 0.70% and a decline in the user cost of almost 0.80%. The simulated responses for the other two model specifications display much smaller movements of either the new-hire wage or the user cost (in all cases, the peak declines are less than 0.10%).

The main problem with the impulse responses of the sticky-price model relative to the data is the lack of persistence of output following a monetary contraction. Output in the model attains its maximum response three quarters after the shock, as opposed to six quarters in the data. The new hire wage and the user cost of labor hit their troughs at the same time as output, meaning that they display a phase shift relative to the empirical impulse responses. Thus, we conjecture that a more persistent behavior of real variables after a monetary shock would bring the model and the data into closer alignment.

At the same time, it is easy to see why the model lacks persistence. Models such as CEE use sticky wages as an important persistence mechanism, but as Fig. 8 shows, allocative wage stickiness is inconsistent with the observed behavior of the UCL following a monetary contraction. Thus, our preferred model specification with sticky prices and flexible wages is missing one of the key propagation mechanisms featured in many standard medium-scale DSGE models in the literature. An important agenda for future research is to find new propagation mechanisms for sticky-price models to replace the assumption of sticky allocative wages, which seems to be fundamentally inconsistent with the data.

7. CONCLUSION

Recent empirical studies suggest that the cyclicality of real wages is greater than conventional wisdom would suggest. The literature emphasizes two reasons for this enhanced cyclicality. First, endogenous changes in the composition of the workforce mechanically causes average hourly wage payments to understate the change in wages relative to wage changes holding workforce composition fixed. Second, there are indications that the allocative wage—the wage that governs hours worked and that firms internalize when making production and pricing decisions—may not equal the contemporaneous remitted wage. In particular, firms and workers may well have an implicit understanding that the remitted wage will be a smoothed version of the expected allocative wage. By estimating the expected present value of wage payments, one can construct a "user cost of labor," which should measure the underlying allocative wage.

In this chapter, we have reproduced and extended the key empirical results in Kudlyak's (2014) work. Our empirical analysis confirms her calculations for the cyclicality of the allocative wage. In addition, the NLSY also allows us to decompose the cyclical response of wages by controlling separately for compositional changes and at the same time controlling for the wage smoothing effects of implicit contracts. The data suggest that while compositional changes contribute significantly to the dynamics of average hourly earnings, the effects of implicit contracts and wage smoothing are even greater.

Using the annual estimates of the user cost of labor and the new-hire wages from the NLSY as a starting point, we extend the estimated series to a quarterly series and include the extended data in a structural VAR for the purposes of studying the reactions of real wages to monetary shocks. The estimated structural VAR suggests that the user cost of labor and new-hire wages both decline sharply following a contractionary monetary shock. In contrast, average hourly earnings—the usual measure of the wage in macroeconomic research—barely respond to such shocks. Our model, if extended to allow for wage smoothing within long-term worker-firm associations, can match the fact that average hourly earnings and even the wage paid to new hires are significantly less cyclical than the allocative user cost of labor.

The differential reactions of these wage measures present two key challenges for prevailing New Keynesian models of the monetary transmission mechanism. First, in most New Keynesian models, there is no conceptual difference between the allocative wage, the remitted wage, and average hourly earnings. Thus, at a basic level, these models will not be able to match the empirical findings we study. Second, to the extent that New Keynesian models include a prominent role for sticky nominal wages, the models typically predict that either the allocative wage will counterfactually rise in the wake of an increase in the policy rate or that wages will not respond at all. Neither of these predictions would match our basic finding that allocative wages appear to fall sharply after a monetary tightening.

Analysis of a medium-scale DSGE model suggests that successful models will emphasize price rigidity rather than wage rigidity. In addition, to match the estimates in this chapter, such models will likely allow for a relatively smooth remitted wage which is not allocative. The wage data, therefore, favor the "old New Keynesian economics"—the early models of Rotemberg (1982), Ball and Romer (1989), and Kimball (1995), which all assumed competitive labor markets and flexible allocative wages—rather than the "new New Keynesian economics" with allocative prices and wages both sticky, as in Blanchard and Kiyotaki (1987), Erceg et al. (2000), Smets and Wouters (2007), and CEE.

We conclude by suggesting that research is needed on two fronts, one theoretical and one empirical. The theoretical challenge arising from these results is the need to explain the observed persistence of the real effects of monetary shocks without being able to rely on wage stickiness to temper the response of marginal cost to a monetary shock. Our estimates suggest that real marginal cost, properly computed, is strongly procyclical.[al] This conclusion, if correct, casts doubt on the main persistence mechanism of medium-scale New Keynesian models, such as CEE and Smets and Wouters (2007), which generally rely on assumptions that make marginal cost acyclical. Thus, the problem facing monetary economics can be restated as: Why do prices behave sluggishly, even though wages and hence marginal costs are strongly procyclical?

This question was the focus of a major research program several decades earlier. Relative to the research that took place in the 1980s, new observations on firm-level prices and quantities, and the desire to have persistence mechanisms that are consistent with both time-dependent and state-dependent pricing models, impose additional constraints on the proposed solutions.[am] To use the language of Ball and Romer (1990), the search for "real rigidities" in price setting must arrive at a satisfactory conclusion in order to make models of the monetary transmission mechanism consistent with recent observations of the data.

The empirical challenge is to extend the measurement of real wage cyclicality to other data sets and other countries. It would be particularly interesting to compare the results reported here with similar calculations for the major continental European economies, or for the Euro area as a whole. The labor market is one area where economists have argued that the differences between the United States and Europe are most pronounced. Galí (2016) follows in this tradition by incorporating "hysteresis" effects into a standard New Keynesian framework, arguing that this modification is necessary to match the greater persistence of the unemployment rate in Europe. Yet this change, where the unemployed exert little downward pressure on wages, makes real wages even less sensitive to the business cycle than they are in the standard New Keynesian models developed to explain US macro data. Do European micro data indicate that there is enormously more allocative wage rigidity in Europe than in the United States? Finding out whether the answer is yes or no is clearly of first-order importance for understanding cyclical fluctuations in these two major economies.

[al] This agrees with some, although not all, of the literature on the countercyclicality of the price markup, which is of course just the inverse of real marginal cost. See for example, Rotemberg and Woodford (1999) and Bils et al. (2014).

[am] See, for example, Klenow and Willis (2016), Dotsey and King (2005), and Nakamura and Steinsson (2010). Leahy (2011) and Nakamura and Steinsson (2013, section 12) provide insightful discussions based on Ball and Romer (1990).

ACKNOWLEDGMENTS

We thank Tyler Atkinson and, especially, Rich Ryan for outstanding research assistance. We thank the editors, John Taylor and Harald Uhlig. We thank our formal discussants, Eric Sims and Andreas Westermark, for their insights. We received many useful comments and suggestions from seminar participants at the University of Michigan, the Handbook of Macroeconomics conference at the Becker-Friedman Institute, University of Chicago, Boston College, and the conference on New Developments in the Macroeconomics of Labor Markets at CREI, Pompeu Fabra University.

Abstract

Interconnections between banking crises and fiscal crises have a long history. We document the long-run evolution from classic banking panics toward modern banking crises where financial guarantees are associated with crisis resolution. Recent crises feature a feedback loop between bank guarantees and bank holdings of local sovereign debt thereby linking financial to fiscal crises. Earlier examples

Handbook of Macroeconomics, Volume 2A
ISSN 1574-0048, http://dx.doi.org/10.1016/bs.hesmac.2016.04.001

include the crises in Chile (early 1980s), Japan (1990), Sweden and Finland (1991), and the Asian crisis (1997). We discuss the evolution in economic theorizing on crises since the 1950s, and then provide an overview of the long-run evolution of connections between different types of crises. Next we explore the empirics of financial crises. We discuss the methodological issue of crisis measurement encompassing the definition, dating, and incidence of financial crises. Leading datasets differ markedly in terms of their historical frequency of crises leading to *classification uncertainty*. There is a range of estimates of output losses from financial crises in the literature, and these are also dependent upon definitions. We find economically significant output losses from various types of crises using a consistent methodology across time and datasets. Predicting crises also remains a challenge. We survey the *Early Warnings Indicators* literature finding that a broad range of variables are potential predictors. Credit booms have been emphasized recently, but other factors still matter. Finally, we identify a new policy trilemma. Countries can have two of the following three choices: a large financial sector, fiscal bailouts devoted to financial crises, and discretionary fiscal policy aimed at raising demand during the recessions induced by financial crises.

1. INTRODUCTION

The recent financial crisis in the Eurozone involved both sovereign debt and the banking system. The circumstances of this crisis were unique as were the country experiences, but the combined incidence of fiscal and financial crises is actually not new. In fact, these connections have changed progressively over the long run. Recurrent and systemic financial crises emerged as a side effect of the modern process of financial development, globalization, and economic growth which got underway in the early 19th century. Over time, economic theory, economic data, and changes in the objectives of policy makers have shaped the reactions to crises and their subsequent contours. Interconnections between types of financial crises indeed have a long history.

From the mid-19th century, financial crises in the banking sector moved from being the responsibility of markets alone to receiving aid from central banks in a lender of last resort capacity. In the post-World War II period, especially since the 1970s, banking, currency, and debt crises became linked because governments became more willing to guarantee significant fractions of the liabilities of the banking system. The seminal paper by Diaz-Alejandro (1985) generated an enormous literature to explain the Latin American crises of the early 1980s. The Nordic crisis of 1991–92 and the Japanese Banking crisis of 1990 involved many of these elements. The Asian crisis of 1997–98 led to new theories which explained "triple crises" based on guarantees and foreign currency denominated debt. Finally, the recent Eurozone crisis has led to new work which emphasizes the feedback loop between bank guarantees and banks' holding of member states' sovereign debt which links financial to debt crises.

In this chapter, we examine the interconnections between financial and fiscal crises based on history, theory, and empirics. Section 2 presents a brief historical overview of financial crises. Banking crises can be traced back hundreds of years. Before the advent of deposit insurance and effective use of the lender of last resort, banking crises were banking panics. In the depression of the 1930s, governments instituted numerous interventions and guarantees effectively laying a strong precedent for subsequent fiscal resolutions. Since the breakdown of the Bretton Woods system in the 1970s and the advent of liberalized domestic and international financial markets, banking panics have increasingly evolved into fiscally resolved banking crises. Banking crises have often been global or regional events as countries have been linked together by fixed exchange rates, capital flows, and other sources of contagion. Debt crises—sovereign debt defaults—have also been around for centuries, associated with overborrowing and have been triggered by international and domestic shocks. Today they occur primarily in emerging countries, but again, several advanced countries in the Eurozone faced a tough test after 2008 (with a sovereign default in Greece). Currency crises—speculative attacks on pegged exchange rates—often accompanied banking crises and sometimes debt crises because of linkages between monetary policy and crisis resolution.

Section 3 surveys theoretical perspectives on financial crises. Banking crises traditionally were analyzed using three approaches: the monetarist approach, the financial fragility approach, and the business cycle approach. Modern perspectives build upon these earlier theories. The key approach is based on the Diamond and Dybvig (1983) notion of the inherent instability of banking because of a maturity mismatch. Also seminal are theories based on asymmetric information. In the recent decade, the financial frictions studied in partial equilibrium models have successfully been added to dynamic general equilibrium models. The pioneering modern work to explain why countries issue sovereign debt and try to avoid debt crises traces back to Eaton and Gersovitz (1981) who emphasize reputation. By contrast Bulow and Rogoff (1989a) focus on the deterrence effect of sanctions. Reinhart and Rogoff (2009) emphasize serial defaults, debt intolerance, and the distinction between domestic and foreign debt. New research in dynamic general equilibrium models also incorporates connections between the fiscal and financial side of the economy.

Section 4 provides empirical perspectives on financial crises. We discuss the methodological issue of crisis measurement which encompasses the definition, dating, and incidence of financial crises. Different approaches to definition and dating which are taken in the literature lead to very different patterns of recorded incidence and hence very different interpretations of the historical record. These classification problems must be acknowledged before any definitive general statements can be made. We also discuss the many and varied causes or determinants of financial crises, including bank credit-driven asset booms which have resonance for the recent crisis. A number of approaches have been taken to identify the key determinants of crises and to assess the predictive power of empirical models. This early warning indicators (EWIs) literature has made significant advances in the past two decades. However, our reading of the literature is that it remains very difficult to predict crises with a high level of accuracy both because of Goodhart's law as well as because of the complex economic ecosystem represented by the financial sector and the high dimensionality of the potential causes.[a] We then review measures of the output costs of financial crises and provide some measures of these losses using a comparable methodology across datasets. Again, different approaches in the literature and different classification systems lead to significantly different conclusions and hence different perspectives on the economic costs of crises.

Section 5 contains a preliminary examination of the empirical connection between financial and fiscal crises and identifies a potential new policy "trilemma." In the future, countries will be able to have two of the following three: a large financial sector, fiscal bailouts devoted to the inevitable crises that accompany leverage and financial deepening, and discretionary fiscal policy aimed at raising demand in the recessions occasioned by financial crises. This story is different from the older argument in the literature that fiscal policy is procyclical in less-developed countries. Moreover, as the recent crisis suggests, this trilemma may become more binding at higher initial levels of debt-to-GDP.

Section 6 concludes. Here we discuss the strengths and weaknesses of the literature and we consider some issues for further research.

2. HISTORICAL OVERVIEW

Financial crises can be traced back hundreds of years (Kindleberger, 1978). Historical narratives identify separate banking, currency, and debt crises and combinations of them (Bordo and Eichengreen, 1999; Bordo and Meissner, 2006; Reinhart and Rogoff, 2009). While financial crises cum fiscal crises are certainly not a new phenomenon, it would be incorrect to say that the recent global financial crisis and the subsequent Eurozone crisis were no different than all of those that have come before. The nature and origins of fiscal crises and their relationship to financial crises have in fact changed dramatically over the long run in important ways.

Banking crises before the advent of deposit insurance (and other components of the financial sector safety net) were banking panics—attempts by the public to convert their

[a] Goodhart's law proposed that "any observed statistical regularity will tend to collapse once pressure is placed upon it for control purposes." So for instance, if policy makers were to regulate financial variables previously associated with crises, previous relationships will break down, but crises will still occur. See Arnold et al. (2012) on macroprudential policy and financial stability.

deposits into currency en masse. Unless resolved by lender of last resort actions, banking panics could seriously impact the real economy by reducing the money supply (Friedman and Schwartz, 1963) and by reducing financial intermediation (Bernanke, 1983). Banking panics would propagate through asset markets as banks under threat dumped assets in fire sales. They could also propagate via interbank connections and other institutional arrangements to create a systemic collapse (Mitchener and Richardson, 2014).

Banking panics could also be caused by shocks leading to the failure of important financial firms outside the traditional banking sector like shadow banks (Rockoff, 2014). They could occur as a consequence of a bank credit-driven asset price boom–bust cycle. Schularick and Taylor (2012), Brunnermeir and Oehmke (2013) and many others recently have argued that systemic banking crises are very likely to follow bank credit-driven asset price booms.

Finally banking crises can also have an international dimension as for example during the Baring crisis of 1890–91, the global instability of 1907, the Credit Anstalt crisis of 1931, the Asian financial crisis of 1997–98, and the subprime mortgage crisis of 2007–09. Bordo and Landon-Lane (2012) identify five global financial crises (1890–91, 1914, 1929–30, 1980–81, and 2007–08) where the incidence of banking crises affected banks in multiple countries and in several continents in the same year. In all of these cases of "contagion," cross-border claims and faltering foreign banks or counterparties led to insolvency or liquidity problems at home. In addition, interest rate shocks emanating from leading financial centers (eg, by the Bank of England in 1890, the Federal Reserve in 1929 and in 1980–81) could contribute directly or indirectly to starting or exacerbating financial stress especially in emerging countries (Kaminsky and Vega-García, 2016).

The incidence of banking panics was high in many advanced countries in the 19th century before monetary authorities learned to act as lenders of last resort. In the United Kingdom, the last depositor-led banking panic was in 1866. In France it was in 1882, and in Germany it was in 1873. In the United States, it took until 1933 and the advent of deposit insurance before banking panics ceased (Schwartz, 1987).

With the advent of deposit insurance and other forms of government guarantees during the Great Depression, and progressively in some countries even earlier, the nature of banking crises changed from panics to crises which were increasingly resolved by a fiscal rescue.[b] This created a direct link between the banking system and the government's

[b] Banking crises which were resolved by a fiscal bailout were quite common in emerging countries before World War I (Grossman, 2010). Even some prominent advanced countries like France in 1889 and Britain in 1890 violated Bagehot's (1873) stricture for a central bank to lend only to illiquid and not insolvent institutions and arranged a government-led, fiscally backed lifeboat operation rescue (White, 2015). Bordo and Flandreau (2003) show that in emerging countries, the bailouts of the late 19th century on several occasions led to a big run up in the debt-to-GDP ratio and serious fiscal crises (eg, Portugal, Greece, and Russia). However, there were no cases in advanced countries where banking crises led to fiscal crises before the 1930s (Schularick, 2012).

balance sheet. Once this precedent was set, a costly bailout now had the potential to create significant fiscal imbalance and even lead to a default. Moreover, guarantees could lead to moral hazard (ie, protected banks would increase their balance sheets and take on more risk knowing that they would be bailed out).[c] This would in turn increase the cost of bailouts ex post and increase the strain on the government's finances. In turn, if the deficits were money financed with an expansion in the monetary base, this would increase the likelihood of inflation, currency crisis, or a sovereign default.

Before the 1930s, sovereign defaults had long been a fact of life reflecting the precarious nature of borrowing (often in foreign currencies) to finance wars, cover revenue gaps, or build infrastructure none of which had immediate growth or revenue payoffs leaving a maturity mismatch. Sudden stops of capital flows often led to sovereign defaults for this reason (Bordo, 2006; Bordo et al., 2010). Banking crises, even in the absence of guarantees, could lead to fiscal distress by reducing real income and government revenues.

A wave of sovereign defaults tied to international capital flows occurred in the 1820s in many Latin American Republics as overoptimistic investors from Europe lent these fledgling republics more than their weak public finances could handle. It took four decades before these countries paid into arrears and could access international capital markets again. In the next two centuries, Latin America had three more waves of default (Marichal, 1989).[d] Most countries, with the principal exception of a few advanced countries, had sovereign debt defaults in the 19th and 20th centuries (Reinhart and Rogoff, 2009). Many of them were serial defaulters (Reinhart et al., 2003).

Currency crises—a speculative attack on a pegged exchange rate reflecting an inconsistency between domestic fundamentals and the peg—also were a frequent occurrence for emerging countries throughout the 19th and 20th centuries (Bordo and Schwartz, 1999). Advanced countries generally avoided them under the pre-1914 gold standard, but they became a bigger problem for them in the interwar and during the Bretton Woods system (Bordo et al., 2001).

Currency crises often occurred simultaneously with banking crises, referred to as twin crises (Kaminsky and Reinhart, 1999). Causality between them was often two way. A banking crisis could lead to capital flight by foreign depositors as occurred in 1931 in Germany (Eichengreen, 1992). Per contra, a currency crisis could lead to insolvency for banks with extensive foreign currency denominated liabilities and domestic currency denominated assets as occurred in a number of emerging countries in both the pre-1914

[c] According to Akerlof and Romer (1993) and White (2000) in the case of the US Savings and Loan crisis of the 1980s, guarantees led directly to regulatory forbearance which engendered moral hazard leading to a crisis.

[d] Kaminsky and Vega Garcia (2016) show that most of these defaults followed systemic financial crises in the core countries of Europe.

and post-1973 eras of financial globalization (Bordo and Meissner, 2006; Reinhart and Rogoff, 2009).

Currency crises became linked to debt crises for emerging countries who had borrowed abroad in foreign currencies in the 1890s (Bordo and Flandreau, 2003). With the advent of government guarantees on top of foreign currency denominated debt, currency, banking, and debt crises became interlinked in the emerging market crises of the late 1990s and early 2000s.

Thus, the recent Eurozone crisis was the culmination of a long history of different types of crises and their growing interconnections which evolved along with the deep seated forces of financial globalization and a belief in the necessity for government to socialize the income losses of financial crises.

3. FINANCIAL AND FISCAL CRISES: A LONG-RUN REVIEW OF THEORETICAL DEVELOPMENTS

In this section, we survey the theoretical literature on financial and fiscal crises. We first survey traditional approaches. Most of the literature treats the two types of crises, along with currency crises separately. We then examine more recent approaches that often combine banking and fiscal crises along with currency crises.

3.1 Banking Crises

The traditional view of a banking crisis was a banking panic or a liquidity crisis. It involved a scramble by the public for means of payment. Two frequent scenarios in which it occurred were: contagious banking panics when the public fearful that banks will not be able to convert their deposits into currency attempts en masse to do so; the second is a stock market crash that leads to fears that loans will become unavailable at any price. Without intervention by the monetary authorities or lender of last resort—through open market operations or liberal discount window lending—the real economy will be impacted by a decline in the money supply, by impairment of the payment system, and by the interruption of bank lending.

In the post-World War II period, with the widespread adoption of deposit insurance (both explicit and implicit), and with a generalized understanding of the role of the lender of last resort, old fashioned banking panics have become rare events. Instead, banking crises largely involve the insolvency of significant parts of the banking system. They have occurred when asset prices have plunged, whether prices of equities, real estate or commodities; when the exchange value of a national currency experiences substantial depreciation; when a large financial firm or nonfinancial firm faces bankruptcy; or a sovereign debtor defaults. Unlike banking panics which are brief episodes resolved by the central bank, a banking crisis is a prolonged disturbance that is resolved by means other than the lender of last resort, although at some stage it may supply liquidity through the discount window or open market operations.

Three traditional approaches to conceptualizing banking crises are: the *monetarist approach*, the *financial fragility approach*, and the *business cycles approach*. The contemporary literature based on rational expectations and game theory follows from these.

3.1.1 The Monetarist Approach

The monetarist approach of Friedman and Schwartz (1963) identifies financial crises with banking panics that either produce or aggravate the effects of monetary contractions. In a *Monetary History of the United States 1867–1960*, Friedman and Schwartz devote considerable attention to the role of banking panics in producing monetary instability in the United States. For Friedman and Schwartz, banking panics are important because of their effects on the money supply, and hence on economic activity.

According to them, banking panics occur because the public loses confidence in the ability of banks to convert deposits into currency. A loss of confidence is typically associated with the failure of some important financial institution (as happened in 1873, 1893, and 1907). Attempts by the public in a fractional reserve banking system to increase currency as a fraction of its money holdings, if not offset, can only be met by a multiple contraction of deposits. A banking panic, in turn, if not short-circuited by the monetary authorities, will lead to massive bank failures of otherwise sound banks.[e] They are forced into insolvency by a fall in the value of their assets in a vain attempt to satisfy a mass scramble for liquidity. Banking panics, such as occurred in 1930–33, have deleterious effects on economic activity primarily by reducing the money stock through a decline in both the deposit–currency and deposit–reserve ratios.

An extensive literature in economic history has been devoted to reexamining the banking panics of the 1930s. The debate swirled over the issue of whether the banking crises were really liquidity panics driven by "a contagion of fear" or whether they reflected bank insolvency as an endogenous response to the recession. Temin (1976) and most recently Calomiris and Mason (2003) provided evidence that cast doubt on the Friedman and Schwartz liquidity panic story. Richardson (2007) and Bordo and Landon-Lane (2010) provide evidence in its favor.

3.1.2 The Financial Fragility Approach

A tradition going back to the 19th century regards financial crises as an essential part of the upper turning point of the business cycle and as a necessary consequence of the "excesses" of the previous boom. Its 20th century proponents, Minsky (1977) and Kaufman (1986), basically extend the views Irving Fisher expressed in *Booms and Depressions* (Fisher, 1932) and in the "Debt deflation theory of Great Depressions" (Fisher, 1933).

[e] Carlson et al. (2011) and Richardson and Troost (2009) provide historical evidence on these issues.

According to Fisher, the business cycle is explained by two key factors: overindebtedness and deflation. Some exogenous event (displacement) provides new, profitable opportunities for investment in key sectors of the economy which increases output and prices initiating the upswing in the cycle. Rising prices, by raising profits, encourages more investment and also speculation for capital gain. The whole process is debt financed, primarily by bank loans, which in turn, by increasing deposits and the money supply, raise the price level. An overall sense of optimism raises velocity, fueling the expansion further. Moreover, the rising price level, by reducing the real value of outstanding debt encourages further borrowing. The process continues until a general and precarious state of "over-indebtedness" is reached. It exists when individuals, firms, and banks have insufficient cash flow to service their liabilities perhaps due to a shock to demand or supply. In such a situation, a crisis can be triggered by errors in judgment by debtors or creditors. Debtors, unable to pay debts when due or to refinance their positions, may be required to liquidate their assets.

Distress selling, if engaged in by a sufficiently large segment of the market, produces a decline in the price level because, as loans are extinguished and not renewed, bank deposits decline. Falling prices reduce net worth and profits, leading to bankruptcy. Both factors contribute to a decline in output and employment. In addition, while nominal interest rates fall with deflation, real rates increase, worsening the situation. The process continues until either widespread bankruptcy has eliminated the overindebtedness or at any stage reflationary monetary policy is adopted. However, once recovery begins, the whole process will repeat itself.

This approach has been revived since the financial crisis of 2007–09. Indeed some commentators have described the failure of Lehman Brothers in September 2007 as a "Minsky moment" (Brunnermeir and Oehmke, 2013).[f] It is also consistent with the credit boom approach of the BIS (Borio, 2012) and the long-run comparative empirical work on credit and asset price booms by Schularick and Taylor (2012) and Jordà et al. (2011).

3.1.3 The Business Cycle Approach

This approach views banking panics as more likely during a recession because the returns on bank assets are likely to fall as borrowers become less like likely to repay their loans (Mitchell, 1941). Depositors anticipating an increase in nonperforming loans will try to protect their wealth by withdrawing their deposits precipitating a bank run (Allen and Gale, 2007). Gorton (1988) following this approach finds that depositors anticipating a decline in income, and in an attempt to smooth their consumption, remove their funds from banks before the business cycle peak.

[f] See Wray (2015).

3.2 Recent Approaches to Banking Crises

3.2.1 Diamond and Dybvig: The Inherent Instability of Banking

In a seminal article, Diamond and Dybvig (1983) argue that banks transform illiquid claims by offering liabilities with a different smoother pattern of returns over time. Banks provide efficient risk sharing/insurance which the private market cannot provide. However, banks are vulnerable to runs because of the illiquidity of their assets. Thus there is a maturity mismatch. One equilibrium in this setup is a run which can be triggered, even on a sound bank, by a random event (a sunspot) because rational depositors, not wishing to be last in line, will rush to convert deposits into currency. Only the presence of deposit insurance or a lender of last resort can prevent banking instability.

An explosion of articles in the past two decades builds upon the Diamond and Dybvig model. A number of articles were critical of the sequential servicing constraint in the original Diamond and Dybvig model—that depositors had to wait their turn at the bank to access their cash. It was argued that as in the pre-1914 National Banking era, banks could suspend convertibility (Jacklin, 1987). On the other hand, Wallace (1988) justified the sequential constraint endogenously in his model. Other papers that rationalized the Diamond Dybvig (DD) sequential service constraint were Diamond and Rajan (2001) and Calomiris and Kahn (1991). Another issue was that of multiple equilibria leading to an inability to make strong predictions. In an influential article on currency crises, Morris and Shin (1998) used the global games approach to reach a unique equilibrium as a function of fundamentals without using a sunspot equilibrium as a coordinating device as in DD. Banking crises were analyzed in a similar way by Rochet and Vives (2004) and Goldstein and Pauzner (2005).

Subsequent literature extended the basic DD framework to encompass financial markets and the banking system (Allen and Gale, 1998, 2004); to include bubbles and crises (Allen and Gale, 2000); to include money and monetary policy in the basic DD type model (Diamond and Rajan, 2001, 2005, 2011, 2012); to include interbank markets (Bhattacharya and Gale, 1987). The DD model also is embedded in several articles justifying lender of last resort intervention to provide liquidity in a financial crisis (Holmström and Tirole, 1998; Gorton and Huang, 2004; Rochet and Vives, 2004).

3.2.2 Information Asymmetry

The explanation of banking panics that the asymmetric information approach offers is that depositors cannot costlessly value individual bank assets, and hence they have difficulty in monitoring the performance of banks (Jacklin and Bhattacharya, 1988; Chari and Jagannathan, 1989). On this view, a panic is a form of monitoring. Faced with new information, which raises the perceived riskiness of bank assets, depositors force out both sound and unsound banks by a system-wide panic.

3.3 Fiscal Crises

The canonical fiscal crisis is a debt crisis. It is a situation where a sovereign debtor is unable to service the interest and or principle as scheduled. A debt crisis arises when the fiscal authorities are unable to raise sufficient tax revenue in the present and the future to service and amortize the debt.

A debt crisis can then become a financial crisis when it impinges on the banking system and a currency crisis when it threatens the reserves of the central banks as was the case in the Asian crisis of the 1990s. Banking crises can feed into debt crises when the fiscal authorities bailout insolvent banks which then increases sovereign debt to a point where it becomes unsustainable. Debt crises can also spill into banking crises when banks hold significant amounts of sovereign debt whether by choice or because of government attempts to force banks to hold significant levels of government debt.

Later we survey the literature on sovereign debt crises and their linkages to financial (banking) crises.

3.3.1 Sovereign Debt Crises: Theory

Two seminal articles have driven much of the modern literature on sovereign debt crises.[g] Eaton and Gersovitz (1981) explained the existence of sovereign debt markets and the incentive of sovereign borrowers to repay their debt by access to credit markets. Debtors worried that a default could ruin their reputation and cutoff future access to the foreign capital needed to finance economic development and to smooth consumption over time. Bulow and Rogoff (1989a,b) argued that other methods of self-insurance can substitute for foreign borrowing and that the main reasons countries avoid default is because of the threat of sanctions. In the 19th century, the British (and other European lenders) would send in the gunboats or use other means to seize the defaulting country's customs revenues or other assets. Today, trade sanctions, withholding of trade credit and other legal interference could matter. Another early development was the analysis of excusable default. Grossman and van Huyck (1988) argue that countries that defaulted because of a large shock to their economy not of their own making were treated better by the credit markets than countries which defaulted because of bad economic policy decisions.

The subsequent literature was doubtful of sanctions in the post-World War II era (Cole and Kehoe, 1995; Eaton, 1996; Kletzer and Wright, 2000) although there is considerable historical evidence for this (Mitchener and Wiedenmeir, 2010) for the pre-World War I era. Emphasis was placed by some on the collateral damage to the economy from default (Cole and Kehoe, 1998).[h] Bulow and Rogoff (2015) defend the sanctions approach as a way to understanding recent events in Greece and Argentina.

[g] See Panizza et al. (2009) for a recent survey.

[h] Two recent models of sovereign defaults which occur following adverse shocks to the economy are Aguiar and Gopinath (2006) and Arellano (2008).

An additional development was the focus on serial default. Reinhart et al. (2003) showed that a number of defaulting emerging countries had a long historical record of debt default. This pattern of persistence extended to a number of European countries (eg, Spain and France) which had an earlier history of serial defaulting. Moreover, they found that countries which were serial defaulters also had *debt intolerance* (ie, that they would tend to default at significantly lower debt-to-GDP ratios than advanced countries). For example, Argentina defaulted in 2002 at a debt-to-GDP ratio of 35% whereas Japan today has a debt-to-GDP ratio well above 200% and it is not even close to defaulting.

Reinhart and Rogoff (2009) make an important distinction between domestic debt and foreign debt. They argue that domestic debt default by inflation, financial repression, redenomination, abrogation of gold clauses, etc., can have consequences as serious as external default. In addition, they argue that defaulting on high domestic debt may be a strong rationale for the use of the inflation tax in many countries.

3.4 Fiscal Crises and Financial Crises

After the breakdown of the Bretton Woods system and the liberalization of global financial markets, as well as domestic financial systems across the world, the stage was set for waves of systemic financial and fiscal crises. A key integrating element between financial and fiscal crises was the widespread use of guarantees by the government of the liabilities of the banking system.[i] The seminal article which lays out clearly the dynamics of fiscal–financial crises interaction was by Diaz-Alejandro (1985).[j] He describes the unfolding disaster that occurred in Chile from 1977 to 1982 after it liberalized its domestic financial system and opened up its capital account. Chile, like the other Latin American countries, had extensive controls over the domestic financial system as well as capital controls since the 1930s.

The Pinochet regime, under the influence of the "Chicago boys"—students of Al Harberger—liberalized every aspect of the economy. They reduced tariffs, eliminated controls over the domestic financial system, and removed capital controls. They also in 1977 reduced barriers to entry into banking, explicitly did not introduce deposit insurance, and forswore a bailout of the banking system in the event of trouble. They also pegged the Chilean peso to the US dollar.

The new liberalized regime encouraged massive capital inflows which led to increases in bank credit and fueled an asset price boom. A major bank failure in 1977 led to a bailout for fear of contagion. Afterwards, the government again forswore against future bailouts. The bailout which soon followed encouraged moral hazard and the credit boom

[i] See Schularick (2012) and Alessandri and Haldane (2009).

[j] See Reinhart (2015).

continued. In early 1982, more banks failed and their liabilities were guaranteed. This meant that the government had taken on a new contingent liability which in turn led to a growing fiscal deficit. The central bank financed the deficit with the inflation tax. This led to inflation and set the stage for a speculative attack on its reserves. A major banking and currency crisis ensued in the summer of 1982 leading Chile to abandon its peg and nationalize its banking system. It was followed by a debt crisis in 1983.[k]

McKinnon and Pill (1986) model the effects of liberalization and reform on a previously financially repressed emerging country. In their model, like in Diaz-Alejandro (1985), there is a large unsustainable lending boom financed by foreign capital, intermediated by the banks. The banks believe that their foreign loans are guaranteed by the government. This overborrowing phenomenon leads to rising domestic credit, an increase in money growth, inflation, and an asset price boom. A foreign shock leads to a collapse in the boom, a banking crisis, a currency crisis, and a reversal of the reforms.

3.4.1 The Japanese and Nordic Banking Crises 1990–92

The background to the Japanese banking crisis in 1890 was a boom–bust cycle, which began in the mid-1980s with a run up of real estate prices fueled by an increase in bank lending and loose monetary policy. The Bank of Japan began following a looser monetary policy in the aftermath of the Plaza Accord of 1985 which led to an appreciated yen and a weaker dollar (Funabashi, 1988). The resulting property price boom in turn led to a stock market boom as the increased value of property owned by the firms raised expected future profits and hence stock prices (Iwaisako and Ito, 1995). Both rising land prices and stock prices in turn increased firms' collateral encouraging further bank loans adding more fuel for the boom. The bust may have been triggered by the Bank of Japan's pursuit of a tight monetary policy in 1989 to stem the asset price boom.

The subsequent asset price collapse in the next 5 years led to a collapse in bank lending with a decline in the collateral backing corporate loans. The collapse in asset prices further impinged on the banking system's capital making many banks insolvent.[l] Lender of last resort policy prevented a classic banking panic, but regulatory forbearance propped up insolvent (zombie) banks. The bailout costs of the bank rescue and the slow economic growth that ensued swelled the already high Japanese debt-to-GDP ratio since then, but Japan has never defaulted on its debt. A fiscal crisis was avoided because Japanese sovereign debt is denominated in yen and is mainly domestically owned.

The Nordic financial crisis of 1991–92 involved a banking crisis, a currency crisis, and a large fiscal bailout. In the case of Norway, quantitative restrictions on bank lending were lifted in 1984. This led to a bank credit financed real estate boom and a serious

[k] Velasco (1987) provided a model of this experience.

[l] Many aspects of the Japanese experience resonate with the financial accelerator approach of Bernanke et al. (1999).

banking crisis (Steigum, 2009). The Swedish financial crisis of 1992 involved both the banking sector and the exchange rate. Liberalization of the financial sector and the capital account in the 1980s after decades of financial repression led to a bank credit fueled asset price boom (stocks and real estate). The deflationary shock of the ERM crisis triggered an asset price bust and a collapse of the banking sector as well as a massive currency crisis and devaluation. A fiscal bailout led to a run up of the debt-to-GDP ratio but not sufficient to trigger a fiscal crisis (Jonung et al., 2009).

A similar severe crisis occurred in Finland at the same time with the collapse of the Soviet Union a key real fundamental (Honkapohja, 2009). The loan losses in all three countries were considered large (Norway 6% of GDP; Sweden 7% of GDP; Finland 7% of GDP) but the fiscal resolutions in all three cases did not threaten a fiscal crisis (Drees and Pazarbasioglu, 1994). Thus the Nordic crisis may be the forerunner of the guarantee-induced fiscal crisis/financial crisis nexus earlier identified for emerging countries.

3.4.2 The Asian Crisis

The Asian crisis of 1997–98 involved banking, currency, and debt crises and these crises were all connected by government guarantees and an ostensibly new factor "original sin" or foreign currency liabilities.[m] A key mechanism by which foreign borrowing led to banking crises was that the Asian tigers (Thailand, Indonesia, Malaysia, and Korea) borrowed abroad extensively in foreign currency. They did this because they had not yet financially developed enough to issue debt in their own currencies as could the advanced countries. Borrowing abroad (eg, in dollars), gave access to foreign capital at low international interest rates. The risk associated with original sin is that if the country has a currency crisis and ends up devaluing its currency then it will have to generate greater tax revenues in domestic currency and export earnings to service its foreign debt. This in turn would depress the real economy and increase the likelihood of a sovereign default. The likelihood that exports could rise sufficiently depended on strong global demand and high elasticities. Moreover, the banking systems in these countries funded their loans with foreign securities (often short term) and after the devaluation, their balance sheets would become impaired increasing the likelihood of insolvency and a banking crisis.

The Asian crisis led to the creation of "third-generation" speculative attack models. They were an extension of both first- and second-generation speculative attack models. The first-generation model of currency crises (Krugman, 1979) posited that a speculative attack would inevitably occur when domestic fiscal and monetary fundamentals were inconsistent with adherence to a pegged exchange rate. The second-generation models (Obstfeld, 1995) posited that speculative attacks would occur when agents, who

[m] See Eichengreen and Hausmann (2005).

understood the weights that the government placed on the stability of the domestic economy and adhering to a peg, anticipated that the government would prefer domestic stability in the event of a crisis. Speculators would thereby sell the currency short and generate a crisis.

Several authors extended the first- and second-generation models to incorporate special features of the Asian crisis including moral hazard (guarantees), short-term borrowing in foreign currencies, and currency depreciation. Krugman (1998) argued that the currency and financial crises in Asia reflected the role of moral hazard as the progenitor of financial instability which in turn was a key cause of currency crises. According to his story, financial institutions in these countries engaged in risky lending on the assumption that they would be bailed out while at the same time they financed themselves with offshore loans at close to international interest rates. The capital inflow and domestic bank lending fueled an asset market boom which in turn encouraged the banks to lend more. This process encouraged a domestic investment and consumption boom and a growing current account deficit. When external factors revealed the exchange rate to be overvalued, a classic speculative attack led to devaluation. The devaluation in turn sparked a financial crisis as the banks' short term, foreign currency denominated loans mushroomed, making them both illiquid and insolvent. Bailouts of the financial system and especially of their dollar obligations in turn precipitated further speculative attacks and exhausted the monetary authorities' international reserves.

Dooley (2000) viewed the liabilities of the monetary authorities backing the financial safety net as an alternative claimant on emerging countries' international reserves. Market agents understood this and staged a speculative attack at the moment that net liabilities exceeded international reserves.

Krugman (1999) focused on the balance sheets of firms which borrowed abroad in foreign currencies. A speculative attack would occur when the market anticipates that a depreciating currency will lead to insolvency and contracting economic activity hence pulling out funds and precipitating the adverse chain of events.

Burnside et al. (2004) also emphasize the key role of government guarantees in explaining the Asian crisis. In their model, banks borrow in foreign currencies unhedged because their foreign debt is guaranteed by the government. But when a devaluation occurs, following an external shock, the banks default on their foreign debt and declare bankruptcy, but the government does not have the resources to pay for a bailout. This leads to both a banking crisis and a currency crisis when the central bank uses seigniorage to fund the fiscal deficit.

Corsetti et al. (1999) also model the Asian crisis. In their model, the government guarantees the banks' foreign currency loans which are used to finance domestic investment. This leads to a capital inflow boom, a current account deficit, and an investment boom. Private sector borrowers believe that they and the banks will be bailed out. When a shock occurs, this leads to both a banking crisis and a possible debt crisis as the contingent liabilities that the government has to cover increase the fiscal deficit.[n] Thus the Asian crisis had many elements of the Diaz-Alejandro story with guarantees that induced fiscal deficits and which were financed largely by money issue rather than increased sovereign borrowing.

3.4.3 The Eurozone Crisis

The Eurozone crisis of 2010–14 was a sequel to the global financial crisis of 2007–09 involving strong connections between banking and fiscal crises. Reinhart and Rogoff (2009, 2011) suggest that the link between banking and fiscal crises has strong historical roots. They show that banking crises often precede debt crises and that for a large panel of advanced and emerging countries in the 20th century that the debt-to-GDP ratio rises by 86% in the 3 years following a banking crisis setting the stage for a downgrading of credit and a possible default. Schularick (2012) notes that this has mainly occurred in the post-World War II period.

The Eurozone crisis seems to fit the prediction that fiscal and financial crises have a strong connection. In the aftermath of the subprime mortgage crisis, several European countries that had been connected to the US crisis or which had bank credit-driven house price booms, engaged in expensive bond financed bank bailouts. These bailouts and economic collapse increased the fiscal deficit leading to debt surges. The bailouts across Europe followed in some respects the example of Ireland which in September 2008 guaranteed its entire financial system. To fight the recession that accompanied the crisis, they also engaged in expansionary automatic fiscal policy which also increased the deficits.

Reinhart and Rogoff (2009) argue that the decline in tax revenues produced by the fall in output plus the expansionary government expenditures explained more of the run up in deficits and debt than the bailouts themselves. Laeven and Valencia (2012) provide a crude measure that separates out the rise in debt due to bailouts and resolution activity and a remaining portion due to discretionary and automatic fiscal expansion. In their sample, the median rise in the debt-to-GDP ratio after a crisis is 12 (percentage points) with the majority (6.8) attributable to fiscal rescue packages. For advanced economies, the figures are 21.4 and 3.8, and in emerging economies they are 9 and 10. Significant heterogeneity across countries is evident. Inference should recognize this fact and the historical record should be assessed in light of these data.

Against this background of weakening fiscal positions across the Eurozone, the announcement in 2009 that the Greek government had falsified its fiscal books set the stage for the Eurozone debt crisis which first involved the threat of a Greek default

[n] Other papers that model the Asian crisis and place emphasis on government guarantees include: Arellano and Kocherlakota (2014), Burnside et al. (2001), Burnside (2004), and Schneider and Tornell (2004).

and then contagion to other members via their banks which had significant holdings of Greek and other peripheral countries' sovereign debt.

The threatened sovereign default by Greece fed into a banking crisis because banks in Greece and the other financially integrated Eurozone countries held large amounts of Greek and other peripheral Eurozone sovereign debt. In the case of Ireland, a blanket guarantee of the Irish financial sector by the Irish government followed the collapse of a property price boom. This collapse made the Irish banks insolvent, and led to a fiscal crisis because markets expected that the Irish government would not be able to service the large run up in its debt that followed. An 85 billion euro international rescue by the IMF, the EU, and others followed in 2010. Later, some private sector actors were bailed-in.

In Spain, where another housing boom turned to bust, the crisis also led to fiscal problems. Spain introduced several costly bailout packages with enhanced guarantees, and took on a European bailout package. Throughout, international pressure—both political and market based—was harsh leading to higher risk premia. From 2010, Spain adopted a series of "austerity" plans coincident with these bailouts. In addition, Spanish banks increased demand for Spanish sovereign debt in order to take advantage of liquidity funding from the European Central Bank threatening an outcome whereby fiscal problems could be transmitted to the banks. Bond spreads in Portugal and Italy spiked after 2010, but countries such as France and Belgium also faced significant bond market pressure. European countries displayed vulnerabilities in the run up to the crisis, but the collapse of confidence in international bond markets for many European countries reflected the constraints of nations in a monetary union with no strong fiscal union, a weak/nonexistent banking union and (at least initially) hesitant monetary policy from the ECB.

The recent crisis presents several fine examples of the interconnection between fiscal and banking crises and new theoretical models and empirical evidence have been supportive of these links. Bolton and Jeanne (2011) model the interconnection between sovereign risk and the banking system in a currency union where the banks in each country diversify their portfolios by holding the sovereign debt of other member states. Holding government bonds serves as safe collateral which allows them to increase their leverage. The default by one member spreads to the others via the weakening of bank portfolios.[o]

Gennaioli et al. (2014) also model the interconnection between sovereign default and the banking system. As in Bolton and Jeanne, banks hold sovereign debt as collateral which allows them to increase their lending. A debt crisis leads to a credit crunch and a decline in real income. The authors demonstrate that the costs of a fiscal shock are higher for more financially developed countries.[p]

[o] Battistini et al. (2014) observe that in the Eurozone banks increase their holdings of domestic debt even when yields (and risk) rise and when systemic risk rises. Various policy implications for monetary unions like the EMU are discussed.

[p] Also see Uhlig (2013).

Acharya et al. (2014) model a two-way interconnection between fiscal crises and banking crises. Bank bailouts lead to an increase in sovereign risks because of the increase in fiscal deficits and debt ratios. This in turn weakens the banking system which holds sovereign debt as collateral.

They use the Irish bailout of 2008 as their example. Their model predicts that the spreads between bank CDSs and sovereign CDSs should rise during the banking crisis. Then after the bailout, bank CDSs should decline and sovereign CDSs should rise. This reflects the transfer of risk from the banks to the government. Empirical evidence for the advanced countries in the Eurozone backs this up. After the subprime crisis began in 2007, bank CDSs rise dramatically with no change in sovereign CDSs. Then after the Lehman collapse and the Irish guarantee at the end of September 2008, sovereign CDSs rise and bank CDSs decline.

Mody and Sandri (2012) examine the behavior of sovereign risk spreads of the Eurozone countries before and after the crisis of 2007–09. They show that after the creation of the Euro in 1999 sovereign spreads converged across the Eurozone. Then after the Bear Stearns bailout in March 2008 spreads increased in countries which had vulnerable financial sectors likely to be bailed out. After the Lehman failure in September 2008, spreads increased dramatically in countries that had higher debt ratios. Then, after the failure of Anglo Irish bank in January 2009, spreads increased across the Eurozone reflecting the increased vulnerability of the financial systems of all the member countries.

Martin and Philippon (2015) compare the behavior of member states of the Eurozone to that of the states in the United States during the Great Recession. The key difference between the Eurozone and the United States was the absence of a well-functioning fiscal union in the former (Bordo et al., 2013). What their analysis shows is that the United States and European cross-sectional experience in household debt and employment were quite similar in the period 2007–10. However, after 2010 there was a marked difference between the two currency areas. The peripheral Eurozone countries experienced a sudden stop in capital flows reflected in a spike in borrowing costs (spreads) and a drop in employment and growth. By contrast, the pattern of these variables across US states did not diverge. Past fiscal policy in the Eurozone countries, because of its effect on accumulated debt, impacted their economies both through the perceived risks to repayment and sustainability and the constraints on expansionary fiscal policy it generated after 2010.

Thus the Eurozone crisis represents the culmination of a guarantees-induced connection between financial crises and fiscal crises. The special characteristics of the Eurozone (the absence of fiscal and banking unions, the absence of floating exchange rates, and the ability to offset shocks with domestic monetary policy) made things worse.

4. EMPIRICS OF FINANCIAL CRISES OVER THE LONG RUN

In the following sections, we discuss the empirics of financial crises. We take a close look at defining and dating financial crises also exploring the coincidence of several types of crises. We highlight that a key concern for researchers should be classification uncertainty. Simply put, leading authors disagree on the definition of a crisis leading to discrepancies between authors and ultimately different conclusions about the impact and causes of crises. We discuss various methods and findings on the empirical determinants of financial crises in the next subsection. After this, we discuss how to measure output losses associated with financial crises and provide an overview of the literature. A closely related topic is recoveries. We explore the linkages between government debt and the fiscal costs of bailouts and guarantees. We note a new trade-off: when bailouts are costly, discretionary fiscal policy may be constrained especially in the face of a large financial crisis.

4.1 Dating of Financial Crises: A History of Comprehensive Chronologies

A number of different chronologies of financial crises exist. The crisis dates enumerated by each source are quite different as we will show. The coverage also varies in terms of the years and number of countries included in each sample. Because of all these discrepancies, the conclusions from each study are likely to differ and sometimes dramatically so. In this section, we survey the methodologies of the leading databases for dating financial crises.

Economists for the last 200 years have been drawn to major financial events and used them to learn about the macroeconomy. Conant (1915) surveys the history of central banking in many different nations in the early 20th century along the way detailing the prospective causes and impacts of financial events. The National Monetary Commission of the United States held lengthy hearings from leading financial experts, and significant amounts of evidence on the financial histories of many countries were submitted as evidence. Grossman (1994) was one of the first papers to systematically collect data on banking crises in the Great Depression.

Edwards and Santaella (1993) provide a chronology of currency devaluations from the Bretton Woods period. By the 1990s, researchers at the World Bank like Caprio and Klingebiel (1996) were providing dates for systemic banking crises in a large sample of countries. These crises were an economic phenomenon that had mainly disappeared between the 1940s and the early 1970s. By the late 1970s and into the early 1990s, such crises became increasingly commonplace first in Less Developed Countries and Emerging Market Economies (EMEs) and then in advanced countries. These events attracted significant interest by policy makers and academic researchers alike.

Kaminsky and Reinhart (1999) provide an account of banking, currency, and "twin" crises for nonadvanced countries. Laeven and Valencia (2008, 2012) compile a comprehensive dataset of banking, currency, and debt crises for the period 1970–2011. Laeven and Valencia's dataset covers the experience of 162 advanced, emerging, and less-developed economies.

For the long run, three major, comprehensive contributions stand out. Bordo et al. (2001) date banking, currency, and twin crises for all years between 1880 and 1997. For the years 1880–1945 their sample includes 21 now mostly advanced countries (with the exceptions of Argentina, Brazil, and Chile) and from 1945 data from 56 countries is available. Reinhart and Rogoff (2009) and Reinhart (2010) provide accessible data on banking, currency, and debt crises for 70 countries. Their record on sovereign debt crises extends back to the medieval period but only for a selected number of European polities. From 1800 Reinhart and Rogoff track banking, currency, and debt crises. Carmen Reinhart's website provides a set of open-access excel spreadsheets.[q] Finally, Taylor (2015), based on research with Jordà et al. (2011) provides the dates for "systemic" financial crises (mainly banking crises) for 17 countries 1870–2010.

Recently, Romer and Romer (2015) have collected a new set of dates for *financial distress* based on readings of the OECD Economic Outlook 1967–2007. While previous studies have mainly provided binary indicators of the various financial crises, Romer and Romer generate a measure based on a scale of 0–15. This measure is substantially different from traditional measures of crises, so we do not use it further in our analysis.

4.2 Crises Definitions

Table 1 gives the stated definitions for dating the various types of crises in each of the leading datasets: Bordo et al. (BEKM), Laeven and Valencia (LV), Reinhart and Rogoff (RR), and Jordà et al. (JST). As is evident, for banking and currency crises, the definitions vary by sets of authors leading to significant disagreements both about timing and whether there was or was not a crisis. In particular, for banking crises, authors disagree about how many banks must be closed or what percentage of the financial system's capital must be impaired for a crisis to be classified as systemic. Laeven and Valencia require that major policy interventions take place. Reinhart and Rogoff classify more crises than other authors likely because they only require bank runs to lead to the "closing of *one* or more financial institutions" (our emphasis).

Currency crises are generally defined as sharp declines in the nominal exchange rate. Many authors use a threshold decline (eg, 15% or 30%) in the nominal exchange rate possibly conditional on having only limited flexibility in the preceding years. BEKM use an exchange market pressure (EMP) index as developed in Eichengreen et al. (1995) where possible. Prior to the 1970s, and especially prior to the 1930s, the required data are relatively hard to obtain and so the emphasis is generally on nominal exchange rate movements. Laeven and Valencia follow Frankel and Rose (1996) as do Reinhart and Rogoff. There are some differences in the cutoffs used by the latter two sets of authors.

[q] http://www.carmenreinhart.com/.

Table 1 Crisis Definitions Four Leading Datasets

Authors	Sample	Banking Crisis Definition	Currency Crisis Definition	Debt Crisis Definition
Bordo et al. (2001)	1880–1939 21 Advanced countries 1945–97 21 Advanced countries + 35 less developed countries and emerging market economies.	Financial distress resulting in the erosion of most or all of aggregate banking system capital as in Caprio and Klingebiel (1996).	Forced change in parity, abandonment of a pegged exchange rate, or an international rescue. Or: an exchange market pressure (EMP) above a critical threshold (calculated as a weighted average of exchange rate change, short-term interest rate change, and reserve change relative to the same for the center country, the United Kingdom before 1913 and the United States after). A crisis is said to occur when this index exceeds a critical threshold. BEKM score an episode as a currency crisis when it shows up according to either or both of these indicators.	No debt crises are dated in this dataset.
Reinhart and Rogoff (2009)	1800–2011 70 Countries	A banking crisis occurs when there are one of two types of events: (1) bank runs that lead to the closure, merging, or takeover by the public sector of one or more financial institutions or (2) if there are no runs, the closure, merging, takeover, or large-scale government assistance of an important financial institution (or group of institutions), that marks the start of a string of similar outcomes for other financial institutions.	Reinhart (2010) refers to a working paper version of Reinhart and Rogoff (2011) stating they follow Frankel and Rose (1996). Frankel and Rose date a currency crisis as a period with a nominal depreciation of more than 25% which represents a greater than 10% increase in the rate of depreciation. Reinhart's website provides the following definition: "An annual depreciation versus the US Dollar… of 15 percent or more."	"External debt crises involve outright default on payment of debt obligations incurred under foreign legal jurisdiction, repudiation, or the restructuring of debt into terms less favorable to the lender than in the original" (Reinhart and Rogoff, 2011).

Continued

Table 1 Crisis Definitions Four Leading Datasets—cont'd

Authors	Sample	Banking Crisis Definition	Currency Crisis Definition	Debt Crisis Definition
Laeven and Valencia (2012)	1970–2011 162 Countries	Two conditions 1. "Significant signs of financial distress in the banking system (as indicated by significant bank runs, losses in the banking system, and/or bank liquidations)." 2. Significant banking policy intervention measures in response to significant losses in the banking system.	Nominal depreciation of the currency against the dollar of at least 30% that is also 10 percentage points higher than the rate of depreciation in the year before	"Default and restructuring" Data from Calomiris and Beim (2001), World Bank (2002), Sturzenegger and Zettelmeyer (2006), IMF staff reports and reports from rating agencies.
Taylor (2015)/ Jordà et al. (2011)	1870–2011 17 Countries	Taylor (2015) and Jordà et al. (2011) describe their coding as following Bordo et al., Reinhart and Rogoff, Laeven and Valencia and Cecchetti et al. (2009).	Not dated.	Not dated.

Comprehensive data on sovereign debt crises from the 19th century up to the 21st century come from Reinhart et al. (2003) and are also presented in the spreadsheets on Reinhart's website. Laeven and Valencia also provide their own dates based on a multitude of sources. The latter do not cite Reinhart and Rogoff as a source for their crisis dates. Laeven and Valencia date moments of sovereign default and restructuring. Reinhart and Rogoff date external debt crises when there is "outright default on payment of debt obligations incurred under foreign legal jurisdiction, repudiation, or the restructuring of debt into terms less favorable to the lender than in the original" (Reinhart and Rogoff, 2011).

As is visible, substantial disagreement across teams of authors exists. We revisit this later after exploring the record on the frequency of financial crises.

4.3 Financial Crises: The Historical Record

Fig. 1A–D shows the sample percentage of country-year observations for the first year of four different kinds of financial crisis. This variable is calculated as the ratio of the number of years in which the set of countries in the sample is in the first year of a banking, currency, debt, twin (banking and currency), or triple (banking, currency, debt) crisis to the total number of country-years.[r] We compare outcomes for various chronologies and across four time periods: The classical gold standard (1880–1913), the interwar period (1919–39), Bretton Woods (1945–72), and the recent period of globalization (1973–present). We note, as Bordo et al. (2001) do, the sample of countries does change over time within the BEKM dataset going from 21 to 56 countries in the post-1972 period which changes sample frequencies somewhat.

Currency crises are the most frequent variety of crisis followed by banking crises, debt crises, twin crises, and finally triple crises. By and large, all of the different chronologies agree on the trends. For the three datasets that cover the interwar period, only two out of three agree (Bordo et al. and Jordà et al.) that this period saw the highest frequency. Reinhart and Rogoff's data suggest that the recent period has a higher incidence of banking, triple, and debt crises (not pictured) than in the interwar period. Reinhart and Rogoff also show roughly the same frequency of twin crises in the interwar and the post-1973 period and a higher likelihood of a currency crisis in the Bretton Woods period and the post-1973 period. As in Bordo et al. (2001), there is little evidence that crises became more frequent over the long run with the possible exception of currency crises.

[r] Twin crises happen when a currency crisis event takes place within 1 year before or after a banking crisis. Triple crises are twin crises with an associated sovereign default within a 1-year window of either a currency or banking crisis. We avoid double counting by assigning a zero to all banking and currency crises that occur in the context of twin or triple crisis. Similarly any twin crisis that occurs with a sovereign default within a year is only counted as a triple crisis.

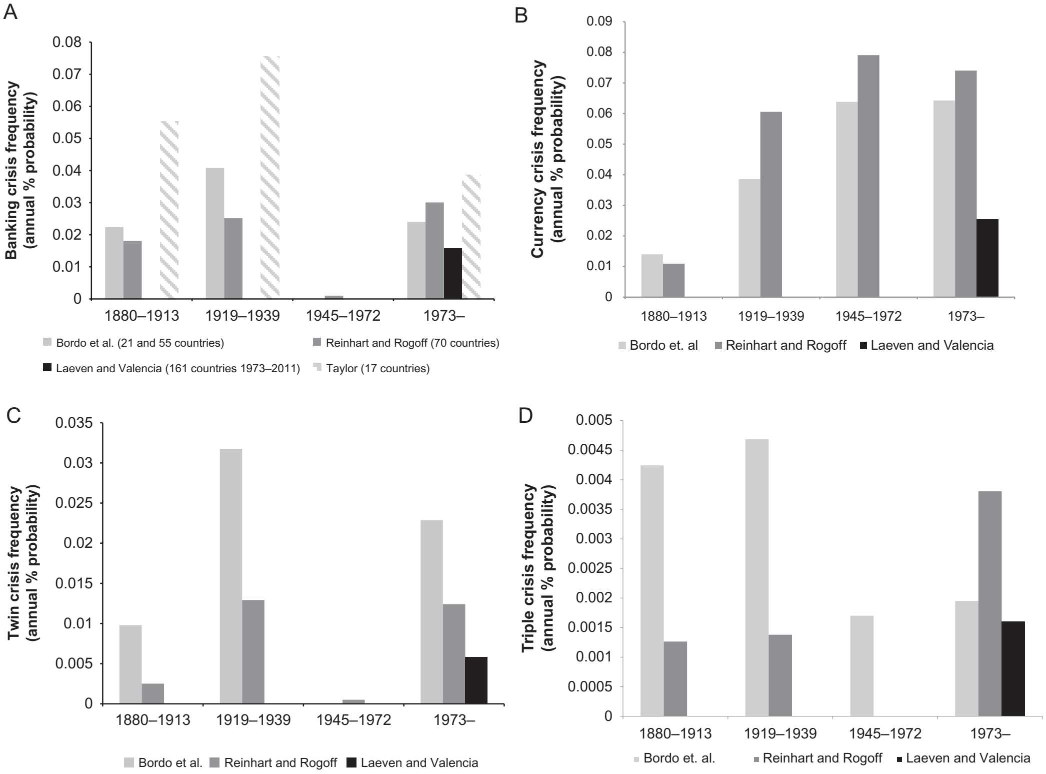

Fig. 1 (A) Banking crisis frequencies, 1880–2012. (B) Currency crisis frequencies, 1880–2009. (C) Twin crisis frequencies three datasets, 1880–2012. (D) Triple crisis frequencies, four datasets, 1880–2012. *Notes*: (A–D) Bars in (A) show the ratio of the number of country-years when a country was in the first year of a banking crisis to the total number of country-years in the sample. A banking crisis is defined differently according to each dataset. Banking crises are events not preceded or followed within 1 year by a currency crisis or a currency and debt crisis. Taylor (2015) studies "systemic crises." Laeven and Valencia have no data prior to 1970 so these data are excluded from the first three subsamples. Bars in (B) show the ratio of the number of country-years when a country was in the first year of a currency crisis to the total number of country-years in the sample. A currency crisis is defined differently according to each dataset. Currency crises are events not preceded or followed by banking crises or banking and debt crises. Laeven and Valencia have no data prior to 1970 so these data are excluded from the first three subsamples. Bars in (C) show the ratio of the number of country-years when a country was in the first year of a twin crisis to the total number of country-years in the sample. Currency and banking crises are defined differently according to each dataset. Twin crises are banking crises preceded or followed within 1 year by a currency crisis. Triple crises involving a debt default, banking, and currency crisis are excluded. Laeven and Valencia have no data prior to 1970 so these data are excluded from the first three subsamples. Bars in (D) show the ratio of the number of country-years when a country was in the first year of a triple crisis to the total number of country-years in the sample. Currency and banking crises are defined differently according to each dataset. Triple crises are banking crises preceded or followed within 1 year by a currency crisis and a debt crisis. Laeven and Valencia have no data prior to 1970 so these data are excluded from the first three subsamples.

Fig. 1B shows that currency crises shot up in probability in the interwar period and from then on have intensified slightly with Bordo et al. and Reinhart and Rogoff reporting probabilities in the range of 0.06–0.08. These two datasets are in strong disagreement with the Laeven and Valencia dataset in the recent period (1973–present). Even in samples where the years and countries overlap exactly, Laeven and Valencia report only half the currency crises that are recorded in Reinhart and Rogoff or Bordo et al.

In terms of time trends in twin crises, Bordo et al. find that their frequency was the highest in the interwar period (0.03) and the lowest in the Bretton Woods period. Reinhart and Rogoff's data disagree showing that a country would be equally likely to suffer a twin crisis in the interwar period as in the recent period (1973–2012). Laeven and Valencia date far fewer twin crises due to the comparatively low number of currency crises recorded.

Finally, for triple crises, both Bordo et al. and Reinhart and Rogoff agree that these are rare events and they occur in less than 1% of the country-years within sample. The datasets disagree with Reinhart and Rogoff showing that they are now more frequent than in the previous three periods while Bordo et al. show the pre-World War I period and the interwar as those with the highest likelihood of a triple crisis.[s] Once again, Laeven and Valencia do not concur with Reinhart and Rogoff for the 1973–2012 period suggesting that triple crises are much more rare than in the other two datasets.

Fig. 2A–E shows the number of crises that occur alone or coincident with other types of crises. With these diagrams, the connection between banking crises and outright sovereign default can be explored. The fraction of debt crises associated with banking crises (or both a banking crisis and a currency crisis) was nearly 0.21 in the years 1880–1913. In this constant country sample, this figure falls by over one half to 0.10 for the period 1919–39. Since 1973, the figure is 0.30 when we use crisis dates from Laeven and Valencia. Using Reinhart and Rogoff's data, the number stands at 0.29 for the 1973–2012 period.[t]

Of course research along the lines of Kaminsky and Reinhart (1999) provides evidence that currency crises frequently accompany banking crises in LDCs and Reinhart and Rogoff (2009) suggest that many debt crises are preceded by banking crises. It is interesting to note that according to our strict definitions "many" here equals only about 17% if a 1-year window is given. Bordo and Meissner (2006) discuss the historical relationship between banking, currency, and debt crises. They find that a significant

[s] Note we use Reinhart and Rogoff's debt crisis dates when dating a triple crisis within the Bordo et al. dataset.

[t] Some readers will note a difference between our numbers in Fig. 2D and those in the comparably designed fig. 4 of Laeven and Valencia (2012). There are some discrepancies within the Laeven and Valencia dataset which we have corrected.

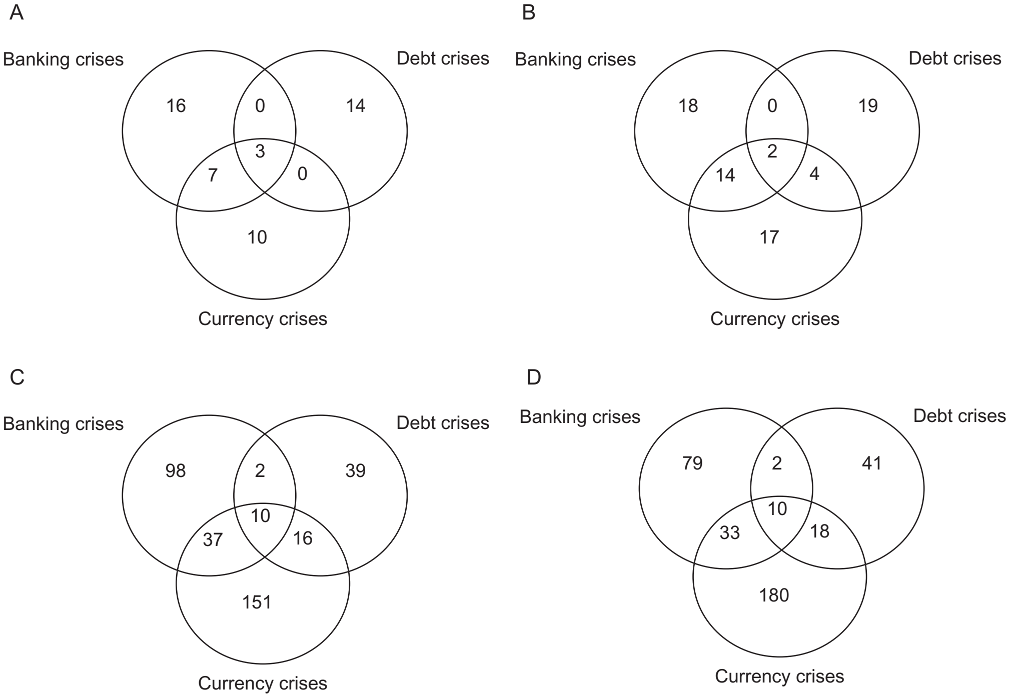

Fig. 2 (A) Coincidence of banking, currency, and debt crises, 1880–1913 (Bordo et al.). (B) Coincidence of banking, currency, and debt crises, 1919–39 (Bordo et al.). (C) Coincidence of banking, currency, and debt crises, 1970–2012 (Laeven and Valencia). (D) Coincidence of banking, currency, and debt crises, 1970–2012 (Reinhart and Rogoff dates). Notes: *(A–D) Source data for (A) and (B) are Bordo, M.D., Eichengreen, B., Klingebiel, D., Martinez-Peria, S. 2001. Is the crisis problem growing more severe? Econ. Policy 16 (32), 52–82. Source data for (C) is Laeven and Valencia (2013). Source data for (D) is Reinhart and Rogoff (2009).*

fraction of crises in the pre-World War I era could be classified as twin or triple crises. As Fig. 2A shows, 50% of the recorded currency crises prior to 1913 were accompanied by a banking crisis.

4.4 Classification Uncertainty: Definitions and Disagreements in Crisis Dates

In our view, the leading chronologies are those based on data underlying Bordo et al. (2001), Reinhart and Rogoff (2009), and Laeven and Valencia (2012). The dataset provided by Taylor (2015), which underlies Jordà et al. (2011), is somewhat limited and less comparable since it restricts attention to "systemic crises" only for a small set of 17 advanced countries. The other three datasets allow researchers to separate currency, banking, debt, twin, and triple crises, each of which are important phenomena in their own right. Two questions immediately arise. How well do these sources agree on their documented dates, and which source(s) is(are) the best?

In answer to the first question, regarding agreement, there is some significant evidence that the correlation between dating methodologies is not extremely high even within constant country samples. Tables 2a–2d show cross tabulations of banking crisis indicators for each of four sources (Bordo et al., Reinhart and Rogoff, Taylor, and Laeven and Valencia) for four different periods (1880–1913, 1919–39, 1945–72, and the years after 1973). We restrict attention in these tables to the first year of a banking crisis for a country.

In each subtable, we show the number of noncrisis country-years, and the number of country-years with a crisis in either of two datasets for the countries that are common to both datasets. The entry in row 2 column 2 of each table records the number of times both datasets are in agreement, and the last two columns provide a measure of the agreement between sources calculated as the percentage of all crisis-years dated within the period and the country sample in which the two sources agree. We provide this

Table 2a Comparison of Leading Crisis Chronologies, 1880–1913

	1880–1913	Reinhart and Rogoff		% Agree

Notes: Tables present cross tabulations of banking crisis indicators for each of four sources (Bordo et al., Reinhart and Rogoff, Taylor, and Laeven and Valencia) in four periods. We restrict attention to the first year of a banking crisis for a country. In each entry, we show the number of noncrisis country-years and the number of country-years with a crisis in either of two datasets for the countries that are common to both datasets. The entry in row 2 column 2 of each table records the number of times both datasets agree. The last two columns provide a measure of the agreement between sources calculated as the percentage of all crisis-years dated within the period and the country sample in which the two sources agree. We provide this percentage for crises occurring in the same year and then allow for a 1-year window to allow for small variations in timing.

percentage for crises occurring in the same year and then allow for a 1-year window to allow for small, but reasonable variations in timing.

The minimum percentage in Tables 2a–2d is 0.26 (comparing Bordo et al. and Laeven and Valencia for 55 countries in the years 1973–97). For the years excluding the Bretton Woods period when all datasets are in agreement, the maxima are 0.69 (Jordà et al. vs Reinhart and Rogoff for 17 countries 1919–39) and 0.65 (Bordo et al. vs Jordà et al. for 17 countries 1919–39). The average percentage of times that the head-to-head comparisons agree is 0.42 excluding the Bretton Woods period where agreement is nearly complete.

Matters are obviously slightly worse in terms of correspondence than these numbers suggest since the figures are calculated based only on overlapping samples of countries. The fact that Reinhart and Rogoff and Laeven and Valencia provide much larger samples means that the absolute number of crises reported will be higher. Frequencies also vary as seen in Fig. 1A–D.[u]

Disagreement and classification uncertainty among datasets exists for several reasons. Datasets differ on their definitions of what constitutes a particular kind of crisis. As seen in Table 1, definitions of banking crises vary substantively across researchers. In addition, since we have divided the sample space or possible outcomes into non-overlapping categories (banking, currency, debt, twin, triple, etc.) disagreement for example can occur when one dataset codes a twin crisis but another dataset codes only a banking or currency crisis. A third reason datasets can disagree is due to near-miss timing when one set of authors has a particular date more than two or more years away from another set of authors. Finding the exact timing of an event is also a challenge in periods of high volatility. Latin American countries had prolonged periods of currency distress and banking instability in the 1970s, 1980s, and 1990s leading to such discrepancies.

An example comparing the Reinhart and Rogoff dataset with that of Bordo et al. is germane. The case of Argentina 1973–92 is particularly difficult. Reinhart and Rogoff date a currency crisis in every year from 1973 to 1992 and two banking crises that occur during this extended currency crisis (1980–82) and (1989–90). Bordo et al. have the following: currency crisis (1975–78), twin crisis (1980–82), currency crisis (1984–85), currency crisis (1987), and twin crisis (1989) which was not associated with the currency crisis in 1987. It is evident that different authors take different routes to finding the first year of a given type of crisis and discrepancies emanate from periods of great macroeconomic instability.

[u] Cecchetti et al. (2009) report that all crises in Laeven and Valencia are in Reinhart and Rogoff. However, this cannot strictly be true since Laeven and Valencia have a much larger sample of countries. In addition, we separate banking crisis from twin and triple crises which Cechetti et al. did not do.

Another issue with the historical dating of crises is that authors must rely on the research of other economic historians or significant amounts of scattered primary sources from multiple country-specific sources. Often historical sources are vague as to how many financial institutions were closed or faced runs which leads to discrepancies in the dating of banking crises. Jalil (2015) studies six leading chronologies of the American banking system in the 19th and early 20th centuries and observed major disagreements among them. Jalil argues that "quantitative sources alone are not sufficient to identify banking panics" and carries out an extensive and careful reading of contemporary sources to identify banking panics (as opposed to systemic banking crises).

Matters are significantly worse for dating currency crises in history especially in the 19th century. As it turns out, finding reliable exchange rate data for samples outside of the leading 21 countries is extremely difficult, if not impossible, since active and liquid markets in foreign exchange did not exist without some prior financial development. Reinhart and Rogoff (2009) provide an extensive list of dates for which nominal exchange rates are available with some relevant cases in point such as: Argentina (available from 1880 only), Finland (from 1900), Korea (1905), Greece (1872), New Zealand (1892), South Africa (1900), Uruguay (1900), etc. In other cases, using an EMP index will be difficult prior to the 1930s or even the 1950s due to missing reserve and interest rate data. In these cases, the Frankel and Romer approach of using a cutoff for changes in the nominal exchange rate will have to suffice. Relying exclusively on exchange rate changes however neglects many important episodes.

More disconcerting is the disagreement on sovereign defaults in the period since 1973. These data are mainly gathered from primary and secondary sources as noted in Laeven and Valencia (2012) and Reinhart and Rogoff (2009). While Reinhart and Rogoff find 64 defaults between 1973 and 2009, Laeven and Valencia (2012), *in the same set of countries*, only find 34. This is not simply a matter of widening the window of years in which a default is classified. Many defaults in Reinhart and Rogoff such as Algeria (1991), Brazil (2002), Uruguay (1990), etc., are not recorded in the Laeven and Valencia dataset. This is due to the fact that Laeven and Valencia record an event only when a payment is missed. Reinhart and Rogoff seem to follow a more lenient approach classifying events where there are ratings downgrades, loss of market access, issues of confidence, etc.[v] This classification is seemingly at odds with the seemingly stricter definition described in Table 1 and Reinhart and Rogoff (2011). Such discrepancies across authors obviously seriously impinge on interpretation of the historical record and inferences drawn about the frequency, duration, costs, and causes of crises.

[v] This conclusion is drawn from direct email correspondence with Luc Laeven on February 11, 2016. He cites the case of Brazil in 2002 as an example where no payments were missed but Reinhart and Rogoff declare a debt crisis.

4.5 Causes of Crises

With the reappearance of financial crises associated with financial liberalization in the 1970s and 1980s and better international data, researchers began to focus energy on isolating the leading determinants of financial crises. Theory and analytical frameworks developed in the 1970s and 1980s provided guidelines for the key variables of interest, but explicit structural tests of particular models still remain few and far between. Most of the research in this area focuses on a large set of macroeconomic, financial, and international variables and attempts to exclude variables with the lowest statistical power for predicting financial crises.

Subsequent to these early efforts, a new (near-consensus) view emerged, based in part on the experience of the 2007 crisis, assigning a primary role to credit booms as the key determinant and predictor of financial crises (eg, Borio and Drehman, 2009; Schularick and Taylor, 2012; Gourinchas and Obstfeld, 2012). Notwithstanding this view, it is appropriate to recognize that not all banking crises are driven by credit booms. It is also useful to recognize that not all housing, equity booms, or capital inflow bonanzas end in crises.[w] A more satisfactory approach to understanding the drivers of financial crises recognizes that the microstructure of the financial system matters as well as credit's interaction with a number of other macroeconomic determinants.

Four key approaches to understanding the causes of crises have been taken since the 1990s with subsequent refinements in recent years. The first approach uses cross-country data and limited dependent variable models such as logit or conditional logit to find statistically significant determinants (eg, Demirgüç-Kunt and Detragiache, 1998). Kaminsky et al. (1998), Kaminsky and Reinhart (1999), and Kaminsky (1999) show that the early warning indicators (EWI/EWS) methodology developed for predicting the business cycle can be satisfactorily employed. In addition, qualitative and descriptive analyses as well as "Big Data" methods have been used.

In a highly influential paper, Kaminsky and Reinhart (1999) apply and adapt the EWI approach to predict banking, currency, and twin crises in a sample of 20 countries between 1970 and 1995. From a large set of variables, they select 16 as the most important based on their changes in the months preceding and following the different types of crises in play. These variables are classified into four categories (financial sector, external sector, real sector, and fiscal sector). Kaminsky and Reinhart (1999) check whether a variable signaled a crisis within a particular window of time (12 months for a banking crisis and 24 months for a currency crisis) and then find thresholds by finding the level or

[w] See Bordo and Landon-Lane (2014), Jordà et al. (forthcoming) and Goetzmann (2015) for perspectives on housing booms and financial crises. Gorton and Ordoñez (2016) study *good booms* and *bad booms* arguing that not all credit booms end in crises.

change in a variable that minimizes the noise-to-signal ratio. In this way, a sophisticated use of information criteria is used to balance type I vs type II errors.

Two tradeoffs relevant to policy makers are immediately evident in the context of this strand of the EWI literature. First, what is the optimal size of the prediction window? Calling a crisis too early could put the brakes on an otherwise healthy economy, but failing to act at an early date might preclude avoiding a crisis. Another tradeoff concerns the loss function for policy makers. Babecký et al. (2014) note that minimizing the noise-to-signal indicator ignores the relative losses (to the policy maker) from missed crises vs false alarms. In this case, the optimal threshold would depend on the relative weights in a loss function as well as the predictive power of the signals. Obviously such a calculation has direct relevance for macroprudential policy. Jordà et al. (2011) illustrate the tradeoffs in finding an optimal threshold for any given indicator of a crisis with a correct classification frontier (CCF) akin to a production possibilities frontier trading off type I and type II errors. They suggest that the area under their CCF, which is equivalent to the AUC criteria, be used in determining whether a particular model has predictive power.

Returning to the pioneering study of Kaminsky and Reinhart, their data suggest that growth of money and interest rates are above trend before crises, while an appreciating real exchange rate and exports below trend help predict crises. In addition, in their sample, output falls below trend prior to a crisis. The best predictors (ie, those with the lowest noise-to-signal ratio) for banking crises are: appreciation of the real exchange rate, equity price booms, and the money multiplier. The lowest type I error (missed crises) is provided by high real interest rates which were strongly associated with financial liberalization especially in the 1980s.

Recent research in a similar vein (Babecký et al., 2014; Drehman et al., 2012; Gourinchas and Obstfeld, 2012) emphasizes the financial cycle highlighting above trend growth in the ratio of domestic private credit-to-GDP, equity, and property prices. The earlier literature (eg, Kaminsky and Reinhart, 1999) did not deny that credit was important, but in Kaminsky and Reinhart's sample the percentage of crises correctly called by this variable (when above its threshold) is only 50% while its noise-to-signal ratio was a relatively low 0.59. While these results are not equally comparable to the results in Schularick and Taylor (2012) who argue that credit is a very strong predictor of crises alone and of itself, it would appear that the role of credit depends on the particular sample chosen and definition of a crisis.

Another strand of the literature attempted to predict banking crises using logit analysis. Demirgüç-Kunt and Detragiache (1998) find the following:

– Low GDP growth, high real interest rates, and high inflation are significantly correlated with the occurrence of a banking crisis.
– Banking sector variables such as the ratio of broad money to foreign exchange reserves, credit to the private sector, and mismanaged liberalization are associated with banking crises.

- The level of GDP/capita is negatively related to crises.
- Deposit insurance which is overly generous may also be associated with moral hazard and banking instability.

Subsequent work by the same authors emphasized the role of financial liberalization in environments with weak regulatory capacity and generally weak institutions giving rise to corruption, weak rule of law, and poor contract enforcement. This result echoes the general experience we highlight above that deposit insurance and guarantees have fomented regulatory forbearance and in many instances this has led to banking crises.

Research over the past 5–10 years has made refinements to the general methods proposed earlier. For instance, Bussiere and Fratzscher (2006) note that a binary logit model that predicts the onset of a crisis may ignore the fact that macroeconomic variables and relationships may behave differently in the wake of a crisis. Using information from the quarters immediately following a crisis to predict a crisis may thus lead to poor predictions. Instead of running binary response models to predict banking crises, Bussiere and Fratzscher estimate a multinomial response which allows for three states of the world: noncrisis, crisis, and postcrisis. Better prediction is also achieved by using the tools from the model selection literature. In this vein, Babecký et al. (2014) use Bayesian averaging of regression estimates to select the strongest set of determinants rather than focusing on a small set of indicators.

Other authors have moved the goalposts slightly by incorporating more information to generate continuous indicators of crises. Rose and Spiegel (2011) and Babecký et al. (2013) cover banking crises while Frankel and Saravelos (2012) study currency crises. Here the indicators of crises incorporate information on the severity of the crisis. Rose and Spiegel (2012) study a multiple indicators multiple causes model to study the crisis of 2007–08. Their indicators are quite distinct from the simple binary banking crisis indicators in Table 1. Instead their indicators focus on the output drop between 2007 and 2008, exchange rate movements, credit ratings changes, and equity price changes. The advantages in such procedures are that one does not need to use limited dependent variable models which are biased in the case of rare events and deal poorly with unobservable heterogeneity. However, the regressand of interest has changed significantly in terms of the economic meaning compared to the previous literature on EWIs.

The conclusions from this strand of the literature are not entirely consistent with the earlier EWI literature. Frankel and Saravelos (2012) conclude that foreign exchange reserves, the real exchange rate, the growth rate of credit, GDP, and the current account are the most frequent statistically significant indicators (of currency crises) in the literature reviewed. While somewhat consistent with Kaminsky and Reinhart, the finding obviously has little light to shed on the correlates of banking crises. Rose and Spiegel (2011, 2012) use indicators that overlap with those in Kaminsky and Reinhart but find little predictive power for any of the leading causes explored in Kaminsky and Reinhart—most notably the level of the ratio of domestic credit-to-GDP. Since the crisis of 2007 manifested itself in different ways in different countries, it is not surprising that Rose and Spiegel (2011, 2012) find few reliable predictors to explain the diversity of experience. Exploration of this issue by Sayek and Taksin (2014) provides interesting evidence. In fact, the Eurozone crises were different from each other, but they bore some similarity to previous crises (ie, a small set of variables moved in the same way prior to these and previous crises). They emphasize that each recent crisis has a reasonable match to other historical crises in the model, but that each match is likely to be to a separate and distinct crisis. In other words, the causes of the most recent crisis are heterogeneous and not driven by one particular variable.

IMF (2009) discusses some of the differences in the way the recent crisis unfolded across countries, and hence why EWI analysis may be challenging. While some countries were exposed to offshore borrowing, others had significant housing booms. Still others had cross-border assets in the United States—the epicenter of the crisis, and several countries had unsustainable fiscal and financial problems (as discussed earlier) as well as policy constraints (eg, countries in the EMU). While one might infer from some of the recent theoretical and empirical literature that growth of the ratio of domestic credit-to-GDP is the key to understanding financial crises, this does not appear to be the only, nor the main, determinant of crises over the last few decades. Consequently, a focus solely on credit may not go very far in helping us understanding the recent crisis or future crises.

In addition, a large debate exists on the role of capital inflow surges vs credit booms. Both factors were cited as potential risks in the run up to the 2007 crisis and have perennially been in the spotlight in the empirical and theoretical literature. Many conceptual frameworks suggest that capital inflows fuel lending booms in open economies (Borio et al., 2014; Diaz-Alejandro, 1985; McKinnon and Pill, 1986). In a widely cited study, Jordà et al. (2011) find that prior to 1945 current account deficits are associated with systemic crises, but that after 1945 this is no longer the case. These authors cite the growth of the ratio of credit-to-GDP as a key determinant and a good predictor of systemic crises. In addition, they find no evidence that capital inflows which coincide with credit booms raise the probability of a systemic crisis.

In opposition to these findings, Caballero (2014) reexamines the connections between credit and capital flows in an interesting empirical treatment finding a role for both capital inflow surges and credit booms. Caballero (2014) uses a limited dependent variable model that allows for unobservable country level heterogeneity and yet allows for noncrisis countries to appear in the sample, unlike in Jordà et al. (2011) who use conditional logit models. Caballero's sample covers a large sample of countries (both developed and less developed) from 1973 to 2008 while Jordà et al. (2011) feature data from 14 countries 1870–2008.

Caballero finds that inflow bonanzas and credit booms are both statistically significant predictors of banking crises (using a similar definition of crises to Laeven and Valencia). However capital inflow bonanzas do not solely operate through bank intermediated credit booms. Moreover, portfolio-equity capital flows, but not bonanzas associated with a rise in net debt are statistically significant. The evidence here suggests capital inflow bonanzas may also generate instability by fueling asset price booms and enhancing liquidity. Based on these results, it seems imprudent to ignore the role of large capital inflows even if domestic private credit is not growing above trend.

Could monitoring of the credit-to-GDP ratio have been sufficient to avoid the recent global crisis? It is unlikely. Caballero (2014) as well Babecky et. al. (2014) and IMF (2009) suggest a more eclectic approach that simultaneously incorporates multiple variables. In addition, IMF (2009) emphasizes that while the subprime crisis is often thought of as a credit-driven event accompanied by unsustainable levels of leverage this characterization is at odds with the data. In the United States, for instance, private domestic credit-to-GDP did not grow strongly above trend because borrowing by corporates eased while household debt and leverage increased.[x] Contrariwise, the East Asian crisis was associated with strong growth of leverage in the corporate and financial sector and less so in the household sector (IMF, 2009). In addition, leverage among financial institutions in the 1990s was as high as in the years before 2007 (Portes, 2010). It should not be forgotten that in the recent crisis, leverage in many financial institutions was hidden in off-balance sheet vehicles and so forth giving credence to the idea that Goodhart's law is in play. Ideally, any surveillance of the financial system, any conclusions regarding causes of crises, and any macroprudential policy would pay close attention to where exactly risk was concentrated and where maturity mismatches are the most pronounced. Surveillance and policy must also carefully weigh the costs and benefits of imposing policy in light of the potential for type I and type II errors as highlighted in this literature.

4.6 Output Losses of Financial Crises

Financial crises are often associated with economic downturns and deviations of output from long-run trends. A large number of studies investigate the impact of crises on output, output growth, other macroeconomic aggregates, and even health indicators (Stuckler et al., 2012).

Table 3 provides a list of leading papers, methodologies, and baseline estimates for the impact of financial crises on output.[y] In this literature, most authors define output losses as

[x] Jordà et al. (2013) note that the level of "excess credit" was in the 60th percentile for all crisis events in their data and emphasize the issues related to shadow banking. They emphasize that a broader measure of credit shows a more significant boom.

[y] The Basel Committee on Banking Supervision, Bank for International Settlements (2010) also provides a similar table and calculates median and average output losses across studies (with no "permanent" effects) as 19%. See table A1.1 in that paper.

Table 3 Definitions and Values of Output Losses from Financial Crises

Authors	Sample	Crisis definition	Methodology for calculating the economic costs of financial crises	Average "losses"
Bordo et al. (2001)	1880–1939 21 Advanced countries 1945–97 21 Advanced countries + 35 LDCs and emerging markets	Banking crises	Cumulative loss of output between onset and recovery found by subtracting actual growth from pre-crisis trend growth. Recovery occurs when growth obtains its precrisis trend level.	7% (21 countries, 1973–97) 6.2% (56 countries, 1973–97)

Hoggarth et al. (2002)	1977–98
	47 Countries
	47 Banking crises
		Banking crises (systemic and borderline)	**1.** *GAP1* Sum of the differences between growth in potential output and actual output growth during the crisis period. Potential growth = arithmetic average of GDP growth in the 3 years prior to the crisis. End of crisis is when output growth returns to trend.
			2. *GAP2* Cumulative difference between level of potential output and actual output over the crisis period. Output potential is based on trend growth over the 10-year precrisis period using an HP filter.
				GAP1 = 14.5%
				GAP2 = 16.5%

Hutchison and Noy (2005)	1975–97 24 Emerging markets	Twin crises	Regressions of growth of real GDP on crisis indicators and lags.	Average loss of GDP of 15–18% over the average

Table 3 Definitions and Values of Output Losses from Financial Crises—cont'd

Authors	Sample	Crisis definition	Methodology for calculating the economic costs of financial crises	Average "losses"
				duration of 3–4 years after the onset of a crisis.
Dell'Ariccia et al. (2008)	1980–2000 41 Countries 48 Crises	Banking crises: there were extensive depositor runs; the government took emergency measures to protect the banking system, such as bank holidays or nationalization; the fiscal cost of the bank rescue was at least 2% of GDP; or nonperforming loans reached at least 10% of bank assets.	Marginal impact of banking crises on the annual growth rate of sectoral value added.	Growth rate is 1.1 percentage points lower in sectors highly dependent on external finance.
Angkinand (2009)	1970s–2003 35 Countries 47 Crises (systemic and nonsystemic)	Banking crises identified in Caprio and Klingebiel (2003).	Cumulative deviation in real GDP from an extrapolated HP trend. Calculated between the onset of a crisis and time when GDP reaches the trend.	3.13% (mean for all banking crises) 3.99% (mean for systemic banking crises)
Cecchetti et al. (2009)	1980–2007 Number of countries is not stated 40 crises	Banking crisis defined as in Laeven and Valencia.	Output loss is the cumulative loss in GDP from the onset of a crisis until GDP reaches the precrisis peak.	18.4% (mean) 9.2% (median)
Laeven and Valencia (2013)	1970–2011 162 Countries	Systemic banking crises possibly accompanied by currency, or debt crises or both.	Cumulative loss of real GDP between onset of crisis and 3 years after crisis starts calculated as the difference between actual output and the HP filter trend	23% (median) 32% (median advanced) 26% (median emerging markets)

			calculated over the 20 years prior to a crisis (or fewer years if data are not available)	
Jordà et al. (2013)	1870–2008 14 Countries	"Financial Recessions" (ie, recessions associated with systemic financial crises) with and without large growth in real credit.	Local projections from year $T+1$, to $T+5$ of log differences of GDP per capita in year t from peak year level.	16.9% Cumulative deviations from peak for "financial recessions" for $T+1$ to $T+5$ (table 7 row 1, p. 19)
Reinhart and Rogoff (2014)	1800–2011 70 Countries	100 Systemic banking crises defined as in Reinhart and Rogoff (2009) possibly accompanied by currency, or debt crises or both.	**1.** Peak to trough decline in GDP per capita. **2.** Severity index $=-1\times$ (peak to trough decline in GDP per capita) + number of years until peak level of GDP per capita is attained. This is defined as recovery time.	11.5% (mean) 8.8% (median) 8.3 Years peak to recovery (mean) 6.5 Years peak to recovery (median)
da Rocha and Solomou (2015)	24 Countries 1920–38 19 Crises	Systemic banking crises: "Classification is based on qualitative informed judgment, documenting the extent of financial distress in the banking system of a country."	Cumulative growth in real GDP and industrial production up to 7 years after a crisis starts.	33% Cumulative deviations from peak for T to $T+7$.

the deviations from a precrisis peak in output or a precrisis output trend. However, there is substantial variation in the methodologies used for calculating the costs of financial crises. Some authors study the marginal impact of crises and financial distress on growth rates. Others calculate the cumulative loss of output or GDP per capita from the peak of economic activity at various postpeak window lengths. Differences in methodologies, dependent variables, and samples lead to significant differences in the point estimates of the output costs of financial crises. Still, nearly all studies agree that financial crises are associated with economically significant downturns in output and output growth.

One major issue in determining the size of the output losses attributable to a crisis is causality or endogeneity. Real shocks may cause an output decline and problems in the financial sector, but equally, financial shocks are widely believed to generate output declines.[z] The problem comes down to identifying the sources of variation in outcomes when unobservable financial frictions and shocks matter and are correlated. More precisely demand and supply may change in response to the same shocks that contribute to financial problems thus making it difficult to cleanly identify the impact of the financial shock itself. Empirically, Reinhart and Rogoff (2014) observe in their sample that the peak of economic expansions usually coincides with banking crises but that in several instances the peak predates the crisis. Calomiris and Hubbard (1989) argue that output turns down prior to difficulties in the financial sector.

Two main approaches have been taken to deal with heterogeneity, unobservable factors, and endogeneity bias. Bordo et al. (2001) compare recessions without financial crises to recessions with financial crises. After controlling for a small set of observables, the authors find that financial crises are associated with higher output losses than recessions without financial crises. In a similar vein, Jordà et al. (2013) report statistically and economically significant differences between output downturns associated with financial crises and downturns not associated with financial crises even after conditioning on a number of predetermined macroeconomic variables. Jordà et al. (2011) also find that output losses in financial recessions are positively associated with the size of the precrisis rise in the ratio of credit-to-GDP.

Another way of dealing with causality is to put more theoretical structure on the data. Dell'Ariccia et al. (2008) argue that if financial sector distress matters then it should be the case that sectors which are more dependent on external finance should be the hardest hit when the banking sector is in trouble. Their evidence is consistent with this line of reasoning. Mladjan (2012) provides similar evidence for the Great Depression. In addition, Ziebarth (2013) found quasiexperimental evidence from the 1930s that where bank

[z] In general, the theoretical literature in macroeconomics shows how output losses due to shocks can be amplified in the presence of financial frictions. Financial shocks arise from capital quality shocks in a model with financial frictions as in Gertler and Karadi (2011). See also Bernanke et al. (1999).

failures were larger these were associated with greater declines in output, lower revenue, and a slower pace of entry by firms.

We provide some baseline estimates for output losses that are comparable in terms of methodology. We use crisis data from Bordo et al., Reinhart and Rogoff, and Laeven and Valencia, and data on output per capita for 42 countries between 1865 and 2009 from Barro and Ursúa (2008). For the period 2000–14, we use real GDP per capita (in local currency) from the World Economic Outlook database in order to calculate trends and output losses from the recent crisis that started in 2007. We calculate unconditional output losses in different periods using the crisis dates from the various datasets surveyed in Section 4. In particular, we study the cumulative percentage deviation of GDP per capita from the precrisis trend level of GDP per capita. The window we use is the year of the crisis to 3 years after the crisis starts. Precrisis trends are given by the average annual change of the logarithm of GDP per capita in up to 10 years prior to a crisis.[aa]

We provide these losses for banking, twin, and triple crises in Fig. 3A–D. Fig. 4A–F provides illustrations of specific country examples. Output losses, as we define them here, are economically very large. In the period 1880–1913, Fig. 3A shows that for banking crises average output losses are nearly 3% in BEKM's data (median = 0.20, standard deviation = 38.9) and 6% in RR (median = 5, standard deviation = 33). Losses are much larger in the interwar, largely driven by the Great Depression. Here, for the three different types of crises, losses are never lower than 40% in the BEKM dataset. In the post-Bretton Woods period, losses in the BEKM and RR datasets are smaller than the interwar period but larger than the 1880–1913 period. Here the average losses are on the order of 14% in the BEKM data (median = 18, standard deviation = 23), 21% in the RR data (median = 24 standard deviation = 28), and 29% in the LV data (median = 30, standard deviation = 28). The higher losses in the LV dataset stem from the inclusion of a wider range of countries and the inclusion of the crisis of 2007 which witnessed much higher output losses than previous crises.

Output losses are different in size due to different methodologies in calculating trends, in dating crises, defining the type of crisis of interest, and country/time coverage. When we restrict the sample to BEKM's 56 countries and the years 1973–97 which are covered in all datasets, then the output losses from banking crises are calculated as 14% (BEKM), 15% (RR), and 19% (LV). Using different sample years and countries lead to different headline numbers as is immediately obvious. In addition, LV use GDP and not per capita GDP, although, in practice this has only a minimal effect. LV also use an HP filter whereas we have opted for a simplified exponential detrending procedure. While we find

[aa] We eliminate crises that occur within 3 years of another crisis. Previous crises may have an impact on the trend and level of output. We also estimate losses separately for banking crises without currency and currency and debt crises so as to separate the sample space into mutually exclusive bins as above.

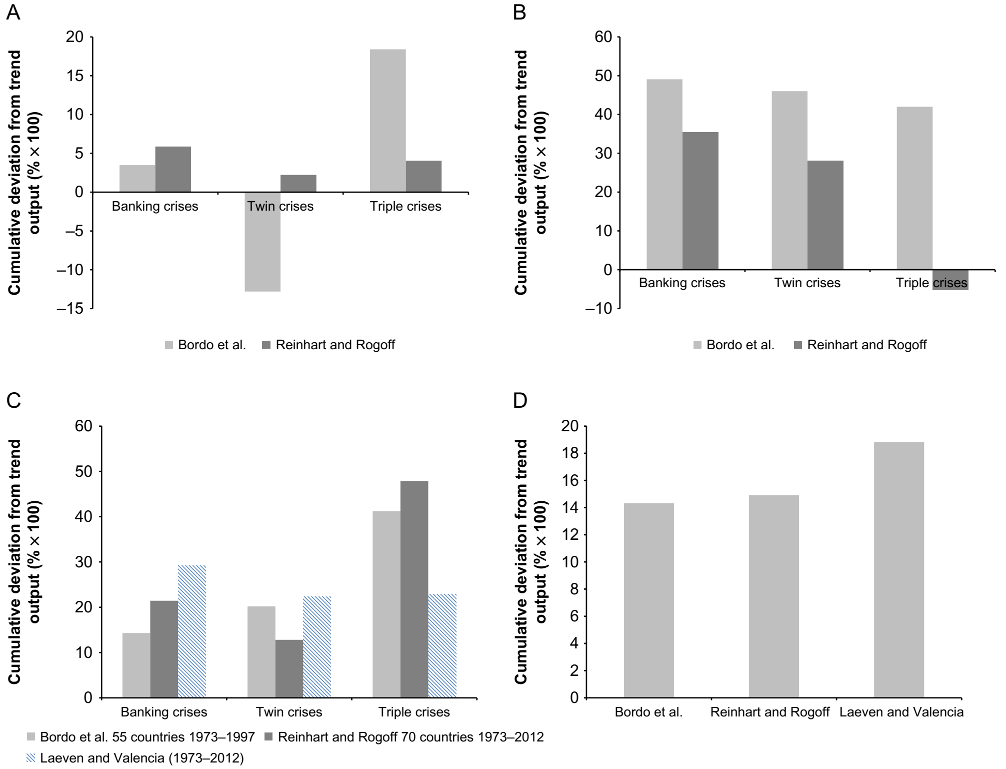

Fig. 3 (A) Output losses for three varieties of crises, 1880–1913 Bordo et al. vs Reinhart and Rogoff. (B) Output losses, three varieties of crises, 1919–39 Bordo et al. and Reinhart and Rogoff. (C) Output losses, three varieties of crises, 1973–97 (Bordo et al.), 1973–2012 (Reinhart and Rogoff), and 1973–2012 (Laeven and Valencia). (D) Output losses from banking crises, 1973–97 three datasets. *Notes*: (A–D) Output losses are calculated as the difference between the level of GDP per capita in the 3 years following a crisis and the extrapolated trend of GDP per capita. The trend is calculated as the average growth rate in the 10 years prior to crisis. See the text for additional information.

some instances where losses are not positive (ie, output per capita is not below trend), probably because the pretrend is already quite low, LV report no instances where this is the case. It appears that the lag length for calculating the trend also matters. Jordà et al. (2013) study deviations from the business cycle peak (table 5, p. 13, table 6, p. 15, and table 7 p. 19). This could lead them to offer smaller losses since no assumptions are made regarding the continuing trend of GDP per capita.

One surprise when looking at the long run is that output losses seem to be larger in the recent period compared to the pre-World War I period despite today's greater reliance on liquidity support, fiscal interventions, and other policies which attempt to remedy the market failures associated with financial shocks. However, compared to the interwar

period/Great Depression years, a period when policy was counterproductive, the losses from banking crises are lower on average. Without recent interventions, output losses might have been higher—although without further work and careful research design to sort out endogeneity and selection biases we can take no firm stance on the causal impact of financial distress and systemic banking crises. As for the pre-World War I period, it may be the case that the economies of the time were more flexible or that the financial sector's size was limited mitigating the overall negative impact on output. In the historical period, countries avoided output drops comparable to those today even without a comprehensive crisis-fighting playbook beyond lender of last resort actions and ad hoc rescues. An interesting avenue for future empirical research is to study the size of output losses after properly accounting for variance in policy action.

4.7 The Speed of Recovery After Financial Crises

Reinhart and Rogoff (2009, 2014) posited that recessions with financial crises (ie, financial recessions) are followed by slow recoveries. These authors generally gauge time to recovery as the number of years until the level of real per capita GDP attains the prior peak it reached. Reinhart and Rogoff (2009) study a small sample of "severe" financial crises while Reinhart and Rogoff (2014) study 100 systemic banking crises 1857–2013. Reinhart and Rogoff find that recessions with systemic crises have longer times to recovery than those recessions which are not accompanied by a crisis.

In contrast to the earlier studies, Bordo and Haubrich (2012) posit that financial recessions generally are followed by faster recoveries. They start with Friedman's (1993) plucking model which shows that deep recessions will be followed by fast recoveries. Zarnowitz (1992) documents this stylized fact for the United States. Bordo and Haubrich then compare the recovery from recessions with crises to those that did not have crises for 22 business cycles 1880–2010 in the United States. Bordo and Haubrich measure the depth of the contraction as the percentage drop in quarterly GDP from the peak to the trough of NBER cycles. They then measure the "strength" of the recovery as the percentage change in GDP in the first four quarters of the expansion. Bordo and Haubrich also measured the recovery as the same number of quarters that output declined in the preceding downturn, so eg, if output declined for six quarters they measure the strength of the recovery as the percentage change in GDP in the first six quarters of the expansion. They find that recessions with financial crises (using crisis dates in BEKM) were 1 percentage point deeper than nonfinancial recessions and the recoveries were 1.5 percentage points stronger than recoveries in nonfinancial recessions. Other studies confirm Bordo and Haubrich including: Howard et al. (2011) and Romer and Romer (2015). Results in Jordà et al. (2013) show that the US recovery after 2007 was faster than what would have been predicted by their empirical models.

5. FISCAL CRISES, BANKING CRISES, AND THE FISCAL CRISIS TRILEMMA

Following the research of Reinhart and Rogoff (2009) and after observation of events in Europe, research has focused on the impact of banking crises on the probability of a debt crisis especially in advanced countries. While developing countries faced such troubles from the 1970s, advanced countries largely had fewer and smaller crises until recently. The exceptions being of course Japan, Sweden, and Finland in the 1990s. Reinhart and Rogoff suggest however that public debt (not the debt-to-GDP ratio) increased by about 86% in the wake of banking crises due to the impact of falling revenues. According to Reinhart and Rogoff, these increases, "in several cases," were not wholly due to the fiscal costs of bailouts. Schularick (2012) shows that the (systemic) crises of the late 20th century are associated with large rises in the debt-to-GDP ratio, but that in the same sample of 14 advanced countries, the crises prior to the 1970s were not associated with significant rises in this ratio.

Laeven and Valencia provide a systematic dataset on the rise in debt-to-GDP ratios for all of the banking crises in their dataset. The median rise in the debt-to-GDP ratio for all systemic crises in their data was 12% of GDP while in advanced economies this figure rises to 21.4% of GDP. Fiscal costs, measured as the rise in outlays due to restructuring the financial sector had a median of 6.8% of GDP. Laeven and Valencia subtract the rise in fiscal outlays due to restructuring from the rise in total debt to calculate a rough measure of the degree of discretionary fiscal policy. The median for this variable is 7% of GDP.

Tagkalakis (2013) empirically examines the feedback loop from fiscal policy to financial markets and back in a sample of 20 OECD countries 1990–2010. Fiscal instability leads to financial instability and financial instability leads to fiscal instability via bailouts. Fratzscher and Rieth (2015) using structural VARs with daily financial markets data for 2003–13 confirm the two-way causality between sovereign risk shocks and bank risk. They find that sovereign risk shocks are more important in explaining bank risk than the reverse. In another report carried out by the European Commission (2009), the average unconditional postcrisis rise in the debt-to-GDP ratio was 18.9% of GDP. This figure is cumulative until the "end" of each crisis in the sample and covers 49 crises (Laeven and Valencia dates) for advanced and emerging economies 1970–2007.

The findings in Tagkalakis (2013) are intriguing since it appears that the rise in debt following a financial crisis is larger the bigger the size of the financial sector relative to total output. Laeven and Valencia (2013) also argue that the largest fiscal costs of crises since the 1970s have been in Ireland, Iceland, Israel (1977), Greece, and Japan (1990s).

Putting all of these findings together suggests the possibility that there is a potential tradeoff for countries along the lines of a trilemma. This financial/fiscal trilemma suggests that countries have *two* of the following three choices: a large financial sector, a large bailout package, and a strong discretionary reaction to the downturn associated with financial crises. The logic is as follows by way of an example. Assume a country with a large financial sector faces a banking crisis. If so, then the government can provide a bailout package of a size that is commensurate with the size of the financial sector. If so it uses up its fiscal space. Otherwise, it could lower the size of the bailout and devote its fiscal space to discretionary fiscal policy. With a smaller financial sector, and the same amount of fiscal space, since the size of the bailout would by definition be smaller, the size of the rise in debt due to expansionary policy could rise.

The cases of the United States and Greece post-2007 are illustrative. The United States had a large financial sector, but its bailout, as measured by the fiscal costs was relatively small (4.5% of GDP). On the other hand, the rise in the debt-to-GDP ratio not attributable to the gross costs of the bailout was on the order of 19% of GDP (Laeven and Valencia, 2012). While Greece had a rise in the ratio of debt-to-GDP (after accounting for the fiscal rescue costs) of about 17%, its downturn was much larger and likely merited, based on past experience, a much larger discretionary response. Greece's fiscal costs of the bailout are reported by LV to be 27% of GDP. Obviously, the ability of countries to finance either a bailout or a discretionary package depends on the willingness of capital markets to fund deficits. In this regard, the trilemma would be more applicable or more binding for countries which had better debt sustainability measures at the beginning of their crisis events.

To test the idea of a financial trilemma we used data from Laeven and Valencia (2012) on the change in the ratios of total government debt-to-GDP in the 3 years following a banking, twin, or triple crisis, the fiscal costs of bailouts to GDP and a residual which is the difference between the change in the debt-to-GDP ratio and the ratio of the fiscal costs-to-GDP. We used data for 19 banking crises in the advanced countries since 1970. We omit the case of Switzerland in 2008 since it had a decline in the overall debt-to-GDP ratio and our econometric model is in logs. Also emerging economies had many episodes of declines in the debt-to-GDP due to inflation which poses some issues for our initial exploration in a log-linear regression.

In the spirit of measuring a tradeoff we run the following regression:

$$\ln\left(\Delta\frac{Debt_{it}}{GDP_{it}}\right) = \kappa + \theta_1\left[\ln\left(\Delta\frac{Fiscal\ costs_{it}}{GDP_{it}}\right)\right] + \theta_2\left[\ln\left(\Delta\frac{Discretion_{it}}{GDP_{it}}\right)\right] + \varepsilon_{it} \qquad (1)$$

We do not use panel data methods in this case. Instead we study 19 episodes for the years 1970–2012. Data are for 18 countries (Austria, Belgium, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Japan, Luxembourg, Netherlands, Norway, Portugal, Sweden, United Kingdom, and United States). Fiscal costs are given by Laeven and Valencia and "Discretion" is the change in the debt-to-GDP ratio minus the ratio of fiscal costs-to-GDP. Of course, countries have differing abilities and desires for the target variable "debt" depending on market conditions, political economy issues, and the size of the financial crisis. Here we assume that crises create a need for bailouts, but that when a country spends resources on a bailout that this is associated with a tradeoff in the size of the “discretionary” response.

The results of the regression, with robust standard errors underneath the coefficients in parentheses are:

$$\ln\left(\Delta\frac{Debt_{it}}{GDP_{it}}\right)=\underset{(0.13)}{0.69}+\underset{(0.03)}{0.25}\left[\ln\left(\Delta\frac{Fiscal\ costs_{it}}{GDP_{it}}\right)\right]+\underset{(0.04)}{0.74}\left[\ln\left(\Delta\frac{Discretion_{it}}{GDP_{it}}\right)\right]$$

The results suggest that the coefficients on the two regressors add up to one and imply a tradeoff between bailouts and discretion. In Fig. 5, we plot the predicted iso-lines at given levels of the change in the ratio of debt-to-GDP. Alongside these iso-lines, we also plot the data for the 18 countries and 19 crises in our sample. The rise in the ratio of debt-to-GDP matches the data relatively well especially in the mid-range of the changes in the debt-to-GDP ratio (the R^2 of Eq. (1) is 0.97).

We also checked whether the tradeoff is apparent by interacting the fiscal costs variable with the size of the financial sector (the ratio of domestic private credit-to-GDP from IMF IFS). If the interaction term is positive then it implies that the countries with large financial sectors devote more of their fiscal space to bailouts. This is indeed what we find as seen in the following results:

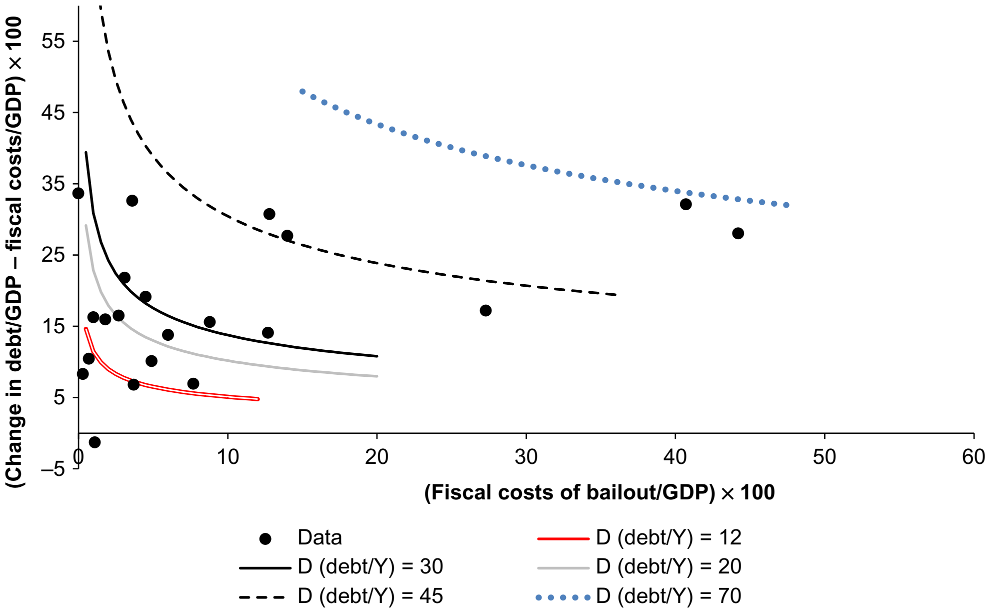

Fig. 5 Fiscal costs of bailouts vs the rise in government debt/GDP from other nonbailout costs, 19 crises, 1970–2012. Notes: *Data are from Laeven, L., Valencia, F., 2012. Systemic banking crises database: an update. IMF working paper no. 12/163. Iso-lines are the predicted values for the debt-to-GDP ratio from Eq. (1).*

$$\ln\left(\Delta\frac{Debt_{it}}{GDP_{it}}\right) = \underset{(0.49)}{1.72} + \underset{(0.24)}{-0.27}\left[\ln\left(\Delta\frac{Fiscal\ costs_{it}}{GDP_{it}}\right)\right] + \underset{(0.05)}{0.11}\Bigg[\ln\left(\Delta\frac{Fiscal\ costs_{it}}{GDP_{it}}\right)\times$$

$$\ln\left(\frac{Domestic\ credit_{it}}{GDP_{it}}\right)\Bigg] + \underset{(0.04)}{0.72}\left[\ln\left(\Delta\frac{Discretion_{it}}{GDP_{it}}\right)\right] - \underset{(0.10)}{0.22}\left[\ln\left(\frac{Domestic\ credit_{it}}{GDP_{it}}\right)\right]$$

Further investigation from a univariate regression reveals that the share of the rise in the ratio of debt-to-GDP accounted for by bailouts was a positive function of the size of the financial sector though this coefficient is not highly statistically significant. Results of the regression are seen in Fig. 6. Overall then, we find that as the size of fiscal bailouts increases, that what might be termed the discretionary component of the fiscal response is often smaller. A third factor generates a trilemma. Large financial sectors necessitate larger bailouts. If countries had small financial sectors, the constraints on discretionary fiscal action would be less binding.

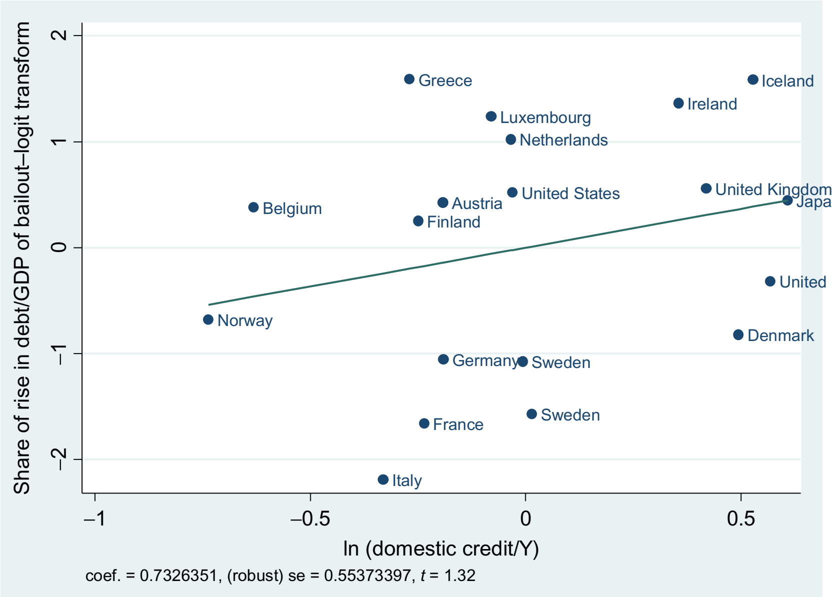

Fig. 6 Fiscal costs of a bailout as a share of the rise in debt-to-GDP vs size of the financial sector. *Notes*: Figure presents the predicted regression line/partial regression plot from a univariate regression of the share in the rise in debt as a percentage of GDP against the logarithm of the level of private domestic credit-to-GDP. We perform a logit transform on the dependent variable prior to estimation. *Debt data are from Laeven and Valencia and the credit data are from IMF IFS.*

6. CONCLUSIONS

This chapter surveyed the history, theory, and empirics of financial crises, fiscal crises and their interconnections. The history of the last two centuries shows clearly the presence of financial crises, currency crises, and debt crises somewhere in the world about every decade with five global systemic crises since the advent of globalization in the 19th century. The connection between financial crises and fiscal crises is primarily a more recent event, at least since the 1930s, although there were a number of such events in emerging market countries going back to the late 20th century. The key link between the two types of crises has been the increased use of government guarantees of financial institutions. These have surged in incidence and magnitude greatly since the Great Depression and especially since the 1980s. Governments after the Great Slump realized that banking panics were very costly events both in economic and political terms, and they have gone to great lengths to avoid the classic banking panics of the 19th and early 20th centuries and to avoid the perception of inaction. The consequence has been both more virulent modern banking crises with an increasingly strong likelihood of fiscal resolution and the accompanying fiscal resolution costs. This reflects the general phenomenon that when government intervenes to prevent costly events like forest fires and floods from occurring that economic agents adjust their behavior accordingly and use more of the protected resource than is in the long-run optimal (Ip, 2015). This has been the case with banking crises where the establishment of a safety net based on deposit insurance and other guarantees has led to regulatory forbearance and moral hazard and increased leverage by the protected financial institutions. Thus there is a tradeoff between the costs of the financial crises that accompany financial development and growth and the moral hazard costs of insurance. Under many plausible assumptions, eliminating financial crises entirely is not necessarily an achievable nor a desirable outcome (Tornell and Westermann, 2005). But neither is letting crises burn out on their own as was common in the early 19th century an ideal strategy. The optimal amount of financial crisis insurance in a world rife with market and regulatory imperfections is a subject for ongoing and future research.[bb]

The theoretical literature has evolved greatly since the mid-20th century in its treatment of different crisis phenomenon incorporating the tools of rational expectations, game theory, and dynamics. There was a burst of literature explaining banking panics in qualitative terms after the Great Depression (Friedman and Schwartz, 1963) among others. Then, after the opening up of global financial markets and the liberalization of financial markets from the post-Great Depression controls and repression, a wave of currency and banking crises swept the global economy. New innovations in theory including the Diamond–Dybvig model and first-generation speculative attack models were developed. The emerging market crises of the 1990s led to a spate of new theory

[bb] Allen and Gale (2007) discuss these issues from a theoretical perspective.

with emphasis on multiple equilibria and endogenous self-fulfilling crises. Since the 1990s, most macroeconomic models emphasize the interplay between real shocks and financial frictions with increasing sophistication. In addition, dynamic general equilibrium models are beginning to incorporate a banking sector with bank runs and liquidity.[cc] The recent subprime mortgage crisis followed by the Eurozone crisis has led to new literature focusing on the link between financial and fiscal crises linked together by government guarantees. Many of the ideas developed recently stemmed from work done after the Asian crisis of 1997. Judging from the explosion in theoretical modeling that followed the earlier waves of crises, more work will likely be done in the future on the fiscal–financial crisis nexus. Some questions that might be posed include:

- What do we know about optimal bank regulation, macroprudential policy, and the political economy of resolution? What do we know about the market failures that generate a need for such interventions?
- If it is hard to predict financial crises, can macroprudential policy and fiscal rules be reliable? Empirical research based on cross-country panel datasets has only just begun here (eg, Cerutti et al., forthcoming).
- What role does fiscal space play in the resolution phase of systemic financial crises?
- Is the way in which resolution proceeds dependent upon initial conditions and other institutional constraints?[dd]
- What kinds of fiscal union are feasible both economically and politically in a monetary union and how important are fiscal constraints under such arrangements? What fiscal arrangements are feasible and efficient in a monetary union facing systemic shocks?

Our survey of the empirical evidence on financial and fiscal crises led to our uncovering two very basic controversies: (1) Classification uncertainty: how do we define different types of financial crises and how do we date them? (2) What do we know about the costs and causes of crises? Our review of the literature and our own results based on a multi-country and multiyear database reveal that there are crucial differences over the definition of crises among the leading approaches taken in the literature. This has led to very different chronologies of the incidence of crises. This creates a serious problem for theorists and policy makers. Who should you believe? Picking the wrong approach can lead to misleading models calibrated to the wrong targets and ultimately to incorrect or misguided policy prescriptions.

If economists and policy makers truly believed that crises were an important phenomenon to understand and possibly avoid then it might be the case that an independent crisis dating committee could help set the standard in much the same way the NBER business

[cc] See, for example, Gertler and Kiyotaki (2015), Boissay et al. (forthcoming), and Paul (2016).

[dd] Steinkamp and Westermann (2014) show that the way in which resolution lending proceeds especially as regards junior or senior creditor status is associated with the country interest rate.

cycle dating committee works. The advantage of following this model is that the NBER is a respected nongovernmental, nonpartisan organization. Other organizations such as the IMF are not sufficiently politically independent. If crises are becoming increasingly global and crisis fighting is a global public good, then the importance of such a reform should be obvious. Such a committee could, if initiated, choose not only how to sensibly define crises in a uniform and consistent way, but also with an agreed definition this could help predict crises and to inform about the costs of crises.

With respect to measuring output losses, there are great differences in methodologies taken and techniques used. However, despite these differences, all of the studies agree that the output losses of financial crises are economically significant. This suggests that the stakes are high and the need for new theoretical and policy approaches to mitigate the crisis problem more compelling. The literature has some initial evidence that crises can be more severe when guarantees are not safeguarded or embedded in a reliable institutional framework. As of yet, we do not have a clear understanding of the magnitude of the impact of policies intended to mitigate crises (monetary policy, bailouts, fiscal policy). This surely must be a priority for research going forward. Any work in this direction must surely strive to meet the empirical standards set by the policy evaluation literature using credible research designs and/or sensible structural models of the phenomena in question.

Other empirical issues open up the door for further work. The question whether financial recessions lead to slow recoveries has not been resolved. Determining the leading causes of financial crises also is an open question. It is not at all obvious from the historical record that credit financed asset price boom–busts (ie, what has come to be known as the financial cycle) have always been, or will always be, the key explanation despite the recent emphasis on that explanation. Given the complexities of the financial ecosystem, perhaps some very general precepts should be at hand such as what is the level of risk and where are the risks residing?[ee] Overemphasis on one or a handful of indicators can be misleading if not dangerous for economic and financial stability. Due regard to the interconnections and systemic risks is required. Finally a question that needs more research is the connection between financial development, fiscal resolutions of crises, and overall fiscal policy goals.

Answering these questions is of the utmost importance for public policy toward financial crises. Understanding theoretically the causes and mechanics of crises and how they impinge on the real economy are crucial for the development of reasonable policies for crisis prevention, crisis management, and crisis resolution. But of course, getting the historical facts straight is also crucial. It is vital to avoid making rash generalizations which are based on overreading or misreading of economic history. Such analysis leads to pitfalls for theorizing based on stylized events that may be very far from reality and for policies

[ee] See Haldane and May (2011) on complexity and interconnections in the financial system.

designed to fight the next crisis based on a misunderstanding of what happened the last time.

The bottom line from our study is more work needs to be done on getting the historical facts correct in measuring the incidence and impact of financial crises and in understanding the true causes of crises and how they impact the real economy.

ACKNOWLEDGMENTS

We thank Sarah Quincy for invaluable research assistance. We thank conference and seminar participants at the BIS, Bonn, Bank of France, Copenhagen Business School, Hoover Institute, Kyoto World Economic History Conference, Lund, and Rutgers. Chris Cumming, Lars Jonung, Oscar Jordà, Yannick Kalantzis, John Landon-Lane, Ashoka Mody, Moritz Schularick, Anders Ögren, John B. Abstract

This chapter provides an overview of and user's guide to dynamic factor models (DFMs), their estimation, and their uses in empirical macroeconomics. It also surveys recent developments in methods for identifying and estimating SVARs, an area that has seen important developments over the past 15 years. The chapter begins by introducing DFMs and the associated statistical tools, both parametric (state-space forms) and nonparametric (principal components and related methods). After reviewing two mature applications of DFMs, forecasting and macroeconomic monitoring, the chapter lays out the use of DFMs for analysis of structural shocks, a special case of which is factor-augmented vector autoregressions (FAVARs). A main focus of the chapter is how to extend methods for identifying shocks in structural vector autoregression (SVAR) to structural DFMs. The chapter provides a unification of SVARs, FAVARs, and structural DFMs and shows both in theory and through an empirical application to oil shocks how the same identification strategies can be applied to each type of model.

Keywords

State-space models, Structural vector autoregressions, Factor-augmented vector autoregressions, Principal components, Large-model forecasting, Nowcasting, Structural shocks

1. INTRODUCTION

The premise of dynamic factor models (DFMs) is that the common dynamics of a large number of time series variables stem from a relatively small number of unobserved (or latent) factors, which in turn evolve over time. Given the extraordinary complexity and regional and sectoral variation of large modern economies, it would seem surprising a priori that such a simple idea would have much empirical support. Remarkably, it does.

Fig. 1 shows a key result for a single-factor DFM fit to 58 quarterly US real activity variables (sectoral industrial production (IP), sectoral employment, sales, and National Income and Product Account (NIPA) series); the details are discussed in Section 6. A single common factor for these series was estimated using principal components analysis, a least-squares method for estimating the unobserved factors nonparametrically discussed in Section 2. The figure shows the detrended[a] four-quarter growth rates of four measures of aggregate economic activity (real Gross Domestic Product (GDP), total nonfarm employment, IP, and manufacturing and trade sales), along with the fitted value from a regression of the quarterly growth rate of each series on the single common factor. None of the four series plotted in Fig. 1 were used to estimate the factor: although disaggregated NIPA variables like consumption of durables, of nondurables, and of services were used, total consumption, GDP, and other high-level aggregates were not. As can be seen in the figure, the single factor explains a large fraction of the four-quarter variation in these four series. For these four series, the R^2s of the four-quarter fits range from 0.73 for GDP to 0.92 for employment. At the same time, the estimated factor does not equal any one of these series, nor does it equal any one of the 58 series used to construct it.

DFMs have several appealing properties that drive the large body of research on methods and applications of DFMs in macroeconomics. First, as Fig. 1 suggests and as is discussed in more detail later, empirical evidence supports their main premise: DFMs fit the data. The idea that a single index describes the comovements of many macroeconomics variables arguably dates at least to Burns and Mitchell (1946), and additional early references are discussed in Section 2.

Second, as is discussed in the next section, the key DFM restriction of a small number of latent factors is consistent with standard dynamic equilibrium macroeconomic theories.

Third, techniques developed in the past 15 years have allowed DFMs to be estimated using large datasets, with no practical or computational limits on the number of variables. Large datasets are now readily available,[b] and the empirical application in this chapter uses a 207-variable DFM. Estimation of the factors, DFM parameters, and structural DFM impulse response functions (IRFs) takes only a few seconds. Forecasts based on large

[a] Following Stock and Watson (2012a) and as discussed in Section 6.1, the trends in the growth rates were estimated using a biweight filter with a bandwidth of 100 quarters; the displayed series subtract off these trends.

[b] For example, McCracken and Ng (2015) have compiled an easily downloaded large monthly macroeconomic dataset for the United States (FRED-MD), which is available through the Federal Reserve Bank of St. Louis FRED data tool at https://research.stlouisfed.org/econ/mccracken/fred-databases/.

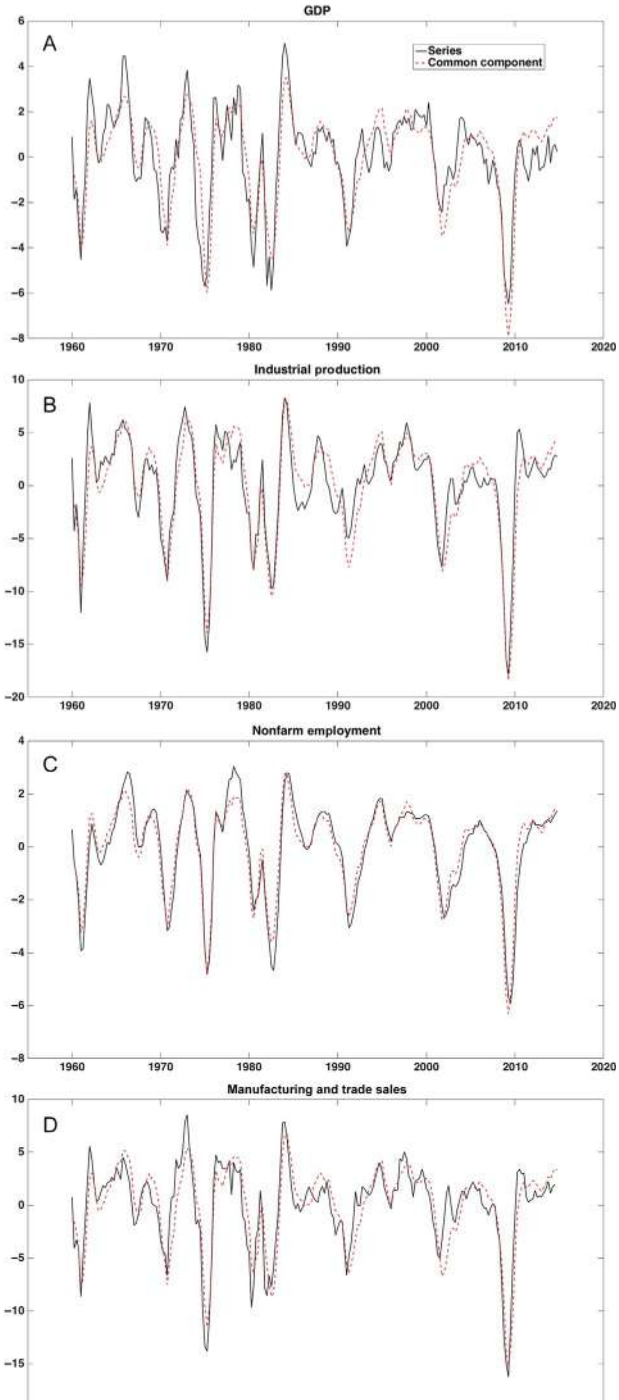

Fig. 1 Detrended four-quarter growth rates of US GDP, industrial production, nonfarm employment, and manufacturing and trade sales (*solid line*), and the common component (*fitted value*) from a single-factor DFM (*dashed line*). The factor is estimated using 58 US quarterly real activity variables. Variables all measured in percentage points.

DFMs have rich information sets but still involve a manageably small number of predictors, which are the estimates of the latent factors, and do so without imposing restrictions such as sparsity in the original variables that are used by some machine learning algorithms. As a result, DFMs have been the main "big data" tool used over the past 15 years by empirical macroeconomists.

Fourth, DFMs are well suited to practical tasks of professional macroeconomists such as real-time monitoring, including construction of indices from conceptually similar noisy time series.

Fifth, because of their ability to handle large numbers of time series, high-dimensional DFMs can accommodate enough variables to span a wide array of macroeconomic shocks. Given a strategy to identify one or more structural shocks, a structural DFM can be used to estimate responses to these structural shocks. The use of many variables to span the space of the shocks mitigates the "invertibility problem" of structural vector autoregressions (SVARs), in which a relatively small number of variables measured with error might not be able to measure the structural shock of interest.

The chapter begins in Section 2 with an introduction to structural dynamic factor models (SDFMs) and methods for estimating DFMs, both parametric (state-space methods) and nonparametric (principal components and related least-squares methods). This discussion includes extensions to data irregularities, such as missing observations and mixed observation frequencies, and covers recent work on detecting breaks and other forms of instability in DFMs.

The chapter then turns to a review of the main applications of DFMs. The first, macroeconomic monitoring and forecasting, is covered in Section 3. These applications are mature and many aspects have been surveyed elsewhere, so the discussion is relatively brief and references to other surveys are provided.

Sections 4 and 5 examine estimation of the effects of structural shocks. One of the main themes of this chapter is that the underlying identification approaches of SVARs carry over to structural DFMs. This is accomplished through two normalizations, which we call the unit effect normalization for SVARs and the named factor normalization for DFMs. These normalizations set the stage for a unified treatment, provided in these sections, of structural DFMs, factor-augmented VARs (FAVARs), and SVARs.

The basic approaches to identification of structural shocks are the same in SVARs, FAVARs, and SDFMs. Section 4 therefore surveys the identification of structural shocks in SVARs. This area has seen much novel work over the past 10 years. Section 4 is a stand-alone survey of SVAR identification that can be read without reference to other sections of this chapter and complements Ramey (2016). Section 4 discusses another of the main themes of this chapter: as modern methods for identification of structural shocks in SVARs become more credible, they raise the risk of relying on relatively small variations in the data, which in turn means that they can be weakly identified. As in applications with microdata, weak identification can distort statistical inference using both Bayes and frequentist methods. Section 4 shows how weak identification can arise in various SVAR identification strategies.

Section 5 shows how these SVAR identification schemes extend straightforwardly to SDFMs and FAVARs. Section 5 also develops another main theme of this chapter that structural DFMs, FAVARs, and SVARs are a unified suite of tools with fundamentally similar structures that differ in whether the factors are treated as observed or unobserved. By using a large number of variables and treating the factors as unobserved, DFMs "average out" the measurement error in individual time series, and thereby improve the ability to span the common macroeconomic structural shocks.

Sections 6 and 7 turn to an empirical illustration using an eight-factor, 207-variable DFM. Section 6 works through the estimation of the DFM, first using only the real activity variables to construct a real activity index, then using all the variables.

Section 7 uses the 207-variable DFM to examine the effect of oil market shocks on the US economy. The traditional view is that unexpected large increases in oil prices have large and negative effects on the US economy and have preceded many postwar US recessions (Hamilton, 1983, 2009). Subsequent work suggests, however, that since the 1980s oil shocks have had a smaller impact (eg, Hooker, 1996; Edelstein and Kilian, 2009; Blanchard and Galí, 2010), and moreover that much of the movement in oil prices is due to demand shocks, not oil supply shocks (eg, Kilian, 2009). We use a single large DFM to illustrate how SVAR identification methods carry over to structural DFMs and to FAVARs, and we compare structural DFM, FAVAR, and SVAR results obtained using two different methods to identify oil market shocks. The structural DFM results are consistent with the main finding in the modern literature that oil supply shocks explain only a fraction of the variation in oil prices and explain a very small fraction of the variation in major US macroeconomic variables since the mid-1980s.

In Section 8, we step back and assess what has been learned, at a high level, from the large body of work on DFMs in macroeconomics. These lessons include some practical recommendations for estimation and use of DFMs, along with some potential pitfalls.

There are several recent surveys on aspects of DFM analysis which complement this chapter. Bai and Ng (2008) provide a technical survey of the econometric theory for principal components and related DFM methods. Stock and Watson (2011) provide an overview of the econometric methods with a focus on applications. Bańbura et al. (2013) survey the use of DFMs for nowcasting. The focus of this chapter is DFMs in macroeconomics and we note, but do not go into, the vast applications of factor models and principal components methods in fields ranging from psychometrics to finance to big data applications in the natural and biological sciences and engineering.

2. DFMs: NOTATION AND SUMMARY OF ECONOMETRIC METHODS

2.1 The DFM

The DFM represents the evolution of a vector of N observed time series, X_t, in terms of a reduced number of unobserved common factors which evolve over time, plus uncorrelated disturbances which represent measurement error and/or idiosyncratic dynamics of the individual series. There are two ways to write the model. The dynamic form represents the dependence of X_t on lags (and possibly leads) of the factors explicitly, while the static form represents those dynamics implicitly. The two forms lead to different estimation methods. Which form is more convenient depends on the application.

The DFM is an example of the much larger class of state-space or hidden Markov models, in which observable variables are expressed in terms of unobserved or latent variables, which in turn evolve according to some lagged dynamics with finite dependence (ie, the law of motion of the latent variables is Markov). What makes the DFM stand out for macroeconometric applications is that the complex comovements of a potentially large number of observable series are summarized by a small number of common factors, which drive the common fluctuations of all the series.

Unless stated explicitly otherwise, observable and latent variables are assumed to be second-order stationary and integrated of order zero; treatment of unit roots, low-frequency trends, and cointegration are discussed in Section 2.1.4. In addition, following convention all data series are assumed to be transformed to have unit standard deviation.

Throughout this chapter, we use lag operator notation, so that $a(\mathrm{L}) = \sum_{i=0}^{\infty} a_i \mathrm{L}^i$, where L is the lag operator, and $a(\mathrm{L})X_t = \sum_{i=0}^{\infty} a_i X_{t-i}$.

2.1.1 Dynamic Form of the DFM

The DFM expresses a $N \times 1$ vector X_t of observed time series variables as depending on a reduced number q of unobserved or latent factors f_t and a mean-zero idiosyncratic component e_t, where both the latent factors and idiosyncratic terms are in general serially correlated. The DFM is,

$$X_t = \lambda(\mathrm{L}) f_t + e_t \tag{1}$$

$$f_t = \Psi(\mathrm{L}) f_{t-1} + \eta_t \tag{2}$$

where the lag polynomial matrices $\lambda(\mathrm{L})$ and $\Psi(\mathrm{L})$ are $N \times q$ and $q \times q$, respectively, and η_t is the $q \times 1$ vector of (serially uncorrelated) mean-zero innovations to the factors. The idiosyncratic disturbances are assumed to be uncorrelated with the factor innovations at all leads and lags, that is, $Ee_t\eta'_{t-k} = 0$ for all k. In general, e_t can be serially correlated. The ith row of $\lambda(\mathrm{L})$, the lag polynomial $\lambda_i(\mathrm{L})$, is called the dynamic factor loading for the ith series, X_{it}.

The term $\lambda_i(\mathrm{L})f_t$ in (1) is the *common component* of the ith series. Throughout this chapter, we treat the lag polynomial $\lambda(\mathrm{L})$ as one sided. Thus the common component of each series is a distributed lag of current and past values of f_t.[c]

The idiosyncratic disturbance e_t in (1) can be serially correlated. If so, models (1) and (2) are incompletely specified. For some purposes, such as state-space estimation discussed later, it is desirable to specify a parametric model for the idiosyncratic dynamics. A simple and tractable model is to suppose that the ith idiosyncratic disturbance, e_{it}, follows the univariate autoregression,

[c] If $\lambda(\mathrm{L})$ has finitely many leads, then because f_t is unobserved the lag polynomial can without loss of generality be rewritten by shifting f_t so that $\lambda(\mathrm{L})$ is one sided.

$$e_{it} = \delta_i(\mathrm{L})e_{it-1} + \nu_{it}, \tag{3}$$

where ν_{it} is serially uncorrelated.

2.1.1.1 Exact DFM

If the idiosyncratic disturbances e_t are uncorrelated across series, that is, $Ee_{it}e_{js} = 0$ for all t and s with $i \neq j$, then the model is referred to as the *exact dynamic factor model.*

In the exact DFM, the correlation of one series with another occurs only through the latent factors f_t. To make this precise, suppose that the disturbances (e_t, η_t) are Gaussian. Then (1) and (2) imply that,

$$\begin{aligned} E\left[X_{it}|X_t^{-i}, f_t, X_{t-1}^{-i}, f_{t-1}, \ldots\right] &= E\left[\lambda_i(L)f_t + e_{it}|X_t^{-i}, f_t, X_{t-1}^{-i}, f_{t-1}, \ldots\right] \\ &= E\left[\lambda_i(L)f_t|X_t^{-i}, f_t, X_{t-1}^{-i}, f_{t-1}, \ldots\right] \\ &= \lambda_i(L)f_t, \end{aligned} \tag{4}$$

where the superscript "$-i$" denotes all the series other than i. Thus the common component of X_{it} is the expected value of X_{it} given the factors and all the other variables. The other series X_t^{-i} have no explanatory power for X_{it} given the factor.

Similarly, in the exact DFM with Gaussian disturbances, forecasts of the ith series given all the variables and the factors reduce to forecasts given the factors and X_{it}. Suppose that e_{it} follows the autoregression (3) and that (ν_t, η_t) are normally distributed. Under the exact DFM, $E\nu_{it}\nu_{jt} = 0$, $i \neq j$. Then

$$\begin{aligned} E[X_{it+1}|X_t, f_t, X_{t-1}, f_{t-1}, \ldots] &= E[\lambda_i(L)f_{t+1} + e_{it+1}|X_t, f_t, X_{t-1}, f_{t-1}, \ldots] \\ &= \alpha_i^f(\mathrm{L})f_t + \delta_i(\mathrm{L})X_{it}, \end{aligned} \tag{5}$$

where $\alpha_i^f(\mathrm{L}) = \lambda_{i0}\Psi(\mathrm{L}) - \delta_i(\mathrm{L})\lambda_i(\mathrm{L}) + \mathrm{L}^{-1}(\lambda_i(\mathrm{L}) - \lambda_0)$.[d]

If the disturbances (e_t, η_t) satisfy the exact DFM but are not Gaussian, then the expressions in (4) and (5) have interpretations as population linear predictors.

Eqs. (4) and (5) summarize the key dimension reduction properties of the exact DFM: for the purposes of explaining contemporaneous movements and for making forecasts, once you know the values of the factors, the other series provide no additional useful information.

2.1.1.2 Approximate DFM

The assumption that e_t is uncorrelated across series is unrealistic in many applications. For example, data derived from the same survey might have correlated measurement error,

[d] Substitute (2) and (3) into (1) to obtain, $X_{it+1} = \lambda_{i0}(\Psi(\mathrm{L})f_t + \eta_{t+1}) + \sum_j \lambda_{ij}f_{t-j+1} + \delta_i(\mathrm{L})e_{it} + \nu_{it+1}$. Note that $\sum_j \lambda_{ij}f_{t-j+1} = \mathrm{L}^{-1}(\lambda_i(\mathrm{L}) - \lambda_{i0})f_t$ and that $\delta_i(\mathrm{L})e_{it} = \delta_i(\mathrm{L})(X_{it} - \lambda_i(\mathrm{L})f_t)$. Then $X_{it+1} = \lambda_{i0}(\Psi(\mathrm{L})f_t + \eta_{t+1}) + \mathrm{L}^{-1}(\lambda_i(\mathrm{L}) - \lambda_{i0})f_t + \delta_i(\mathrm{L})(X_{it} - \lambda_i(L)f_t) + \nu_{it+1}$. Eq. (5) obtains by collecting terms and taking expectations.

and multiple series for a given sector might have unmodeled sector-specific dynamics. Chamberlain and Rothschild's (1983) *approximate factor model* allows for such correlation, as does the theoretical justification for the econometric methods discussed in Section 2.2. For a discussion of the technical conditions limiting the dependence across the disturbances in the approximate factor model, see Bai and Ng (2008).

Under the approximate DFM, the final expressions in (4) and (5) would contain additional terms reflecting this limited correlation. Concretely, the forecasting Eq. (5) could contain some additional observable variables relevant for forecasting series X_{it}. In applications, this potential correlation is best addressed on a case-by-case basis.

2.1.2 Static (Stacked) Form of the DFM

The *static*, or *stacked*, form of the DFM rewrites the dynamic form (1) and (2) to depend on *r static factors* F_t instead of the q dynamic factors f_t, where $r \geq q$. This rewriting makes the model amenable to principal components analysis and to other least-squares methods.

Let p be the degree of the lag polynomial matrix $\lambda(\mathrm{L})$ and let $F_t = \left(f_t', f_{t-1}', \ldots, f_{t-p}'\right)'$ denote an $r \times 1$ vector of so-called "static" factors—in contrast to the "dynamic" factors f_t. Also let $\Lambda = (\lambda_0, \lambda_1, \ldots, \lambda_p)$, where λ_h is the $N \times q$ matrix of coefficients on the hth lag in $\lambda(\mathrm{L})$. Similarly, let $\Phi(\mathrm{L})$ be the matrix consisting of 1s, 0s, and the elements of $\Psi(\mathrm{L})$ such that the vector autoregression in (2) is rewritten in terms of F_t. With this notation the DFM (1) and (2) can be rewritten,

$$X_t = \Lambda F_t + e_t \tag{6}$$

$$F_t = \Phi(\mathrm{L}) F_{t-1} + G\eta_t, \tag{7}$$

where $G = \begin{bmatrix} \mathrm{I}_q & 0_{q\times(r-q)} \end{bmatrix}'$.

As an example, suppose that there is a single dynamic factor f_t (so $q=1$), that all X_{it} depend only on the current and first lagged values of f_t, and that the VAR for f_t in (2) has two lags, so $f_t = \Psi_1 f_{t-1} + \Psi_2 f_{t-2} + \eta_t$. Then the correspondence between the dynamic and static forms for X_{it} is,

$$X_{it} = \lambda_{i0} f_t + \lambda_{i1} f_{t-1} + e_{it} = \begin{bmatrix} \lambda_{i0} & \lambda_{i1} \end{bmatrix} \begin{bmatrix} f_t \\ f_{t-1} \end{bmatrix} + e_{it} = \Lambda_i F_t + e_{it}, \tag{8}$$

$$F_t = \begin{bmatrix} f_t \\ f_{t-1} \end{bmatrix} = \begin{bmatrix} \Psi_1 & \Psi_2 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} f_{t-1} \\ f_{t-2} \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \end{bmatrix} \eta_t = \Phi F_{t-1} + G\eta_t, \tag{9}$$

where the first expression in (8) writes out the equation for X_{it} in the dynamic form (1), $\Lambda_i = \begin{bmatrix} \lambda_{i0} & \lambda_{i1} \end{bmatrix}$ is the ith row of Λ, and the final expression in (8) is the equation for X_{it} in the static form (6). The first row in Eq. (9) is the evolution equation of the dynamic factor in (2) and the second row is the identity used to express (2) in first-order form.

In the static form of the DFM, the common component of the ith variable is $\Lambda_i F_t$, and the idiosyncratic component is e_{it}.

With the additional assumptions that the idiosyncratic disturbance follows the autoregression (3) and that the disturbances (ν_t, η_t) are Gaussian, the one step ahead forecast of the ith variable in the static factor model is,

$$E[X_{it+1}|X_t, F_t, X_{t-1}, F_{t-1}, \ldots] = \alpha_i^F(\mathrm{L})F_t + \delta_i(\mathrm{L})X_{it}, \tag{10}$$

where $\alpha_i^F = \Lambda_i\Phi(\mathrm{L}) - \delta_i(\mathrm{L})\Lambda_i$. If the disturbances are non-Gaussian, the expression is the population linear predictor.

The forecasting Eq. (10) is the static factor model counterpart of (5). In both forms of the DFM, the forecast using all the series reduces to a distributed lag of the factors and the individual series. The VAR (7) for F_t can be written in companion form by stacking the elements of F_t and its lags, resulting in a representation in which the stacked factor follows a VAR(1), in which case only current values of the stacked vector of factors enter (10).

Multistep ahead forecasts can be computed either by a direct regression onto current and past F_t and X_{it}, or by iterating forward the AR model for e_{it} and the VAR for F_t (Eqs. (3) and (7)).

In general, the number of static factors r exceeds the number of dynamic factors q because F_t consists of stacked current and past f_t. When $r > q$, the static factors have a dynamic singularity, that is, $q - r$ linear combinations of F_t are perfectly predictable from past F_t. In examples (8) and (9), there is a single dynamic factor and two static factors, and the perfectly predictable linear combination is $F_{2t} = F_{1t-1}$.

When the numbers of static and dynamic factors are estimated using macroeconomic data, the difference between the estimated values of r and q is often small, as is the case in the empirical work reported in Section 6. As a result, some applications set $r = q$ and $G = I$ in (7). Alternatively, if $q < r$, the resulting covariance matrix of the static factor innovations, that is, of $F_t - \Phi(\mathrm{L})F_{t-1} = G\eta_t$, has rank q, a constraint that can be easily imposed in the applications discussed in this chapter.

2.1.3 Normalization of the Factors

Because the factors are unobserved, they are identified only up to arbitrary normalizations. We first consider the static DFM, then the dynamic DFM.

In the static DFM, the space spanned by F_t is identified, but F_t itself is not identified: $\Lambda F_t = (\Lambda \mathrm{Q}^{-1})\ (\mathrm{Q}F_t)$, where Q is any invertible $r \times r$ matrix. For many applications, including macro monitoring and forecasting, it is necessary only to identify the space spanned by the factors, not the factors themselves, in which case Q in the foregoing expression is irrelevant. For such applications, the lack of identification is resolved by imposing a mathematically convenient normalization. The two normalizations discussed in this chapter are the "principal components" normalization and the "named factor" normalization.

2.1.3.1 Principal Components Normalization

Under this normalization, the columns of Λ are orthogonal and are scaled to have unit norm:

$$N^{-1}\Lambda'\Lambda = I_r \text{ and } \Sigma_F \text{ diagonal ("principal components" normalization)} \tag{11}$$

where $\Sigma_F = E\left(F_t F_t'\right)$.

The name for this normalization derives from its use in principal components estimation of the factors. When the factors are estimated by principal components, additionally the diagonal elements of Σ_F are weakly decreasing.

2.1.3.2 Named Factor Normalization

An alternative normalization is to associate each factor with a specific variable. Thus this normalization "names" each factor. This approach is useful for subsequent structural analysis, as discussed in Section 5 for structural DFMs, however it should be stressed that the "naming" discussed here is only a normalization that by itself it has no structural content.

Order the variables in X_t so that the first r variables are the naming variables. Then the "named factor" normalization is,

$$\Lambda^{NF} = \begin{bmatrix} I_r \\ \Lambda^{NF}_{r+1:n} \end{bmatrix}, \quad \Sigma_F \text{ is unrestricted ("named factor" normalization).} \tag{12}$$

Under the named factor normalization, the factors are in general contemporaneously correlated.[e]

The named factor normalization aligns the factors and variables so that the common component of X_{1t} is F_{1t}, so that an innovation to F_{1t} increases the common component of X_{1t} by one unit and thus increases X_{1t} by one unit. Similarly, the common component of X_{2t} is F_{2t}, so the innovation to the F_{2t} increases X_{2t} by one unit.

For example, suppose that the first variable is the price of oil. Then the normalization (12) equates the innovation in the first factor with the innovation in the common component of the oil price. The innovation in the first factor and the first factor itself therefore can be called the oil price factor innovation and the oil price factor.

The named factor normalization entails an additional assumption beyond the principal components normalization, specifically, that matrix of factor loadings on the first r variables (the naming variables) is invertible. That is, let $\Lambda_{1:r}$ denote the $r \times r$ matrix of factor loadings on the first r variables in the principal components normalization. Then $\Lambda^{NF}_{r+1:N} = \Lambda^{-1}_{1:r}\Lambda_{r+1:N}$. Said differently, the space of innovations of the first r common components must span the space of innovations of the static factors. In practice, the naming variables must be sufficiently different from each other, and sufficiently representative

[e] Bai and Ng (2013) refer to (11) and (12) normalizations as the PC1 and PC3 normalizations, respectively, and also discuss a PC2 normalization in which the first $r \times r$ block of Λ is lower triangular.

of groups of the other variables, that the innovations to their common components span the space of the factor innovations. This assumption is mild and can be satisfied by suitable choice of the naming variables.

2.1.3.3 Timing Normalization in the Dynamic Form of the DFM

In the dynamic form of the DFM, an additional identification problem arises associated with timing. Because $\lambda(\mathrm{L})f_t = [\lambda(\mathrm{L})q(\mathrm{L})^{-1}][q(\mathrm{L})f_t]$, where $q(\mathrm{L})$ is an arbitrary invertible $q \times q$ lag polynomial matrix, a DFM with factors f_t and factor loadings $\lambda(\mathrm{L})$ is observationally equivalent to a DFM with factors $q(\mathrm{L})\,f_t$ and factor loadings $\lambda(\mathrm{L})q(\mathrm{L})^{-1}$. This lack of identification can be resolved by choosing q variables on which f_t loads contemporaneously, without leads and lags, that is, for which $\lambda_i(\mathrm{L}) = \lambda_{i0}$.

2.1.4 Low-Frequency Movements, Unit Roots, and Cointegration

Throughout this chapter, we assume that X_t has been preprocessed to remove large low-frequency movements in the form of trends and unit roots. This is consistent with the econometric theory for DFMs which presumes series that are integrated of order zero (I(0)).

In practice, this preprocessing has two parts. First, stochastic trends and potential deterministic trends arising through drift are removed by differencing the data. Second, any remaining low-frequency movements, or long-term drifts, can be removed using other methods, such as a very low-frequency band-pass filter. We use both these steps in the empirical application in Sections 6 and 7, where they are discussed in more detail.

If some of the variables are cointegrated, then transforming them to first differences loses potentially important information that would be present in the error correction terms (that is, the residual from a cointegrating equation, possibly with cointegrating coefficients imposed). Here we discuss two different treatments of cointegrated variables, both of which are used in the empirical application of Sections 6 and 7.

The first approach for handling cointegrated variables is to include the first difference of some of the variables and error correction terms for the others. This is appropriate if the error correction term potentially contains important information that would be useful in estimating one or more factors. For example, suppose some of the variables are government interest rates at different maturities, that the interest rates are all integrated of order 1 (I(1)), that they are all cointegrated with a single common I(1) component, and the spreads also load on macro factors. Then including the first differences of one rate and the spreads allows using the spread information for estimation of their factors.

The second approach is to include all the variables in first differences and not to include any spreads. This induces a spectral density matrix among these cointegrated variables that is singular at frequency zero, however that frequency zero spectral density matrix is not estimated when the factors are estimated by principal components. This approach is appropriate if the first differences of the factors are informative for the common trend but the cointegrating residuals do not load on common factors. For example, in the empirical example in Sections 7 and 8, multiple measures of real oil prices are included in first differences. While there is empirical evidence that these oil prices, for example Brent and WTI, are cointegrated, there is no a priori reason to believe that the WTI-Brent spread is informative about broad macro factors, and rather that spread reflects details of oil markets, transient transportation and storage disruptions, and so forth. This treatment is discussed further in Section 7.2.

An alternative approach to handling unit roots and cointegration is to specify the DFM in levels or log levels of some or all of the variables, then to estimate cointegrating relations and common stochastic trends as part of estimating the DFM. This approach goes beyond the coverage of this chapter, which assumes that variables have been transformed to be I(0) and trendless. Banerjee and Marcellino (2009) and Banerjee et al. (2014, 2016) develop a factor-augmented error correction model (FECM) in which the levels of a subset of the variables are expressed as cointegrated with the common factors. The discussion in this chapter about applications and identification extends to the FECM.

2.2 DFMs: A Brief Review of Early Literature

Factor models have a long history in statistics and psychometrics. The extension to DFMs was originally developed by Geweke (1977) and Sargent and Sims (1977), who estimate the model using frequency-domain methods. Engle and Watson (1981, 1983) showed how the DFM can be estimated by maximum likelihood using time-domain state-space methods. An important advantage of the time domain over the frequency-domain approach is the ability to estimate the values of the latent factor using the Kalman filter. Stock and Watson (1989) used these state-space methods to develop a coincident real activity index as the estimated factor from a four-variable monthly model, and Sargent (1989) used analogous state-space methods to estimate the parameters of a six-variable real business cycle model with a single common structural shock.

Despite this progress, these early applications had two limitations. The first was computational: estimation of the parameters by maximum likelihood poses a practical limitation on the number of parameters that can be estimated, and with the exception of the single-factor 60-variable system estimated by Quah and Sargent (1993), these early applications had only a handful of observable variables and one or two latent factors. The second limitation was conceptual: maximum likelihood estimation requires specifying a full parametric model, which in practice entails assuming that the idiosyncratic components are mutually independent, and that the disturbances are normally distributed, a less appealing set of assumptions than the weaker ones in Chamberlain and Rothschild's (1983) approximate DFM.[f] For these reasons, it is desirable to have methods that can

[f] This second limitation was, it turns out, more perceived than actual if the number of series is large. Doz et al. (2012) show that state-space Gaussian quasi-maximum likelihood is a consistent estimator of the space spanned by the factors under weak assumptions on the error distribution and that allow limited correlation of the idiosyncratic disturbances.

handle many series and higher dimensional factor spaces under weak conditions on distributions and correlation among the idiosyncratic terms.

The state-space and frequency-domain methods exploit averaging both over time and over the cross section of variables. The key insight behind the nonparametric methods for estimation of DFMs, and in particular principal components estimation of the factors, is that, when the number of variables is large, cross-sectional variation alone can be exploited to estimate the space spanned by the factors. Consistency of the principal components (PC) estimator of F_t was first shown for T fixed and $N \to \infty$ in the exact factor model, without lags or any serial correlation, by Connor and Korajczyk (1986). Forni and Reichlin (1998) formalized the cross-sectional consistency of the unweighted cross-sectional average for a DFM with a single factor and nonzero average factor loading dynamics. Forni et al. (2000) showed identification and consistency of the dynamic PC estimator of the common component (a frequency-domain method that entails two-sided smoothing). Stock and Watson (2002a) proved consistency of the (time domain) PC estimator of the static factors under conditions along the lines of Chamberlain and Rothschild's (1983) approximate factor model and provided conditions under which the estimated factors can be treated as observed in subsequent regressions. Bai (2003) derived limiting distributions for the estimated factors and common components. Bai and Ng (2006a) provided improved rates for consistency of the PC estimator of the factors. Specifically, Bai and Ng (2006a) show that as $N \to \infty$, $T \to \infty$, and $N^2/T \to \infty$, the factors estimated by principal components can be treated as data (that is, the error in estimation of the factors can be ignored) when they are used as regressors.

2.3 Estimation of the Factors and DFM Parameters

The parameters and factors of the DFM can be estimated using nonparametric methods related to principal components analysis or by parametric state-space methods.

2.3.1 Nonparametric Methods and Principal Components Estimation

Nonparametric methods estimate the static factors in (6) directly without specifying a model for the factors or assuming specific distributions for the disturbances. These approaches use cross-sectional averaging to remove the influence of the idiosyncratic disturbances, leaving only the variation associated with the factors.

The intuition of cross-sectional averaging is most easily seen when there is a single factor. In this case, the cross-sectional average of X_t in (6) is $\bar{X}_t = \overline{\Lambda} F_t + \bar{e}_t$, where $\bar{X}_t$, $\overline{\Lambda}$, and $\bar{e}_t$, denote the cross-sectional averages $\bar{X}_t = N^{-1}\sum_{i=1}^{N} X_{it}$, etc. If the cross-sectional correlation among $\{e_{it}\}$ is limited, then by the law of large numbers $\bar{e}_t \xrightarrow{p} 0$, that is, $\bar{X}_t - \overline{\Lambda} F_t \xrightarrow{p} 0$. Thus if $\overline{\Lambda} \neq 0$, $\bar{X}_t$ estimates F_t up to scale. With more than one factor, this argument carries through using multiple weighted averages of X_t. Specifically, suppose that $N^{-1}\Lambda'\Lambda$ has a nonsingular limit; then the weighted average

$N^{-1}\Lambda' X_t$ satisfies $N^{-1}\Lambda' X_t - N^{-1}\Lambda'\Lambda F_t \xrightarrow{p} 0$, so that $N^{-1}\Lambda' X_t$ asymptotically spans the space of the factors. The weights $N^{-1}\Lambda$ are infeasible because Λ is unknown, however principal components estimation computes the sample version of this weighted average.

2.3.1.1 Principal Components Estimation

Principal components solve the least-squares problem in which Λ and F_t in (6) are treated as unknown parameters to be estimated:

$$\min_{F_1,\ldots,F_T,\Lambda} V_r(\Lambda, F), \quad \text{where } V_r(\Lambda, F) = \frac{1}{NT}\sum_{t=1}^{T}(X_t - \Lambda F_t)'(X_t - \Lambda F_t), \tag{13}$$

subject to the normalization (11). Under the exact factor model with homogeneous idiosyncratic variances and factors treated as parameters, (13) is the Gaussian maximum likelihood estimator (Chamberlain and Rothschild, 1983). If there are no missing data, then the solution to the least-squares problem (13) is the PC estimator of the factors, $\hat{F}_t = N^{-1}\hat{\Lambda}' X_t$, where $\hat{\Lambda}$ is the matrix of eigenvectors of the sample variance matrix of X_t, $\hat{\Sigma}_X = T^{-1}\sum_{t=1}^{T} X_t X_t'$, associated with the r largest eigenvalues of $\hat{\Sigma}_X$.

2.3.1.2 Generalized Principal Components Estimation

If the idiosyncratic disturbances have different variances and/or some are cross correlated, then by analogy to generalized least squares, efficiency gains should be possible by modifying the least-squares problem (13) for a more general weight matrix. Specifically, let Σ_e denote the error variance matrix of e_t; then the analogy to generalized least-squares regression suggests that F_t and Λ solve a weighted version of (13), where the weighting matrix is Σ_e^{-1}:

$$\min_{F_1,\ldots,F_T,\Lambda} T^{-1}\sum_{t=1}^{T}(X_t - \Lambda F_t)'\Sigma_e^{-1}(X_t - \Lambda F_t). \tag{14}$$

A solution to (14) is the infeasible generalized PC estimator, $\tilde{F}_t = N^{-1}\tilde{\Lambda}' X_t$, where $\tilde{\Lambda}$ are the scaled eigenvectors corresponding to the r largest eigenvalues of $\Sigma_e^{-1/2}\hat{\Sigma}_X\Sigma_e^{-1/2'}$.[g]

The feasible generalized PC estimator replaces the unknown Σ_e in (14) with an estimator $\hat{\Sigma}_e$. Choi (2012) shows that if $\hat{\Sigma}_e$ is consistent for Σ_e then the feasible generalized PC estimator of $\{F_t\}$ and Λ is asymptotically more efficient than principal components. Several estimators of Σ_e have been proposed. The limited amount of evidence from simulation and empirical work comparing their performance suggests that a reasonable approach is to use Boivin and Ng's (2006) two-step diagonal weight matrix approach, in which the first step is principal components (that is, identity weight matrix) and

[g] As stated in the beginning of this section, the series in X are typically preprocessed to have unit standard deviation, so in this sense the unweighted principal components estimator (13) implicitly also has weighting if it is expressed in terms of the nonstandardized data.

the second step uses a diagonal $\hat{\Sigma}_e$, where the diagonal element is the sample variance of the estimated idiosyncratic component from the first step.

Other approaches include Forni et al.'s (2005), which allows for contemporaneous covariance across the idiosyncratic terms but does not adjust for serial correlation, and Stock and Watson's (2005) and Breitung and Tenhofen's (2011), which adjusts for serial correlation and heteroskedasticity in e_{it} but not cross correlation. See Choi (2012) for additional discussion.

2.3.1.3 Extension to Restrictions on Λ

The principal components methods described in Sections 2.3.1.1 and 2.3.1.2 apply to the case that Λ and F are exactly identified using the principal components normalization. If there are additional restrictions on Λ, then principal components no longer applies but the least-squares concept does. Specifically, minimization can proceed using (13), however Λ is further parameterized as $\Lambda(\theta)$ and minimization now proceeds over θ, not over unrestricted Λ.

In general this minimization with respect to θ entails nonlinear optimization. In some leading cases, however, closed-form solutions to the least-squares problem are available. One such case is a hierarchical DFM in which there are common factors that affect all variables, and group-level factors that affect only selected variables; for example, suppose the groups are countries, the group factors are country factors, and the cross-group common factors are international factors. If the factors are normalized to be orthogonal, the first-level factors can be estimated by principal components using all the series, then the factors unique to the gth group can be estimated by principal components using the residuals from projecting the group-g variables on the first-level factors. A second case is when the restrictions are linear, so that $\text{vec}(\Lambda) = R\theta$, where R is a fixed known matrix; in this case, standard regression formulas provide an explicit representation of the minimizer $\hat{\theta}$ given $\{\hat{F}_t\}$ and vice versa.

2.3.2 Parametric State-Space Methods

State-space estimation entails specifying a full parametric model for X_t, e_t, and f_t in the dynamic form of the DFM, so that the likelihood can be computed.

For parametric estimation, additional assumptions need to be made on the distribution of the errors and the dynamics of the idiosyncratic component e_t in the DFM. A common treatment is to model the elements of e_t as following the independent univariate autoregressions (3). With the further assumptions that the disturbances ν_{it} in (3) are i.i.d. $\text{N}(0, \sigma^2_{\nu_i})$, $i = 1, \ldots, N$, η_t is i.i.d. $\text{N}(0, \Sigma_\eta)$, and $\{\nu_t\}$ and $\{\eta_t\}$ are independent, Eqs. (1)–(3) constitute a complete linear state-space model. Alternatively, the static DFM can be written in state-space form using (6), (7), and (3).

Given the parameters, the Kalman filter can be used to compute the likelihood and the Kalman smoother can be used to compute estimates of f_t given the full-sample data on

$\{X_t\}$. The likelihood can be maximized to obtain maximum likelihood estimates of the parameters. Alternatively, with the addition of a prior distribution, the Kalman filter can be used to compute the posterior distribution of the parameters and posterior estimates of the unobserved factors can be computed from the Kalman smoother. The fact that the state-space approach uses intertemporal smoothing to estimate the factors, whereas principal components approaches use only contemporaneous smoothing (averaging across series at the same date) is an important difference between the methods.

Parametric state-space methods have several advantages, including the use of quasi-maximum likelihood estimation, the possibility of performing Bayes inference, efficient treatment of missing observations (this latter point is discussed further in the next section), and the use of intertemporal smoothing to estimate the factors. However, state-space methods also have drawbacks. Historically, their implementation becomes numerically challenging when N is large because the number of parameters grows proportionately to N, making maximum likelihood estimation of the parameter vector prohibitive.[h] In addition, state-space methods require specifying the degree of the factor loading lag polynomial and models for the factors and for the idiosyncratic terms. These modeling choices introduce potential misspecification which is not reflected in the model-based inference, that is, standard errors and posterior coverage regions are not robust to model misspecification.

2.3.3 Hybrid Methods and Data Pruning

2.3.3.1 Hybrid Methods

One way to handle the computational problem of maximum likelihood estimation of the state-space parameters is to adopt a two-step hybrid approach that combines the speed of principal components and the efficiency of the Kalman filter (Doz et al., 2011). In the first step, initial estimates of factors are obtained using principal components, from which the factor loadings are estimated and a model is fit to the idiosyncratic components. In the second step, the resulting parameters are used to construct a state-space model which then can be used to estimate F_t by the Kalman filter. Doz et al. (2011) show that, for large N and T, the resulting estimator of the factors is consistent for the factor space and is robust to misspecification of the correlation structure of the idiosyncratic components, and thus has a nonparametric interpretation.

2.3.3.2 Pruning Datasets and Variable Selection

The discussion so far assumes that all the variables have been chosen using a priori knowledge to include series that are potentially valuable for estimating the factors. Because the emphasis is on using many variables, one possibility is that some extraneous variables

[h] Durbin and Koopman (2012, section 6.5) discuss computationally efficient formulae for Kalman filtering when N is large.

could be included, and that it might be better to eliminate those variables. Whether this is a problem, and if so how to handle it, depends on the empirical application. If there is a priori reason to model the factors as applying to only some variables (for example, there are multiple countries and interest is in obtaining some country-specific and some international factors) then it is possible to use a hierarchical DFM. In effect this prunes out variables of other countries when estimating a given country factors. Another approach is to use prescreening methods to prune the dataset, see for example Bai and Ng (2006a). Alternatively, sparse data methods can be used to eliminate some of the variables, for example using a sparsity prior in a state-space formulation (eg, Kaufmann and Schumacher, 2012).

2.3.4 Missing Data and Mixed Data Sampling Frequencies

Missing data arise for various reasons. Some series might begin sooner than others, the date of the final observation on different series can differ because of timing of data releases, and in some applications the series might have different sampling frequencies (eg, monthly and quarterly). The details of how missing data are handled differ in principal components and state-space applications. All the procedures in common use (and, to the best of our knowledge, all the procedures in the literature) adopt the assumption that the data are missing at random. Under the missing-at-random assumption, whether a datum is missing is independent of the latent variables (no endogenous sample selection). The missing-at-random assumption arguably is a reasonable assumption for the main sources of missing data in DFMs in most macroeconomic applications to date.

2.3.4.1 Principal Components Estimation with Missing Data

The solution to the least-squares problem (13) in terms of the eigenvalues of $\hat{\Sigma}_X$ holds when all NT observations are nonmissing, that is, when the panel is balanced. When there are missing observations, least-squares still can be used to estimate F_t and Λ, however the solution must be obtained numerically. Specifically, the modification of (13) when there is missing data is,

$$\min_{F_1,\ldots,F_T,\Lambda} \frac{1}{NT}\sum_{i=1}^{N}\sum_{t=1}^{T} S_{it}(X_{it} - \Lambda_i F_t)^2, \tag{15}$$

where $S_{it} = 1$ if an observation on X_{it} is available and $S_{it} = 0$ otherwise and where Λ_i is the ith row of Λ. The objective function in (15) can be minimized by iterations alternating with Λ given $\{F_t\}$ then $\{F_t\}$ given Λ; each step in the minimization has a closed-form expression. Starting values can be obtained, for example, by principal component estimation using a subset of the series for which there are no missing observations. Alternatively, Stock and Watson (2002b) provide an EM algorithm for handling missing observations.

Given an estimate of the factor loadings and factors based on missing data, the estimated common component for the ith series remains $\hat{\Lambda}_i\hat{F}_t$ and the one step ahead forecast is given by (10), where the parameters of (10) are estimated treating $\hat{F}_t$ as data.

2.3.4.2 State-Space Estimation with Missing Data

The state-space framework can be adapted to missing data by allowing the measurement Eq. (1) to vary depending on what data are available at a given date t; see Harvey (1989, p. 325). Alternatively, the dimension of the measurement equation can be kept the same by including a proxy value for the missing observation while adjusting the model parameters so that the Kalman filter places no weight on the missing observation. See Giannone et al. (2008), Mariano and Murasawa (2010), and Marcellino and Sivec (2014) for variations on this latter approach.

For large N, one computational challenge is keeping the dimension of the state vector small as N grows, which is more complicated with missing observations than with all observations nonmissing; see Jungbacker et al. (2011) and Bańbura and Modugno (2014) for discussion and proposed computationally efficient solutions.

One theoretical advantage of the state-space approach to mixed frequencies is that it can pin down when precisely the measurement occurs (eg, the US establishment survey measures payroll employment during the week including the 12th of the month). A second theoretical advantage of the state-space approach is that it can explicitly differentiate between stock variables (observed at a point in time, like employment) and flow variables (temporal averages, like GDP). In practice, dealing with flows is complicated, however, because the flow aggregation identities are in levels but the variables being measured, such as sectoral output, are typically best modeled in growth rates. These complications require approximations and can substantially increase the dimension of the latent state variable. For an application with mixed sampling frequencies and mixed stock and flow variables, see Aruoba et al. (2009). See Foroni and Marcellino (2013) for a survey of methods for handling mixed-frequency data, including DFMs and alternative approaches.

There appears to be little research comparing the performance of parametric and nonparametric approaches to mixed-frequency data.

2.3.5 Bayes Methods

An alternative approach to estimating DFMs is to use Bayes methods. In Bayesian estimation, the DFM parameters are treated as random draws from a prior distribution. Because the factors are unobserved and multiplied by the coefficients, Bayesian inference is more complicated than it is in the standard regression model with observed regressors and conjugate priors, and Bayesian DFM estimation requires using modern numerical techniques.

The first Bayesian treatments of DFMs of which we are aware are Kim and Nelson (1998) and Otrok and Whiteman (1998), who both estimated a small single-factor system using Markov Chain Monte Carlo methods. Kim and Nelson (1998) also incorporated Markov switching in the process for the latent factor. In other early work, Kose et al. (2003) extend Otrok and Whiteman (1998) to a 180-variable system with international macroeconomic data, using a hierarchical regional/country structure. Aguilar and West (2000) developed Bayes methods for estimating dynamic factor models with stochastic volatility, which they apply to multivariate financial time series.

A theoretical advantage of Bayes methods is that the mean squared error of some functions of the estimated parameters (such as in forecast functions) can be reduced by shrinkage. Koopman and Mesters (forthcoming) take an empirical Bayes approach to estimating the efficient amount of shrinkage. Their algorithm iterates between estimation of the factors by Gaussian signal extraction (Kalman smoother) and Bayes estimation of the parameters given the consistently estimated factors.

To date, the dominant methods used in macro applications are Frequentist, especially the computationally straightforward methods based on principal components. This chapter therefore focuses on Frequentist methods for estimation of DFMs. However, because the number of parameters in Λ is large, Bayes methods for DFMs are a promising area for improving estimator and forecast performance from a Frequentist perspective.

2.4 Determining the Number of Factors

2.4.1 Estimating the Number of Static Factors r

The number of static factors r can be determined by a combination of a priori knowledge, visual inspection of a scree plot, and the use of information criteria and other statistical measures.

2.4.1.1 Scree Plots

A *scree plot* displays the marginal contribution of the kth principal component to the average R^2 of the N regressions of X_t against the first k principal components. This marginal contribution is the average additional explanatory value of the kth factor. When there are no missing data, the scree plot is a plot of the ordered eigenvalues of $\hat{\Sigma}_X$, normalized by the sum of the eigenvalues.

2.4.1.2 Information Criteria

Information criteria, such as the Akaike information criterion, use a penalized objective function to trade off the benefit of including an additional parameter against the cost of increased sampling variability. Bai and Ng (2002) extend this idea to including an additional factor using the penalized sum of squares,

$$IC(r) = \ln V_r\left(\hat{\Lambda}, \hat{F}\right) + rg(N, T), \tag{16}$$

where $V_r\left(\hat{\Lambda}, \hat{F}\right)$ is the least-squares objective function in (13) evaluated at the PCs $\left(\hat{\Lambda}, \hat{F}\right)$, and where $g(N,T)$ is a penalty factor such that $g(N,T) \rightarrow 0$ and $\min(N,T)g\ (N,T) \rightarrow \infty$ as $N,\ T \rightarrow \infty$. Bai and Ng (2002) provide conditions under which the value of r that minimizes an information criterion with $g(N,T)$ satisfying these conditions is consistent for the true value of r. A commonly used penalty function is the Bai and Ng (2002) IC_{p2} penalty, for which $g(N,T) = [(N+T)/NT]\ln[\min(N,T)]$. When $N = T$, this penalty simplifies to two times the BIC penalty, $T^{-1}\ln T$. Monte Carlo evidence suggests that this penalty function works well in designs calibrated to macroeconomic data.

2.4.1.3 Other Approaches

Onatski (2010) provides an alternative consistent estimator of r which estimates r as the largest value of k for which the difference between eigenvalues k and $k+1$ of $\hat{\Sigma}_X$ exceeds a threshold provided in that paper; this estimator corresponds to finding the final "cliff" in the scree plot larger than that threshold. Similarly, Ahn and Horenstein (2013) show that an alternative consistent estimator of r is obtained as the maximizer of the ratio of eigenvalue k to eigenvalue $k+1$; their estimator corresponds to locating the largest "relative cliff" in the scree plot. Onatski (2009) takes a different approach and considers tests as opposed to estimation of r by information criteria.

Practical experience suggests that different methods frequently give different estimates. There is limited research comparing the performance of the different methods. This sensitivity suggests that it is important to augment the statistical estimators with inspection of the scree plot and with judgment informed by the application at hand.

2.4.2 Estimating the Number of Dynamic Factors q

In principle, the number of dynamic factors can be less than the number of static factors and if so, the static factors follow a singular dynamic process. Framed in terms of (7), these singularities arise because the covariance matrix of the innovations to F_t (that is, $G\eta_t$ in (7)) is singular with rank $q < r$. This implies that the spectral density matrix of F_t is singular. Estimation of q given r entails estimating the rank of this singularity. Although in principle an information criterion could be used to estimate the number of dynamic factors based on the likelihood of the dynamic form of the DFM, estimating q given r has the advantage that it is unnecessary to compute that likelihood.

There are three related methods for consistently estimating q given r. Amengual and Watson (2007) first compute the residual of the projection of X_t onto lagged values of the PC estimator of F_t, then apply the Bai and Ng (2002) information criterion to the covariance matrix of those residuals. Bai and Ng (2007) work directly with the factors and use an information criterion to estimate the rank of the residual covariance matrix of a VAR estimated using the r principal components. In contrast to these two approaches, Hallin and Liška (2007) propose a frequency-domain procedure which uses an information criterion to estimate the rank of the spectral density matrix of X_t. There seems to be limited research comparing these methods.

2.5 Breaks and Time-Varying Parameters

The discussion so far has considered DFMs with time-invariant parameters. In many applications, however, there is at least the possibility of parameter instability. This section reviews the robustness of PC estimator of the factors to small breaks. If, however, the instability is large and widespread, the full-sample PC estimator breaks down. As a result, in many applications it is important to check for and/or model structural instability in the factor loadings. There are two broad approaches to handling instability in DFMs: positing a break in the parameters, and modeling the parameters as evolving stochastically.

2.5.1 Robustness of PC to Limited Instability

If the amount of instability is small and/or limited across variables, the PC estimator of the factors remains consistent. The intuition behind this initially surprising result can be seen by returning to the example of Section 2.3.1 of the cross-sectional average when there is a single factor. Suppose that the static factor loading matrix is time dependent, so that Λ in (6) is replaced by Λ_t. Then $\bar{X}_t = \bar{\Lambda}_t F_t + \bar{e}_t$, where $\bar{\Lambda}_t$ is the cross-sectional average of Λ_t. Let $\bar{\bar{\Lambda}}$ denote the time average of $\bar{\Lambda}_t$. Then $\bar{X}_t - \bar{\bar{\Lambda}} F_t = \left(\bar{\Lambda}_t - \bar{\bar{\Lambda}}\right) F_t + \bar{e}_t$. If only a vanishing fraction of series have a break in their factor loadings, or if the breaks in Λ_{it} are stochastic, have limited temporal dependence, and are uncorrelated across series, or if Λ_{it} has persistent drift which has mean zero and is uncorrelated across series, then by the law of large numbers $\bar{\Lambda}_t - \bar{\bar{\Lambda}} \xrightarrow{p} 0$ and $\bar{e}_t \xrightarrow{p} 0$ so that $\bar{X}_t - \bar{\bar{\Lambda}} F_t \xrightarrow{p} 0$. Thus, despite this nontrivial instability, if $\bar{\bar{\Lambda}}$ is nonzero, $\bar{X}_t$ estimates the factor up to scale.

Bates et al. (2013) provide general conditions on parameter instability under which the PC estimator remains consistent. They show, for example, that the factor estimates remain consistent if there is a large discrete break in the factor loadings for a fraction $O(N^{-1/2})$ of the series, or if the factor loadings follow independent random walks with relatively small innovations, as long as those innovations are independent across series.[i] For these instabilities, tests for stability of Λ would reject with probability tending to one in large samples but the PC estimator remains consistent.[j]

Despite these robustness results for the estimated factors, the coefficients in any specific equation could have large drift or breaks. Stock and Watson (2009) provide evidence

[i] Specifically, Bates et al. (2013) show that if $\Lambda_t = \Lambda_0 + h_{NT}\xi_t$, where $h_{NT} = O(1/\min[N^{1/4}T^{1/2}, T^{3/4}])$, then the estimated factors achieve the Bai and Ng (2002) mean square consistency rate of $1/\min(N,T)$.

[j] Stock and Watson (2009) provide some empirical evidence that suggests the relevance of such breaks. In a pseudo out-of-sample forecasting exercise using US macroeconomic data, they find evidence of a break in 1984 in the factor loadings, but also find that the best forecasts are produced by estimating the factors over the full data span but estimating the factor loadings over the post-1984 subset.

that allowing for such instability can be important in practice when interest is in a specific series (say, for forecasting), even if full-sample principal components estimates of the factors are used.

2.5.2 Tests for Instability

Despite this insensitivity of the PC estimator to some forms of instability in the factor loadings, principal components is not robust to widespread large breaks or to large time variation in Λ that is systematically correlated across series. Following Stock and Watson (2009) and Breitung and Eickmeier (2011), consider the case in which Λ takes on two values:

$$X_t = \Lambda_t F_t + e_t, \quad \Lambda_t = \begin{cases} \Lambda^{(1)} \text{ if } t < \tau \\ \Lambda^{(2)} \text{ if } t \geq \tau \end{cases}. \tag{17}$$

For this discussion, suppose the dynamics of the factor structure does not change. Thus the DFM holds in both regimes, with the same r factors, but with different factor loadings. As shown by Stock and Watson (2009) and Breitung and Eickmeier (2011), if the break in Λ is widespread across the series, the split-sample PC estimators of the factors will differ from each other. Moreover, if there are r factors in each subsample and a widespread break in Λ, then in the full sample it will appear as though there are $2r$ factors. Breitung and Eickmeier (2011) provide Monte Carlo evidence that as a result the Bai and Ng (2002) procedure would systematically overestimates the number of factors.

There are now a number of tests for breaks in the factor loadings. Stock and Watson (2009) consider the problem of breaks in a single equation and suggest regressing each variable on the estimated factors and implementing break tests for each regression. Breitung and Eickmeier (2011) consider a related Lagrange multiplier test that handles breaks in a fixed finite number of DFM equations; their test appears to improve size control, relative to the Stock and Watson (2009) approach. Tests proposed by Chen et al. (2014) and Han and Inoue (2015) test for a general break in Λ (all equations) by noting that, if Λ changes, the covariance matrix of the full-sample PC estimator will change at the break date in Λ. Chen et al.'s (2014) test entails testing for a break in the regression of one of the estimated factors on the others. Han and Inoue (2015) test for a break in the full covariance matrix of the PC estimator of the factors. All the foregoing break tests generalize to unknown break dates using standard methods. Cheng et al. (Forthcoming) take a different approach and extend LASSO methods to consider changes in the factor loadings and/or changes in the number of factors.

Care must be taken when interpreting these break tests for at least two reasons. First, although these tests are for a discrete break, break tests have power against other types of parameter instability, in particular against drifting parameters.[k]

[k] See, for example, Stock and Watson (1998) and Elliott and Müller (2006).

Second, a more subtle issue of interpretation is that, although these tests are designed to detect breaks in Λ and thus breaks in the factor space, at least some of them will have power against heteroskedasticity in the factor innovations and/or breaks in the VAR process followed by the factors. This power against heteroskedasticity in some tests but not others arises because of different normalizations used in the tests. In principle, these different sources of instability—breaks in Λ, heteroskedasticity in the factor innovations, and breaks in the VAR process for F_t—are separately identified. These tests are new and their relative power against different types of breaks has not been studied in any detail. Because the modeling and substantive implications of a widespread break in Λ are quite different from those of a change in the volatility of the factor innovations, interpretation of rejections must be sensitive to this ambiguity.[1]

2.5.3 Incorporating Time-Varying Factor Loadings and Stochastic Volatility

Although tests for stability can detect breaks or evolution of the DFM parameters, the empirical significance of that instability must be assessed by estimating the model taking into account the instability.

The most straightforward way to estimate the DFM taking into account the instability is through subsample estimation. However, doing so presumes a single common break date, and in many applications one might be concerned about continuous parameter drift, volatility clustering, or breaks for different series at different dates. If so, then it is appropriate to use a more flexible model of parameter change than the single common break model.

An alternative approach to time variation is to model the parameters as evolving stochastically rather than breaking at a single date. If parameter variation is small, this approach can be implemented in two steps, first estimating the factors by least squares, then estimating a time-varying model treating the factors as observed. See, for example, Cogley and Sargent (2005) for time-varying parameter VAR methods for observed variables; for recent contributions and references see Korobilis (2014). Eickmeier et al. (2015)

[1] Empirical work applying break tests to DFMs suggests that DFM parameters have changed over the postwar sample. In particular, there is evidence of a break in the factor loadings around onset of the Great Moderation. Stock and Watson (2009) find evidence of a break in 1984, the only date they consider. Breitung and Eickmeier (2011) apply their tests for breaks at an unknown date and find breaks in multiple equations with estimated break dates around 1984. Chen et al. (2014) also find breaks around 1980. Stock and Watson (2012a) and Cheng et al. (Forthcoming) find evidence of breaks at the onset of the 2007 recession. Stock and Watson (2012a) find that this break is in the variances of the factor innovations (in Σ_η), whereas Cheng et al. find that the breaks are in Λ. However, the Cheng et al. normalization imposes homoskedasticity in the factor innovations, so in their test a change in Σ_η would appear as a change in Λ; thus both sets of results are consistent with the break being in Σ_η. All these papers examine quarterly US data.

work through the details of this two-step approach to time variation in DFMs. Using the results in Bates et al. (2013) as motivation, Eickmeier et al. (2015) suggest estimating the factors by principal components and treating them as observed. The time variation in the DFM is now easily handled equation-by-equation. They apply these methods in a time-varying FAVAR, but the methods equally apply to DFMs once one treats the estimated factors as observed.

If, however, the parameter variation is large then (as discussed in the previous section) this approach will yield misleading estimates of the factors. Consequently, recent work has focused on treating the factors as unobserved while allowing for and estimating time-varying stochastic processes for the factor loadings. An additional extension is to stochastic volatility in the innovations to the factors and idiosyncratic terms, which allows both for additional time variation in the implied filter and for volatility clustering in the data.

Much of the current work on time-varying DFMs uses or extends the model of del Negro and Otrok (2008). Their model allows the factor loadings to evolve according to a random walk: $\Lambda_{it} = \Lambda_{it-1} + \sigma_{\Delta\Lambda,i}\zeta_{\mathrm{it}}$, where ζ_{it} is an i.i.d. $N(0,1)$ disturbance. They also allow for time variation in the factor VAR coefficients and in the autoregressive coefficients describing the idiosyncratic dynamics. Finally, del Negro and Otrok (2008) allow for stochastic volatility in the innovations to the factors and to the idiosyncratic disturbances. The result of these extensions of the DFM is that the state evolution equation is a nonlinear function of the state variables so that while it remains a hidden Markov model, it can no longer be estimated by the Kalman filter. Del Negro and Otrok (2008) show how the model can instead be estimated by numerical Bayes methods. Papers that apply this algorithm or variants to DFMs with time-varying parameters include Mumtaz and Surico (2012), Bjørnland and Thorsrud (2015a), and Stock and Watson (2015). The details of these methods go beyond the scope of this chapter.

3. DFMs FOR MACROECONOMIC MONITORING AND FORECASTING

Two classic applications of DFMs are to real-time macroeconomic monitoring and to forecasting. The early hope of some researchers for DFMs—initially small DFMs and later "big data" high-dimensional DFMs—was that their ability to extract meaningful signals (factors) from noisy data would provide a breakthrough in macroeconomic forecasting. This early optimism turned out to be misplaced, arguably mainly because so many of the shocks that matter the most for the economy, such as the invasion of Kuwait by Iraq in August 1990 and the financial crisis in the fall of 2008, are simply not known in advance. This said, DFMs have resulted in meaningful forecasting improvements, especially for measures of real economic activity. They have also proven particularly useful for the important task of macroeconomic monitoring, that is, tracking economies in real time. The literature on using DFMs for forecasting and macro monitoring is vast. This section provides a selective survey of that literature, discusses some technical issues at a high level, and provides references for readers interested in the technical details.

3.1 Macroeconomic Monitoring

Economists at central banks, executive branches of government, and in the private sector track the evolution of the economy in real time, that is, they monitor the macroeconomy. A key part of macroeconomic monitoring is following and interpreting data releases to glean insights as to where the economy is at present, and where the economy is going. Macroeconomic monitoring has two salient challenges. First, data releases are peppered throughout the month and quarter, so that the available data change from day to day or even within a day, a feature referred to as the "ragged edge" problem. Second, the number of data releases and series contained within those releases is vast. Handling this flow of large volumes of disparate data requires judgment and knowledge of idiosyncratic events. Increasingly, the job of macroeconomic monitoring has also benefited from systematic high-dimensional modeling in the form of DFMs.

DFMs are used for two related macro monitoring tasks. The first is the construction of indices that distill the currently available data into a concise summary of economic conditions. The second is *nowcasting*, which is the task of "forecasting" the current value of a specific series which has not yet been released, for example, forecasting the value of fourth-quarter GDP in November.

3.1.1 Index Construction

A natural application of DFMs is to a classic problem in empirical macroeconomics, the construction of an index of indicators of economic activity. In the DFM, the latent factor summarizes the comovements of the observed variables, so in a DFM with a single factor, the estimate of the latent factor is a natural index of the movements of the relevant time series.

The first application of DFMs for real-time macromonitoring was the Stock and Watson (1989, 1991) experimental coincident index (XCI), which was released monthly through the National Bureau of Economic Research from May 1989 to December 2003. The XCI was the Kalman filter estimate of the single common factor among four monthly coincident indices: total nonfarm employment, the index of IP, real manufacturing and trade sales, and real personal income less transfers. The DFM was estimated by maximum likelihood in state-space form. This system handled the "ragged edge" problem of one of the series (real personal income less transfers) being available with a substantial delay, so the initial release of the index used a reduced-dimension measurement equation for the final observation. Retrospective analysis of the real-time experience showed that the XCI was successful in contemporaneous monitoring and (using a companion model for the probability of recessions) in real-time detection of the recession of 1990, however, the XCI and its associated leading index did not forecast the recession at the target 6-month horizon (Stock and Watson, 1993).

Subsequent work with small state-space DFMs include the construction of monthly real activity indices for US states (Crone and Clayton-Matthews, 2005), which has been released in real time by the Federal Reserve Bank of Philadelphia since 2005. Mariano and Murasawa (2003) extended the XCI to mixed-frequency data by including quarterly GDP. Aruoba et al. (2009) developed a weekly index using mixed-frequency data (weekly, monthly, and quarterly), and the resulting "ADS" index is released in real time by the Federal Reserve Bank of Philadelphia.

Much of the recent work on index construction has focused on higher dimensional systems. Since January 2001, the Federal Reserve Bank of Chicago has released in real time the monthly Chicago Fed National Activity Index (CFNAI), which is the principal components estimate of the common factor in 85 real activity variables based on the real activity index constructed in Stock and Watson (1999). Since January 2002, the UK Centre for Economic Policy Research has released in real time the monthly EuroCOIN index of EU real economic activity. EuroCOIN was developed by Altissimo et al. (2001) and initially incorporated 951 Euro-area activity variables.[m] The index was updated in Altissimo et al. (2010); that version entails estimating the factors by principal components using 145 Euro-area real activity variables.

3.1.2 Nowcasting

Nowcasting focuses on predicting the current value of observable variables, such as current-quarter GDP. Nowcasting has long been done by economists using methods that allow the use of mixed-frequency data and intermittent releases. The older methods do not specify joint distributions and in general are variable-specific, often without a model structure tying together nowcasts across variables or over time as data become available. In contrast, DFMs permit specifying an internally consistent model that can be used for nowcasting multiple variables while placing appropriate weight on new data releases. Early nowcasting applications that use high dimensions and mixed frequencies in a state-space setting are Evans (2005), Giannone et al. (2008), and Angelini et al. (2010). Aastveit et al. (2014) extend these methods to compute density nowcasts (not just point nowcasts) of GDP growth. Bańbura, Giannone, Modugno, and Reichlin (2013) survey recent developments and technical issues in nowcasting.

[m] The index is calibrated to the smoothed component of GDP growth, specifically the reported index is the common component of Euro-area GDP, filtered to eliminate high-frequency variation.

3.2 Forecasting

The literature on forecasting with DFMs is very large and we do not attempt a comprehensive survey, instead we make some high-level comments. Eickmeier and Ziegler (2008) provide a survey and meta-analysis of work in the field through the mid-2000s. They find that factor forecasts tend to outperform small-model forecasts, and that factor forecasts tend to work better for US real activity than for US inflation. For more recent references, extensions of DFM forecasting methods, and comparisons to other high-dimensional methods, see Stock and Watson (2012b), D'Agostino and Giannone (2012), Clements (Forthcoming), and Cheng and Hansen (2015).

4. IDENTIFICATION OF SHOCKS IN STRUCTURAL VARs

This section provides a self-contained survey of contemporary methods for identification of structural VARs. The methods are presented in a unified way that allows them to be adapted directly to structural DFMs, as discussed in the next section.

A long-standing goal of empirical macroeconomics is to estimate the effect on the economy of unanticipated structural disturbances, commonly called shocks. Examples of shocks include an unanticipated rate hike by the central bank (a monetary policy shock), an unexpected jump in oil prices due to oil supply disruptions (oil supply shock), an unexpected improvement in productivity (productivity shock), and an unanticipated shift in aggregate demand (demand shock). These shocks induce unexpected changes in the values of economic variables, for example, a contractionary monetary policy shock increases the short-term interest rate. Because these shocks are autonomous, they are uncorrelated with other shocks. Because shocks are unanticipated, they are serially uncorrelated.[n]

If a time series of shocks were observed, it would be straightforward to estimate the effect of that shock, say ε_{1t}, on a macro variable y_t by regressing y_t on current and past values of ε_{1t}. Because the shock ε_{1t} is uncorrelated with the other shocks to the economy, that regression would have no omitted variable bias. The population coefficients of that regression would be the dynamic causal effect of that shock on the dependent variable, also called the structural impulse response function (SIRF). The cumulative sum of those population coefficients would be the cumulative causal effect of that shock over time, called the cumulative SIRF. Thus if the time series of shocks were observed, its dynamic effect could be estimated in a way that required no additional modeling assumptions. Unfortunately, a complete time series of shocks is rarely if ever observed—a constructed time series of shocks will have measurement error and/or miss some events—so that this ideal regression of y_t on current and past ε_{1t} typically is infeasible.

[n] See the chapter by Ramey (2016, this Handbook) for an extensive discussion of shocks in structural VARs.

Because direct observation of a complete series of shocks without measurement error typically is infeasible, a large number of methods have been developed to identify shocks in time series models with a minimum of additional assumptions. The dominant framework for this identification, due to Sims (1980), is structural vector autoregressions. The premise of SVARs is that the space of the innovations to a vector of time series variables Y_t—that is, the one step ahead forecast errors of Y_t based on a population projection of Y_t onto its past values—spans the space of the structural shocks. Said differently, in population the econometrician is assumed to be as good at one step ahead forecasting of the economy as an agent who directly observes the structural shocks in real time. The task of identifying the structural shock of interest thus reduces to the task of finding the linear combination of the innovations that is the structural shock. Sims (1980) originally proposed doing this construction using short-run "timing" restrictions. Subsequently, a host of other approaches for identifying structural shocks have been developed, including long-run restrictions based on the cumulative SIRFs, identification by heteroskedasticity, partial identification by sign restrictions on the SIRFs, and most recently by the use of external instruments.

This section has four themes. The first is the quest in the literature for increasingly credible identification schemes. This emphasis on identification parallels the identification revolution in microeconometrics, which stresses the importance of credible restrictions, typically in the form of isolating as-if random variation in the data, to identify a causal effect of interest.

Second, methods that identify a unique SIRF of interest (that is, identification schemes in which the SIRF is point identified) have natural interpretations in terms of instrumental variables or generalized method of moments (GMM) regression.

Third, we stress the importance of the choice of normalization of the shocks and make the case for what we call the unit effect normalization, which is different than the prevalent normalization that sets the shock variance to one. Although this normalization choice does not matter in population, it *does* matter in sample, and we argue that the unit effect normalization is the most natural in most applications. Moreover, the unit shock normalization makes the extension of SVAR methods to structural DFMs straightforward.

The fourth theme ties the previous three together: this quest for credible identification can push a research design to focus on exogenous movements that explain only a small fraction of the variation in the data, which in turn can affect inference. In the point-identified settings, we cast this potential pitfall in terms of weak instruments or weak identification. In the set-identified settings (eg, identification of SVARs by sign restrictions), these issues arise in the form of sensitivity of inference to Bayesian prior distributions, even if those priors are intended to be, in some sense, uninformative.

The focus of this section is explicating the normalization, identification schemes, and issues raised by weak identification. We provide references to, but spend little time on, conventional methods of inference, which is typically done using bootstrap methods (Kilian, 1998, 2001) or by computing a Bayesian posterior distribution (Sims and Zha, 1998, 1999). For textbook treatments of VARs, conventional asymptotics, and conventional inference, see Lütkepohl (2015). Kilian (2015) and Bjørnland and Thorsrud (2015b) provide complementary summaries of SVAR methods, with more details and examples than are given here but without the focus on our four themes.

This section is written to complement the chapter by Ramey (2016, this Handbook); while the broad coverage of material is similar, this section focuses more on methods and econometric issues, while Ramey's chapter focuses more on applications and assessing identification in practice.

Section 4.1 lays out the SVAR notation and assumptions, including the normalization condition in Section 4.1.3. Various methods for identifying the SIRFs are discussed in Sections 4.2–4.7.

4.1 Structural Vector Autoregressions

SVAR analysis undertakes to identify the structural impulse responses of observable variables to one or more shocks, which are linear combinations of the VAR innovations.

4.1.1 VARs, SVARs, and the Shock Identification Problem

4.1.1.1 The VAR

Let Y_t be a $n \times 1$ vector of stationary time series, assumed for convenience to have mean zero. A pth order VAR model represents Y_t as a linear function of its first p lagged values plus a serially uncorrelated disturbance η_t. This disturbance η_t, which is referred to as the innovation in Y_t, has conditional mean zero given past Y; thus η_t is the population one step ahead forecast error under squared-error loss. That is, the VAR(p) model of Y_t is,

$$Y_t = A_1 Y_{t-1} + \cdots + A_p Y_{t-p} + \eta_t \quad \text{or} \quad A(\mathrm{L}) Y_t = \eta_t, \tag{18}$$

where $A(\mathrm{L}) = I - A_1 \mathrm{L} - \cdots - A_p \mathrm{L}^p$ and L is the lag operator, and where the disturbance η_t is a martingale difference sequence with covariance matrix Σ_η, so that η_t is serially uncorrelated.

In practice, Y_t will generally have nonzero mean and the VAR in (18) would include an intercept. The assumption of zero mean and no intercept in the VAR is made without loss of generality to simplify notation.

The VAR (18) is called the *reduced-form VAR*. The ith equation in (18) is the population regression of Y_{it} onto lagged values of Y_t. Because (18) is the population regression of Y_t onto its lags, its parameters $A(\mathrm{L})$ and Σ_η are identified.

The *innovation* in Y_{it} is the one step ahead forecast error, η_{it}, in the ith equation in (18).

The *vector moving average representation* of Y_t, which in general will be infinite order, expresses Y_t in terms of current and past values of the innovations:

$$Y_t = C(\mathrm{L})\eta_t, \quad \text{where } C(\mathrm{L}) = I + C_1\mathrm{L} + C_2\mathrm{L}^2 + \cdots = A(\mathrm{L})^{-1}. \tag{19}$$

4.1.1.2 The SVAR

A structural VAR model represents Y_t not in terms of its innovations η_t, but rather in terms of a vector of underlying *structural shocks* ε_t, where these structural shocks represent unexpected exogenous disturbances to structural economic relationships such as production functions (productivity shocks), central bank reaction functions (monetary policy shocks), or oil supply functions (oil supply shocks).[o] The SVAR assumes that the innovations are a linear combination of the unobserved structural shocks:

$$\eta_t = H\varepsilon_t. \tag{20}$$

The structural shocks are assumed to be uncorrelated[p]:

$$E\varepsilon_t\varepsilon_t' = \Sigma_\varepsilon = \begin{pmatrix} \sigma^2_{\varepsilon_1} & & 0 \\ & \ddots & \\ 0 & & \sigma^2_{\varepsilon_n} \end{pmatrix}. \tag{21}$$

Substituting (20) into (18) and (19) delivers the structural VAR and the structural moving average representation of the observable variables in terms of the structural shocks:

$$A(\mathrm{L})Y_t = H\varepsilon_t \text{ or } B(\mathrm{L})Y_t = \varepsilon_t, \quad \text{where } B(\mathrm{L}) = H^{-1}A(\mathrm{L}) \text{ (Structural VAR)} \tag{22}$$

$$Y_t = D(\mathrm{L})\varepsilon_t, \quad \text{where } D(\mathrm{L}) = C(\mathrm{L})H, \text{ (Structural MA)} \tag{23}$$

where the second expression in (22) holds if H^{-1} exists.

4.1.1.3 The SVAR Identification Problem

Because A(L) and Σ_η are identified from the projection of Y_t onto its past, the parameters of the structural VAR (22) and the structural MA (23) are identified if H and Σ_ε are identified. The problem of identifying H and Σ_ε is known as the SVAR identification problem. Strictly speaking, the concept of identification refers to nonrandom parameters or functions, but because D(L) is the projection of Y_t onto current and past shocks, the SVAR identification problem is also called the problem of identifying the structural shocks.

[o] Ramey (2016) characterizes structural shocks as having three characteristics: (1) they are exogenous and unforecastable, (2) they are uncorrelated with other shocks, and (3) they represent either unanticipated movements in exogenous variables or news about future movements in exogenous variables.

[p] This assumption that Σ_ε is diagonal is a natural part of the definition of an autonomous structural shock. For example, if one was to posit that two structural shocks were correlated, presumably there would be some structural reason or linkage, but if so then one of the shocks (or both) would be responding to the other endogenously in which case it would not be an exogenous structural shock. See Ramey (2016) for a discussion of this assumption.

4.1.1.4 SIRFs, Historical Decompositions, and Forecast Error Variance Decompositions

The structural MA (23) summarizes the dynamic causal effect of the shocks on current and future Y_t, and it directly delivers two key objects in SVAR analysis: the SIRF and the decomposition of Y_t into structural shocks. With the additional assumption (21) that the structural shocks are uncorrelated, the structural moving average representation also delivers the structural forecast error variance decomposition (FEVD).

The SIRF is the time path of the dynamic causal effect on variable Y_{it} of a unit increase in ε_{jt} at date 0. Let D_h denote the hth lag matrix of coefficients in $D(\mathrm{L})$. Then $D_{h,ij}$ is the causal effect on the ith variable of a unit increase in the jth shock after h periods, that is, $D_{h,ij}$ is the effect on Y_{it+h} of a unit increase in ε_{jt}. Thus the *structural impulse response function* ($SIRF_{ij}$) is the sequence of structural MA coefficients,

$$SIRF_{ij} = \left\{D_{h,ij}\right\}, \quad h = 0, 1, \ldots, \text{ where } D_h = C_h H, \tag{24}$$

where from (19) $C(\mathrm{L}) = A(\mathrm{L})^{-1}$. The contemporaneous effect, D_0, is called the impact effect; note that $D_0 = H$ because $C_0 = I$.

The *cumulative structural impulse response function* is the cumulative dynamic causal effect on Y_t of a unit shock at date 0. Expressed in terms of $D(\mathrm{L})$, the cumulative SIRF on variable i of shock j after h periods is $\sum_{k=0}^{h} D_{k,ij}$.

Because $D(\mathrm{L})\varepsilon_t$ is a linear function of current and lagged values of ε_t, (23) is the historical decomposition of the path of Y_t into the distinct contributions of each of the structural shocks; given $D(\mathrm{L})$, this decomposition is unique.

The FEVD$_{h,ij}$ measures how important the jth shock is in explaining the variation in Y_{it} by computing the relative contribution of that shock to the variance of the unexpected changes in Y_{it} over h periods, that is, to the variance of its h-step ahead forecast errors. The FEVD is,

$$FEVD_{h,ij} = \frac{\sum_{k=0}^{h} D_{k,ij}^2 \sigma_{\varepsilon_j}^2}{\operatorname{var}\left(Y_{it+h} \middle| Y_t, Y_{t-1}, \ldots\right)} = \frac{\sum_{k=0}^{h} D_{k,ij}^2 \sigma_{\varepsilon_j}^2}{\sum_{j=1}^{n} \sum_{k=0}^{h} D_{k,ij}^2 \sigma_{\varepsilon_j}^2}, \tag{25}$$

where $D(\mathrm{L}) = A(\mathrm{L})^{-1} H$.

4.1.1.5 System Identification

System identification entails identification of the full matrix H and thus the full matrix $D(\mathrm{L})$ of SIRFs. System identification makes the assumption that the space of innovations spans the space of structural shocks, so that H is invertible:

$$H^{-1} \text{ exists so that } \varepsilon_t = H^{-1} \eta_t. \tag{26}$$

Assumption (26) is equivalent to saying that the system SVAR representation (22) exists.

Eqs. (20) and (21) imply that

$$\Sigma_\eta = H\Sigma_\varepsilon H'. \tag{27}$$

The number of free parameters is $n(n+1)$ (n^2 in H and n in Σ_ε). Because covariance matrices are symmetric, the number of unique equations in $\Sigma_\eta = H\Sigma_\varepsilon H'$ is $n(n+1)/2$. Thus identification of H and Σ_ε requires $n(n+1)/2$ additional assumptions. Of these, n are obtained from normalizing the scale of the shocks, leaving $n(n-1)/2$ additional restrictions for identification of H.

When the shocks are i.i.d. Gaussian, the restrictions (27) are the only ones available for identification. If the shocks are not Gaussian then additional restrictions on higher moments can be available, and some research pursues the use of these restrictions. Typically these restrictions require strong additional assumptions, for example that the shocks are independently distributed (as opposed to simply uncorrelated) and in any event this approach does not enhance identification in the Gaussian case. We do not pursue further identification that exploits non-Gaussianity.

4.1.1.6 Single Shock Identification

In many applications, such as the application to the effect of oil supply shocks in Section 7, interest is in the effect of just one shock. Without loss of generality, let the shock of interest be the first shock, ε_{1t}. In general, the other shocks need not be identified to identify the SIRF for the first shock, and the innovations need not span the shocks other than ε_{1t} to identify the first SIRF. To stress this point, for single shock identification we rewrite (20) as,

$$\eta_t = H\begin{pmatrix}\varepsilon_{1t}\\ \tilde{\eta}_{\bullet t}\end{pmatrix} = [H_1 \quad H_\bullet]\begin{pmatrix}\varepsilon_{1t}\\ \tilde{\eta}_{\bullet t}\end{pmatrix} = \begin{pmatrix}H_{11} & H_{1\bullet}\\ H_{\bullet 1} & H_{\bullet\bullet}\end{pmatrix}\begin{pmatrix}\varepsilon_{1t}\\ \tilde{\eta}_{\bullet t}\end{pmatrix}, \tag{28}$$

where H_1 is the first column of H and $H_\bullet$ denotes the remaining columns and the final expression partitions these columns similarly, and where $\tilde{\eta}_{\bullet t}$ spans the space of η_t orthogonal to ε_{1t}. Because these other shocks are uncorrelated with $\varepsilon_{1t}, \mathrm{cov}(\varepsilon_{1t}, \tilde{\eta}_{\bullet t}) = 0$.

In single shock identification, the aim is to identify H_1. Given H_1, the structural moving average representation (23) can be written,

$$Y_t = C(\mathrm{L})\eta_t = C(\mathrm{L})H_1\varepsilon_{1t} + C(\mathrm{L})H_\bullet\tilde{\eta}_{\bullet t}, \quad \text{where } \mathrm{cov}(\varepsilon_{1t}, \tilde{\eta}_{\bullet t}) = 0. \tag{29}$$

Evidently, the SIRF for shock 1 is $C(\mathrm{L})H_1$ and the historical contribution of shock 1 to Y_t is $C(\mathrm{L})H_1\varepsilon_{1t}$.

If H in (28) is invertible, then ε_{1t} can be obtained as a linear combination of η_t. Denote the first row of H^{-1} by H^1. It follows from the partitioned inverse formula and the assumption (21) that the shocks are mutually uncorrelated that if H_1 is identified, then H^1 is identified up to scale. In turn, knowing H^1 up to scale allows construction of the shock ε_{1t} up to scale:

$$\varepsilon_{1t} = H^1\eta_t \propto \left[1 \quad \tilde{H}^{1\bullet}\right]\eta_t, \tag{30}$$

where $\widetilde{H}^{1\bullet}$ is a function of H_1 and Σ_η.[q] Thus identification of H_1 permits the construction of ε_{1t} up to scale. An implication of (30) is that identification of H_1 and identification of the shock are interchangeable.[r]

Note that (30) obtains without the additional assumption that the innovations span all the shocks or, for that matter, that they span any shock other than ε_{1t}.

4.1.2 Invertibility

The structural MA representation $Y_t = D(\mathrm{L})\varepsilon_t$ represents Y_t in terms of current and past values of the structural shocks ε_t. The moving average is said to be *invertible* if ε_t can be expressed as a distributed lag of current and past values of the observed data Y_t. SVARs typically assume $\varepsilon_t = H^{-1}\eta_t = H^{-1}A(\mathrm{L})Y_t$, so an SVAR typically imposes invertibility.[s] Yet, an economic model may give rise to a structural moving average process that is not invertible. If so the VAR innovations will not span the sapce of the structural shocks. Because identification of the shocks and identification of the SIRF are equivalent, if the true SIRF is not invertible, a SVAR constructed from the VAR innovations will not recover the true SIRF.

[q] Use the partitioning notation for H in the final expression in (28) and the partitioned matrix inverse formula to write, $H^1 = \left[H^{11} \quad -H^{11}H_{1\bullet}H_{\bullet\bullet}^{-1}\right] \propto \left[1 \quad -H_{1\bullet}H_{\bullet\bullet}^{-1}\right]$, where H^{11} is the scalar, $H^{11} = \left(H_{11} - H_{1\bullet}H_{\bullet\bullet}^{-1}H'_{\bullet 1}\right)^{-1}$. Because the goal is to identify ε_{1t} up to scale, the scale of ε_{1t} is arbitrary, so for convenience we adopt the normalization that $\Sigma_\varepsilon = I$; this is the unit standard deviation normalization of Section 4.1.3 and is made without loss of generality. Then (27) implies that $\Sigma_\eta = HH'$. Adopt partitioning notation for Σ_η conformable with that of H in (28). Then $\Sigma_\eta = HH'$ implies that $\Sigma_{\eta,1\bullet} = H_{11}H'_{\bullet 1} + H_{1\bullet}H'_{\bullet\bullet}$ and $\Sigma_{\eta,\bullet\bullet} = H_{\bullet 1}H'_{\bullet 1} + H_{\bullet\bullet}H'_{\bullet\bullet}$, which in turn implies $H_{1\bullet}H'_{\bullet\bullet} = \Sigma_{\eta,1\bullet} - H_{11}H'_{\bullet 1}$ and $H_{\bullet\bullet}H'_{\bullet\bullet} = \Sigma_{\eta,\bullet\bullet} - H_{\bullet 1}H'_{\bullet 1}$. Using these final two expressions and the fact that $H_{1\bullet}H'_{\bullet\bullet}\left(H_{\bullet\bullet}H'_{\bullet\bullet}\right)^{-1} = H_{1\bullet}H_{\bullet\bullet}^{-1}$ yields $H_{1\bullet}H_{\bullet\bullet}^{-1} = \left(\Sigma_{\eta,1\bullet} - H_{11}H'_{\bullet 1}\right)\left(\Sigma_{\eta,\bullet\bullet} - H_{\bullet 1}H'_{\bullet 1}\right)^{-1}$. Thus $H^1 \propto \left[1 \quad \widetilde{H}^{1\bullet}\right]$, where $\widetilde{H}^{1\bullet} = -\left(\Sigma_{\eta,1\bullet} - H_{11}H'_{\bullet 1}\right)\left(\Sigma_{\eta,\bullet\bullet} - H_{\bullet 1}H'_{\bullet 1}\right)^{-1}$. Because Σ_η is identified from the reduced form, knowledge of H_1 and the uncorrelated shock assumption therefore determines H^1, and thus the shock ε_{1t}, up to scale.

[r] Here is a second, perhaps more intuitive, method for constructing ε_{1t} from η_t given H_1, the assumption (21) that the shocks are mutually uncorrelated, and the invertibility of H. Let $H_1^\perp$ be any $n \times (n-1)$ matrix with linearly independent columns that are orthogonal to H_1. Then $H_1^{\prime\perp}\eta_t = H_1^{\prime\perp}H\varepsilon_t = H_1^{\prime\perp}[H_1 \quad H_\bullet]\varepsilon_t = \left[0 \quad H_1^{\prime\perp}H_\bullet\right]\varepsilon_t = H_1^{\prime\perp}H_\bullet\varepsilon_{\bullet t}$. If H is invertible, then $H_1^{\prime\perp}H_\bullet$ is invertible, so $\varepsilon_{\bullet t} = \left(H_1^{\prime\perp}H_\bullet\right)^{-1}H_1^{\prime\perp}\eta_t$. In addition, $H'_1\eta_t = H'_1H\varepsilon_t = H'_1H_1\varepsilon_{1t} + H'_1H_\bullet\varepsilon_{\bullet t}$. Because ε_{1t} and $\varepsilon_{\bullet t}$ are uncorrelated, $H'_1\eta_t - \mathrm{Proj}\left(H'_1\eta_t|\varepsilon_{\bullet t}\right) = H'_1H_1\varepsilon_{1t}$, where $\mathrm{Proj}(X|Y)$ is the population projection of X on Y. Because $\varepsilon_{\bullet t} = \left(H_1^{\prime\perp}H_\bullet\right)^{-1}H_1^{\prime\perp}\eta_t$, $\varepsilon_{1t} = \left(H'_1H_1\right)^{-1}\left[H'_1\eta_t - \mathrm{Proj}\left(H'_1\eta_t|\varepsilon_{\bullet t}\right)\right] = \left(H'_1H_1\right)^{-1}\left[H'_1\eta_t - \mathrm{Proj}\left(H'_1\eta_t|H_1^{\prime\perp}\eta_t\right)\right]$; this is an alternative representation of the linear combination of η_t given by $H^1\eta_t$ in (30).

[s] In linear filtering theory, a time series representation is called *fundamental* if the disturbances are a function of current and past values of the observable data. Accordingly, the invertibility assumption is also referred to as the assumption that the structural shocks are fundamental.

There are at least three reasons why the structural moving average might not be invertible. One is that there are too few variables in the VAR. For example, suppose that there are four shocks of interest (monetary policy, productivity, demand, oil supply) but only three variables (interest rates, GDP, the oil price) in the VAR. It is impossible to reconstruct the four shocks from current and lagged values of the three observed time series, so the structural moving average process is not invertible. Estimates from a SVAR constructed from the VAR innovations will therefore suffer from a form of omitted variable bias.

Second, some elements of Y may be measured with error, which effectively adds more shocks (the measurement error) to the model. Again, this makes it impossible to reconstruct the structural shocks from current and lagged values of Y. This source of noninvertibility can be thought of as errors-in-variables bias.

Third, noninvertibility can arise when shocks contain news about the future. To see the mechanics of the problem, consider the first-order moving average univariate model with a single lag: $Y_t = \varepsilon_t - d\varepsilon_{t-1}$. Solving for ε_t as a function of current and lagged values of Y_t yields $\varepsilon_t = \sum_{i=0}^{h-1} d^i Y_{t-i} + d^h \varepsilon_{t-h}$. If $|d| < 1$, then $d^h \approx 0$ for h large and $E\left(\varepsilon_t - \sum_{i=0}^{h-1} d^i Y_{t-i}\right)^2 \rightarrow 0$ as $h \rightarrow \infty$, so that ε_t can be recovered from current and lagged values of y and the process is invertible. In contrast, when $|d| > 1$, the initial value of ε_0 remains important, so the process is not invertible. In this case, however, ε_t can be recovered from current and future values of y_t: solving the moving average process forward yields the representation, $\varepsilon_t = -(1/d)\sum_{i=1}^{h}(1/d)^i Y_{t+i} + (1/d)^h \varepsilon_{t+h}$, where $E\left((1/d)^h \varepsilon_{t+h}\right)^2 \rightarrow 0$ when $|d| > 1$. In economic models, noninvertibility can arise, for example, because technological innovations (shocks) may have small initial effects on productivity and much larger effects on future productivity, so a technology shock today (an invention today) is actually observed in the data as a productivity increase in the future. As a second example, if the central bank announces that it will raise interest rates next month, the monetary policy shock occurs today but is not be observed in the overnight rate until next month. Like the case of omitted variables, news shocks are an example of economic agents knowing more about shocks than the econometrician can decipher from current and past data.

Unfortunately, statistics based on the second moments of the data—which include the parameters of the SVAR—cannot determine whether the true SIRF is invertible or not: each noninvertible moving average representation has an invertible moving average representation that is observationally equivalent based on the second moments of the data. To see this, consider the univariate first-order moving average example of the previous paragraph, $y_t = \varepsilon_t - d\varepsilon_{t-1}$. By direct calculation, $\text{var}(y_t) = \left(1 + d^2\right)\sigma_\varepsilon^2$, $\text{cov}(y_t, y_{t-1}) = -d\sigma_\varepsilon^2$, and $\text{cov}(y_t, y_{t-i}) = 0$, $|i| > 1$. It is readily verified that for any set of parameter values

$(d, \sigma_\varepsilon^2)$ with $|d| < 1$, the alternative parameter values $\left(\tilde{d}, \tilde{\sigma}_\varepsilon^2\right) = \left(d^{-1}, d^2\sigma_\varepsilon^2\right)$ produce the same autocovariances; that is, $(d, \sigma_\varepsilon^2)$ and $\left(d^{-1}, d^2\sigma_\varepsilon^2\right)$ are observationally equivalent values of the parameters based on the second moments of the data. If the data are Gaussian, then these two sets of parameter values are observationally equivalent based on the likelihood. Because these pairs have the same autocovariances, they produce the same reduced-form VAR, but they imply different SIRFs.

Noninvertibility is an important threat to the validity of SVAR analysis. Hansen and Sargent (1991) provide an early and important discussion, Sargent (1987) provides an illuminating example using the permanent income model of consumption, and Fernández-Villaverde et al. (2007) discuss the restrictions on linear economic models that give rise to invertibility. For more detailed discussion of the literature and references, see Forni et al. (2009), Leeper et al. (2013), Plagborg-Møller (2015), and Ramey (2016, this Handbook). As Forni et al. (2009) point out and as discussed in more detail in Section 5, SDFMs can resolve the problems of measurement error, omitted variables, and in some cases timing (news) through the use of large numbers of series.

4.1.3 Unit Effect Normalization

Because the structural shocks are unobserved, their sign and scale are arbitrary and must be normalized. There are two normalizations commonly used, the unit standard deviation normalization and the unit effect normalization.

The unit *standard deviation normalization* makes each shock have unit variance:

$$\Sigma_\varepsilon = I \quad \text{(unit standard deviation normalization)}. \tag{31}$$

The normalization (31) fixes the units of the shock, but not its sign. The sign must be fixed separately, for example by defining a positive monetary shock to increase the target rate on impact.

The *unit effect normalization* fixes the sign and scale of the jth shock so that a unit increase in ε_{jt} induces a contemporaneous unit increase in a specific observed variable, which we take to be Y_{jt}. Written in terms of the H matrix, the unit effect normalization sets

$$H_{jj} = 1 \quad \text{(unit effect normalization)}. \tag{32}$$

Equivalently, under the unit effect normalization a unit increase in ε_{jt} increases η_{jt} by one unit, which in turn increases Y_{jt} by one unit. For example, if the Federal Funds rate is measured in percentage points, then a unit monetary shock induces a one percentage point increase in the Federal Funds rate. A unit shock to productivity growth increases the growth rate of productivity by one percentage point, and so forth.

For system identification, both normalizations provide n additional restrictions on H, so that $n(n-1)/2$ additional restrictions are needed.

For single shock identification, both normalizations set the scale of ε_{1t}. Under the unit standard deviation assumption, $\sigma_{\varepsilon_1}^2 = 1$. Under the unit effect normalization,

$$H_1 = \begin{pmatrix} 1 \\ H_{1\bullet} \end{pmatrix}. \tag{33}$$

In both cases, $n-1$ additional restrictions are needed to identify H_1.

In population, these two normalizations are interchangeable. Nevertheless, the unit effect normalization is preferable for three reasons.

First, the unit effect normalization is in the units needed for policy analysis or real-world interpretation. A monetary policy maker needs to know the effect of a 25 basis point increase in the policy rate; providing the answer in standard deviation units does not fulfill that need. When oil prices fall by, say, 10%, because of an oil supply shock, the question is what the effect of that fall is on the economy; again, stating the SIRFs in standard deviation units does not answer that question.

Second, although the two formulations are equivalent in population, statistical inference about the SIRFs differs under the two normalizations. In particular, it is an inferential error to compute confidence intervals for SIRFs under the unit standard deviation normalization, then renormalize those bands so that they answer the questions relevant to policymakers. The inferential error is that this renormalization entails dividing by an estimator of H_{11}, which introduces additional sampling uncertainty. If, under the unit standard deviation normalization, H_{11} is close to zero, then this sampling variability can be considerable and renormalization introduces inference problems related to weak instruments.[t]

Third, as discussed in the next section, the unit effect normalization allows SVAR identification schemes to be extended directly to SDFMs.

For these reasons, we adopt the unit effect normalization throughout this chapter.

Finally, we note that the unit effect normalization could alternatively involve the normalization that shock j induces a unit increase in variable i. In this case, the normalization for shock j would be $H_{ij} = 1$ instead of $H_{jj} = 1$ as in (32). If each shock has a unit impact on a different VAR innovation, the distinction we are making here is trivial because the named shocks can always be ordered to align with the order of the variables in the VAR. For example, without loss of generality the Fed funds rate can be listed first, the monetary policy shock can be taken to be the first shock, and $H_{11} = 1$ is the unit effect normalization.

[t] Another way to state this problem is in the context of bootstrap draws of the IRFs. If the bootstrap uses the unit standard deviation normalization to compute confidence intervals, then multiplies the confidence intervals by a scaling coefficient which converts from standard deviation to native units, the resulting IRF confidence intervals do not incorporate the sampling uncertainty of that scaling coefficient. In contrast, if the bootstrap does that conversion for every draw, which is equivalent to using the unit effect normalization, then the IRF confidence intervals do incorporate the sampling uncertainty of the unit conversion step.

This distinction, however, becomes nontrivial when two distinct shocks are normalized to have unit effects on the same variable. For example, suppose one was interested in investigating the separate effects of an oil supply shock (ε_{1t}, say) and an oil inventory demand shock (ε_{2t}, say), and for the purpose of the investigation it was useful to fix the scales of the two shocks so that they each produced a one percentage point increase in the price of oil. Without loss of generality, let the oil price be the first variable so η_{1t} is the innovation in the oil price. Then this alternative unit effect normalization would be that $H_{11}=1$ and $H_{12}=1$. If the results will be presented using this normalization, then adopting this normalization from the outset ensures that confidence intervals will correctly incorporate the data-dependent transformations to impose this normalization.

Because the circumstance described in the previous paragraph is unusual, throughout this chapter we use the version of the unit effect normalization in (32).

4.1.4 Summary of SVAR Assumptions.

We now collect the assumptions underlying SVAR analysis:

(SVAR-1) The innovations in Y_t, η_t, span the space of the one or more structural shocks:

- **(a)** for system identification, $\eta_t = H\varepsilon_t$ as in (20) and H^{-1} exists and
- **(b)** for single shock identification, (28) holds and H^1 exists.

(SVAR-2) The structural shocks are uncorrelated as in (21).

(SVAR-3) The scale of the shocks is normalized using either the unit standard deviation normalization (31) or the unit effect normalization (32).

With one exception, these assumptions, which were discussed earlier, are needed for all the shock identification schemes discussed in this section. The exception is single shock identification based on direct measurement of the time series of structural shocks, which, because the shock is observed, requires only assumption SVAR-2.

For this chapter, we make the further assumptions:

(SVAR-4) The innovations η_t are the one step ahead forecast errors from the VAR(p) (18) with time-invariant parameters A(L) and Σ_η.

(SVAR-5) The VAR lag polynomial A(L) is invertible.

Assumptions SVAR-4 and SVAR-5 are technical assumptions made for convenience. For example, SVAR-4 can be relaxed to allow for breaks, or time variation can be introduced into the VAR parameters using the methods of, for example, Cogley and Sargent (2005) or Sims and Zha (2006). Assumption SVAR-5 presumes that the variables have been transformed to stationarity, typically using first differences or error correction terms. Alternatively the series could be modeled in levels in which case the SIRF would have the interpretation of a cumulative SIRF. Levels specifications are used in much of the literature. These relaxations of SVAR-4 and SVAR-5 do not materially affect any of the subsequent discussion and they are made here to streamline the discussion.

4.2 Contemporaneous (Short-Run) Restrictions

Contemporaneous restrictions rest on timing arguments about the effect of a given shock on a given variable within the period (monthly if monthly data, etc.). Typically these are zero restrictions, indicating that shock ε_{jt} does not affect Y_{it} (equivalently, does not affect η_{it}) within a period because of some sluggish or institutional feature of Y_{it}. These contemporaneous timing restrictions can identify all the shocks, or just some shocks.

4.2.1 System Identification

Sims's (1980) original suggestion for identifying the structural shocks was of this form, specifically he adopted an ordering for the variables in which the first innovation responds only to the first shock within a period, the second innovation responds only to the first and second shocks, etc. Under this recursive scheme, the shocks are simply linear regression residuals, where the first regression only controls for lagged observables, the second regression controls for lags and one contemporaneous variable, etc. For example, in many recursive monetary SVARs, the monetary policy shock is identified as the residual from an Taylor rule-type regression.

This recursive identification scheme is a Wold (1954) causal chain and corresponds to assuming that H is lower triangular. Because $\Sigma_\eta = H\Sigma_\varepsilon H'$, the lower-triangular assumption implies that $H\Sigma_\varepsilon^{1/2} = Chol\left(\Sigma_\eta\right)$, where $Chol$ denotes the Cholesky factorization. With the unit effect normalization, H is obtained as the renormalized Cholesky factorization, that is, $H = Chol\left(\Sigma_\eta\right)\Sigma_\varepsilon^{-1/2}$, where $\Sigma_\varepsilon = diag(\{[Chol(\Sigma_\eta)_{jj}]^2, j = 1, \ldots, n\})$. This lower-triangular assumption remains a common identification assumption used in SVAR empirical applications.

Nonrecursive restrictions also can provide the $n(n-1)/2$ contemporaneous restrictions for system identification. For example, some of the elements of H can be specified by drawing on application-specific information. An early example of this approach is Blanchard and Watson (1986), who used information about automatic stabilizers in the budget to determine the contemporaneous fiscal response to aggregate demand shocks which, along with zero restrictions based on timing arguments, identified H.

Blanchard and Watson (1986) also show how short-run restrictions on the coefficients can be reinterpreted from an instrumental variables perspective.

4.2.2 Single Shock Identification

Identification of a single shock requires fewer restrictions on H; here we give three examples. The first example is to suppose that a given variable (without loss of generality, Y_{1t}) responds within the period only to a single structural shock; if so, then $\varepsilon_{1t} = \eta_{1t}$ and no additional assumptions are needed to identify ε_{1t}. This first example corresponds to ordering the variable first in a Cholesky factorization, and no additional assumptions are needed about the ordering of the remaining variables (or in fact whether the remaining shocks are identifiable).

The second example makes the opposite assumption: that a given shock affects only one variable within a period, and that variable (and innovation) potentially responds to all other shocks as well. This second example corresponds to ordering the variable last in a Cholesky factorization.

The third example is the "Slow-*r*-Fast" identification scheme frequently used to identify monetary policy shocks, see, for example, Christiano, Eichenbaum, and Evans, (1999) and Bernanke et al. (2005). Under this scheme, so-called slow-moving variables Y_t^s such as output and prices do not respond to monetary policy or to movements in asset prices within the period; through monetary policy, the Fed funds rate r_t responds to shocks to the slow-moving variables within a period but not to asset price developments; and fast-moving variables Y_t^f, such as asset prices and expectational variables, respond to all shocks within the period. This delivers the block recursive scheme,

$$\begin{pmatrix} \eta_t^s \\ \eta_t^r \\ \eta_t^f \end{pmatrix} = \begin{pmatrix} H_{ss} & 0 & 0 \\ H_{rs} & H_{rr} & 0 \\ H_{fs} & H_{fr} & H_{ff} \end{pmatrix} \begin{pmatrix} \varepsilon_t^s \\ \varepsilon_t^r \\ \varepsilon_t^f \end{pmatrix} \text{ where } Y_t \text{ is partitioned } \begin{pmatrix} Y_t^s \\ r_t \\ Y_t^f \end{pmatrix}, \tag{34}$$

where H_{ss} is square. Under (34), η_t^s spans the space of ε_t^s, so the monetary policy shock ε_t^r is the residual in the population regression of the Fed funds rate innovation η_t^r on η_t^s. Equivalently, ε_t^r is identified as the residual in the regression of the monetary instrument on current values of slow-moving variables as well as lags of all the variables.

4.3 Long-Run Restrictions

Identification of the shocks, or of a single shock, can also be achieved by imposing restrictions on the long-run effect of a given shock on a given variable (Shapiro and Watson, 1988; Blanchard and Quah, 1989; King, Plosser, Stock, and Watson, 1991). Because Y_t is assumed to be stationary, the cumulative long-run effect of ε_t on future values of Y_t is the sum of the structural MA coefficients $D(1)$, where $D(1) = C(1)H = A(1)^{-1}H$, where $C(1)$ and $A(1)$ are, respectively, the sums of the reduced-form MA and VAR coefficients.

4.3.1 System Identification

Let Ω denote the long-run variance matrix of Y_t, that is, $\Omega = \text{var}\left(\sqrt{n}\bar{Y}\right) = 2\pi$ times the spectral density matrix of Y_t at frequency zero. Then

$$\Omega = A(1)^{-1}\Sigma_\eta A(1)^{-1'} = A(1)^{-1}H\Sigma_\varepsilon H' A(1)^{-1'} = D(1)\Sigma_\varepsilon D(1)'. \tag{35}$$

Imposing $n(n-1)/2$ restrictions on $D(1)$ permits identifying $D(1)$ and, because $A(1)^{-1}H = D(1)$, H is identified by $H = A(1)D(1)$.

A common approach is to adopt identifying assumptions that imply that $D(1)$ is lower triangular. For example, Blanchard and Quah (1989) identify a demand shock as having no long-run effect on the level of output. Let $Y_t =$ (GDP growth, unemployment rate) and let ε_{1t} be an aggregate supply shock and ε_{2t} be an aggregate demand shock. The assumption that ε_{2t} has no long-run effect on the *level* of output is equivalent to saying that its cumulative effect on output *growth* is zero. Thus the long-term effect of ε_{2t} (the demand shock) on Y_{1t} (output growth) is zero, that is, $D_{12}(1) = 0$, so $D(1)$ is lower triangular.

In another influential paper, Gali (1999) used long-run restrictions to identify a technology shock. Specifically, Gali (1999) uses a small aggregate structural model to argue that only the technology shock has a permanent effect on the level of labor productivity. Let $Y_t =$ (labor productivity growth, hours growth), ε_{1t} be a technology shock, and ε_{2t} be a non-technology shock. Gali's (1999) restriction that the nontechnology shock has zero long-run effect on the *level* of labor productivity implies that $D_{12}(1) = 0$, so that $D(1)$ is lower triangular.

Blanchard and Quah (1989), King, Plosser, Stock, and Watson (1991), and Gali (1999) use the unit standard deviation normalization, so that $\Sigma_\varepsilon = I$ and, by (35), $\boldsymbol{\Omega} = D(1)D(1)'$. The lower triangular factorization of $\boldsymbol{\Omega}$ is uniquely the Cholesky factorization, $D(1) = Chol(\boldsymbol{\Omega})$. Using the first expression in (35) and $H = A(1)D(1)$, the combination of the unit standard deviation normalization and the identifying restriction that $D(1)$ is lower triangular provides the closed-form expression for H,

$$H = A(1)Chol\left[A(1)^{-1}\Sigma_\eta A(1)^{-1}\right]. \tag{36}$$

In general, the sample estimate of H can be estimated by substituting sample counterparts for the reduced-form VAR, $\hat{A}(1)$ and $\hat{\Sigma}_{\hat{\eta}}$, for the population matrices, imposing the restrictions on $D(1)$, and solving (35). In the case that $D(1)$ is lower triangular and the unit standard deviation assumption is used, the estimator of H has the closed-form solution which is the sample version of (36).

4.3.2 Single Shock Identification

Long-run restrictions can also identify a single shock. The Blanchard and Quah (1989) and Gali (1999) examples have $n = 2$, but suppose that $n > 2$. Then the assumption that only ε_{1t} affects Y_{1t} in the long run imposes $n - 1$ zero restrictions on the first row of $D(1)$, and implies that ε_{1t} is proportional to $A(1)^1\eta_t$, where $A(1)^1$ is the first row of $A(1)^{-1}$. Thus this assumption identifies ε_{1t} up to scale, and the scale is then set using either the unit effect normalization or the unit standard deviation normalization.

4.3.3 IV Interpretation of Long-Run Restrictions

Shapiro and Watson (1988) provide an instrumental variables interpretation of identification by long-run restrictions. We illustrate this interpretation for a two-variable

VAR(1). Following (22), write the SVAR as $B(\mathrm{L})Y_t = \varepsilon_t$, where $B(\mathrm{L}) = H^{-1}A(\mathrm{L}) = B_0 + B_1\mathrm{L}$, where the final expression assumes the VAR lag length $p = 1$. Add and subtract $B_0\mathrm{L}$ so that $B(\mathrm{L})Y_t = (B_0 + B_1\mathrm{L})Y_t = B_0\Delta Y_t + B(1)Y_{t-1}$, and note that $B_0 = H^{-1}$ so that the SVAR can be written, $H^{-1}\Delta Y_t = -B(1)Y_{t-1} + \varepsilon_t$. Under the unit effect normalization, $H_{11} = H_{22} = 1$ so, using the formula for the inverse of a 2×2 matrix, the SVAR can be written,

$$\begin{aligned} \Delta Y_{1t} &= H_{12}\Delta Y_{2t} - \det(H)B(1)_{11}Y_{1t-1} - \det(H)B(1)_{12}Y_{2t-1} + \det(H)\varepsilon_{1t} \\ \Delta Y_{2t} &= H_{21}\Delta Y_{1t} - \det(H)B(1)_{21}Y_{1t-1} - \det(H)B(1)_{22}Y_{2t-1} + \det(H)\varepsilon_{2t}. \end{aligned} \tag{37}$$

The parameters H_{12} and H_{21} are unidentified without a further restriction on the simultaneous equations model (37), however, long-run restrictions on $D(1)$ provide such a restriction. Specifically, the assumption that $D(1)$ is lower triangular implies that $D(1)^{-1} = B(1)$ is lower triangular, so that $B(1)_{12} = 0$. Thus, the assumption that $D(1)$ is lower triangular implies that Y_{2t-1} is excluded from the first equation of (37), and thus is available as an instrument for ΔY_{2t} to estimate H_{12} in that equation. Because Y_{2t-1} is predetermined, $E(\varepsilon_{1t}Y_{2t-1}) = 0$ so Y_{2t-1} satisfies the exogeneity condition for a valid instrument.

As an example, consider the special case of the VAR(1) (37) where,

$$\begin{aligned} \Delta Y_{1t} &= H_{12}\Delta Y_{2t} + \det(H)\varepsilon_{1t} \\ \Delta Y_{2t} &= H_{21}\Delta Y_{1t} + (\alpha - 1)Y_{2t-1} + \det(H)\varepsilon_{2t}. \end{aligned} \tag{38}$$

Because ΔY_{2t} depends on ΔY_{1t}, (38) is a system of simultaneous equations and neither H_{12} nor H_{21} can be estimated consistently by OLS. However, because Y_{2t-1} does not appear in the first equation, it can be used as an instrument for ΔY_{2t} to estimate H_{12}. The instrumental variables estimator of H_{12} is,

$$\hat{H}_{12} = \frac{\sum_{t=2}^{T}\Delta Y_{1t}Y_{2t-1}}{\sum_{t=2}^{T}\Delta Y_{2t}Y_{2t-1}}. \tag{39}$$

This instrumental variables interpretation is noteworthy for two reasons. First, although standard estimation algorithms for long-run identification, such as the Cholesky factor expression (36), appear to be quite different from instrumental variables, when the system is exactly identified the two estimation approaches are equivalent. Thus, the "equation counting" identification approach to identification is the same as having a valid instrument for ΔY_{2t}.

Second, the IV interpretation links the inference problem under long-run restrictions to the well-studied topic of inference in IV regressions. Here, we focus on one aspect of inference in IV regression which turns out to be relevant for SVARs with long-run restrictions: inference when instruments are weak.

4.3.4 Digression: Inference in IV Regression with Weak Instruments

An instrument in IV regression is said to be weak if its correlation with the included endogenous regressor is small. Although a detailed discussion of weak instruments and weak identification is beyond the scope of this chapter, it is useful to lay out the central ideas here because they also arise in other SVAR identification schemes. For this digression only, we modify notation slightly to align with the standard regression model. With this temporary notation, the IV regression model is,

$$\begin{aligned} Y_{1t} &= \beta Y_{2t} + u_t \\ Y_{2t} &= \pi' Z_t + V_t \end{aligned} \tag{40}$$

where Y_{2t} is the single included endogenous variable, β is the coefficient of interest, and the second equation in (40) is the first-stage equation relating the included endogenous variable to the vector of k instruments, Z_t. The instruments are assumed to be exogenous in the sense that $E(Z_t u_t) = 0$. When there is a single instrument, the IV estimator is

$$\hat{\beta}_{IV} = \frac{\sum_{t=1}^{T} Y_{1t} Z_t}{\sum_{t=1}^{T} Y_{2t} Z_t}. \tag{41}$$

With multiple instruments, there are multiple estimators available, such as two-stage least squares.

The weak-instrument problem arises when the included endogenous variable Y_{2t} is weakly correlated with Z_t or, equivalently, when π in (40) is small. In this case, the sample covariance in the denominator of (41) can have a mean sufficiently close to zero that, in some samples, the denominator itself could be close to zero or even have a sign different from the population covariance. When the sampling distribution of the denominator includes small values, the result is bias in the IV estimator, heavy tails in its distribution, and substantial departures from normality of its associated t-statistic. These features are general and arise in time series, panel, and cross-sectional regression, with multiple instruments, multiple included endogenous regressors, and in GMM estimation (eg, Nelson and Startz, 1990a,b; Staiger and Stock, 1997; Stock and Wright, 2000).

In linear IV regression, the primary measure of strength of an instrument is the so-called concentration parameter, divided by the number of instruments. The concentration parameter is defined in the classical linear instrumental variables model with homoscedasticity and i.i.d. observations. The concentration parameter is $\mu^2 = \pi' Z' Z \pi / \sigma_v^2$, where σ_v^2 is the variance of the first-stage error. The quantity μ^2/k is the noncentrality parameter of the F-statistic testing the coefficient on the instrument in the first-stage regression. One rule of thumb is that weak-instrument problems are an important concern when this first-stage F-statistic is less than 10 (Staiger and Stock, 1997).[u]

4.3.5 Inference Under Long-Run Restrictions and Weak Instruments

A number of studies have pointed out that SVAR inference based on long-run restrictions can be delicate to seemingly minor changes, such as different sample periods or different number of VAR lags. In addition, in Monte Carlo simulations, IRFs based on long-run restrictions have been found to be biased and/or have confidence intervals that do not have the desired coverage probability; see, for example, Christiano et al. (2006). One interpretation of these problems, as put forth by Faust and Leeper (1997), is that they arise because it is difficult to estimate the long-run variance $\mathbf{\Omega}$, which entails estimating $A(1)^{-1}$. In our view, however, this interpretation, while not incorrect, is less useful than posing the problem in terms of the IV framework earlier. Viewing the problem as weak identification both explains the pathologies of the sampling distribution and points the way toward inference procedures that are robust to these problems.

We therefore focus on the IV interpretation of identification by long-run restrictions and weak-instrument issues, initially raised by Sarte (1997), Pagan and Robertson (1998), and Watson (2006). We focus on the special case (38) and the IV estimator (39), however as shown by these authors these comments apply generally to inference using long-run restrictions.

Comparison of the SVAR example (38) and (39) to the IV model and estimator (40) and (41) indicates that the instrument Y_{2t} will be weak when α is sufficiently close to one. Consider the special case $H_{21}=0$, so that the second equation in (38) is the first stage and the first-stage coefficient is $\alpha-1$. A direct calculation in this case shows that the concentration parameter is $T(\alpha-1)^2/(1-\alpha^2)$. For $T=100$, the concentration parameter is 5.3 for $\alpha=0.9$ and is 2.6 for $\alpha=0.95$. These are small concentration parameters, well below the rule-of-thumb cutoff of 10.

Gospodinov (2010) provides a more complete treatment of the distribution theory when the excluded variable is persistent and shows that in general standard inferences will be misleading when the instrument is weak (estimated IRFs are biased, confidence intervals do not have the advertised coverage rates).

Because the weak-instrument problems arise when roots are large, standard methods for inference in the presence of weak instruments under stationarity (eg, Stock and Wright, 2000) no longer apply directly. Chevillon et al. (2015) develop a method for constructing

[u] There is now a very large literature on weak instruments in IV regression and weak identification in generalized method of moments estimation. Andrews and Stock (2007) survey the early econometrics literature on weak instruments. For a recent survey of weak instruments in the context of estimation of the New Keynesian Phillips curve, see Mavroeidis et al. (2014).

confidence sets in this application that is robust to this weak-instruments problem, and they find that using weak-instruments procedures change conclusions in some classic long-run identification SVAR papers, including Blanchard and Quah (1989).

4.4 Direct Measurement of the Shock

Measuring ε_{1t} through direct observation solves the identification problem, and some papers undertake to do so.

One approach to direct measurement of shocks uses narrative sources to determine exogenous policy changes. This method was developed by Romer and Romer (1989) for the measurement of monetary policy shocks, and the same authors have used this approach to measure tax, financial distress, and monetary policy shocks (Romer and Romer, 2004, 2010, 2015). For example, Romer and Romer (2010) use textual data including presidential speeches and congressional reports to construct a series of exogenous tax changes. Ramey and Shapiro (1998) and Ramey (2011) use related methods to measure government spending shocks.

A series of papers take this approach to measuring monetary policy shocks by exploiting the expectations hypothesis of the term structure and/or high-frequency financial data. Early contributions include Rudebusch (1998), Kuttner (2001), Cochrane and Piazzesi (2002), Faust et al. (2003, 2004), Gürkaynak et al. (2005), and Bernanke and Kuttner (2005), and recent contributions (with references) are Campbell et al. (2012), Hanson and Stein (2015), and Nakamura and Steinsson (2015). For example, Kuttner (2001) measures the monetary policy shock as the change in the Fed Funds futures rate on the day that the Federal Open Market Committee (FOMC) announces a target rate change. Under the expectations hypothesis, any expected change in the target rate will be incorporated into the preannouncement rate, so the change in the Fed Funds futures rate on the announcement date measures its unexpected movement. Cochrane and Piazzesi (2002) take a similar approach, using changes in the Eurodollar rate around FOMC target change announcements. Upon aggregation to the monthly level, this yields a series of monetary policy shocks, which they use as a regressor to estimate SIRFs.

Another set of applications of this method is to the direct measurement of oil supply shocks. Hamilton (2003) and Kilian (2008a) develop an historical chronology of OPEC oil supply disruptions based on exogenous political events to construct numerical estimates of exogenous oil production shortfalls, that is, exogenous shocks to oil supply.

The approach of directly measuring shocks is ambitious and creative and often delivers new insights. This approach, however, has two challenges. The first is that there are inevitable questions about whether the constructed series measures only the exogenous shock of interest. For example, short-term interest rates can change at announcement dates because of an exogenous monetary shock resulting in a change in a target rate, or because the change in the target rate revealed inside knowledge that the Fed might have about the economy (that is, about the values of other shocks). Additionally, if the window around the announcement is too wide, then rate changes can reflect influences other than the monetary shock (Nakamura and Steinsson, 2015).

The second challenge is that these constructed shocks rarely measure the entirety of the structural shock. For example, some of the monetary shock could be revealed in speeches by Federal Reserve officials in the weeks leading up to a FOMC meeting, so that the change in short rates before and after the FOMC meeting understates the full shock. Whether this omission leads to bias in the estimator of the effect of the monetary policy shock depends on whether the measured shock is correlated with the unmeasured shock. If the measured and unmeasured components are correlated, then this measurement error produces bias in the SIRF estimated using the constructed shock.

The first of these problems, exogeneity, is intrinsic to the research design and does not have a econometric resolution. The second of these problems, errors-in-variables bias, can be solved using econometric methods, in particular by using the measured shock series as an external instrument as discussed in Section 4.7.

4.5 Identification by Heteroskedasticity

Identification can also be achieved by assuming that the H matrix remains fixed but the structural shocks are heteroskedastic. This heteroskedasticity can take the form of different heteroskedasticity regimes, or conditional heteroskedasticity.

4.5.1 Identification by Heteroskedasticity: Regimes

Rigobon (2003) and Rigobon and Sack (2003, 2004) showed that H can be identified by assuming it is constant across regimes in which the variance of the structural shocks change.

Suppose that H is constant over the full sample, but there are two variance regimes, one in which the structural shocks have diagonal variance matrix Σ_ε^1 and a second with diagonal variance matrix Σ_ε^2. Because $\eta_t = H\varepsilon_t$ in both regimes, the variance matrices of η_t in the two regimes, Σ_η^1 and Σ_η^2 satisfy,

$$\begin{aligned}\Sigma_\eta^1 &= H\Sigma_\varepsilon^1 H' \\ \Sigma_\eta^2 &= H\Sigma_\varepsilon^2 H'\end{aligned} \tag{42}$$

The first matrix equation in (42) (the first regime) delivers $n(n+1)/2$ distinct equations, as does the second, for a total of n^2+n equations. Under the unit effect normalization that the diagonal elements of H are 1, H has n^2-n unknown elements, and there are an additional $2n$ unknown diagonal elements of Σ_ε^1 and Σ_ε^2, for a total of n^2+n unknowns. Thus the number of equations equals the number of unknowns.

For these equations to solve uniquely for the unknown parameters, they must provide independent information (satisfy a "rank" condition). For example, proportional heteroskedasticity $\Sigma_\varepsilon^2 = a\Sigma_\varepsilon^1$ provides no additional information because then $\Sigma_\eta^2 = a\Sigma_\eta^1$ and the equations from the second regime are the same as those from the first regime. In practice, it is difficult to check the "rank" condition because Σ_η^1 and Σ_η^2 must be estimated. For example, in the previous example $\Sigma_\eta^2 = a\Sigma_\eta^1$ in population, but the sample estimates of Σ_η^1 and Σ_η^2 would not be proportional because of sampling variability.

Economic reasoning or case-specific knowledge is used in identification by heteroskedasticity in one and, in some applications, two places. The first is to make the case that H does not vary across heteroskedasticity regimes, that is, that H is time-invariant even though the variances of the structural shocks are time varying. The second arises when some of the shocks are not naturally associated with a specific observable variable. For example, Rigobon (2003) works through a bivariate example of supply and demand in which the variance of the supply disturbance is posited to increase, relative to the variance of the demand disturbance, and he shows that this increase identifies the slope of the demand curve, however this identification requires a priori knowledge about the nature of the change in the relative shock variances. Similarly, Rigobon and Sack (2004) and Wright (2012) exploit the institutional fact that monetary policy shocks arguably have a much larger variance at announcement dates than otherwise, while plausibly their effect (H_1) is the same on announcement dates and otherwise. This heteroskedasticity around announcement dates provides a variant of the approach discussed in Section 4.3 in which the shock itself is measured as changes in some market rate around the announcement.

For additional references and discussion of regime-shift heteroskedasticity, see Lütkepohl and Netšunajev (2015) and Kilian (2015).

4.5.2 Identification by Heteroskedasticity: Conditional Heteroskedasticity

The idea of identification by conditional heteroskedasticity is similar to that of identification by regime-shift heteroskedasticity. Suppose that the structural shocks are conditionally heteroskedastic but H is constant. Then $\eta_t = H\varepsilon_t$ implies the conditional moment matching equations,

$$E\left(\eta_t\eta_t' | Y_{t-1}, Y_{t-2}, \ldots\right) = HE\left(\varepsilon_t\varepsilon_t' | Y_{t-1}, Y_{t-2}, \ldots\right)H'. \tag{43}$$

The conditional covariance matrix of ε_t is diagonal. If those variances evolve according to a GARCH process, then they imply a conditionally heteroskedastic process for η_t. Sentana and Fiorentini (2001) and Normandin and Phaneuf (2004) show that a GARCH process for ε_t combined with (43) can identify H. Lanne et al. (2010) extend this reasoning from GARCH models to Markov switching models. These are similar to the regime-shift model in Section 4.5.1, however the regime-shift indicator is latent; see Hamilton (2016). For further discussion, see Lütkepohl and Netšunajev (2015).

4.5.3 Instrumental Variables Interpretation and Potential Weak Identification

As pointed out by Rigobon (2003) and Rigobon and Sack (2003), identification by heteroskedasticity regimes has an instrumental variables interpretation, and this interpretation illustrates the potential inference challenges when the change in the variance provides only limited identification power either because the change is small, or because there are few observations in one of the regimes.

To illustrate the instrumental variables interpretation of identification by heteroskedasticity, let $n=2$ and suppose that the variance of the first shock varies between the two regimes while the variance of the other shock does not. This is the assumption used by Rigobon and Sack (2004) and Wright (2012) with high-frequency data, in which the variance of the monetary policy shock (ε_{1t}) is elevated around FOMC announcement dates while the variance of the other shocks does not change around announcement dates. Then under the unit effect normalization, (42) becomes,

$$\begin{pmatrix} \Sigma^j_{\eta_1\eta_1} & \Sigma^j_{\eta_1\eta_2} \\ \Sigma^j_{\eta_2\eta_1} & \Sigma^j_{\eta_2\eta_2} \end{pmatrix} = \begin{pmatrix} 1 & H_{12} \\ H_{21} & 1 \end{pmatrix} \begin{pmatrix} \sigma^2_{\varepsilon_1,j} & 0 \\ 0 & \sigma^2_{\varepsilon_2} \end{pmatrix} \begin{pmatrix} 1 & H_{21} \\ H_{12} & 1 \end{pmatrix}, \quad j=1,2, \tag{44}$$

where $\sigma^2_{\varepsilon_1}$ varies across regimes (announcement dates, or not) while $\sigma^2_{\varepsilon_2}$ does not.

Writing out the equations in (44) and solving shows that H_{21} is identified as the change in the covariance between η_{1t} and η_{2t}, relative to the change in the variance of η_{1t}:

$$H_{21} = \frac{\Sigma^2_{\eta_1\eta_2} - \Sigma^1_{\eta_1\eta_2}}{\Sigma^2_{\eta_1\eta_1} - \Sigma^1_{\eta_1\eta_1}}. \tag{45}$$

This suggests the estimator,

$$\hat{H}_{21} = \frac{\sum_{t=1}^{T} \hat{\eta}_{2t} Z_t}{\sum_{t=1}^{T} \hat{\eta}_{1t} Z_t}, \tag{46}$$

where $Z_t = D_t\hat{\eta}_{1t}$, where $D_t = -1/T_1$ in the first regime and $D_t = 1/T_2$ in the second regime, where T_1 and T_2 are the number of observation in each regime, and where $\hat{\eta}_t$ are the innovations estimated by full-sample OLS or weighted least squares.

The estimator in (46) is the instrumental variables estimator in the regression of $\hat{\eta}_{2t}$ on $\hat{\eta}_{1t}$, using Z_t as an instrument. Note the similarity of this IV interpretation to the IV interpretation in (39) arising from the very different identifying assumption that the cumulative IRF is lower triangular, so that H_{21} is estimated by the instrumental variables estimator using Y_{2t-1} as an instrument for ΔY_{2t}.

The IV expression (46) connects inference in the SVAR identification by heteroskedasticity to inference in instrumental variables regression, and in particular to inference when instruments might be weak. In (46), a weak instrument corresponds to the case that

Z_t is weakly correlated with $\hat{\eta}_{1t}$, that is, when the population change in the variance of η_{1t}, which appears in the denominator of (45), is small. Using the weak-instrument asymptotic nesting of Staiger and Stock (1997), one can show that, under standard moment conditions, $\hat{H}_{21} \xrightarrow{d} z_2/z_1$, where z_1 and z_2 are jointly normally distributed variables and where the mean of z_1 is $T^{1/2}\left(\Sigma^2_{\eta_1\eta_1} - \Sigma^1_{\eta_1\eta_1}\right)$. If the variability in z_1 is sizeable compared with this mean, then the estimator will in general have a nonnormal and potentially bimodal distribution with heavy tails, and inference based on conventional bootstrap confidence intervals will be misleading.

These weak-instrument problems can arise if the regimes each have many observations, but the difference between the regime variances is small, or if the differences between the variances is large across regimes but one of the regimes has only a small number of observations. In either case, what matters for the distribution of $\hat{H}_{21}$ is the precision of the estimate of the change in the variance of η_{1t}, relative to the true change.

Work on weak-identification robust inference in SVARs identified by heteroskedasticity is in its early stages. Magnusson and Mavroeidis (2014) lay out a general approach to construction of weak-identification robust confidence sets, and Nakamura and Steinsson (2015) implement weak-identification robust inference in their application to differential monetary policy shock heteroskedasticity around FOMC announcement dates.

4.6 Inequality (Sign) Restrictions

The identification schemes discussed so far use a priori information to identify the parameters of H, or the parameters of the first column of H in the case of single shock identification. The sense in which these parameters are identified is the conventional one: different values of the parameter induce different distributions of the data, so that the parameters of H (or H_1) are identified up to a single point. But achieving point identification can entail strong and, in many cases, controversial assumptions. As a result, in two seminal papers, Faust (1998) and Uhlig (2005) argued that instead identification could be achieved more convincingly by imposing restrictions on the signs of the impulse responses. They argued that such an approach connects directly with broad economic theories, for example a broad range of monetary theories suggest that monetary stimulus will have a nonnegative effect on economic activity over a horizon of, say, 1 year. This alternative approach to identification, in which the restriction takes the form of inequality restrictions on the IRF, does not produce point identification, however it does limit the possible values of H (or H_1) to a set. That is, under inequality restrictions, H (or H_1) is set identified.

Set identification introduces new econometric issues for both computation and inference. The standard approach to set identification in SVARs is to use Bayesian methods, which are numerically convenient. This section therefore begins by reviewing the mechanics of Bayesian inequality restriction methods, then turns to inferential issues arising from set identification with a focus on Bayesian sign-identified SVARs. The section concludes with some new research suggesting alternative ways to address these inferential issues.

4.6.1 Inequality Restrictions and Computing an Estimate of the Identified Set

In some applications, economic theory or institutional circumstances might provide a strong argument about the sign of the effect of a given shock on some variable. For example, in a supply and demand example with price and quantity as data, economic theory strongly suggests that the supply elasticity is positive, the demand elasticity is negative, so a positive supply shock increases quantity and decreases price while a positive demand shock increases both quantity and price. More generally, theory might suggest the sign of the effect of a given positive shock on one or more of the variables in the VAR over a certain number of horizons, that is, theory might suggest sign restrictions on elements of the SIRF.

As shown by Faust (1998) and Uhlig (2005) and surveyed by Fry and Pagan (2011), sign restrictions, or more generally inequality restrictions on the SIRF, can be used to help identify the shocks. In general, inequality restrictions provide set, but not point, identification of H, that is, they serve to identify a set of H matrices which contains the unique true H. The econometric problem, then, is how to estimate H and how to perform inference about H given that it is set identified.

The dominant approach in the literature is Bayesian, following Uhlig (2005). The Bayesian inference problem is to compute the posterior distribution of the SIRFs $D(\mathrm{L})$ given the data and a prior. With abuse of notation, we denote this posterior by $f(D|Y)$.

Computing $f(D|Y)$ requires a prior distribution for $D(\mathrm{L})$. Because $D(\mathrm{L})=A(\mathrm{L})^{-1}H$, developing a prior for $D(\mathrm{L})$ in turn entails developing a prior for $A(\mathrm{L})$ and H. Uhlig's (2005) algorithm adopts the unit standard deviation normalization (31), so that $\Sigma_\eta=HH'$. Thus any H can be written as $\Sigma_\eta^{1/2}Q$, where $\Sigma_\eta^{1/2}$ is the Cholesky decomposition of Σ_η and Q is an orthonormal matrix. Thus, under the unit standard deviation normalization, $D(\mathrm{L})=A(\mathrm{L})^{-1}\Sigma_\eta^{1/2}Q$. This expression has substantial computational advantages: $A(\mathrm{L})$ and Σ_η are reduced-form parameters which have conjugate priors under the standard assumption of normally distributed errors, and the only nonstandard part of the prior is Q. Moreover, the dimension for the prior over Q is substantially reduced because $QQ'=\mathrm{I}_n$. Let $\mathfrak{D}$ denote the set of IRFs satisfying the sign restriction, so the prior imposing the sign restrictions is proportional to $\mathbf{1}[D(L)\in\mathfrak{D}]$.

Continuing to abuse notation, and adopting the convention that the priors over $A(\mathrm{L})$, Σ_η, and Q are independent conditional on $D(L)\in\mathfrak{D}$, we can therefore write the posterior $f(D|Y)$ as

$$\begin{aligned} f(D|Y) &\propto f\left(Y|A(L),\Sigma_\eta,Q\right)\pi(A)\pi\left(\Sigma_\eta\right)\pi(Q)\mathbf{1}[D(L)\in\mathfrak{D}] \\ &\propto f\left(A(L),\Sigma_\eta|Y\right)\pi(Q)\mathbf{1}[D(L)\in\mathfrak{D}] \end{aligned} \tag{47}$$

where $f(Y|A(\mathrm{L}),\Sigma_\eta,Q)$ is the Gaussian likelihood for the SVAR $A(\mathrm{L})Y_t=\Sigma_\eta^{1/2}Q\varepsilon_t$, with $\Sigma_\varepsilon=\mathrm{I}_n$, and $f(A(\mathrm{L}),\Sigma_\eta|Y)$ is the posterior of the reduced-form VAR, where the second line in (47) follows because the likelihood does not depend on Q. Uhlig's (2005) algorithm uses conjugate Normal–Wishart priors for A(L) and Σ_{η}^{-1}, so computation of (or drawing from) $f(A(\mathrm{L}),\Sigma_{\eta}|Y)$ is straightforward.

The sign restrictions are imposed using the following algorithm.

(1) Draw a candidate $\widetilde{Q}$ from $\pi(Q)$, and $(\tilde{A}(L), \widetilde{\Sigma}_{\eta})$ from the posterior $f(A(\mathrm{L}),\Sigma_{\eta}|Y)$.

(2) Compute the implied SIRF, $\widetilde{D}(L)=\widetilde{A}(L)^{-1}\widetilde{\Sigma}_{\eta}^{1/2}\widetilde{Q}$.

(3) Retain $\widetilde{D}(L)$ if it satisfies the inequality restrictions.

(4) Repeat Steps (1)–(3) many times to obtain draws from $f(D|Y)$.

This algorithm uses a prior distribution $\pi(Q)$ over the space of orthonormal matrices. In the two-dimensional case all orthonormal matrices can be written as,

$$\widetilde{Q}=\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}. \tag{48}$$

Thus drawing from $\pi(Q)$ reduces to drawing from a prior over θ, $0\leq\theta\leq 2\pi$. Following Uhlig (2005), it is conventional to use (48) with $\theta\sim \mathrm{U}[0,2\pi]$.

For $n>2$, the restrictions are more complicated. For reasons of computational speed, Rubio-Ramírez et al. (2010) recommend using the QR or householder transformation method for drawing $\widetilde{Q}$, also see Arias et al. (2014). The QR method for constructing a draw of $\widetilde{Q}$ in step (1) proceeds by first drawing a $n\times n$ matrix $\widetilde{W}$, with elements that are independent standard normals, then using the QR decomposition to write $\widetilde{W}=\widetilde{Q}\widetilde{R}$, where $\widetilde{Q}$ is orthonormal and $\widetilde{R}$ is upper triangular.

The choice of prior $\pi(Q)$—in the $n=2$ case, the prior distribution for θ in (48)—is consequential and ends up being informative for the posterior, and we return to this issue in the next section.

4.6.1.1 Single Shock Identification

The discussion here has focused on system identification, however it can also be implemented for identification of a single shock. Specifically, if the inequality restrictions only involve one shock ε_{1t}, then those restrictions only involve the first column of $\widetilde{Q}$, $\widetilde{Q}_1$, and the resulting draw of H_1 is $\Sigma_{\eta}^{1/2}\widetilde{Q}_1$.

4.6.2 Inference When H *Is Set Identified*

The statistical problem is to provide a meaningful characterization of what the data tell us about the true value of H (and thus the true SIRFs) when H is only set identified. As pointed out by Fry and Pagan (2011), Moon and Schorfheide (2012), Moon et al. (2013), and Baumeister and Hamilton (2015a), the standard treatment of uncertainty using the posterior computed according to the algorithm in the preceding subsection raises a number of conceptual and technical problems. Central to these problems is that, because the SIRF is a nonlinear transformation of the parameter over which the prior is placed—in the $n=2$ case, over θ in (48)—a seemingly flat prior over Q ends up being highly informative for inference. Thus inference about the SIRFs is driven by assumptions unrelated to the economic issues at hand (priors over the space of orthonormal matrices) and which have opaque but impactful implications.

We focus on two inferential problems. To illustrate the issues, we consider a stripped-down two-variable SVAR.[v] The researcher is interested in constructing SIRFs and makes the sign restriction that the effect of shock 1 on both variables 1 and 2 is nonnegative on impact and for the first four periods; that is, $D_{h,11} \geq 0$ and $D_{h,21} \geq 0$, $h = 0, \ldots, 4$, where $D(\mathrm{L}) = A(\mathrm{L})^{-1}H$ is the SIRF.

To keep the example as simple as possible, suppose that the reduced-form VAR is first order, that $A(\mathrm{L})$ is diagonal, and that the innovations have identity innovation variance. That is,

$$A(\mathrm{L}) = \begin{pmatrix} 1 - \alpha_1 L & 0 \\ 0 & 1 - \alpha_2 L \end{pmatrix} \text{ where } \alpha_1, \alpha_2 > 0 \text{ and } \Sigma_\eta = I \tag{49}$$

so $Chol(\Sigma_\eta) = I$. Further suppose that the sample size is sufficiently large that these reduced-form parameters can be treated as known; thus the only SVAR uncertainty arises from Q or, because $n = 2$, from θ in (48). The researcher draws candidate orthonormal matrices $\widetilde{\mathrm{Q}}$ using (48), where $\theta \sim \mathrm{U}[0, 2\pi]$.[w] What is the resulting inference on the SIRF $D(\mathrm{L})$?

Under these assumptions, both the identified set for the SIRF for the first shock and the posterior distribution can be computed analytically. In large samples, for a particular draw $\widetilde{\mathrm{Q}}$, the candidate IRF is,

$$\widetilde{D}(L) = \widetilde{A}(L)^{-1}\Sigma_\eta^{1/2}\widetilde{\mathrm{Q}} = \begin{pmatrix} (1 - \alpha_1 L)^{-1}\cos\theta & -(1 - \alpha_1 L)^{-1}\sin\theta \\ (1 - \alpha_2 L)^{-1}\sin\theta & (1 - \alpha_2 L)^{-1}\cos\theta \end{pmatrix}, \tag{50}$$

where the equality uses the large-sample assumption that there is no sampling variability associated with estimation of $A(\mathrm{L})$ or Σ_η, so that the posterior draws $\left(\widetilde{A}(L), \widetilde{\Sigma}_\eta\right) = \left(A(\mathrm{L}), \Sigma_\eta\right)$. Applying the sign restrictions to the first column of (50) implies that $\widetilde{D}(L)$ satisfies the sign restrictions if $\cos\theta \geq 0$ and $\sin\theta \geq 0$, that is, if $0 \leq \theta \leq \pi/2$. Thus the identified set for $D_{21}(\mathrm{L})$ is $0 \leq D_{21}(\mathrm{L}) \leq (1 - \alpha_2 \mathrm{L})^{-1}$, so the identified set for the hth lag of the IRF is $[0, \alpha_2^h]$.

Because $D_{21}(\mathrm{L}) = (1 - \alpha_2 \mathrm{L})^{-1}\sin\theta$, the posterior distribution of the h-period SIRF of shock 2 on variable 1, $D_{h,21}$, is the posterior distribution of $\alpha_2^h \sin\theta$, where $\theta \sim \mathrm{U}[0, \pi/2]$. The mean of this posterior is $E[D_{h,21}] = E\left(\alpha_2^h \sin\theta\right) = 2\alpha_2^h/\pi \approx 0.637\alpha_2^h$ and the posterior median is $0.707\alpha_2^h$. By a change of variables, the posterior density of $D_{h,21}$ is $p_{\hat{D}_{21,i}|Y}(x) \propto 2\alpha_2^h/\pi\sqrt{1 - x^2}$, and the equal-tailed 68% posterior coverage region is $[0.259\alpha_2^h, 0.966\alpha_2^h]$.

[v] This example is similar to the $n = 2$ example in Baumeister and Hamilton (2015a), but further simplified.

[w] In the case $n = 2$, this is equivalent to drawing $\widetilde{\mathrm{Q}}$ using the QR algorithm discussed in Section 4.6.1.

This example illustrates two issues with sign-identified Bayesian inference. First, the posterior coverage interval concentrates strictly within the identified set. As pointed out by Moon and Schorfheide (2012), this result is generic to set-identified Bayesian econometrics in large samples. From a frequentist perspective, this is troubling. In standard parametric settings, in large samples Bayesian 95% posterior intervals coincide with frequentist 95% confidence intervals so, from a frequentist perspective, Bayes confidence sets contain the true parameter value in 95% of all realizations of the sample for all values of the true parameter. This is not the case in this sign-identified setting, however: over repeated samples, the Bayesian interval contains the true parameter value all of the time for some values of the parameter, and none of the time for others.[x]

Second, although the sign restrictions provide no a priori knowledge over the identified region, the "flat" prior on θ induces an informative posterior over the identified set, and in this example places most of the mass on large values of $D_{h,21}$. Although this effect is transparent in this simple example, Baumeister and Hamilton (2015a) show that the implied posteriors over the identified set can have highly informative and unintuitive shapes in more complicated models and in higher dimensions. The presence of sampling uncertainty in A(L) and Σ_η, which this example assumes away, further complicates the problem of knowing how inference is affected by the prior distribution.

In practice there is additional sampling variability in the reduced-form parameters A(L) and Σ_η. In the Bayesian context, this variability is handled by additionally integrating over the priors for those parameters, and with sampling variability the Moon and Schorfheide (2012) result that the posterior coverage set is strictly contained in the identified set need not hold. The lesson of the example, however, is that Bayesian posterior inference depends on the arbitrary prior over the space of orthonormal matrices. In short, conventional Bayesian methods can be justified from a subjectivist Bayes perspective, but doing so results in inferences that a frequentist would find unacceptable.[y]

[x] The asymptotic coincidence of Bayesian and frequentist confidence sets in standard parametric models, and of the posterior mean and the maximum likelihood estimator, is generally known as the Bernstein–von Mises theorem. Freedman (1999) provides an introduction to the theorem and examples of the breakdown of the theorem other than set-identified inference here. Also see Moon and Schorfheide (2012).

[y] A technical issue with Bayesian sign-identified SVARs is that it is conventional to examine impulse responses pointwise, as we did in the example by examining the posterior for $D_{h,21}$ for a given h rather than as a function of h. Thus the values of the VAR parameters corresponding to the posterior mode at one horizon will in general differ from the value at another horizon. See Sims and Zha (1999) for a discussion. Inoue and Kilian (2013) suggest a way to handle this problem and compute most likely IRFs pathways not pointwise.

4.6.2.1 Implications of the Unit Standard Deviation Normalization

The use of the unit standard deviation normalization in conventional Bayesian algorithms means that the SIRFs are all in standard deviation units. For questions posed in native units (what is the effect of a +25 basis point monetary policy shock to the Federal Funds rate?), it is necessary to rescale by the standard deviation of the shock. As Fry and Pagan (2011) point out, in the set-identified context, this rescaling raises additional inferential problems beyond those in the point-identified setting. Specifically, the conversion to the unit effect normalization must be done for each draw, not at a final step, because there is no consistent estimator for H under this method.

4.6.2.2 New Approaches to Inference in Set-Identified SVARs

These inferential problems are difficult and research is ongoing. Here, we briefly describe five new approaches.

The first two approaches are frequentist. A great deal of econometric research over the past decade has tackled frequentist approaches to set-identified inference in general. Inference when the parameter is identified by moment inequalities is nonstandard and—as in the SVAR application—can have the additional problem that the number of moment inequalities can be large but that only one or a few inequalities might be binding for a given value of the parameters. Including many non-binding inequalities for inference typically widens confidence intervals. The two approaches proposed to date for frequentist inference in set-identified SVARs differ in how to handle the problem of many inequalities. Moon et al. (2013) start with all the inequalities, then use a modification of Andrews and Soares's (2010) moment selection procedure to tighten the confidence intervals. Alternatively, Gafarov and Montiel Olea (2015) use only inequality constraints on H (ie, impact effects), which yield substantial computational simplifications. Their results suggest that, despite using fewer restrictions, confidence intervals can be tighter in some applications than if all the inequalities are used.

The remaining approaches are Bayesian. Baumeister and Hamilton (2015a) suggest replacing the prior on Q (on θ in the two-dimensional case) with a prior directly on the impact multiplier, that is, on H_{21}. That prior could be flat, truncated (for sign restrictions) or otherwise informative. This approach addresses the problem in the example earlier that the "flat" prior $\pi(Q)$ on the space of orthonormal matrices induces an informative posterior for the IRF even in large samples. However, this approach remains subject to the Moon and Schorfheide (2012) critique that the Bayesian posterior set asymptotically falls strictly within the identified set.

Giacomini and Kitagawa (2014) propose instead to use robust Bayes inference. This entails sweeping through the set of possible priors over Q, computing posterior regions for each, and reporting the posterior region that is the union of the prior-specific regions, and range of posterior means which is the range of the prior-specific posterior means.

They provide conditions under which the robust credible set converges to the identified set if the sample is large (thereby avoiding the Moon and Schorfheide (2012) critique).

Plagborg-Møller (2015) takes a very different approach and treats the SIRF as the primitive over which the prior is placed; in contrast to Baumeister and Hamilton (2015a,b) who place priors on the impact effect (H), Plagborg-Møller (2015) places a joint prior over the entire IRF. By directly parameterizing the structural MA representation he also handles the problem of noninvertible representations, where the prior serves to distinguish observationally equivalent SVARs.

4.7 Method of External Instruments

Instrumental variables estimation uses some quantifiable exogenous variation in an endogenous variable to estimate the causal effect of the endogenous variable. If a variable measuring such exogenous variation is available for a given shock, but that variable is not included in the VAR, it can be used to estimate the SIRF using a vector extension of instrumental variable regression. This method, which is due to Stock (2008), has been used in a small but increasing number of recent papers including Stock and Watson (2012a), Mertens and Ravn (2013), and Gertler and Karadi (2015). This method is also called the "proxy VAR" method, but we find the "method of external instruments" more descriptive.

Consider identification of the single shock ε_{1t}. Suppose that there is a vector of variables Z_t that satisfies:

$$\text{(i)}\quad E\left(\varepsilon_{1t}Z_t'\right)=\alpha'\neq 0 \tag{51}$$

$$\text{(ii)}\quad E\left(\varepsilon_{jt}Z_t'\right)=0,\quad j=2,\ldots,n. \tag{52}$$

The variable Z_t is called an *external instrument*: external because it is not an element of Y_t in the VAR, and an instrument because it can be used to estimate H_1 by instrumental variables.

Condition (i) corresponds to the usual relevance condition in instrumental variables regression and requires that the instrument be correlated with the endogenous variable of interest, ε_{1t}. Condition (ii) corresponds to the usual condition for instrument exogeneity and requires that the instrument be uncorrelated with the other structural shocks.

Conditions (i) and (ii), combined with the assumption (21) that the shocks are uncorrelated and the unit effect normalization (32), serve to identify H_1 and thus the structural shock. To see this, use $\eta_t=H\varepsilon_t$ along with (i) and (ii) and the partitioning notation (28) to write,

$$\begin{pmatrix} E\left(\eta_{1t}Z_t'\right) \\ E\left(\eta_{\bullet t}Z_t'\right)\end{pmatrix}=E\left(\eta_tZ_t'\right)=E\left(H\varepsilon_tZ_t'\right)=[H_1\quad H_\bullet]\begin{pmatrix} E\left(\varepsilon_{1t}Z_t'\right) \\ E\left(\varepsilon_{\bullet t}Z_t'\right)\end{pmatrix}=H_1\alpha'=\begin{pmatrix}\alpha' \\ H_{1\bullet}\alpha'\end{pmatrix}, \tag{53}$$

where $\eta_{\bullet t}$ denotes the final $n-1$ rows of η_t, the second equality uses $\eta_t = H\varepsilon_t$, the third equality uses the partitioning notation (28), the fourth equality uses (i) and (ii), and the final equality uses the unit effect normalization $H_{11}=1$ in (33).

Equating the first and the final expressions in (53) show that $H_{1\bullet}$, and thus H_1 and ε_{1t}, are identified. In the case of a single instrument, one obtains the expression,

$$H_{1\bullet} = \frac{E\eta_{\bullet t}Z_t}{E\eta_{1t}Z_t}. \tag{54}$$

This expression has a natural instrumental variables interpretation: the effect of ε_{1t} on η_{jt}, that is, the jth element of H, is identified as the coefficient in the population IV regression of η_{jt} onto η_{1t} using the instrument Z_t.

As with standard instrumental variables regression, the success of the method of external instruments depends on having at least one instrument that is strong and credibly exogenous. Although the literature on SVAR estimation using external instruments is young, at least in some circumstances such instruments are plausibly available. For example, the Cochrane and Piazzesi (2002) measure of the monetary shock discussed in Section 4.2 is not in fact the monetary shock: as they note, even if it successfully captures that part of the shock that was learned as an immediate result of FOMC meetings, it is possible that speeches of FOMC members and other Fed actions could provide signals of rate movements before the actual FOMC meeting. Thus, the Cochrane and Piazzesi (2002) measure is better thought of as an instrumental variable for the shock, not the shock itself; that is, it is plausibly correlated with the monetary policy shock and, because it is measured in a window around the FOMC meeting, it is plausibly exogenous. Viewed in this light, many of the series constructed as measures of shocks discussed in Section 4.4 are not in fact the actual shock series but rather are instruments for the shock series. Accordingly, SVARs that include these measures of shocks as a variable are not actually measuring the SIRF with respect to those shocks, but rather are measuring a reduced-form IRF with respect to this instrument for the shocks. In contrast, the method of external instruments identifies the IRF with respect to the structural shock.

As with IV regression more generally, if the instrument is weak then conventional asymptotic inference is unreliable. The details of external instruments in SVARs are sufficiently different from IV regression that the methods for inference under weak identification do not apply directly in the SVAR application. Work on inference with potentially weak external instruments in SVARs is currently under way (Montiel Olea et al., 2016).

5. STRUCTURAL DFMs AND FAVARs

Structural DFMs hold the possibility of solving three recognized shortcomings of SVARs. First, including many variables increases the ability of the innovations to span the space of structural shocks, thereby addressing the omitted variables problem discussed in Section 4.1.2. Second, because the shocks are shocks to the common factors, DFMs provide a natural framework for allowing for measurement error or idiosyncratic variation in individual series, thereby addressing the errors-in-variables problem in Section 4.1.2. Third, high-dimensional structural DFMs make it possible to estimate SIRFs, historical decompositions, and FEVDs that are consistent across arbitrarily many observed variables. Although these goals can be achieved using high-dimensional VARs, because the number of VAR parameters increases with n^2, those large-n VARs require adopting informative priors which typically are statistical in nature. In contrast, because in DFMs the number of parameters increases proportionately to n, DFMs do not require strong restrictions, beyond the testable restrictions of the factor structure, to estimate the parameters.

This section describes how SVAR methods extend directly to DFMs, resulting in a SDFM. In a SDFM, all the factors are unobserved. With a minor modification, one or more of the factors can be treated as observed, in which case the SDFM becomes a *FAVAR*. The key to meshing SVAR identification straight forwardly with DFMs is two normalizations: the "named factor" normalization in Section 2.1.3 for DFMs and the unit effect normalization described in Section 4.1.3 for SVARs. The named factor normalization ascribes the name of, say, the first variable, to the first factor, so that the innovation in the first factor equals the innovation in the common component of the first variable. The unit effect normalization says that the structural shock of interest, say the first shock, has a unit effect on the innovation to the first factor.

Taken together, these normalizations link an innovation in a factor to the innovation in a common component in a variable (naming) and set the scale of the structural shock (unit effect). For example, a one percentage point positive monetary supply shock increases the innovation in the Fed funds factor by one percentage point, which increases the innovation to the common component of the Federal funds rate by one percentage point, which increases the Federal funds rate by one percentage point. These normalizations do not identify the monetary policy shock, but any scheme that would identify the monetary policy shock in a SVAR can now be used to identify the monetary policy shock from the factor innovations.

This section works through the details of the previous paragraph. The section first considers SDFMs in the case of no additional restrictions on the factor loading matrix Λ, next turns to SDFMs in which Λ has additional restrictions and concludes with the extension of SVAR identification methods to FAVARs. This section provides a unified treatment that clarifies the link between SVARs, SDFMs, and FAVARs, including extensions to overidentified cases.

The literature has taken a number of approaches to extending SVARs to structural DFMs, and this section unifies and extends those approaches. The original FAVAR structure is due to Bernanke et al. (2005). Stock and Watson (2005) propose an approach with different normalizations and the treatment here streamlines theirs. The treatment of exactly identified SDFMs here is the same as in Stock and Watson (2012a). The other closest treatments in the literature are Forni and Gambetti (2010), Bai and Ng (2013), Bai and Wang (2014), and Bjørnland and Thorsrud (forthcoming).

5.1 Structural Shocks in DFMs and the Unit Effect Normalization

The structural DFM posits that the innovations in the factors are linear combinations of underlying structural shocks ε_t.

5.1.1 The SDFM

The SDFM augments the static DFM (6) and (7) with the assumption (20) that the factor innovations η_t are linear combinations of the structural shocks ε_t:

$$\overset{n\times1}{X_t} = \overset{n\times r}{\Lambda}\,\overset{r\times1}{F_t} + \overset{n\times1}{e_t} \tag{55}$$

$$\overset{r\times r}{\Phi}(\mathrm{L})\,\overset{r\times1}{F_t} = \overset{r\times q}{G}\,\overset{q\times1}{\eta_t} \quad \text{where } \Phi(\mathrm{L}) = I - \Phi_1\mathrm{L} - \cdots - \Phi_p\mathrm{L}^p, \tag{56}$$

$$\overset{q\times1}{\eta_t} = \overset{q\times q}{H}\,\overset{q\times1}{\varepsilon_t} \tag{57}$$

where following (7), there are r static factors and q dynamic factors, with $r \geq q$. In this system, the q structural shocks ε_t impact the common factors but not the idiosyncratic terms. Additionally, we assume that (SVAR-1)—(SVAR-3) in Section 4.1.4 hold, that the $q \times q$ matrix H is invertible (so the structural shocks can be recovered from the factor innovations), and that the shocks are mutually uncorrelated, that is, Σ_ε is diagonal as in (21).

The SIRF is obtained by substituting (57) into (56) and the result into (55) to obtain,

$$X_t = \Lambda\Phi(\mathrm{L})^{-1}GH\varepsilon_t + e_t. \tag{58}$$

The dynamic causal effect on all n variables of a unit increase in ε_t is the SIRF, which is $\Lambda\Phi(\mathrm{L})^{-1}GH$. Equivalently, the first term on the right-hand side of (58) is the moving average representation of the common component of X_t in terms of the structural shocks.

If interest is only in one shock, say the first shock, then the SIRF for that shock is $\Lambda\Phi(\mathrm{L})^{-1}GH_1$.

The SDFM generalizes the SVAR by allowing for more variables than structural shocks, and by allowing each variable to have idiosyncratic dynamics and/or measurement error. In the special case that there is no idiosyncratic error term (so $e_t = 0$), $r = q = n$, $\Lambda = I$, and $G = I$, the SDFM (58) is simply the structural MA representation (23), where $\Phi(\mathrm{L}) = A(\mathrm{L})$.

5.1.2 Combining the Unit Effect and Named Factor Normalizations

The SDFM (55)–(57) requires three normalizations: Λ, G, and H. We first consider the case $r = q$, so that the static factors have a full-rank covariance matrix, then turn to the case of $r \geq q$.

5.1.2.1 Normalization with $r=q$

In this case, set $G=I$, so that η_t are the innovations to the factors. We use the named factor normalization (12) for Λ and the unit effect normalization (32) for H. Using these two normalizations provides SIRFs in the native units of the variables and ensure that inference about SIRFs will not err by neglecting the data-dependent rescaling needed to convert from standard deviation units (if the unit standard deviation normalization is used) to native units.

As discussed in Section 2.1.3, the named factor normalization associates a factor innovation (and thus a factor) with the innovation to the common component of the naming variable. Without loss of generality, place the naming variables first, so that the first factor adopts the name of the first variable and so forth up to all r factors. Then $\Lambda_{1:r}=I_r$ where, as in (12), $\Lambda_{1:r}$ denotes rows 1 through r of Λ. If there are no overidentifying restrictions on Λ, Λ and F_t can first be estimated by principal components, then transformed as discussed following (12). That is, letting PC denote the principal components estimators,

$$\hat{\Lambda}=\begin{bmatrix} I_r \\ \hat{\Lambda}^{PC}_{r+1:n}\left(\hat{\Lambda}^{PC}_{1:r}\right)^{-1}\end{bmatrix} \quad \text{and} \quad \hat{F}_t=\hat{\Lambda}^{PC}_{1:r}\hat{F}^{PC}_t. \tag{59}$$

Together, the named factor normalization and the unit effect normalization set the scale of the structural shocks. For example, if the oil price and oil price supply shock are ordered first, a unit oil price supply shock induces a unit innovation in the first factor, which is the innovation in the common component of the oil price, which increases the oil price by one native unit (for example, by one percentage point if the oil price is in percent). Restated in terms of the notation in (58) and (59), the impact effect of ε_{1t} on X_{1t} is $\Lambda_1 H_1$, where Λ_1 is the first row of Λ. Because $\Lambda_1=(1\ 0\ \ldots\ 0)$ and the unit effect normalization sets $H_{11}=1$, $\Lambda_1' H_1=1$. Thus a unit increase in ε_{1t} increases X_{1t} by one (native) unit.

This approach extends to overidentifying restrictions on Λ using the methods of Section 2.3.1. To be concrete, in Section 7 we consider an empirical application to identifying an oil supply shock. Our dataset has four different oil prices (the US producer price index for crude petroleum, Brent, West Texas Intermediate (WTI), and the US refiners' acquisition cost of imported oil estimated by the US Energy Information Administration, all in logs). These series, which are available over different time spans, generally move together but their spreads vary because of local conditions and differences in crude oil grades. All four variables are measures of oil prices that have been, used in the oil-macro literature. We therefore model the real oil price factor innovation as impinging on all four real prices with a unit coefficient. The named factor normalization thus is,

$$\begin{bmatrix} p_t^{PPI-Oil} \\ p_t^{Brent} \\ p_t^{WTI} \\ p_t^{RAC} \\ X_{5:n,t} \end{bmatrix} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \\ & \Lambda_{5:n} & & \end{bmatrix} \begin{bmatrix} F_t^{oil} \\ F_{2:r,t} \end{bmatrix} + e_t, \tag{60}$$

where $p_t^{PPI-Oil}$ is the logarithm of the real price of crude oil from the producer price index, etc. Strictly speaking, any one of the first four rows of (60) is a naming normalization; the remaining rows are additional restrictions that treat the other three oil prices as additional indicators of the single oil price shock. At this point the number of static factors r is left unspecified; in the empirical application of Section 7, we use $r=8$.

Given the restricted Λ in (60), the static factors can be estimated by restricted principal components as described in Section 2.3.1 (by numerical minimization of the least-squares objective function (14) subject to the restrictions on Λ shown in (60)). The first factor computed from this minimization problem is the oil factor.

5.1.2.2 Normalization with $r > q$

If the empirical analysis of the DFM discussed in Section 2.4.2 indicates that the number of dynamic factors q is less than the number of static factors r, then an additional step is needed to estimate G. This step also needs to be consistent with the unit effect normalization. Accordingly, we normalize G so that

$$G = \begin{bmatrix} I_q \\ G_{q+1:r} \end{bmatrix}, \tag{61}$$

where $G_{q+1:r}$ is an unrestricted $(q-r) \times q$ matrix.

In population, G satisfying (61) can be constructed by first obtaining the innovations a_t to the factors, so that $\Phi(\mathrm{L})F_t = a_t$. Because $r > q$, $\Sigma_a = Ea_t a_t'$ has rank q. Partition $a_t = \left(a_{1t}'\, a_{2t}'\right)'$, where a_{1t} is $q \times 1$ and a_{2t} is $(r-q) \times 1$, and similarly partition Σ_a. Assuming that the upper $q \times q$ block of Σ_a is full rank, we can set $\eta_t = a_{1t}$ and $G_{q+1:r} = \Sigma_{a,21}\Sigma_{a,11}^{-1}$. This construction results in the normalization (61).

In sample, these population objects can be replaced by sample objects. That is, let $\hat{a}_t$ be the residuals from a regression of $\hat{F}_t$ onto p lags of $\hat{F}_t$, let $\hat{\eta}_t = \hat{a}_{1t}$ and let $\hat{\Sigma}_a$ denote the sample covariance matrix of $\hat{a}_t$. Then $\hat{G}_{q+1:r} = \hat{\Sigma}_{a,21}\hat{\Sigma}_{a,11}^{-1}$ is the matrix of coefficients in the regression of $\hat{a}_{2t}$ onto $\hat{\eta}_t$.[z]

[z] This algorithm assumes that the sample inverse $\hat{\Sigma}_{a,11}^{-1}$ is well behaved.

5.1.2.3 Estimation Given an Identification Scheme

With the normalization set, the identification schemes discussed in Section 4 carry over directly. The innovation η_t in Section 4 is now the innovation to the factors, however, the factors (or the subset that are needed) have now been named, and the scale has been set on the structural shocks, so all that remains is to implement the identification scheme. The formulas in Section 4 carry over with the notational modification of setting $A(\mathrm{L})$ in Section 4 to $\Phi(\mathrm{L})$. Section 6 illustrates two contemporaneous restriction identification schemes for oil prices.

5.1.3 Standard Errors for SIRFs

There are various ways to compute standard errors for the SIRFs and for other statistics of interest such as FEVDs. The method used in this chapter is the parametric bootstrap, which (like other standard bootstrap methods) applies only when there is strong identification.

The parametric bootstrap used here proceeds as follows.

1. Estimate Λ, F_t, $\Phi(\mathrm{L})$, G, and Σ_η, and compute the idiosyncratic residual $\hat{e}_t = X_t - \hat{\Lambda}\hat{F}_t$.
2. Estimate univariate autoregressive processes for $\hat{e}_t$, $\hat{e}_{it} = d_i(L)\hat{e}_{it-1} + \zeta_{it}$ (this chapter uses an AR(4)).
3. Generate a bootstrap draw of the data by (a) independently drawing $\widetilde{\eta}_t \sim N\left(0, \hat{\Sigma}_\eta\right)$ and $\zeta_{it} \sim N\left(0, \hat{\sigma}^2_{\zeta_i}\right)$; (b) using the draws of ζ_{it} and the autoregression coefficients $\hat{d}_i(L)$ to generate idiosyncratic errors $\tilde{e}_t$; (c) using $\hat{\Phi}(L)$, $\hat{G}$, and $\widetilde{\eta}_t$ to generate factors $\widetilde{F}_t$; and (d) generating bootstrap data as $\widetilde{X}_t = \hat{\Lambda}\widetilde{F}_t + \widetilde{e}_t$.
4. Using the bootstrap data, estimate Λ, F_t, $\Phi(\mathrm{L})$, G, and H to obtain a bootstrap estimate of the SIRF $\Lambda\Phi(\mathrm{L})GH$. For identification of a subset of shocks, replace H with the columns of H corresponding to the identified shock(s).
5. Repeat Steps 3 and 4 for the desired number of bootstrap draws, then construct bootstrap standard errors, confidence intervals, and/or tests.

Variations on this approach are possible, for example the normal errors drawn in Step 3 could be replaced by block bootstrap resampling of the residuals from the factor VAR and the idiosyncratic autoregression.

There is ongoing work on improving inference in DFMs, SDFMs, and FAVARs using the bootstrap. For example, Yamamoto (2012) develops a bootstrap procedure for FAVARs under the unit standard deviation normalization. Corradi and Swanson (2014) consider the bootstrap for tests of the stability of the factor loadings and factor-augmented regression coefficients. Gonçalves and Perron (2015) establish the asymptotic validity of the bootstrap for the parameters in factor-augmented regressions. Gonçalves et al. (forthcoming) develop bootstrap prediction intervals for DFMs for h-period ahead forecasts. Going into detail on these developments is beyond the scope of this paper.

5.2 Factor-Augmented Vector Autoregressions

Originally developed by Bernanke et al. (2005), FAVARs model some of the factors as observed variables while the remaining factors are unobserved. The FAVAR thus imposes restrictions on the DFM, specifically, that one or more of the factors is measured without error by one or more of the observable variables. Accordingly, SVAR identification methods with the unit effect normalization carry over directly to FAVARs.

The FAVAR model can be represented in two ways. The first is as a DFM with parametric restrictions imposed. For simplicity, consider the case of a single observed factor $\widetilde{F}_t$ which is measured without error by the variable Y_t, r unobserved factors F_t, and order the variable observing $\widetilde{F}_t$ first. Then the structural FAVAR model is,

$$\begin{pmatrix} Y_t \\ X_t \end{pmatrix} = \begin{pmatrix} 1 & 0_{1\times r} \\ & \Lambda \end{pmatrix} \begin{pmatrix} \widetilde{F}_t \\ F_t \end{pmatrix} + \begin{pmatrix} 0 \\ u_t \end{pmatrix}, \tag{62}$$

$$F_t^+ = \Phi(\mathrm{L})F_{t-1}^+ + G\eta_t \quad \text{where } F_t^+ = \begin{pmatrix} \widetilde{F}_t \\ F_t \end{pmatrix}, \tag{63}$$

$$\eta_t = H\varepsilon_t. \tag{64}$$

Thus, the FAVAR model combines the unit effect normalization on the factor loadings in (12) with the assumption that there is no idiosyncratic component for the variable observing $\widetilde{F}_t$.

The second, more common representation of the FAVAR model makes the substitution $Y_t = \widetilde{F}_t$ (from the first line of (62)), so that Y_t is included as a factor directly:

$$X_t = \Lambda \begin{pmatrix} Y_t \\ F_t \end{pmatrix} + u_t \tag{65}$$

$$F_t^+ = \Phi(\mathrm{L})F_{t-1}^+ + G\eta_t, \quad \text{where } F_t^+ = \begin{pmatrix} Y_t \\ F_t \end{pmatrix}, \tag{66}$$

$$\eta_t = H\varepsilon_t. \tag{67}$$

With this substitution, the SDFM identification problem becomes the SVAR identification problem, where the VAR is now in terms of $(Y_t \;\; F_t')$. The factors and factor loadings can be estimated by least squares; if there are overidentifying restrictions on Λ, they can be imposed using restricted least squares as in Section 2.3.1[aa].

As an illustration, consider Bernanke et al.'s (2005) FAVAR application of the "slow-R-fast" identification scheme for monetary policy shocks. This original FAVAR application achieves two goals. First, by including a large number of variables, it addresses

[aa] Additional details about implementing this restricted least squares approach are provided in the discussion of the empirical application in Section 7.3.

the omitted variable problem of low-dimensional VARs and in particular aims to resolve the so-called "price puzzle" of monetary VARs (see Ramey, 2016, this Handbook). Second, the joint modeling of these many variables permits estimating internally consistent SIRFs for an arbitrarily large list of variables of interest.

In the slow-*R*-fast scheme, monetary policy shocks or news/financial shocks are assumed not to affect slow-moving variables like output, employment, and price indices within a period, monetary policy responds within a period to shocks to slow-moving variables but not to news or financial shocks, and fast-moving variables (like asset prices) respond to all shocks, including news/financial shocks that are reflected only in those variables.[bb] Let "*s*" and "*f*" denote slow/fast-moving variables, innovations, and shocks, order the slow-moving variables first in X_t, and (departing from the convention earlier) order the slow-moving innovations and factors first, followed by the observable factor ($Y_t = R_t$, the Fed funds rate), then the fast-moving factors and innovations. Then the Bernanke et al. (2005) implementation of the slow-*R*-fast identification scheme is,

$$\begin{pmatrix} X_t^s \\ X_t^f \end{pmatrix} = \begin{pmatrix} \Lambda_{ss} & 0 & 0 \\ \Lambda_{fs} & \Lambda_{fr} & \Lambda_{ff} \end{pmatrix} \begin{pmatrix} F_t^s \\ r_t \\ F_t^f \end{pmatrix} + e_t \qquad (68)$$

$$\boldsymbol{\Phi}(\mathrm{L}) \begin{pmatrix} F_t^s \\ r_t \\ F_t^f \end{pmatrix} = \begin{pmatrix} \eta_t^S \\ \eta_t^r \\ \eta_t^f \end{pmatrix}, \quad \text{and} \qquad (69)$$

$$\begin{pmatrix} \eta_t^S \\ \eta_t^r \\ \eta_t^f \end{pmatrix} = \begin{pmatrix} H_{ss} & 0 & 0 \\ H_{rs} & 1 & 0 \\ H_{fs} & H_{fr} & H_{ff} \end{pmatrix} \begin{pmatrix} \varepsilon_t^S \\ \varepsilon_t^r \\ \varepsilon_t^f \end{pmatrix}. \qquad (70)$$

This scheme imposes overidentifying restrictions on Λ in (68), and those restrictions can be imposed by restricted principal components as in Section 2.3.1.

6. A QUARTERLY 200+ VARIABLE DFM FOR THE UNITED STATES

Sections 6 and 7 illustrate the methods in the previous section using a 207-variable DFM estimated using quarterly data, primarily for the US economy. This section describes the reduced-form DFM: the number of factors, its fit, and its stability. Section 7 uses the reduced-form DFM to estimate structural DFMs that estimate the effect of oil market shocks on the economy under various identification schemes.

[bb] For additional discussion of the slow-*R*-fast scheme, see Christiano et al. (1999).

6.1 Data and Preliminary Transformations

The data are quarterly observations on 207 time series, consisting of real activity variables, prices, productivity and earnings, interest rates and spreads, money and credit, asset and wealth variables, oil market variables, and variables representing international activity. The series are listed by category in Table 1, and a full list is given in the Data Appendix. Data originally available monthly were converted to quarterly by temporal averaging. Real activity variables and several other variables are seasonally adjusted. The dataset updates and extends the dataset used in Stock and Watson (2012a); the main extension is that the dataset used here includes Kilian's (2009) international activity measure and data on oil market, which are used in the analysis in the next section of the effects of oil market shocks on the economy. The full span of the dataset is 1959Q1–2014Q4. Only 145 of the 207 series are available for this full period.

From this full dataset, a subset was formed using the 86 real activity variables in the first four categories in Table 1; this dataset will be referred to as the "real activity dataset." Of the real activity variables, 75 are available over the full sample.

The dataset is described in detail in the Data Appendix.

6.1.1 *Preliminary Transformations and Detrending*

The data were subject to four preliminary transformations. First, the DFM framework summarized in Section 2 and the associated theory assumes that the variables are second-order stationary. For this reason, each series was transformed to be approximately

Table 1 Quarterly time series in the full dataset

	Category	Number of series	Number of series used for factor estimation
(1)	NIPA	20	12
(2)	Industrial production	11	7
(3)	Employment and unemployment	45	30
(4)	Orders, inventories, and sales	10	9
(5)	Housing starts and permits	8	6
(6)	Prices	37	24
(7)	Productivity and labor earnings	10	5
(8)	Interest rates	18	10
(9)	Money and credit	12	6
(10)	International	9	9
(11)	Asset prices, wealth, and household balance sheets	15	10
(12)	Other	2	2
(13)	Oil market variables	10	9
	Total	207	139

Notes: The real activity dataset consists of the variables in the categories 1–4.

integrated of order zero, for example real activity variables were transformed to growth rates, interest rates were transformed to first differences, and prices were transformed to first differences of rates of inflation. The decisions about these transformations were guided by unit root tests combined with judgment, and all similar series within a category were subject to the same transformation (for example, all measures of employment were transformed to growth rates). Selected cointegrating relations were imposed by including error correction terms. Specifically, interest rate spreads are modeled as integrated of order zero.

Second, a small number of outliers were removed. Third, following Stock and Watson (2012a), the long-term mean of each series was removed using a biweight filter with bandwidth of 100 quarters. This step is nonstandard and is discussed in the next subsection. Fourth, after these transformations, the series were standardized to have unit standard deviation.

The Data Appendix provides more details on these steps, including the preliminary transformation of each series.

6.1.1.1 Removing Low-Frequency Trends

Recent research has documented that there has been a long-term slowdown in the mean growth rate of GDP over the postwar period, see Stock and Watson (1996, 2012a), Council of Economic Advisers (2013), and Gordon (2014, 2016). Although there is debate over the cause or causes of this slowdown, it is clear that long-term demographic shifts play an important role. The entry of women into the US labor force during the 1970–90s increased the growth rate of the labor force, and thus increased the growth rate of full-employment GDP, and the aging and retirement of the workforce are now decreasing the labor force participation rate (Aaronson et al., 2014 and references therein). The net effect of these demographic shifts is a reduction in the annual growth rate of GDP due to supply side demographics of approximately one percentage point from the early 1980s to the present. This long-term slowdown is present in many NIPA aggregates and in theory could appear in long-term trends in other series as well, such as interest rates.

These long-term trends, while important in their own right, are relevant to the exercise here for reasons that are technical but nonetheless important. These trends pose two specific problems. First, if the trends are ignored and the series, say employment growth and GDP growth, are modeled as stationary, then because these persistent components are small, the empirically estimated model will be mean reverting. However, the underlying causes of the trends, such as demographics, do not suggest mean reversion. Thus ignoring these long-term trends introduces misspecification errors into forecasts and other reduced-form exercises. Second, structural analysis that aims to quantify the response of macroeconomic variables to specific shocks generally focus on shocks that have transitory effects on GDP growth, such as monetary shocks, demand shocks, or oil supply shocks. Ignoring long-term trends by modeling growth rates as mean reverting introduces specification error in the dynamics of VARs and DFMs: the reduced-form IRFs confound the responses to these transitory shocks with the slowly unfolding trends arising from other sources.

In principal one could model these long-term trends simultaneously with the other factors, for example by adopting a random walk drift term as a factor appearing in the growth rate of some series. This approach has the advantage of explicitly estimating the low-frequency trends simultaneously with the rest of the DFM, however it has the disadvantage of requiring time series models for these trends, thereby introducing the possibility of parametric specification error. Because the purpose of the DFM analysis in this and the next section—and more generally in the vast bulk of the VAR and DFM literature—is analysis and forecasting over short- to medium-horizons (say, up to 4 years), a simpler and arguably more robust approach is simply to remove the low-frequency trends and to estimate the time series model using detrended growth rates.

For these reasons, we detrend all the series prior to estimating the DFM. Although the decline in these growth rates has been persistent, neither the underlying reasons for the declines nor visual inspection of the trends (eg, as displayed in Stock and Watson, 2012a; Gordon, 2014) suggest that they follow a linear trend, so that linear detrending is not appropriate.

The specific detrending method used here follows Stock and Watson (2012a). First, the series is transformed to being approximately integrated of order zero as discussed earlier, for example employment is transformed to employment growth. Second, the trend of each transformed series (for example, employment growth) is estimated nonparametrically using a biweight low-pass filter, with a bandwidth of 100 quarters.[cc]

Fig. 2 compares the biweight filter to three other filters that could be used to estimate the low-frequency trend: an equal-weighted moving average filter with 40 leads and lags (ie, an 81-quarter centered moving average), the Hodrick and Prescott (1997) filter with the conventional quarterly tuning parameter (1600), and the Baxter and King (1999) lowpass bandpass filter with a passband of 200 quarters, truncated to ±100 lags. Each of these filters is linear, so that the estimated trend is $w(\mathrm{L})x_t$ where x_t is the original series (eg, employment growth) and where $w(\mathrm{L})$ generically denotes the filter. Fig. 2A plots the weights of these filters in the time domain and Fig. 2B plots the spectral gain of these filters.[dd]

As can be seen in these figures, the biweight filter is very similar to the Baxter–King lowpass filter. It is also comparable to the equal-weight moving average filter of ±40 quarters, however the biweight filter avoids the noise induced by the sharp cutoff of the moving average filter (these higher frequency components in the moving average filter are evident in the ripples at higher frequencies in the plot of its gain in Fig. 2B). In contrast, all three of these filters focus on much lower frequencies than the Hodrick and

[cc] Tukey's biweight filter $w(\mathrm{L})$ is two sided with $w_j = c(1-(j/B)^2)^2$ for $|j| \leq B$ and $|j| = 0$ otherwise, where B is the bandwidth and c is a normalization constant such that $w(1) = 1$.

[dd] For filter $w(\mathrm{L})$, the estimated trend is $w(\mathrm{L})x_t$ and the detrended series is $x_t - w(\mathrm{L})x_t$. The spectral gain of the filter $w(\mathrm{L})$ is $\|w(e^{i\omega})\|$, where $\|\cdot\|$ is the complex norm.

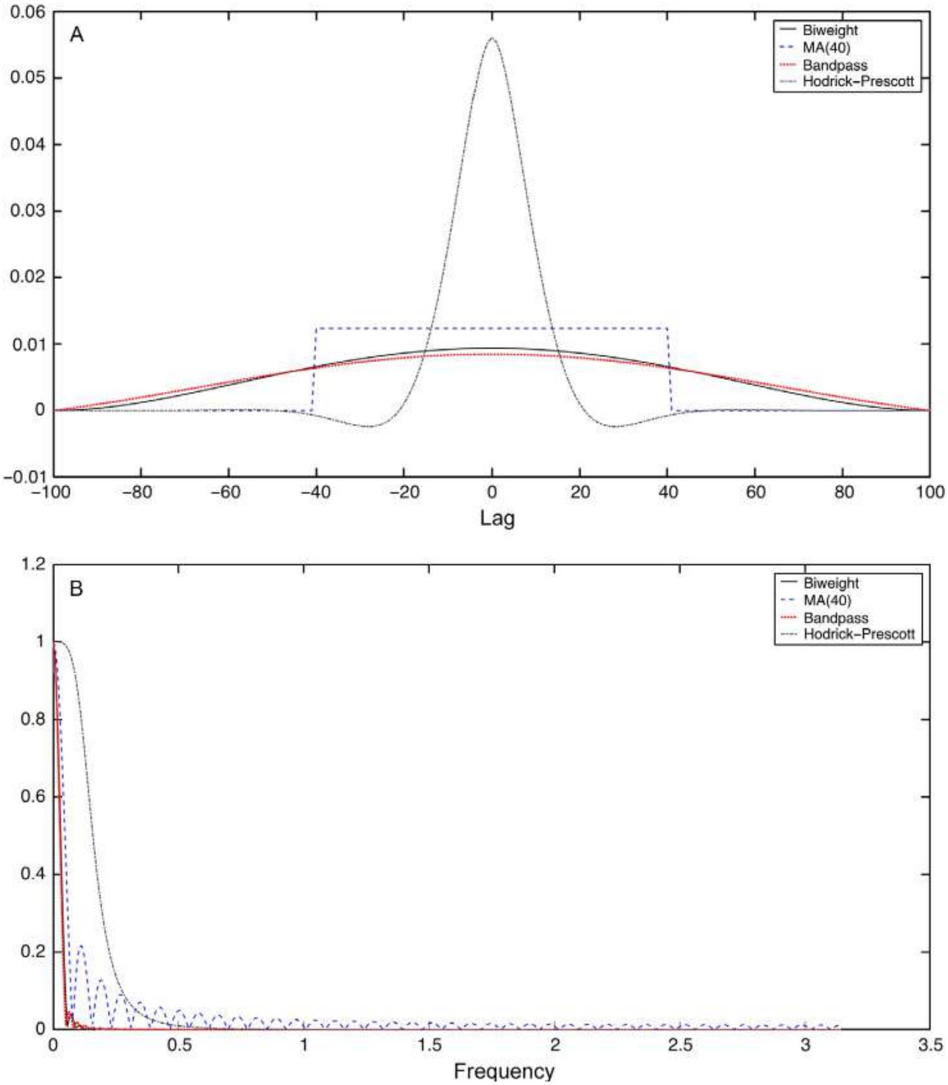

Fig. 2 Lag weights and spectral gain of trend filters. *Notes:* The biweight filter uses a bandwidth (truncation parameter) of 100 quarters. The bandpass filter is a 200-quarter low-pass filter truncated after 100 leads and lags (Baxter and King, 1999). The moving average is equal-weighted with 40 leads and lags. The Hodrick and Prescott (1997) filter uses 1600 as its tuning parameter.

Prescott filter, which places most of its weight on lags of ±15 quarters. The biweight filter estimates trends at multidecadal frequencies, whereas the Hodrick and Prescott trend places considerable weight on fluctuations with periods less than a decade.

The biweight filter needs to be modified for observations near the beginning and end of the sample. One approach would be to estimate a time series model for each series, use forecasts from that model to pad the series at end points, and to apply the filter to this padded series. This approach corresponds to estimating the conditional expectation of the filtered series at the endpoints, given the available data. However, doing so requires estimating a model which raises the problems discussed earlier, which our approach to trend removal aims to avoid: if the trends are ignored when the model is estimated, then the long-term forecasts revert to the mean and this mean reversion potentially introduces misspecification into the trend estimation, but alternatively specifying the trends as part of the model introduces potential parametric misspecification. Instead, the approach used here is to truncate the filter, renormalize, and apply the modified filter directly to the available data for observations within a bandwidth of the ends of the sample.[ee]

6.1.2 *Subset of Series Used to Estimate the Factors*

The data consist of series at multiple levels of aggregation and as a result some of the series equal, or nearly equal, the sum of disaggregated component series. Although the aggregation identity does not hold in logarithms, in the context of the DFM, the idiosyncratic term of the logarithm of higher-level aggregates is highly correlated with the share weighted average of the idiosyncratic term of the logarithms of its disaggregated components. For this reason, when the disaggregated components series are available, the disaggregated components are used to estimate the factors but the higher-level aggregate series are not used.

For example, the dataset contains total IP, IP of final products, IP of consumer goods, and seven sectoral IP measures. The first three series are constructed from the seven sectoral IP series in the dataset, so the idiosyncratic terms of the three aggregates are collinear with those of the seven disaggregated components. Consequently, only the seven disaggregated sectoral IP series are used to estimate the factors.

The aggregates not used for estimating the factors include GDP, total consumption, total employment and, as just stated, total IP. In all, the elimination of aggregates leaves 139 series in the full dataset for estimation of the factors. For the real activity dataset, eliminating aggregates leave 58 disaggregate series for estimating the factor. Table 1 provides the number of series used to estimate the factors by category.

6.2 Real Activity Dataset and Single-Index Model

The first step is to determine the number of static factors in the real activity dataset. Fig. 3 shows three scree plots computed using the 58 disaggregate series in the real activity dataset: using the full dataset and using subsamples split in 1984, a commonly used estimate of the Great Moderation break date. Table 2 (panel A) summarizes statistics related to the number of factors: the marginal R^2 of the factors (that is, the numerical values of the first bar in Fig. 3), the Bai and Ng (2002) IC_{p2} information criterion, and the Ahn and Horenstein (2013) eigenvalue ratio.

[ee] For example, suppose observation t is $m < B$ periods from the end of the sample, where B is the bandwidth. Then the estimated trend at date t is $\sum_{i=-B}^{m} w_i x_{t+i} \Big/ \sum_{i=-B}^{m} w_i$, where w_i is the weight at lag i of the unadjusted two-sided filter.

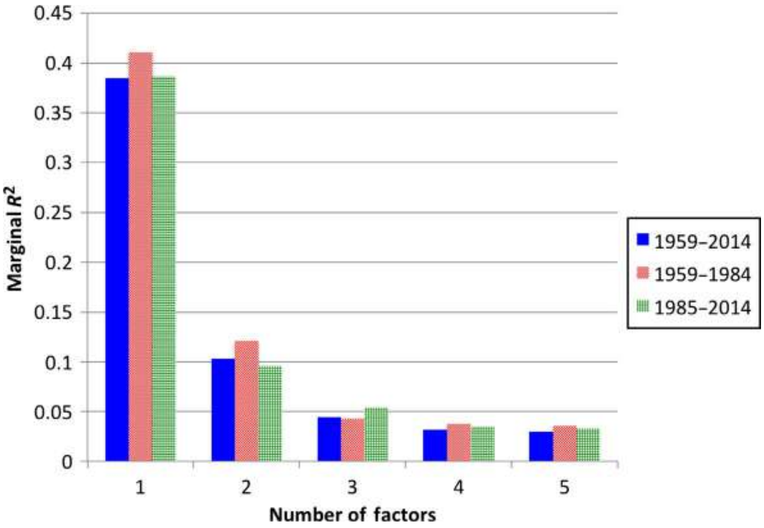

Fig. 3 Scree plot for real activity dataset: full sample, pre-1984, and post-1984.

First consider the full-sample estimates. As seen in Fig. 3, the dominant contribution to the trace R^2 of the 58 subaggregates comes from the first factor which explains fully 38.5% of the variance of the 58 series. Still, there are potentially meaningful contributions to the trace R^2 by the second and possibly higher factors: the marginal R^2 for the second factor over the full sample is 10.3%, for the third is 4.4%, and the total R^2 for the first five is 59.4%, a large increase over the 38.5% explained by the first factor alone. This suggests at least one, but possibly more, factors in the real activity dataset. The Bai and Ng (2002) IC_{p2} criterion estimates three factors, while the Ahn–Horenstein ratio estimates one factor. Unfortunately, such ambiguity is typical, and in such cases judgment must be exercised, and that judgment depends on the purpose to which the DFM is used.

Fig. 1 (shown in Section 1) plots the four-quarter growth rate of GDP, IP, nonfarm employment, and manufacturing and trade sales along with their common components estimated using the single static factor.[ff] Of these, only manufacturing and trade sales were used to estimate the factors, the remaining series being aggregates for which component disaggregated series are in the dataset. Evidently, the full-sample single factor explains the variation of these series at annual through business cycle frequencies.

Fig. 4 presents estimates of the four-quarter growth in GDP and its common components computed using the full sample with 1, 3, and 5 factors (the single-factor common component also appears in Fig. 1). The common component of GDP has an R^2 of 0.73 with a single factor, which increases to 0.88 for five factors. Inspection

[ff] The common component of four-quarter growth is the four-quarter growth of the common component of the series. For the ith series, this common component is $\hat{\Lambda}_i\left(\hat{F}_t + \hat{F}_{t-1} + \hat{F}_{t-2} + \hat{F}_{t-3}\right)$, where $\hat{F}_t$ and $\hat{\Lambda}_i$ are, respectively, the principal components estimator of the factors and the ith row of the estimated factor loadings.

Table 2 Statistics for estimating the number of static factors

(A) Real activity dataset ($N = 58$ disaggregates used for estimating factors)

Number of static factors	Trace R^2	Marginal trace R^2	BN-IC_{p2}	AH-ER
1	0.385	0.385	−0.398	**3.739**
2	0.489	0.103	−0.493	2.338
3	0.533	0.044	**−0.494**	1.384
4	0.565	0.032	−0.475	1.059
5	0.595	0.030	−0.458	1.082

(B) Full dataset ($N = 139$ disaggregates used for estimating factors)

Number of static factors	Trace R^2	Marginal trace R^2	BN-IC_{p2}	AH-ER
1	0.215	0.215	−0.183	**2.662**
2	0.296	0.081	−0.233	1.313
3	0.358	0.062	−0.266	1.540
4	0.398	0.040	**−0.271**	1.368
5	0.427	0.029	−0.262	1.127
6	0.453	0.026	−0.249	1.064
7	0.478	0.024	−0.235	1.035
8	0.501	0.024	−0.223	1.151
9	0.522	0.021	−0.205	1.123
10	0.540	0.018	−0.185	1.057

(C) Amenguel-Watson estimate of number of dynamic factors: BN-IC_{pi} values, full dataset ($N = 139$)

No. of dynamic factors	Number of static factors									
	1	2	3	4	5	6	7	8	9	10
1	−0.098	−0.071	−0.072	−0.068	−0.069	−0.065	−0.064	−0.064	−0.064	−0.060
2		**−0.085**	−0.089	−0.087	−0.089	−0.084	−0.084	−0.084	−0.085	−0.080
3			**−0.090**	**−0.088**	**−0.091**	**−0.088**	**−0.088**	**−0.086**	**−0.086**	**−0.084**
4				−0.077	−0.080	−0.075	−0.075	−0.073	−0.072	−0.069
5					−0.064	−0.060	−0.062	−0.057	−0.055	−0.052
6						−0.045	−0.043	−0.040	−0.037	−0.036
7							−0.024	−0.022	−0.020	−0.018
8								−0.002	0.000	0.003
9									0.021	0.023
10										0.044

Notes: BN-IC_{p2} denotes the Bai and Ng (2002) IC_{p2} information criterion. AH-ER denotes the Ahn and Horenstein (2013) ratio of $(i+1)$th to ith eigenvalues. The minimal BN-IC_{p2} entry in each column, and the maximal Ahn–Horenstein ratio entry in each column, is the respective estimate of the number of factors and is shown in bold. In panel C, the BN-IC_{p2} values are computed using the covariance matrix of the residuals from the regression of the variables onto lagged values of the column number of static factors, estimated by principal components.

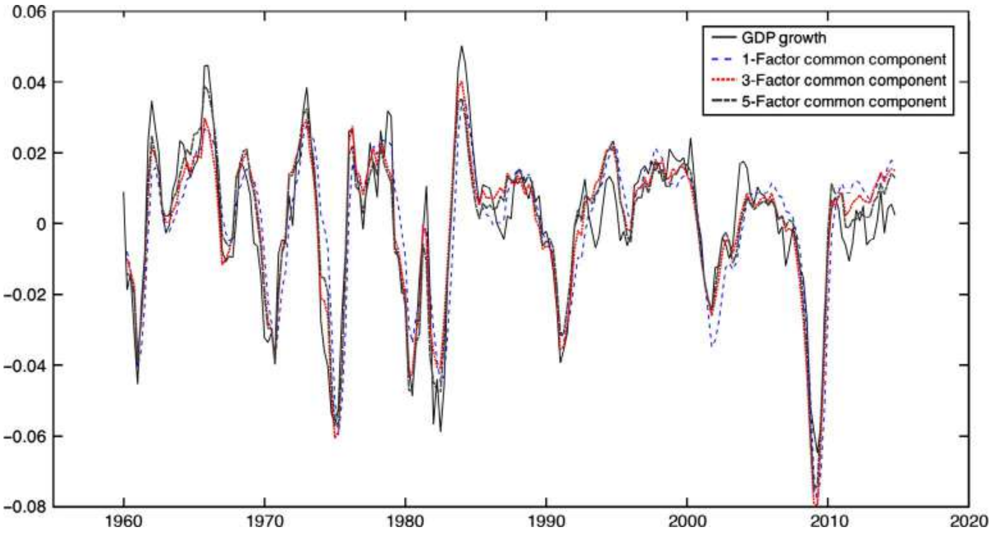

Fig. 4 Four-quarter GDP growth (*black*) and its common component based on 1, 3, and 5 static factors: real activity dataset.

of the fits for all series suggests that the factors beyond the first serve mainly to explain movements in some of the disaggregate series.

In principle, there are at least three possible reasons why there might be more than one factor among these real activity series.

The first possible reason is that there could be a single dynamic factor that manifests as multiple static factors; in the terminology of Section 2, perhaps $q=1$, $r>1$, and G in (7) has fewer rows than columns. As discussed in Section 2, it is possible to estimate the number of dynamic factors given the number of static factors, and applying the Amengual and Watson (2007) test to the real activity dataset, with three static factors, estimates that there is a single dynamic factor. That said, the contribution to the trace R^2 of possible additional dynamic factors remains large in an economic sense, so the estimate of a single dynamic factor is suggestive but not conclusive.

The second possible reason is that these series move in response to multiple structural shocks, and that their responses to those shocks are sufficiently different that the innovations to their common components span the space of more than one aggregated shock.

The third reason, discussed in Section 2, is that structural instability could lead to spuriously large numbers of static factors; for example, if there is a single factor in both the first and second subsamples but a large break in the factor loadings, then the full-sample PC would find two factors, one estimating the first-subsample factor (and being noise in the second subsample), the other estimating the second-subsample factor.

The three scree plots in Fig. 3 does not, however, show evidence of such instability. The scree plots are remarkably stable over the two subsamples and in particular the trace R^2 of the first factor is essentially the same whether the factor is computed over the full sample (38.5%), the pre-1984 subsample (41.1%), or the post-1984 subsample (38.7%). Consistent with this stability, the Bai and Ng (2002) criterion estimates two factors in the first subsample, three in the second, and three in the combined sample.

Fig. 5 provides additional evidence on this stability by plotting the four-quarter growth of the first estimated factor (the first principal component) computed over the full dataset and computed over the pre- and post-1984 subsamples. These series are nearly indistinguishable visually and the correlations between the full-sample estimate and the pre- and post-1984 estimates are high (both exceed 0.99). Thus Figs. 3–5 point to stability of the single-factor model. We defer formal tests for stability to the analysis of the larger DFM based on the full dataset.

Taken together, these results suggest that the first estimated factor (first principal component) based on the full dataset is a good candidate for an index of quarterly real economic activity.

Of course, other variables, such as financial variables, are useful for forecasting and nowcasting real activity. Moreover, while multiple macro shocks plausibly affect the movements of these real variables, the series in the real activity dataset provide only responses to those shocks, not more direct measures, so for an analysis of structural shocks one would want to expand the dataset so that the space of factor innovations more

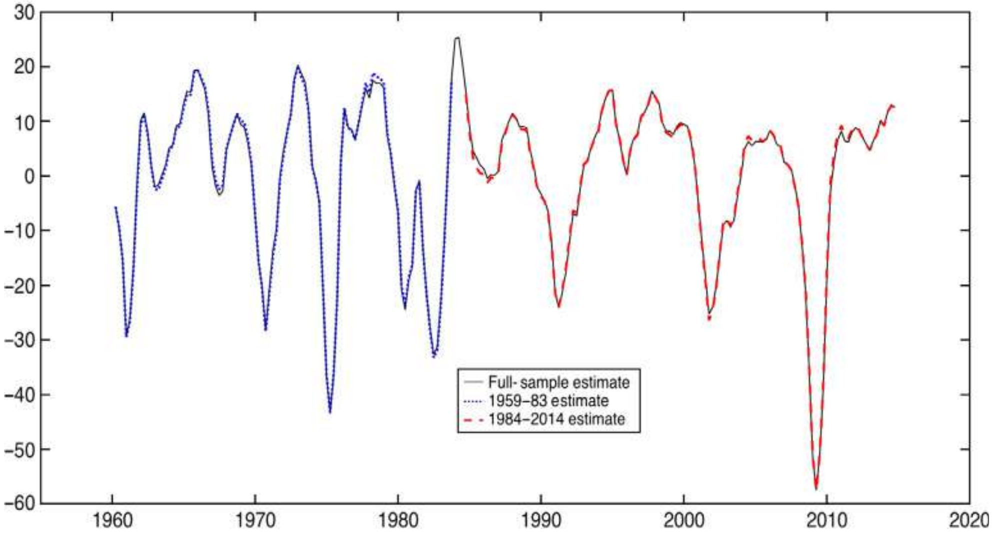

Fig. 5 First factor, real activity dataset: full sample, 1959–84, and 1984–2014.

plausibly spans the space of structural shocks. For example, one would want to include interest rates, which are responsive to monetary policy shocks, measures of oil prices and oil production, which are responsive to oil supply shocks, and measures of inflation, which would respond to both cost and demand shocks.

6.3 The Full Dataset and Multiple-Factor Model

6.3.1 Estimating the Factors and Number of Factors

Fig. 6A is the scree plot for the full dataset with up to 10 factors, and Table 2 (panel B) reports statistics related to estimating the number of factors. The Bai and Ng (2002) criterion chooses four factors, while the Ahn–Horenstein criterion chooses one factor. Compared to the real activity dataset, the first factor explains less of the variation and the decline in higher factors is not as sharp: the marginal R^2 of the fourth factor is 0.040, dropping only to 0.024 for the eighth factor. Under the assumption of anywhere between three and eight static factors, the Amengual and Watson (2007) test selects three dynamic factors (Table 2, panel C), only one less than the four static factors chosen by the Bai and Ng (2002) criterion. As is the case for the static factors, the decline in the marginal R^2 for the dynamic factors is gradual so the evidence on the number of dynamic factors is not clear cut.

Table 3 presents two different measures of the importance of the factors in explaining movements in various series. The first statistic, in columns A, is the R^2 of the common component for the models with 1, 4, and 8 factors; this statistic measures the variation in the series due to contemporaneous variation in the factor. According to the contemporaneous measure in columns A, the first factor explains large fractions of the variation in the growth of GDP and employment, but only small fractions of the variation in prices and financial variables. The second through fourth factors explain the variation in headline inflation, oil prices, housing starts, and some financial variables. The fifth through eighth factors explain much of the variation in labor productivity, hourly compensation, the term spread, and exchange rates. Thus, the additional factors that would be chosen by the Bai and Ng criterion explain substantial fractions of the variation in important classes of series.

Columns B of Table 3 presents a related measure: the fraction of the four quarters ahead forecast error variance due to the dynamic factors, for 1, 4, and 8 dynamic factors, computed under the assumption of eight static factors.[gg] For some series, including housing starts, the Ted spread, and stock prices, the fifth through eighth dynamic factors explain substantial fractions of their variation at the four-quarter horizon. Thus both

[gg] Use (6) and (7) to write $X_t = \Lambda\Phi(\mathrm{L})^{-1}G\eta_t + e_t$. Then the h-period ahead forecast error is $\mathrm{var}\left(\Lambda\sum_{i=0}^{h-1}\Phi_i G\eta_{t-i}\right) + \mathrm{var}(e_t \,|\, e_{t-h}, e_{t-h-1}, \ldots)$, and the fraction of the h-step forecast error variance explained by the dynamic factors is the ratio of the first term in this expression to the total. The term $\mathrm{var}(e_t|e_{t-h}, e_{t-h-1}, \ldots)$ is computed using an AR(4).

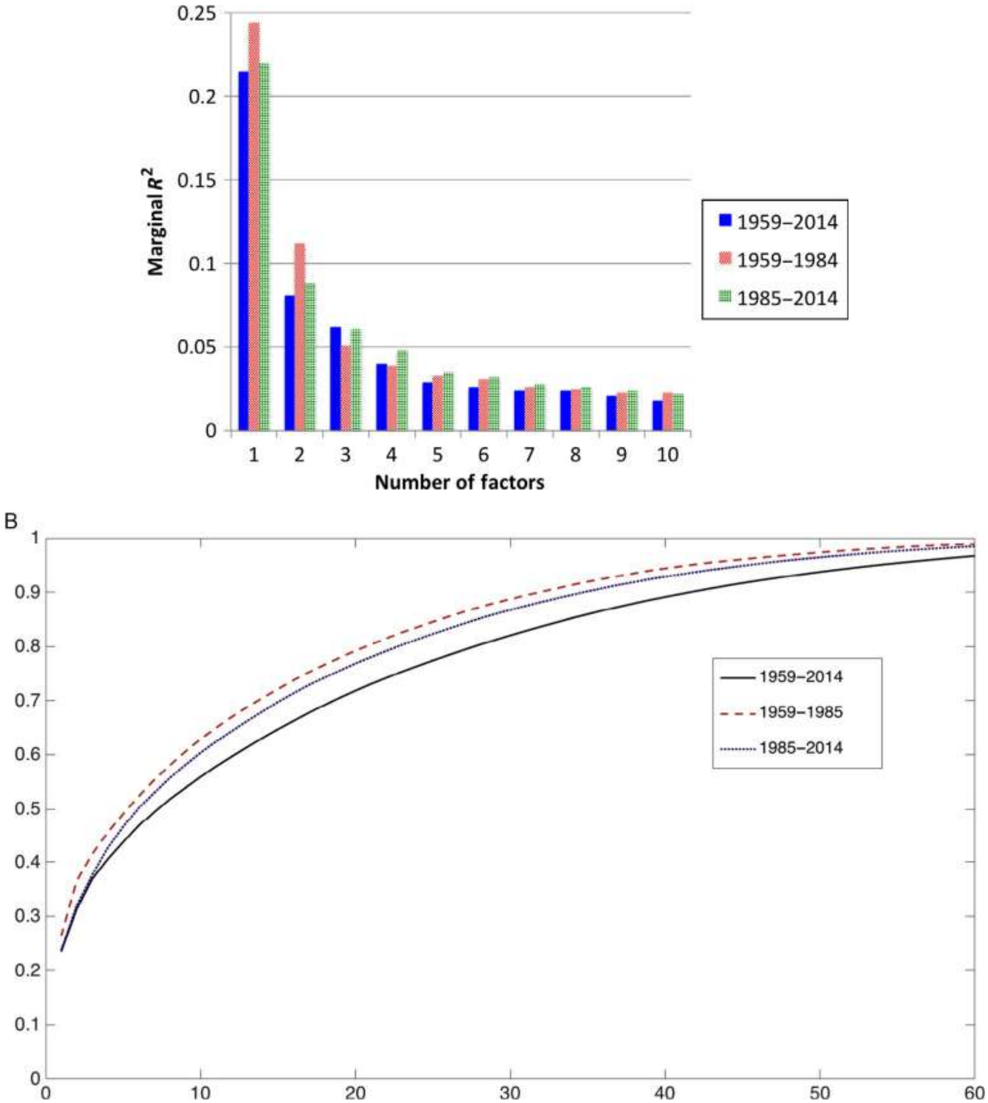

Fig. 6 (A) Scree plot for full dataset: full sample, pre-1984, and post-1984. (B) Cumulative R^2 as a function of the number of factors, 94-variable balanced panel.

blocks of Table 3 suggest that these higher factors, both static and dynamic, capture common innovations that are important for explaining some categories of series.

The scree plot in Fig. 6A and the statistics in Tables 2 and 3 point to a relatively small number of factors—between 4 and 8 factors—describing a large amount of the variation in these series. This said, a substantial amount of the variation remains, and it is germane to ask whether that remaining variation is from idiosyncratic disturbances or whether

Table 3 Importance of factors for selected series for various numbers of static and dynamic factors: full dataset DFM

	A. R^2 of common component			**B. Fraction of four quarters ahead forecast error variance due to common component**		
	Number of static factors *r*			**Number of dynamic factors *q* with *r* = 8 static factors**		
Series	**1**	**4**	**8**	**1**	**4**	**8**
Real GDP	0.54	0.65	0.81	0.39	0.77	0.83
Employment	0.84	0.92	0.93	0.79	0.86	0.90

Stock prices (SP500)	0.06	0.49	0.73	0.14	0.29	0.79
Real money supply (MZ)	0.00	0.25	0.34	0.15	0.24	0.29
Business loans	0.11	0.49	0.51	0.13	0.16	0.23
Real oil prices	0.04	0.68	0.70	0.40	0.66	0.71
Oil production	0.09	0.10	0.12	0.01	0.04	0.12

there are small remaining correlations across series that could be the result of small, higher factors. Fig. 6B shows the how the trace R^2 increases with the number of principal components, for up to 60 principal components. The key question is whether these higher factors represent common but small fluctuations or, alternatively, are simply the consequence of estimation error, idiosyncratic disturbances, or correlated survey sampling noise because multiple series are derived in part from the same survey instrument. There is a small amount of work investigating the information content in the higher factors. De Mol et al. (2008) find that Bayesian shrinkage methods applied to a large number of series closely approximate principal components forecasts using a small number of factors. Similarly, Stock and Watson (2012b) use empirical Bayes methods to incorporate information in higher factors and find that for many series forecasts using this information do not improve on forecasts using a small number of factors. Carrasco and Rossi (forthcoming) use shrinkage methods to examine whether the higher factors improve forecasts. Onatski (2009, 2010) develops theory for factor models with many weak factors. Although the vast bulk of the literature is consistent with the interpretation that variation in macroeconomic data are associated with a small number of factors, the question of the information content of higher factors remains open and merits additional research.

The choice of the number of factors depends on the application at hand. For forecasting real activity, the sampling error associated with additional factors could outweigh their predictive contribution. In contrast, for the structural DFM analysis in Section 7 we will use eight factors because it is important that the factor innovations span the space of the structural shocks and the higher factors capture variation.

6.3.2 Stability

Table 4 summarizes various statistics related to the subsample stability of the four- and eight-factor models estimated on the full dataset. Table 4 (panel A) summarizes results for equation-by-equation tests of stability. The Chow test is the Wald statistic testing the hypothesis that the factor loadings are constant in a given equation, against the alternative that they have different values before and after the Great Moderation break date of 1984q4 (Stock and Watson, 2009; Breitung and Eickmeier, 2011, Section 3). The Quandt likelihood ratio (QLR) version allows for an unknown break date and is the maximum value of the Chow statistic (the sup-Wald statistic) for potential breaks in the central 70% of the sample, see Breitung and Eickmeier (2011) for additional discussion. In both the Chow and QLR tests, the full-sample estimate of the factors is used as regressors. The table reports the fraction of the series that rejects stability at the 1%, 5%, and 10% significance levels.[hh] Table 4 (panel B) reports a measure of the magnitude of the break, the correlation between the common component computed over a subsample and over the full sample, where the two subsamples considered are the pre- and post-1984 periods. Table 4 (panel C) breaks down the results in Table 4 (panels A and B) by category of series.

The statistics in Table 4 all point to a substantial amount of instability in the factor loadings. More than half the series reject stability at the 5% level for a break in 1984 in the four-factor model, and nearly two-thirds reject in the eight-factor model. As seen in Table 4 (panel C), the finding of a break in the factor loadings in 1984 is widespread across categories of series. Rejection rates are even higher for the QLR test of stability of the factor loadings.

A reasonable worry is that these rejection rates are overstated because the tests are oversized, and Monte Carlo evidence in Breitung and Tenhofen (2011) suggests that the size distortions could be large if the idiosyncratic disturbances are highly serially correlated. For this reason, it is also useful to check if the instability is large in an economic sense.

One such measure of the magnitude of the instability is whether the common component estimated over a subsample is similar to the full-sample common component. As shown in Table 4 (panel B), for at least half the series, the common components estimated

[hh] Results are reported for the 176 of the 207 series with at least 80 quarterly observations in both the pre- and post-1984 subsamples.

Table 4 Stability tests for the four- and eight-factor full dataset DFMs
(A) Fraction of rejections of stability null hypothesis

Level of test	Chow test (1984q4 break)	QLR test
(i) Four factors		
1%	0.39	0.62
5%	0.54	0.77
10%	0.63	0.83
(ii) Eight factors		
1%	0.55	0.94
5%	0.65	0.98
10%	0.72	0.98

(B) Distribution of correlations between full- and split-sample common components

	Percentile of distribution				
	5%	25%	50%	75%	5%
(i) Four factors					
1959–84	0.65	0.89	0.96	0.99	1.00
1985–2014	0.45	0.83	0.95	0.97	0.99
(ii) Eight factors					
1959–84	0.57	0.83	0.92	0.97	0.99
1985–2014	0.43	0.80	0.94	0.97	0.99

(C) Results by category (four factors)

			Median correlation between full- and split-sample common components	
Category	Number of series	Fraction of Chow test rejections for 5% test	1959–84	1985–2014
NIPA	20	0.50	0.98	0.96
Industrial production	10	0.50	0.98	0.97
Employment and unemployment	40	0.40	0.99	0.99
Orders, inventories, and sales	10	0.80	0.98	0.96
Housing starts and permits	8	0.75	0.96	0.91
Prices	35	0.49	0.88	0.90
Productivity and labor earnings	10	0.80	0.92	0.67
Interest rates	12	0.33	0.98	0.94
Money and credit	9	0.89	0.93	0.89
International	3	0.00	0.97	0.97
Asset prices, wealth, and household balance sheets	12	0.58	0.95	0.92
Other	1	1.00	0.95	0.91
Oil market variables	6	0.83	0.79	0.79

Notes: These results are based on the 176 series with data available for at least 80 quarters in both the pre- and post-84 samples. The Chow tests in (A) and (C) test for a break in 1984q4.

using the two subsample factor loadings are highly correlated. For a substantial portion of the series, however, there is a considerable difference between the full-sample and subsample estimates of the common components. Indeed, for 5% of the series, the correlation between the common component estimated post-1984 and the common component estimated over the full sample is less than 50% for both the four- and eight-factor models.

Interestingly, when broken down by category, for some categories, most of the subsample and full-sample common components are highly correlated (Table 4 (panel C), final two columns). This is particularly true for the real activity variables, a finding consistent with the stability of the common component shown in Fig. 5 for the single factor from the real activity dataset. However, for some categories the subsample and full-sample common components are quite different, with median within-category correlations of less than 0.9 in at least one subsample for prices, productivity, money and credit, and oil market variables.

On net, Table 4 points to substantial instability in the DFM. One model of this instability, consistent with the results in the table, is that there was a break around 1984, consistent with empirical results in Stock and Watson (2009), Breitung and Eickmeier (2011), and Chen et al. (2014). However, the results in Table 4 could also be consistent with more complicated models of time variation.

6.4 Can the Eight-Factor DFM Be Approximated by a Low-Dimensional VAR?

A key motivation for DFMs is that using many variables improves the ability of the model to span the space of the structural shocks. But is it possible to approximate the DFM by a small VAR[ii]? If so, those few variables could take the place of the factors for forecasting, and SVAR methods could be used directly to identify structural shocks without needing the SDFM apparatus: in effect, the unobserved factors could be replaced by observed factors in the form of this small number of variables. An approximation to the factors by observable variables could take two forms. The strong version would be for a small number of variables to span the space of the factors. A weaker version would be for a small number of variables to have VAR innovations that span the space of the factor innovations.[ij] Bai and Ng (2006b) develop tests for whether observable variables span the space of the unobserved factors and apply those tests to the Fama-French facots in portfolio analysis. Following Bai and Ng (2006b), we use canonical correlations to examine this possibility in our macro data application.

Table 5 examines the ability of four different VARs to approximate the DFM with eight static factors. The first two VARs are representative of small VARs used in empirical work: a four-variable system (VAR-A) with GDP, total employment, personal consumption expenditure (PCE) inflation, and the Fed funds rate, and an eight-variable system (VAR-B) that

[ii] We thank Chris Sims for raising this question.

[ij] If the observable variables are an invertible contemporaneous linear combination of the factors then the VAR and the factors will have the same innovations, but having the same innovations do not imply that the observable variables are linear combinations of contemporaneous values of the factors.

Table 5 Approximating the eight-factor DFM by a eight-variable VAR

	Canonical correlation							
	1	2	3	4	5	6	7	8
(A) Innovations								
VAR-A	0.76	0.64	0.6	0.49				
VAR-B	0.83	0.67	0.59	0.56	0.37	0.33	0.18	0.01
VAR-C	0.86	0.81	0.78	0.76	0.73	0.58	0.43	0.35
VAR-O	0.83	0.80	0.69	0.56	0.50	0.26	0.16	0.02
(B) Variables and factors								
VAR-A	0.97	0.85	0.79	0.57				
VAR-B	0.97	0.95	0.89	0.83	0.61	0.43	0.26	0.10
VAR-C	0.98	0.93	0.90	0.87	0.79	0.78	0.57	0.41
VAR-O	0.98	0.96	0.88	0.84	0.72	0.39	0.18	0.02

Notes: All VARs contain four lags of all variables. The canonical correlations in panel A are between the VAR residuals and the residuals of a VAR estimated for the eight static factors.

VAR-A was chosen to be typical of four-variable VARs seen in empirical applications. Variables: GDP, total employment, PCE inflation, and Fed funds rate.

VAR-B was chosen to be typical of eight-variable VARs seen in empirical applications. Variables: GDP, total employment, PCE inflation, Fed funds, ISM manufacturing index, real oil prices (PPI-oil), corporate paper-90-day treasury spread, and 10 year–3 month treasury spread.

VAR-C variables were chosen by stepwise maximization of the canonical correlations between the VAR innovations and the static factor innovations. Variables: industrial commodities PPI, stock returns (SP500), unit labor cost (NFB), exchange rates, industrial production, Fed funds, labor compensation per hour (business), and total employment (private).

VAR-O variables: real oil prices (PPI-oil), global oil production, global commodity shipment index, GDP, total employment (private), PCE inflation, Fed funds rate, and trade-weighted US exchange rate index.

Entries are canonical correlations between (A) factor innovations and VAR residuals and (B) factors and observable variables.

additionally has the ISM manufacturing index, the oil price PPI, the corporate paper-90-day treasury spread, and the 3 month–10 year treasury term spread. The eight variables in the third VAR (VAR-C) were selected using a stepwise procedure to produce a high fit between VAR residuals and the innovations in the eight static factors (ie, the residuals in the VAR with the eight static factors). This procedure led to the VAR-C variables being the index of IP, real personal consumption expenditures, government spending, the PPI for industrial commodities, unit labor costs for business, the S&P500, the 6 month–3 month term spread, and a trade-weighted index of exchange rates.[kk] The final VAR, VAR-O, is used for the SVAR analysis of the effect of oil shocks in Section 7 and is discussed there.

[kk] The variables in VAR-C were chosen from the 207 variables so that the *i*th variable maximizes the *i*th canonical correlation between the residuals from the *i*-variable VAR and the residuals from the eight-factor VAR. In the first step, the variable yielding the highest canonical correlation between its autoregressive residual and the factor VAR residuals was chosen. In the second step, the variable that maximized the second canonical correlation among all 206 two-variable VAR residuals (given the first VAR variable) and the factor VAR residuals was chosen. These steps continued until eight variables were chosen.

Table 5 (panel A) examines whether the VAR innovations are linear combinations of the eight innovations in the static factors by reporting the canonical correlations between the two sets of residuals. For the four-variable VAR, the first canonical correlation is large, as are the first several canonical correlations in the eight-variable VARs, indicating that some linear combinations of the DFM innovations can be constructed from linear combinations of the VAR innovations. But the canonical correlations drop off substantially. For the eight-variable VAR-B, the final four canonical correlations are less than 0.40, indicating that the innovation space of this typical VAR differs substantially from the innovation space of the factors. Even for VAR-C, for which the variables were chosen to maximize the stepwise canonical correlations of the innovations, the final three canonical correlations are less than 0.60, indicating that there is substantial variation in the factor innovations that is not captured by the VAR innovations.

Table 5 (panel B) examine whether the observable variables span the space of the factors, without leads and lags, by reporting the canonical correlations between the observable variables and the factors for the three VARs. For the four-variable VAR, the canonical correlations measure the extent to which the observable variables are linear combinations of the factors; for the eight-variable VARs, the canonical correlations measure whether the spaces spanned by the observable variables and the factors are the same, so that the eight latent factors estimated from the full dataset could be replaced by the eight observable variables. The canonical correlations in panel B indicate that the observable variables are not good approximations to the factors. In VAR-B, three of the canonical correlations are less than 0.50, and even in VAR-C two of the canonical correlations are less than 0.6.

These results have several caveats. Because the factors are estimated, the sample canonical correlations will be less than one even if in population they equal one, and no measure of sampling variability is provided. Also, VAR-C was chosen by a stepwise procedure, and presumably a better approximation would obtain were it possible to choose the approximating VAR out of all possible eight-variable VARs.[ll]

Still, these results suggest that while typical VARs capture important aspects of the variation in the factors, they fail to span the space of the factors and their innovations fail to span the space of the factor innovations. Overall, these results suggest that the DFM, by summarizing information from a large number of series and reducing the effect of measurement error and idiosyncratic variation, produces factor innovations that contain information not contained in small VARs.

[ll] Other methods for selecting variables, for example stepwise maximization of the *i*th canonical correlation between the variable and the factor (instead of between the VAR innovations and the factor innovations) yielded similar results to those for VAR-C in Table 5.

7. MACROECONOMIC EFFECTS OF OIL SUPPLY SHOCKS

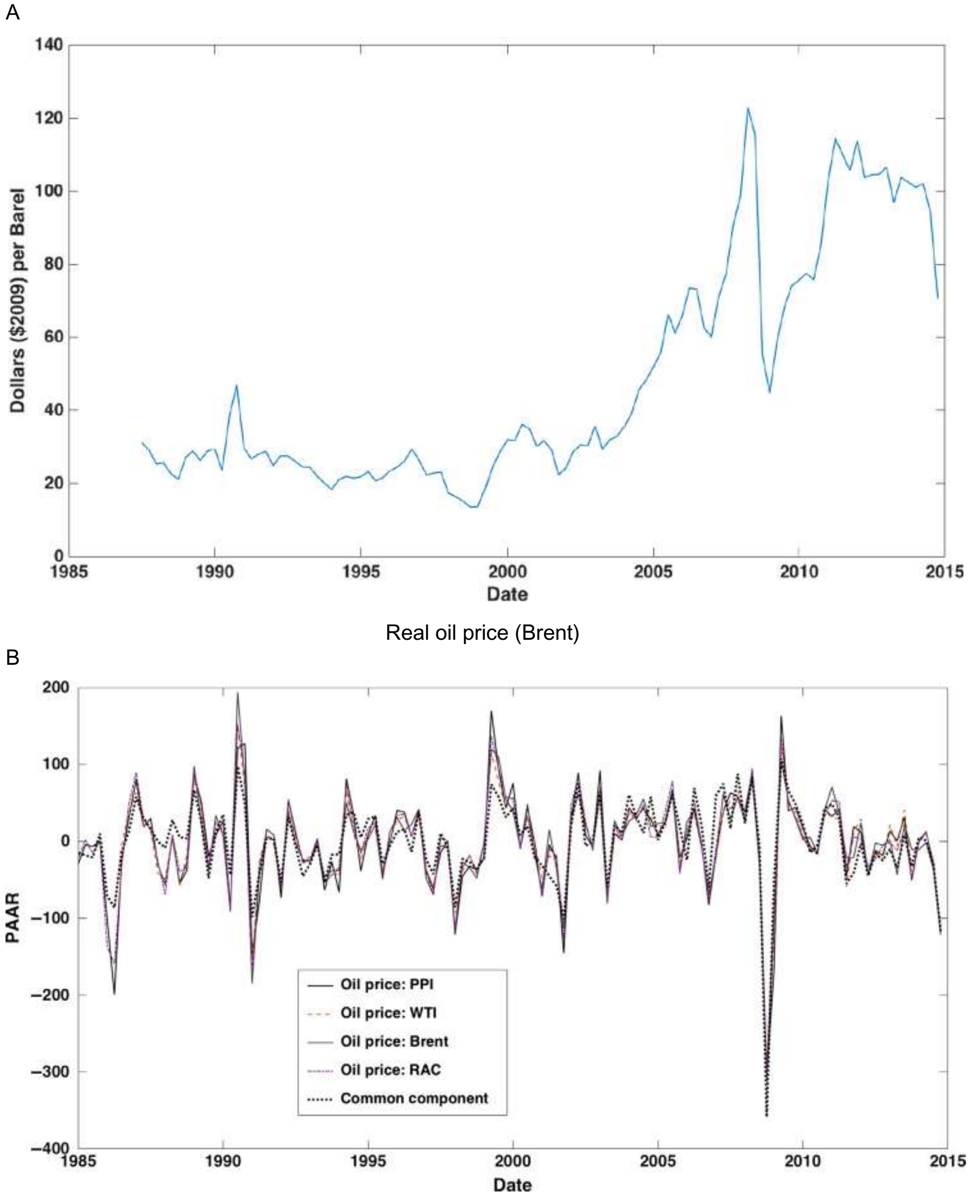
This section works through an empirical example that extends SVAR identification schemes to SDFMs. The application is to estimating the macroeconomic effects of oil market shocks, using identification schemes taken from the literature on oil and the macroeconomy. For comparison purposes, results are provided using a 207-variable SDFM with eight factors, a 207-variable FAVAR in which one or more of factors are treated as observed, and an eight-variable SVAR.

7.1 Oil Prices and the Macroeconomy: Old Questions, New Answers

Oil plays a central role in developed economies, and for much of the past half century the price of oil has been highly volatile. The oil price increases of the 1970s were closely linked to events such as the 1973–74 OPEC oil embargo and wars in the Middle East, as well as to developments in international oil markets (Hamilton, 2013; Baumeister and Kilian, 2016). The late 1980s through early 2000s were a period of relative quiescence, interrupted mainly by the spike in oil prices during the Iraqi invasion of Kuwait. Since the early 2000s oil prices have again been volatile. The nominal price of Brent oil, an international benchmark, rose from under $30/barrel in 2002 to a peak of approximately $140/barrel in June 2008. Oil prices collapsed during the financial crisis and ensuing recession, but by the spring of 2011 recovered to just over $100/barrel. Then, beginning the summer of 2014, oil prices fell sharply and Brent went below $30 in early 2016, a decline that was widely seen as stemming in part from the sharp increase in unconventional oil production (hydraulic fracturing). The real oil price over the last three decades is plotted in Fig. 7A.

Fig. 7B shows four measures of the quarterly percentage change in oil prices, along with its common component estimated using the eight factors from the 207-variable DFM of Section 6. Fig. 7B reminds us that there is no single price of oil, rather oil is a heterogeneous commodity differentiated by grade and extraction location. The four measures of real oil prices (Brent, WTI, US refiners' acquisition cost of imported oil and the PPI for oil, all deflated by the core PCE price index) move closely together but are not identical. As discussed later, in this section these series are restricted to have the same common component, which (as can be seen in Fig. 7B) captures the common movements in these four price indices.

Economists have attempted to quantify the effect of oil supply shocks on the US economy ever since the oil supply disruptions of the 1970s. In seminal work, Hamilton (1983) found that oil price jumps presaged US recessions; see Hamilton (2003, 2009) for updated extensive discussions. Given the historical context of the 1970s, the first wave of analysis of the effect of oil supply shocks on the economy generally treated unexpected changes in oil prices as exogenous and as equivalent to oil supply shocks. In the context of SVAR analysis,



Real oil price (Brent)

Quarterly percent change in real oil price: four oil price series and the common component

Fig. 7 Real oil price (2009 dollars) and its quarterly percent change.

this equivalent allows treating the innovation in the oil price equation as an exogenous shock, which in turn corresponds to ordering oil first in a Cholesky decomposition.[mm]

Recent research, however, has apended this early view that unexpected oil price movements are solely the result of exogenous oil supply shocks and has argued instead that much or most movements in oil prices are in fact due to shocks to global demand or perhaps to demand shocks that are specific to oil (inventory demand). For example, this view accords with the broad perception that the long climb of oil prices in the mid-2000s was associated with increasing global demand, including demand from China, in the face of conventional supply that was growing slowly or even declining before the boom in unconventional oil production began in the late 2000s and early 2010s.

The potential importance of aggregate demand shocks for determining oil prices was proposed in the academic literature by Barsky and Kilian (2002) and has been influentially promoted by Kilian (2008a,b, 2009). Econometric attempts to distinguish oil supply shocks from demand shocks generally do so using SVARs, broadly relying on three identification schemes. The first relies on timing restrictions to impose zeros in the H matrix of Eq. (20). The logic here, due to Kilian (2009), starts by noting that it is difficult to adjust oil production quickly in response to price changes, so that innovations in the quantity of oil produced are unresponsive to demand shocks during a sufficiently short period of time. As is discussed later in more detail, this timing restriction can be used to identify oil supply shocks.

The second identification scheme uses inequality restrictions: standard supply and demand reasoning suggest that a positive shock to the supply of oil will push down oil prices and increase oil consumption, whereas a positive shock to aggregate demand would push up both oil prices and consumption. This sign restriction approach has been applied by Peersman and Van Robays (2009), Lippi and Nobili (2012), Kilian and Murphy (2012, 2014), Baumeister and Peersman (2013), Lütkepohl and Netšunajev (2014), and Baumeister and Hamilton (2015b) among others.

The third identification approach identifies the response to supply shocks using instrumental variables. Hamilton (2003) used a list of exogenous oil supply disruptions, such as the Iraqi invasion of Kuwait, as an instrument in a single-equation estimation of the effect of oil supply shocks on GDP which Kilian (2008b) extended, also in a single-equation context. Stock and Watson (2012a) used the method of external instruments in a SDFM to estimate the impulse responses to oil supply shocks using various instruments, including (like Hamilton, 2003) a list of oil supply disruptions.

Broadly speaking, a common finding from this second wave of research is that oil supply shocks account for a small amount of the variation both in oil prices and in aggregate economic activity, at least since the 1970s. Moreover, this research finds that much or most of

[mm] Papers adopting this approach include Shapiro and Watson (1988) and Blanchard and Galí (2010).

the variation in oil prices (at least through 2014) arises from shifts in demand, mainly aggregate demand or demand more specifically for oil.

This section shows how this recent research on oil supply shocks can be extended from SVARs to FAVARs and SDFMs. For simplicity, this illustration is restricted to two contemporaneous identification schemes. The papers closest to the treatment in this section are Aastveit (2014), who uses a FAVAR with timing restrictions similar to the ones used here, Charnavoki and Dolado (2014) and Juvenal and Petrella (2015), who use sign restrictions in a SDFM, and Aastveit et al. (2015), who use a combination of sign and timing restrictions in a FAVAR. The results of this section are confirmatory of these papers and more generally of the modern literature that stresses the importance of demand shocks for determining oil prices, and the small role that oil supply shocks have played in determining oil production since the early 1980s. Although the purpose of this section is to illustrate these methods, the work here does contain some novel features and new results.

7.2 Identification Schemes

We consider two identification schemes based on the contemporaneous zero restrictions in the H matrix, that is, schemes of the form discussed in Section 4.2. The first identification scheme, which was used in the early oil shocks literature, treats oil prices as exogenous with oil price innovations assumed to be oil price supply shocks. The second identification scheme follows Kilian (2009) and distinguishes oil supply shocks from demand shocks by assuming that oil production responds to demand shocks only with a lag.[nn] The literature continues to evolve, for example Kilian and Murphy (2014) include inventory data and use sign restrictions to help to identify oil-specific demand shocks. The treatment in this section does not aim to push the frontier on this empirical issue, but rather to illustrate SDFM, FAVAR, and SVAR methods in a simple setting that is still sufficiently rich to highlight methods and modeling choices.

[nn] Kilian's (2009) treatment used monthly data, whereas here we use quarterly data. The timing restrictions, for example the sluggish response of production to demand, are more appropriate at the monthly than at the quarterly level. Güntner (2014) used sign restrictions in an oil-macro SVAR to identify demand shocks and find that oil producers respond negligibly to demand shocks within the month, and that most producers respond negligibly within a quarter, although Saudi Arabia is estimated to respond after a delay of 2 months. The recent development of fracking and horizontal drilling technology also could undercut the validity of the timing restriction, especially at the quarterly level, because new wells are drilled and fracked relatively quickly (in some cases in a matter of weeks). In addition, because well productivity declines much more rapidly than for conventional wells, nonconventional production can respond more quickly to price than can most conventional production. If the restrictions are valid at the monthly frequency but not quarterly, our estimated supply shocks would potentially include demand shocks, biasing our SIRFs. Despite these caveats, however, the results here are similar to those in Kilian's (2009) and Aastveit's (2014) monthly treatments with the same exclusion restrictions.

The "oil exogenous" identification scheme is implemented in three related models: a 207-variable SDFM with eight unobserved factors, a 207-variable FAVAR (that is, a SDFM in which some of the eight factors are treated as observed), and an eight-variable SVAR. The Kilian (2009) identification scheme is examined in a eight-variable VAR, in a 207-variable FAVAR with three observed and five unobserved factors, and a 207-variable FAVAR with one observed and seven unobserved factors. As is discussed later, this final FAVAR is used instead of a SDFM with all factors unobserved because the oil production innovation plays such a small macroeconomic role that it appears not to be spanned (or is weakly spanned) by the space of innovations to the macro factors.

For the SVAR, identification requires sufficient restrictions on H to identify the column of H associated with the oil supply shock and, for the second assumption, the columns associated with the aggregate demand and oil-specific demand shocks.

For the FAVARs in which the relevant factors (oil prices in the "oil price exogenous" case, and oil production, aggregate demand, and oil prices in the Kilian (2009) case) are all modeled as observed, no additional identifying restrictions are needed beyond the SVAR identifying restrictions.

For the SDFM and for the FAVAR with only one of the three factors observed, identification also entails normalizations on the factor loadings Λ and on the matrix G relating the dynamic factor innovations to the static factor innovations.

The SDFM and FAVAR models require determining the number of dynamic factors. Although Table 2 (panel C) can be interpreted as suggesting fewer dynamic than static factors, we err on the side of over-specifying the space of innovations so that they span the space of the reduced number of shocks of interest, and therefore set the number of dynamic factors equal to the number of static factors, so in turn the dimension of η_t (the factor innovations) is eight. Thus we adopt the normalization that G is the identity matrix.

7.2.1 Identification by Treating Oil Prices Innovations as Exogenous

The historical starting point of the oil shock literature holds that any unexpected change in oil prices is exogenous to developments in the US economy. One motivation for this assumption is that if unexpected changes in oil prices arise from unexpected developments in supply—either supply disruptions from geopolitical developments or unexpected upticks in production—then those changes are specific to oil supply, and thus can be thought of as oil supply shocks. A weaker interpretation is that oil prices are determined in the world market for oil so that unexpected changes in oil prices reflect international developments in the oil market, and thus are exogenous shocks (although they could be either oil supply or demand shocks). In either case, an unexpected increase in the real price of oil is interpreted as an exogenous oil price shock. Because the oil price shock is identified as the innovation in the (log) price of oil, it is possible to estimate structural impulse responses with respect to this shock.

7.2.1.1 SVAR and FAVAR

Without loss of generality, order the oil price first in the list of variables. The assumption that the oil price shock ε_t^{oil} is exogenous, combined with the unit effect normalization, implies that $\eta_{1t} = \varepsilon_t^{oil}$. Thus the relation between η_t and ε_t in (28) can be written,

$$\eta_t = \begin{pmatrix} 1 & 0 \\ H_{\bullet 1} & H_{\bullet\bullet} \end{pmatrix} \begin{pmatrix} \varepsilon_t^{oil} \\ \widetilde{\eta}_{\bullet t} \end{pmatrix}, \tag{71}$$

where $\widetilde{\eta}_{\bullet t}$ spans the space of η_t orthogonal to η_{1t}. The vector $H_{\bullet 1}$ is identified as the coefficient in the (population) regression of $\eta_{\bullet t}$ on η_{1t}.

In practice, this identification scheme is conveniently implemented by ordering oil first in a Cholesky decomposition; the ordering of the remaining variables does not matter for the purpose of identifying and estimating the SIRFs with respect to the oil shock.

7.2.1.2 SDFM

In addition to the identification of H in (71), identification in the SDFM requires normalization restrictions on the factor loadings Λ and on G. Because the number of static and dynamic factors is the same, we follow Section 5.1.2 and set G to the identity matrix.

If the dataset had a single oil price, then the named factor normalization would equate the innovation in the first factor with the innovations in the common component of oil. Accordingly, with a single oil price measure ordered first among the DFM variables, the first row of Λ would be $\Lambda_1 = (1\ 0\ \dots\ 0)$. The normalization of the next seven rows (there are eight static factors) is arbitrary, although some care must be taken so that the innovations of the common components of those seven variables, plus oil prices, spans the space of the eight factor innovations.

The 207-variable dataset, however, contains not one but four different measures of oil prices: Brent, WTI, refiners' acquisition cost, and the producer price of oil. All four series, specified as percentage changes in price, are used as indicators that measure the percentage change in the common (unobserved) price of oil, which is identified as the first factor by applying the named factor normalization to all four series. This approach entails using the specification of Λ in (60).[oo]

Because G is set to the identity matrix, the innovation to the oil price factor is the oil price innovation.

[oo] Figure 7 suggests that real oil prices are I(1), and we use oil price growth rates in the empirical analysis, ignoring cointegration restrictions. This is the second approach to handling cointegration discussed in Section 2.1.4. In a fully parametric DFM (Section 2.3.2), imposing cointegration improves efficiency of the estimates, but the constraint may lead to less efficient estimates in nonparametric (principal components) models. This treatment also allows all four oil prices to be used to estimate the loading on the first factor and therefore to name (identify) the oil price factor.

7.2.2 Kilian (2009) Identification

Following Kilian (2009), this scheme separately identifies an oil supply shock, an aggregate world commodity demand shock, and an oil-specific demand shock. This is accomplished by augmenting the system with a measure of oil production (barrels pumped during the quarter) and a measure of global real economic activity. The measure of global economic activity we use here is Kilian's (2009) global index of bulk dry goods shipments.

7.2.2.1 SVAR and FAVAR

The justification for the exclusion restrictions in the H matrix is as follows. (i) Because of technological delays in the ability to adjust production at existing wells, to shut down wells, and to bring new wells on line, crude oil production responds with a delay to demand shocks or to any other macro or global shocks. Thus, within a period, an unexpected change in oil production is exogenous and is therefore an exogenous supply shocks (ε_t^{OS}). Thus the innovation to oil production equals the oil supply shock. (ii) Global economic activity can respond immediately to oil supply shocks and responds to global aggregate demand shocks (ε_t^{GD}), but otherwise is sluggish and responds to no other shocks within the period. (iii) Real oil prices respond to oil supply shocks and aggregate demand shocks within the period, and to other oil price-specific shocks as well, but to no other macro or global shocks. Kilian interprets the other oil price-specific shocks (ε_t^{OD}) as shocks to oil demand that are distinct from aggregate demand shocks; examples are oil inventory demand shocks, perhaps driven by anticipated oil supply shocks, or speculative demand shocks.

The foregoing logic imparts an upper triangular structure to H and a Cholesky ordering to the shocks:

$$\begin{pmatrix} \eta_t^{oilproduction} \\ \eta_t^{globalactivity} \\ \eta_t^{oilprice} \\ \eta_{\bullet t} \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ H_{12} & 1 & 0 & 0 \\ H_{13} & H_{23} & 1 & 0 \\ H_{1\bullet} & H_{2\bullet} & H_{3\bullet} & H_{\bullet\bullet} \end{pmatrix} \begin{pmatrix} \varepsilon_t^{OS} \\ \varepsilon_t^{GD} \\ \varepsilon_t^{OD} \\ \tilde{\eta}_{\bullet t} \end{pmatrix}, \tag{72}$$

where the unit coefficients on the diagonal impose the unit effect normalization and the variables are ordered such that the innovations are to global oil production, global aggregate demand, the price of oil, and the remaining series. The first three rows of H identify the three shocks of interest, and the remaining elements of the first, second, and third rows of H are identified as the population regression coefficients of the innovations on the shocks.

For convenience, the identification scheme (72) can be implemented by ordering the first three variables in the order of (72) and adopting a lower triangular ordering (Cholesky factorization) for the remaining variables, renormalized so that the diagonal elements of H equal 1. Only the first three shocks are identified, and the SIRFs with respect to those shocks do not depend on the ordering of the remaining variables.

7.2.2.2 SDFM

The SDFM is identified by the restrictions on H in (72), the named factor normalization for Λ, and setting G to be the identity matrix.

As mentioned earlier, the SDFM implementation treats the oil production factor as observed and the remaining seven factors as unobserved. Of these seven unobserved factors, we are interested in two linear combinations of the factor innovations that correspond to the global activity innovation and the oil price innovation. The combination of one observed factor, two identified unobserved factors, and five unidentified unobserved factors gives a hybrid FAVAR-SDFM. In this hybrid, the named factor normalization is,

$$\begin{bmatrix} Oil\ production_t \\ Global\ activity_t \\ p_t^{PPI-Oil} \\ p_t^{Brent} \\ p_t^{WTI} \\ p_t^{RAC} \\ X_{7:n,t} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ \Lambda_{7:n} & & & & & \end{bmatrix} \begin{bmatrix} F_t^{Oil\ production} \\ F_t^{Global\ activity} \\ F_t^{oil\ price} \\ F_{4:r,t} \end{bmatrix} + \begin{bmatrix} 0 \\ e_{2t} \\ e_{3t} \\ e_{4t} \\ e_{5t} \\ e_{6t} \\ e_{7:n,t} \end{bmatrix} \tag{73}$$

where the first variable is $OilProduction_t$, which is treated as an observed factor, the second variable is the global activity (commodity shipment) index, and the next four variables are the four oil price measures. The first factor is the observed oil production factor. The next two factors, which are unobserved, are the global activity factor and the oil price factor. The identity matrix normalization of G associates the innovations with these factors, so that those innovations align with the first three innovations in (72).

7.3 Comparison SVAR and Estimation Details

7.3.1 Comparison SVAR

Because the SDFM is specified with eight static and dynamic factors, the comparison SVAR was chosen to have eight variables. Of the eight variables in the SVAR, three are those in Kilian's (2009) three-variable SVAR: the real oil price (PPI-oil), global oil production, and Kilian's (2009) global activity index (bulk dry shipping activity). The remaining five variables were chosen to represent different aspects of US aggregate activity, inflation, and financial markets: GDP, total employment, PCE inflation, the Federal funds rate, and a trade-weighted index of exchange rates.

Canonical correlations between the factor innovations and the VAR innovations are summarized in the "VAR-O" row of Table 5 (panel A). While the first few canonical correlations are large, the final four are 0.50 or less. Evidently, the VAR and factor innovations span substantially different spaces.

7.3.2 Summary of SDFM Estimation Steps

7.3.2.1 Summary of Steps

We now summarize the steps entailed in estimating the SIRF for the SDFM of Section 7.2.2 with one observed factor and three identified shocks. From (58), the SIRF with respect to the ith shock is,

$$SIRF_i = \Lambda \Phi(\mathrm{L})^{-1} GH_i, \tag{74}$$

where H_i is the ith column of H and $i = 1, 2, 3$. This *SIRF* is estimated in the following steps.

1. Order the variables as in (73) and, using the restricted Λ in (73), estimate the seven unobserved static factors by restricted least-squares minimization of (13) as discussed in Section 2.3.1.[pp] Augment these seven factors with $OilProduction_t$ so that the vector of eight factors has one observed factor (ordered first) and the seven estimated factors. The next five variables in the named factor normalization can be chosen arbitrarily so long as they are not linearly dependent. This step yields the normalized factors $\hat{F}_t$ and factor loadings $\hat{\Lambda}$.
2. Use $\hat{F}_t$ to estimate the VAR, $\hat{F}_t = \Phi(\mathrm{L})\hat{F}_{t-1} + \eta_t$, where the normalization $G = I$ is used and the number of innovations equals the number of factors.[qq]
3. Use the VAR residuals $\hat{\eta}_t$ to estimate H using the identifying restrictions in (72). Because of the lower triangular structure of H, this can be done using the Cholesky factorization of the covariance matrix of $\hat{\eta}_t$, renormalized so that the diagonal elements of H equal one.

7.3.2.2 Additional Estimation Details

Because of the evidence discussed in Section 6 that there is a break in the DFM parameters, possibly associated with the Great moderation break data of 1984, all models were estimated over 1985q1–2014q4.

Standard errors are computed by parametric bootstrap as discussed in Section 5.1.3.

7.4 Results: "Oil Price Exogenous" Identification

The focus of this and the next section is on understanding the differences and similarities among the SDFM, FAVAR, and SVAR results. We begin in this section with the results for the "oil price exogenous" identification scheme of Section 7.2.1.

Fig. 8 presents SIRFs for selected variables with respect to the oil price shock computed using the SDFM, the FAVAR in which oil is treated as an observed factor, and the

[pp] If there were only one oil price series then Λ and the factors could be estimated as the renormalized principal components estimates in (59).

[qq] If the number of innovations were less than the number of factors, the named factor normalization of G would be the upper diagonal normalization in (61) and the reduced number of innovations could be estimated as discussed following (61).

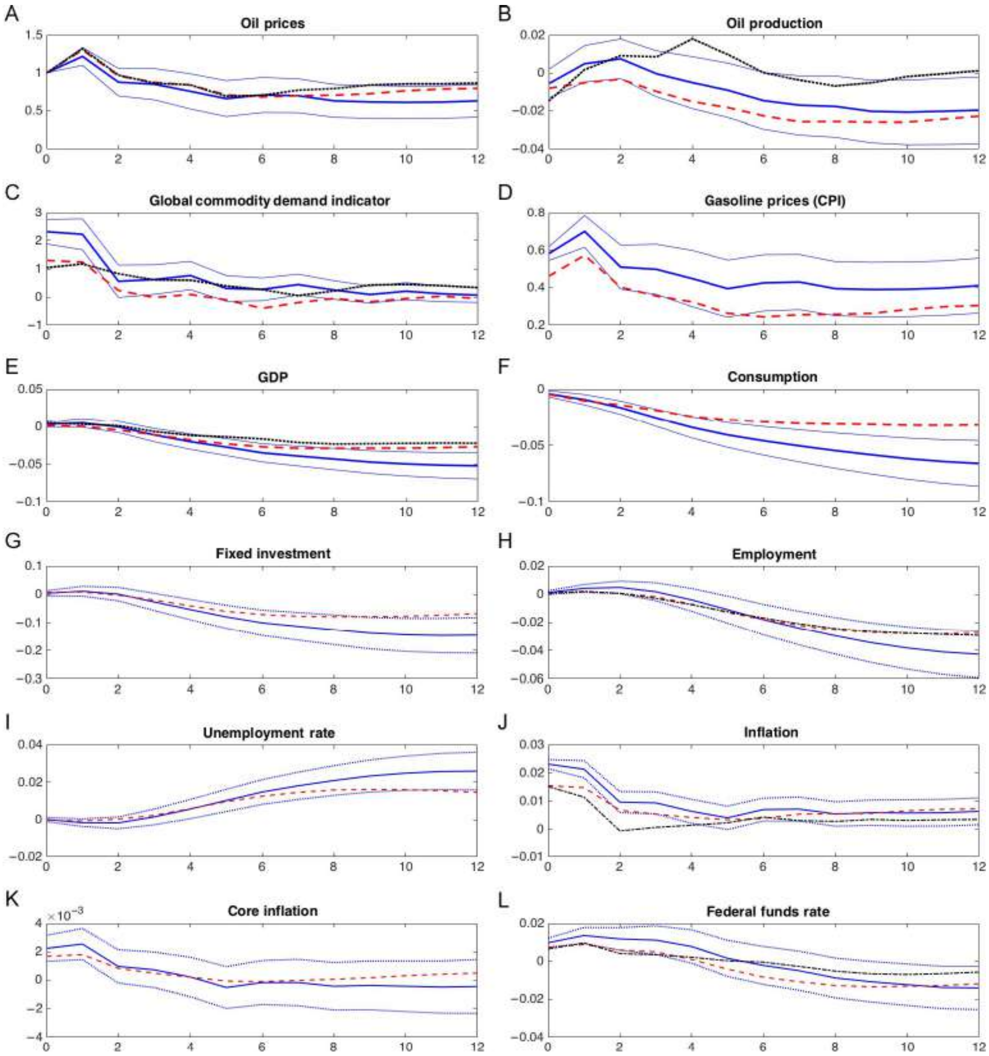


Fig. 8 Structural IRFs from the SDFM (*blue* (*dark gray* in the print version) *solid* with ±1 standard error bands), FAVAR (*red* (*gray* in the print version) *dashed*), and SVAR (*black dots*) for selected variables with respect to an oil price shock: "oil prices exogenous" identification. Units: standard deviations for Global Commodity Demand and percentage points for all other variables.

SVAR. The SVAR SIRFs are available only for the eight variables in the SVAR. The figure shows SIRFs in the log levels of the indicated variables. For example, according to the SDFM SIRFs in the *upper left panel* of Fig. 8, a unit oil price shock increases the level of oil prices by 1% on impact (this is the unit effect normalization), by additional 0.3% after one quarter, then the price of oil reverts partially and after four quarters is approximately

0.8% above its level before the shock. Equivalently, these SIRFs are cumulative SIRFs in the first differences of the variables.

The most striking feature of Fig. 8 is that all three sets of SIRFs are quite close, especially at horizons less than eight quarters. There are two main reasons for this. First, as can be seen in Fig. 7B (and in Table 3), a large fraction of the variance of the change in oil prices is explained by its common component, so the innovation in the common component in the unobserved factor DFM is similar to the innovation in the observed factor FAVAR. Second, the forecast errors for one quarter ahead changes in oil prices are similar whether they are generated using the factors or the eight-variable VAR (changes in oil prices are difficult to predict). Putting these two facts together, the innovations in oil prices (or the oil price factor) are quite similar in all three models and, under the oil price exogenous identification scheme, so are the shocks. Indeed, as shown in Table 8, the oil price shocks in the three models are similar (the smallest correlation is 0.72). In brief, the innovations in oil prices are spanned by the space of the factor price innovations.

This said, to the extent that the SDFM, FAVAR, and SVAR SIRFs differ, the FAVAR and SVAR SIRFs tend to be attenuated relative to the SDFM, that is, the effect of the oil shock in the SDFM is typically larger. This is consistent with the single observed factor in the FAVAR being measured with error in the FAVAR and SVAR models, which use a single oil price, however this effect is minor.

Concerning substantive interpretation, for the SDFM, FAVAR, and SVAR, two of the SIRFs are puzzling: the oil shock that increases oil prices is estimated to have a small effect on oil production that is statistically insignificant (negative on impact, slightly positive after one and two quarters), and a statistically significant *positive* immediate impact on global shipping activity. These two puzzling SIRFs raise the question of whether the oil price shock identified in the oil price exogenous scheme is in fact an oil supply shock, which (one would think) should be associated with a decline in oil production and either a neutral or negative impact effect on global shipping activity. These puzzling SIRFs suggest that it is important to distinguish oil price increases that arise from demand from those that stem from a shock to oil supply.

Table 7 presents six quarters ahead FEVDs for the identified shock; the results for the "oil price exogenous" identification are given in columns A for the FAVAR and SDFM. For most series, the FAVAR and SDFM decompositions are very similar, consistent with the similarity of the FAVAR and SDFM SIRFs in Fig. 8 over six quarters. The results indicate that, over the six-quarter horizon, the identified oil shocks explain no more than 10% of the variation in US GDP, fixed investment, employment, the unemployment rate, and core inflation. Curiously, the oil price shock explains a negligible fraction of the forecast errors in oil production. The series for which the FAVAR and SDFM FEVDs differ the most is the real oil price: not surprisingly, treating the oil price as the observed factor, so the innovation to the oil price is the oil shock, explains much more of the oil price forecast error than does treating the oil price factor as latent.

7.5 Results: Kilian (2009) Identification

As discussed in Section 7.2, the Kilian (2009) identification scheme identifies an oil supply shock, a global aggregate demand shock, and an oil-specific demand shock. Because there are eight innovations total in all the models examined here, this leaves five unidentified shocks (or, more precisely, a five-dimensional subspace of the innovations on which no identifying restrictions are imposed).

7.5.1 Hybrid FAVAR-SDFM

As indicated in Table 6, the innovations in the first eight principal components explain a very small fraction of the one step ahead forecast error of oil production, that is, the innovation in oil production is nearly not spanned by the space of factor innovations. Under the Kilian (2009) identification scheme, the innovation in oil production is the oil supply shock; but this oil supply shock is effectively not in the space of the eight shocks that explain the variation in the macro variables. This raises a practical problem for the SDFM because the identification scheme is asking it to identify a shock from the macro factor innovations, which is arguably not in the space of those innovations, or nearly is not in that space. In the extreme case that the common component of oil production is zero, the estimated innovation to that common component will simply be noise.

For this reason, we modify the SDFM to have a single observed factor, which is the oil production factor. The global demand shock and the oil-specific demand shock are, however, identified from the factor innovations. Thus this hybrid FAVAR–SDFM has one identified observed factor, two identified unobserved factors, and five unidentified unobserved factors.

As discussed in Section 7.2, the FAVAR treats the oil price (PPI-oil), global oil production, and the global activity index as observed factors, with five latent factors.

Table 6 Fraction of the variance explained by the eight factors at horizons $h=1$ and $h=6$ for selected variables: 1985:Q1–2014:Q4

Variable	$h=1$	$h=6$
GDP	0.60	0.80
Consumption	0.37	0.76
Fixed investment	0.38	0.76
Employment (non-ag)	0.56	0.94
Unemployment rate	0.44	0.90
PCE inflation	0.70	0.63
PCE inflation—core	0.10	0.34
Fed funds rate	0.48	0.71
Real oil price	0.74	0.78
Oil production	0.06	0.27
Global commodity shipment index	0.39	0.51
Real gasoline price	0.72	0.80

7.5.2 Results

Figs. 9–11 present SIRFs for the three identified shocks and Table 7, columns B, presents variance decompositions for six quarters ahead forecast errors. It is useful to discuss these results one shock at a time.

First consider the oil supply shock (Fig. 9). All three models identify the oil supply shock in the same way, as the one step ahead forecast error for oil supply. This variable is hard to

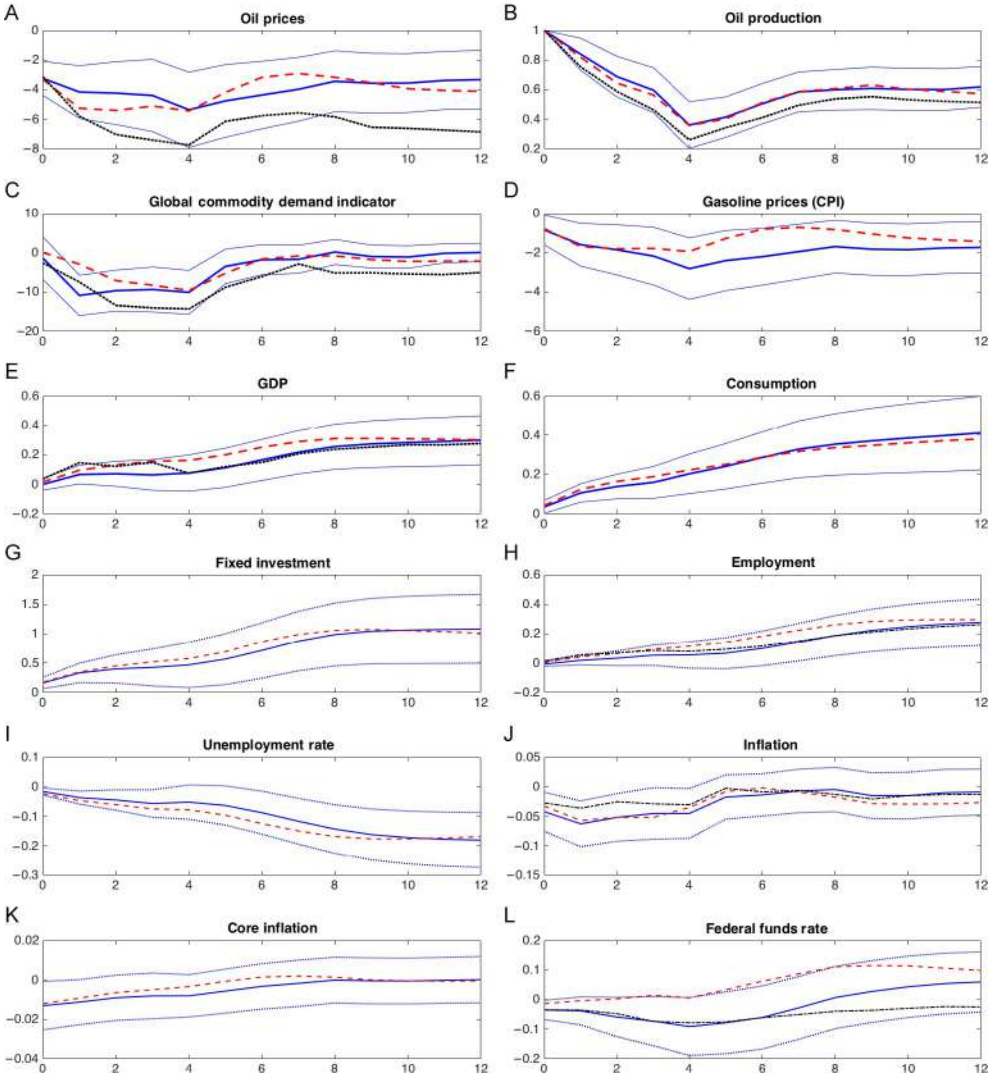

Fig. 9 Structural IRFs from the SDFM (*blue* (*dark gray* in the print version) *solid* with ±1 standard error bands), FAVAR (*red* (*gray* in the print version) *dashed*), and SVAR (*black dots*) for selected variables with respect to an oil supply shock: Kilian (2009) identification. Units: standard deviations for Global Commodity Demand and percentage points for all other variables.

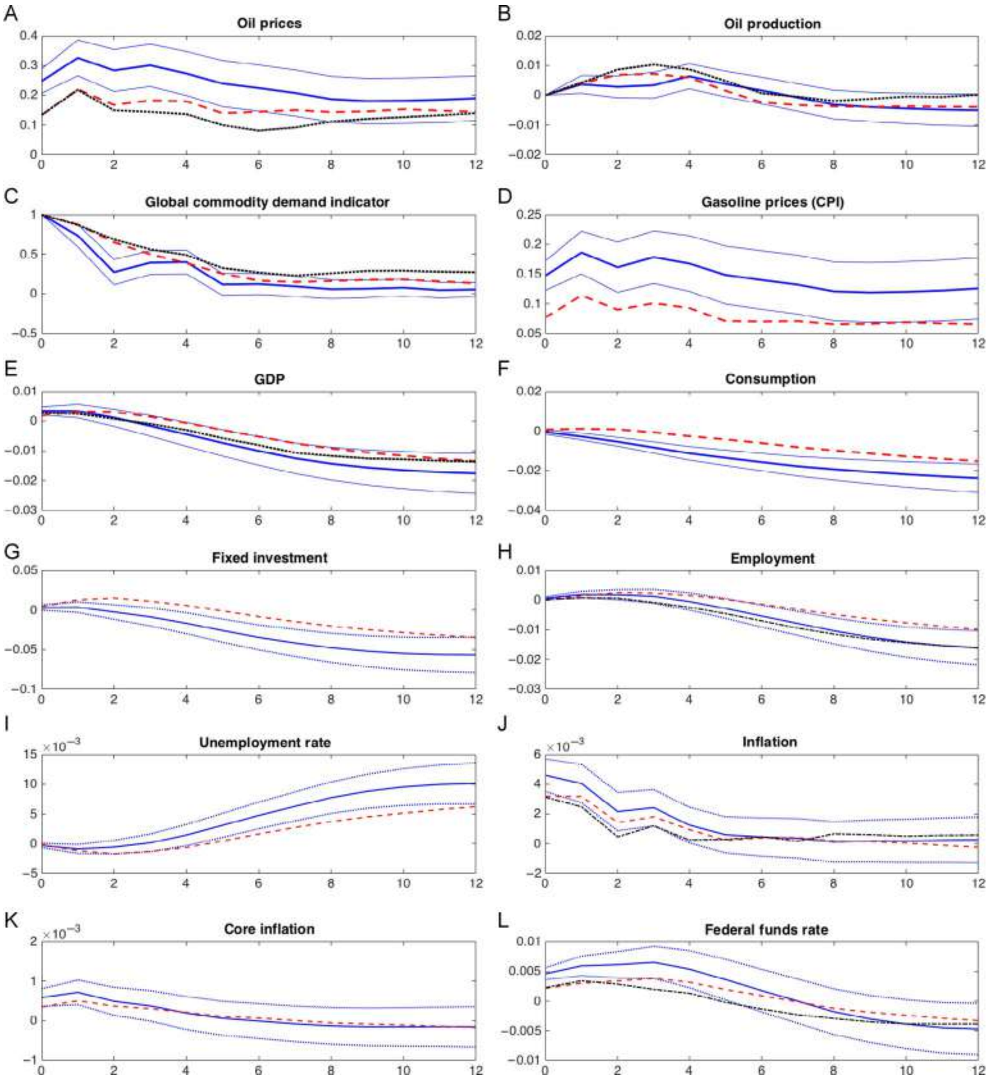

Fig. 10 Structural IRFs from the SDFM (*blue* (*dark gray* in the print version) *solid* with ±1 standard error bands), FAVAR (*red* (*gray* in the print version) *dashed*), and SVAR (*black dots*) for selected variables with respect to a global demand shock: Kilian (2009) identification. Units: standard deviations for Global Commodity Demand and percentage points for all other variables.

forecast and the forecasts, and thus forecast errors, do not substantially depend on the choice of conditioning set (lags of observed variables in the SVAR vs lags of factors in the FAVAR and SDFM). Thus the identified shocks are highly correlated (Table 8) and the SIRFs are quite similar across the three models. On a substantive note, the fraction of the variance of major macroeconomic variables explained by oil supply shocks is quite small (Table 7).

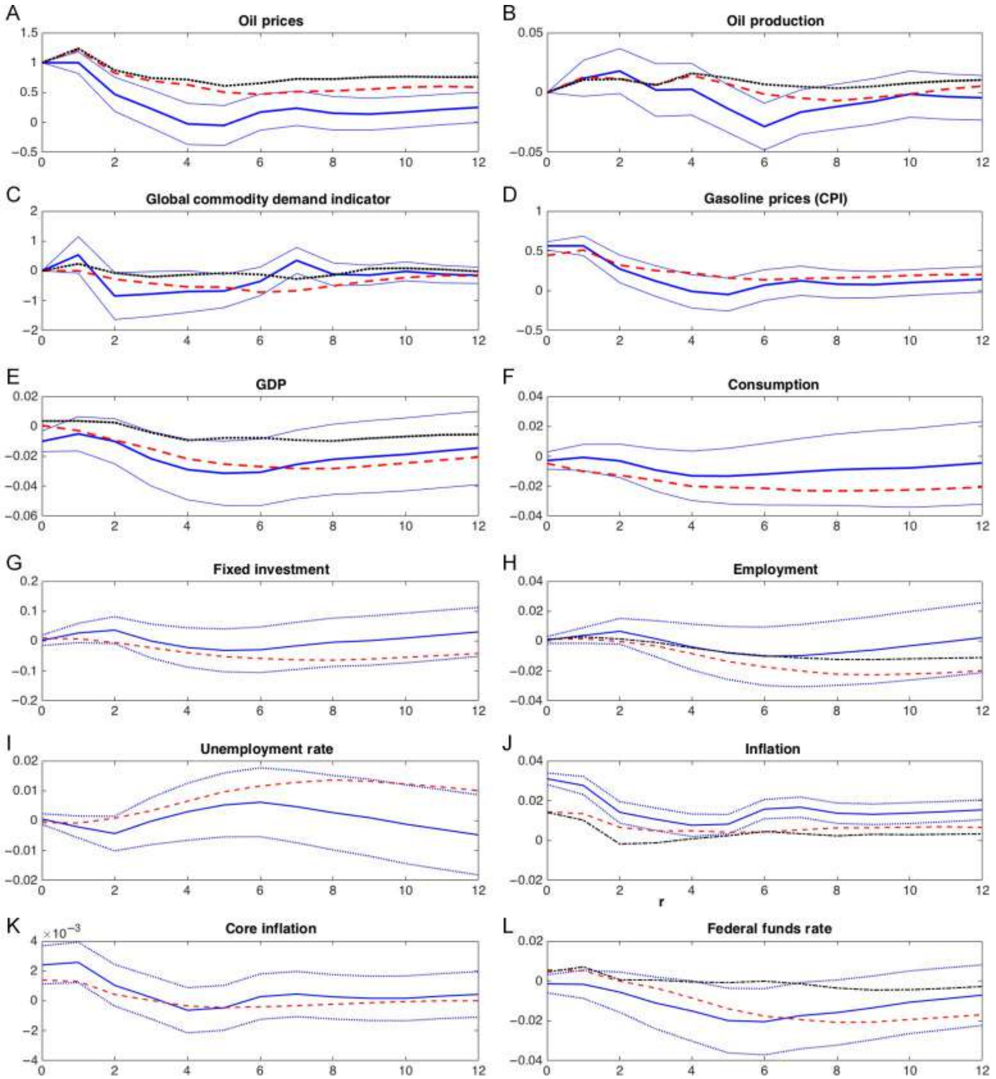

Fig. 11 Structural IRFs from the SDFM (*blue* (*dark gray* in the print version) *solid* with ±1 standard error bands), FAVAR (*red* (*gray* in the print version) *dashed*), and SVAR (*black dash–dot*) for selected variables with respect to an oil-specific demand shock: Kilian (2009) identification. Units: standard deviations for Global Commodity Demand and percentage points for all other variables.

In contrast, there are notable differences between the SDFM SIRFs for global demand shocks and the corresponding SIRFs for the FAVAR and SVAR, however the FAVAR SIRFs are quite similar to the SVAR SIRFs (Fig. 10). Broadly, the FAVAR and SVAR SIRFs are attenuated relative to the SDFM SIRFs. These features are consistent with (a) the global demand shocks—unlike the oil production shocks—being

Notes: Entries are the fractions of the six periods ahead forecast error of the row variable explained by the column shock, for the "oil price exogenous" identification results (columns A) and the Kilian identification scheme (columns B). For each shock, "F" refers to the FAVAR treatment in which the factor is treated as observed and "D" refers to the SDFM treatment. In the hybrid SDFM using the Kilian (2009) identification scheme, the oil supply factor is treated as observed (the oil production variable) (D(O)) while the global demand and oil-specific demand factors are treated as unobserved (D(U)).

spanned by the space of the factor innovations, (b) the innovations in the commodity index being a noisy measure of the unobserved global factor innovations, and (c) the one step ahead forecast errors for the commodity index being close using either the factors or SVAR variables as conditioning sets. Evidence for (a) is the large fraction of the one step ahead forecast error variance of the global commodity index that is explained by the factor innovations (Table 6). But because the global commodity index is just one noisy measure of global demand, it follows from the general discussion of Section 5 that the innovations in the global commodity index in the FAVAR and SVAR models will be noisy measures of—that is, an imperfect proxy for—the innovation in global economic activity (this is point (b)). Evidence for (c) is the high correlation (0.82) between the SVAR and FAVAR estimates of the global demand shocks in Table 8.

For the oil-specific demand shock (Fig. 11), the FAVAR and SVAR SIRFs are also attenuated relative to the SDFM SIRFs. The issues associated with interpreting these differences are subtle. In addition to the oil supply and aggregate demand shocks discussed earlier, the hybrid SDFM allows for two oil price-specific shocks: one that explains some of the comovements of other macro variables, and one that is purely idiosyncratic (actually, an idiosyncratic disturbance for each oil price) which has no effect on other macro

Table 8 Correlations between identified shocks

Kilian (2009) identification	Oil supply	D	−0.22	−0.24	−0.22	1.00								
		F	−0.21	−0.23	−0.23	0.95	1.00							
		V	−0.18	−0.22	−0.22	0.88	0.88	1.00						
	Global demand	D	0.70	0.63	0.56	0.00	0.06	0.07	1.00					
		F	0.45	0.35	0.31	−0.02	0.00	−0.06	0.37	1.00				
		V	0.37	0.28	0.37	0.00	−0.01	0.00	0.40	0.82	1.00			
	Oil-specific demand	D	0.63	0.50	0.43	0.00	−0.05	−0.04	0.00	0.30	0.17	1.00		
		F	0.66	0.83	0.79	0.00	0.00	0.03	0.54	0.00	0.02	0.44	1.00	
		V	0.60	0.76	0.91	−0.03	−0.04	0.00	0.48	0.00	0.00	0.39	0.88	1.00

Notes: Entries are correlations between the identified shocks. D=SDFM or hybrid SDFM, F=FAVAR, and V=SVAR.

variables. According to the FEVDs in Table 7, the oil-specific demand shock spanned by the factor innovations explains only a small amount of the forecast error in oil prices, and virtually none of the variation in major macroeconomic variables. Thus the SDFM relegates the residual variation in oil prices to the idiosyncratic disturbance, which has no effect on variables other than the oil price itself (and on PCE inflation, presumably through the oil price). In contrast, the FAVAR and SVAR have a single oil price-specific shock instead of the two in the SDFM. The single shock in the FAVAR and SVAR mix the purely idiosyncratic movements in oil prices with the oil-specific demand shock that could have broader consequences, so that this shock explains half of the six quarters ahead forecast error variance for oil prices, and one-third of that for gasoline prices, but very small amounts of the variation in other macro variables.

7.6 Discussion and Lessons

The two identification schemes provide two contrasting examples. In the "oil price exogenous" identification scheme, the oil price innovation is effectively spanned by the space of factor innovations, so it makes little difference whether oil prices are treated as an unobserved factor in a SDFM or an observed factor in a FAVAR. Moreover, because it is difficult to predict oil price changes, using the factors for that prediction or using the eight-variable VAR makes little difference. Thus, in all the models, the oil price shock is essentially the same, so the SIRFs and variance decompositions are essentially the same. For this scheme, it turns out that it matters little whether a SDFM, FAVAR, or SVAR is used.

In contrast, in the Kilian (2009) identification scheme, the results depend more sensitively on which model is used for the factors that are treated as unobserved in the SDFM. Moreover, there is the additional feature that the forecast error in oil production seems not to be spanned by the macro factor innovations, indicating both that it has little effect on the macro variables and that an attempt to treat oil production as an unobserved factor will have problems with estimation error so that it is preferable to treat oil production as an observed factor. The dependence of the results for the global activity factor and the oil-specific demand factor are consistent with the theoretical discussion in Section 5: treating those global demand and oil-specific demand as observed in a FAVAR, or as variables in a SVAR, arguably leads to measurement error in those innovations, and thus to measurement error in the IRFs. For these two shocks, it is preferable to recognize that the observed variables measure the shocks with error and thus to rely on SDFM estimates of the IRFs.

Finally, on substance, these results are consistent with the modern literature that oil supply shocks explain little of the variation of US aggregate activity since the early 1980s. Indeed, this result comes through even in the "oil price exogenous" identification scheme estimated post-1984. Instead, aggregate demand shocks are an important force in oil price movements: as estimated using the SDFM, 44% of the variance of six-quarter horizon forecast errors in oil prices is explained by global demand shocks, larger than the FAVAR estimate of 22%, consistent with the measurement error discussion earlier.

8. CRITICAL ASSESSMENT AND OUTLOOK

This section starts with some practical recommendations for empirical use of DFMs, drawn both from the literature and our own experience with these models. It then turns to a broader assessment of lessons learned from the large literature on DFMs, including touching on some remaining open methodological issues.

8.1 Some Recommendations for Empirical Practice

8.1.1 Variable Selection and Data Processing

Selection of the variables in the DFM should be guided by the purpose of the empirical application and knowledge of the data series. For the purposes of index construction, the series should have comparable scope, for example the real activity index constructed in Section 6 used the subset of real activity variables, not the full dataset. For the purposes of nowcasting, forecasting, and factor estimation, a guiding principle is that the factor innovations should span the space of the most important shocks that in turn affect the evolution of the variables of most interest.

The methods described in this chapter apply to variables that are integrated of order zero; in practice, this can require preprocessing the data to remove long-run dependence and trends. In most applications, this is done by transforming the variables to growth rates or more generally using first or second differences of the variables as appropriate. For the application in this chapter, we additionally removed remaining low-frequency swings by subtracting off a trend estimated using a lowpass filter designed to capture changes in mean growth rates at periodicities of a decade and longer. Although this step is uncommon in the literature, we believe it is important when working with US macro data because the drivers of the long-term trends in the data, such as multidecadal demographic swings, confound the short- and medium-term modeling in the DFM.

8.1.2 Parametric vs Nonparametric Methods

The parametric approach of formulating and estimating the DFM in state space has theoretical advantages: it produces the MLE and is amenable to Bayesian analysis under correct specification and it handles data irregularities such as missing observations and mixed-frequency data. But our reading of the literature and our own experience suggest that in practice the differences between parametric implementations and nonparametric implementations (principal components or other least-squares methods for estimating the factors) are slim in most applications. As discussed in Section 2.3.3, like the parametric approach, nonparametric methods can handle missing data, mixed data frequencies, and other data irregularities. The nonparametric methods have the added advantage of computational simplicity and do not require specifying a parametric dynamic model for the key step of estimating the factors. For these reasons, we therefore consider the nonparametric methods to be the appropriate default.

8.1.3 Instability

There is mounting empirical evidence that DFMs, like other time series models, can exhibit instability. This is not a surprise, for example it is well documented that changes associated with the Great Moderation go beyond reduction in variances to include changes in dynamics and reduction in predictability. Thus it is important to check for stability in DFMs, just as it is in other models with time series data. The stability tests used in this chapter are simple to implement and entail applying textbook single-equation stability tests to regressions of a single variable on the factors (other stability tests are discussed in Section 2.5.2).

One subtlety is that the PC estimator of the factors has some desirable robustness to modest amounts of time variation (see the discussion in Section 2.5.1). As a result, if there is a break in the factor loadings of some but not all of the variables, it can be appropriate to use the full sample for estimating the factors but a split sample for estimating the factor loadings, although whether this is warranted depends on the application.

8.1.4 Additional Considerations for Structural Analysis

Four sets of issues are worth stressing when a goal of the analysis is to estimate the effect of structural shocks.

The first, which is a central point of this chapter, is that identification methods developed for SVAR analysis carry over directly to SDFMs with the assistance of the unit effect normalization (32) and the named factor normalization (12).

The second concerns the potential for weak identification. This concern applies equally to SVARs, FAVARs, and SDFMs. One theme of Section 4 is that the various methods used to identify structural shocks and their IRFs in SVARs can all be interpreted as GMM, or in some cases simple instrumental variables, methods. As a result, the possibility arises that the structural parameters (the parameters of the H matrix in (20)) might be weakly identified. If so, SIRFs will in general be biased and confidence intervals will be unreliable. As of this writing, some methods for identification–robust inference in SVARs have been explored but there is not yet a comprehensive suite of tools available.

Third, inference with sign-identified SVARs, FAVARs, and SDFMs has its own challenges. As discussed in Section 4.6.2, nonlinearities in the mapping from the prior to the posterior imply that seemingly uninformative priors induce informative priors over the unidentified set. Resolving this problem is an active area of research.

The fourth issue, which arises for SDFMs but not for SVARs or FAVARs, is the possibility that the identified shock might not be spanned by the innovations of the factor loadings. This could arise either because the variables chosen for the DFM have too narrow a scope, or because the shock of interest simply has little or no macro consequence. This latter situation arose in the empirical application of Section 7, in which the factor innovations explained almost none of the forecast error in global oil production. In this case, the named factor normalization breaks down (because the latent macro factors do not include a global oil production factor so there is effectively no common component of global oil production) so the SDFM approach is not reliable. In Section 7, we addressed this problem by adopting a hybrid SDFM in which global oil production was an observed factor, which was estimated to explain very little of the post-1984 variation in US macro variables.

8.2 Assessment

We conclude by stepping back and returning to three high-level questions about whether DFMs have achieved their promise. First, has the early indication that the comovements of macro variables are well described by a small number of factors held up to scrutiny? Second, have DFMs—the first and still leading tool for "big data" analysis in macroeconomics—improved forecasts and nowcasts of macroeconomic variables? And third, do structural DFMs provide improvements over SVARs and, if so, how?

8.2.1 Do a Small Number of Factors Describe the Comovements of Macro Variables?

The repeated finding in the empirical DFM literature is that the answer is a strong yes. In the 207-variable dataset, the average R^2 of the regression of 207 variables against the eight factors is 51%. For major macroeconomic aggregates, which were not used to estimate the factors, this fraction is higher: 81% for GDP growth and 93% for the growth of nonfarm employment. This R^2 is large for other macro variables as well: 64% for the PCE deflator, 72% for the 10 year–3 month treasury spread, and 73% for the S&P 500. This high fit, for different DFMs and different variables, is evident Figs. 4, 5, and 7B in this chapter, and in many applications in this literature. This general affirmative answer does not mean that every variable is well fit by the few common factors, nor does it imply that there is no remaining common structure. But the stylized fact from Sargent and Sims (1977) of a few factors explaining a large fraction of the variation of many macro series is robust.

8.2.2 Do DFMs Improve Forecasts and Nowcasts?

Our answer is a nuanced yes. Broadly speaking, DFM forecasts are competitive with other methods, and for certain problems, such as forecasting real economic activity, DFM forecasts are in many cases the best available forecasts. For nowcasts, DFMs provide a structured and internally consistent way to handle the "ragged edge" problem with large datasets. For nowcasts, mixed-frequency methods using small datasets have proven competitive in some applications. As a practical matter, in macro forecasting and nowcasting applications DFMs are typically in the mix, sometimes provide the best forecasts, and at a minimum belong in the suite of models considered.

8.2.3 Do SDFMs Provide Improvements Over SVARs?

From the perspective of structural shock analysis, DFMs have two substantial advantages over SVARs and, in many cases, over FAVARs. First, by using many variables, they are better able to span the space of structural shocks than a low-dimensional VAR. As discussed in Section 6.4, in the US quarterly dataset the space of innovations of low-dimensional VARs does not well approximate the space of factor innovations, consistent with the individual series in the VAR having measurement error and idiosyncratic variation. This finding suggests that a method to identify shocks could fail in a SVAR because of measurement error or idiosyncratic variation, but succeed in identifying the shock in a SDFM, a general point that is consistent with the empirical results in Section 7.4.

Second, a side benefit of using many variables is that it the SDFM generates internally consistent SIRFs for a large number of variables. The SDFM separates the tasks of identifying the structural shock and estimating a SIRF for variables of interest.

Abstract

This chapter provides an overview of solution and estimation techniques for dynamic stochastic general equilibrium models. We cover the foundations of numerical approximation techniques as well as statistical inference and survey the latest developments in the field.

Keywords

Approximation error analysis, Bayesian inference, DSGE model, Frequentist inference, GMM estimation, Impulse response function matching, Likelihood-based inference, Metropolis-Hastings algorithm, Minimum distance estimation, Particle filter, Perturbation methods, Projection methods, Sequential Monte Carlo.

JEL Classification Codes

1. INTRODUCTION

The goal of this chapter is to provide an illustrative overview of the state-of-the-art solution and estimation methods for dynamic stochastic general equilibrium (DSGE) models. DSGE models use modern macroeconomic theory to explain and predict comovements of aggregate time series over the business cycle. The term *DSGE model* encompasses a broad class of macroeconomic models that spans the standard neoclassical growth model discussed in King et al. (1988) as well as New Keynesian monetary models with numerous real and nominal frictions along the lines of Christiano et al. (2005) and Smets and Wouters (2003). A common feature of these models is that decision rules of economic agents are derived from assumptions about preferences, technologies, information, and the prevailing fiscal and monetary policy regime by solving intertemporal optimization problems. As a consequence, the DSGE model paradigm delivers empirical models with a strong degree of theoretical coherence that are attractive as a laboratory for policy experiments. Modern DSGE models are flexible enough to accurately track and forecast macroeconomic time series fairly well. They have become one of the workhorses of monetary policy analysis in central banks.

The combination of solution and estimation methods in a single chapter reflects our view of the central role of the tight integration of theory and data in macroeconomics. Numerical solution methods allow us to handle the rich DSGE models that are needed for business cycle analysis, policy analysis, and forecasting. Estimation methods enable us to take these models to the data in a rigorous manner. DSGE model solution and estimation techniques are the two pillars that form the basis for understanding the behavior of aggregate variables such as GDP, employment, inflation, and interest rates, using the tools of modern macroeconomics.

Unfortunately for PhD students and fortunately for those who have worked with DSGE models for a long time, the barriers to entry into the DSGE literature are quite high. The solution of DSGE models demands familiarity with numerical approximation techniques and the estimation of the models is nonstandard for a variety of reasons, including a state-space representation that requires the use of sophisticated filtering techniques to evaluate the likelihood function, a likelihood function that depends in a complicated way on the underlying model parameters, and potential model misspecification that renders traditional econometric techniques based on the "axiom of correct specification" inappropriate. The goal of this chapter is to lower the barriers to entry into this field by providing an overview of what have become the "standard" methods of solving and estimating DSGE models in the past decade and by surveying the most recent technical developments. The chapter focuses on methods more than substantive applications, though we provide detailed numerical illustrations as well as references to applied research. The material is grouped into two parts. Part I: Solving DSGE Models (Sections 2–7) is devoted to solution techniques, which are divided into perturbation and projection techniques. Part II: Estimating DSGE Models (Sections 8–12) focuses on estimation. We cover both Bayesian and frequentist estimation and inference techniques.

PART I. SOLVING DSGE MODELS

2. SOLUTION METHODS FOR DSGE MODELS

DSGE models do not admit, except in a few cases, a closed-form solution to their equilibrium dynamics that we can derive with "paper and pencil." Instead, we have to resort to numerical methods and a computer to find an approximated solution.

However, numerical analysis and computer programming are not a part of the standard curriculum for economists at either the undergraduate or the graduate level. This educational gap has created three problems. The first problem is that many macroeconomists have been reluctant to accept the limits imposed by analytic results. The cavalier assumptions that are sometimes taken to allow for closed-form solutions may confuse more than clarify. While there is an important role for analytic results for building intuition, for understanding economic mechanisms, and for testing numerical approximations, many of the questions that DSGE models are designed to address require a quantitative answer that only numerical methods can provide. Think, for example, about the optimal response of monetary policy to a negative supply shock. Suggesting that the monetary authority should lower the nominal interest rate to smooth output is not enough for real-world advice. We need to gauge the magnitude and the duration of such an interest rate reduction. Similarly, showing that an increase in government spending raises output does not provide enough information to design an effective countercyclical fiscal package.

The second problem is that the lack of familiarity with numerical analysis has led to the slow diffusion of best practices in solution methods and little interest in issues such as the assessment of numerical errors. Unfortunately, the consequences of poor approximations can be severe. Kim and Kim (2003) document how inaccurate solutions may cause spurious welfare reversals. Similarly, the identification of parameter values may depend on the approximated solution. For instance, van Binsbergen et al. (2012) show that a

DSGE model with recursive preferences needs to be solved with higher-order approximations for all parameters of interest to be identified. Although much progress in the quality of computational work has been made in the last few years, there is still room for improvement. This is particularly important as essential nonlinearities—such as those triggered by nonstandard utility functions, time-varying volatility, or occasionally binding constraints—are becoming central to much research on the frontier of macroeconomics. Nonstandard utility functions such as the very popular Epstein–Zin preferences (Epstein and Zin, 1989) are employed in DSGE models by Tallarini (2000), Piazzesi and Schneider (2006), Rudebusch and Swanson (2011, 2012), van Binsbergen et al. (2012), and Fernández-Villaverde et al. (2014), among many others. DSGE models with time-varying volatility include Fernández-Villaverde and Rubio-Ramírez (2007), Justiniano and Primiceri (2008), Bloom (2009), Fernández-Villaverde et al. (2011, 2015b), also among many others. Occasionally binding constraints can be caused by many different mechanisms. Two popular ones are the zero lower bound (ZLB) of nominal interest rates (Eggertsson and Woodford, 2003; Christiano et al., 2011; Fernández-Villaverde et al., 2015a; Aruoba and Schorfheide, 2015; and Gust et al., 2016) and financial frictions (such as in Bernanke and Gertler, 1989; Carlstrom and Fuerst, 1997; Bernanke et al., 1999; Fernández-Villaverde, 2010; Christiano et al., 2014; and dozens of others). Inherent nonlinearities force macroeconomists to move beyond traditional linearization methods.

The third problem is that, even within the set of state-of-the-art solution methods, researchers have sometimes been unsure about the trade-offs (for example, regarding speed vs accuracy) involved in choosing among different algorithms.

Part I of the chapter covers some basic ideas about solution methods for DSGE models, discusses the trade-offs created by alternative algorithms, and introduces basic concepts related to the assessment of the accuracy of the solution. Throughout the chapter, we will include remarks with additional material for those readers willing to dig deeper into technical details.

Because of space considerations, there are important topics we cannot cover in what is already a lengthy chapter. First, we will not deal with value and policy function iteration. Rust (1996) and Cai and Judd (2014) review numerical dynamic programming in detail. Second, we will not discuss models with heterogeneous agents, a task already well accomplished by Algan et al. (2014) and Nishiyama and Smetters (2014) (the former centering on models in the Krusell and Smith (1998) tradition and the latter focusing on overlapping generations models). Although heterogeneous agent models are, indeed, DSGE models, they are often treated separately for simplicity. For the purpose of this chapter, a careful presentation of issues raised by heterogeneity will consume many pages. Suffice it to say, nevertheless, that most of the ideas in our chapter can also be applied, with suitable modifications, to models with heterogeneous agents. Third, we will not spend much time explaining the peculiarities of Markov-switching regime models and models with stochastic volatility. Finally, we will not explore how the massively parallel programming allowed by graphic processor units (GPUs) is a game-changer that opens the door to the solution of a much richer class of models. See, for example, Aldrich et al. (2011) and Aldrich (2014). Finally, for general background, the reader may want to consult a good numerical analysis book for economists. Judd (1998) is still the classic reference.

Two additional topics—a survey of the evolution of solution methods over time and the contrast between the solution of models written in discrete and continuous time—are briefly addressed in the next two remarks.

Remark 1 (The evolution of solution methods) We will skip a detailed historical survey of methods employed for the solution of DSGE models (or more precisely, for their ancestors during the first two decades of the rational expectations revolution). Instead, we will just mention four of the most influential approaches.

Fair and Taylor (1983) presented an extended path algorithm. The idea was to solve, for a terminal date sufficiently far into the future, the path of endogenous variables using a shooting algorithm. Recently, Maliar et al. (2015) have proposed a promising derivation of this idea, the extended function path (EFP), to analyze applications that do not admit stationary Markov equilibria.

Kydland and Prescott (1982) exploited the fact that the economy they were analyzing was Pareto optimal to solve the social planner's problem instead of the recursive equilibrium of their model. To do so, they substituted a linear quadratic approximation to the original social planner's problem and exploited the fast solution algorithms existing for that class of optimization problems. We will discuss this approach and its relation with perturbation in Remark 13.

King, Plosser, and Rebelo (in the widely disseminated technical appendix, not published until 2002), building on Blanchard and Kahn (1980)'s approach, linearized the equilibrium conditions of the model (optimality conditions, market clearing conditions, etc.), and solved the resulting system of stochastic linear difference equations. We will revisit linearization below by interpreting it as a first-order perturbation.

Christiano (1990) applied value function iteration to the social planner's problem of a stochastic neoclassical growth model.

Remark 2 (Discrete vs continuous time) In this chapter, we will deal with DSGE models expressed in discrete time. We will only make passing references to models in continuous time. We do so because most of the DSGE literature is in discrete time. This, however, should not be a reason to forget about the recent advances in the computation of DSGE models in continuous time (see Parra-Alvarez, 2015) or to underestimate the analytic power of continuous time. Researchers should be open to both specifications and opt, in each particular application, for the time structure that maximizes their ability to analyze the model and take it to the data successfully.

3. A GENERAL FRAMEWORK

A large number of solution methods have been proposed to solve DSGE models. It is, therefore, useful to have a general notation to express the model and its solution. This general notation will make the similarities and differences among the solution methods clear and will help us to link the different approaches with mathematics, in particular with the well-developed study of functional equations.

Indeed, we can cast numerous problems in economics in the form of a functional equation.[a] Let us define a functional equation more precisely. Let J^1 and J^2 be two functional spaces, $\Omega \subseteq \mathbb{R}^n$ (where Ω is the state space), and $\mathcal{H} : J^1 \rightarrow J^2$ be an operator between these two spaces. A *functional equation problem* is to find a function $d \subseteq J^1 : \Omega \rightarrow \mathbb{R}^m$ such that:

$$\mathcal{H}(d) = \mathbf{0}. \tag{1}$$

From Eq. (1), we can see that regular equations are nothing but particular examples of functional equations. Also, note that $\mathbf{0}$ is the space zero, different in general than the zero in the real numbers.

Examples of problems in macroeconomics that can be framed as a functional equation include value functions, Euler equations, and conditional expectations. To make this connection explicit, we introduce first the stochastic neoclassical growth model, the ancestor of all modern DSGE models. Second, we show how we can derive a functional equation problem that solves for the equilibrium dynamics of the model in terms of either a value function, an Euler equation, or a conditional expectation. After this example, the reader will be able to extend the steps in our derivations to her application.

3.1 The Stochastic Neoclassical Growth Model

We have an economy with a representative household that picks a sequence of consumption c_t and capital k_t to solve

$$\max_{\{c_t, k_{t+1}\}} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t u(c_t) \tag{2}$$

where $\mathbb{E}_t$ is the conditional expectation operator evaluated at period t, β is the discount factor, and u is the period utility function. For simplicity, we have eliminated the labor supply decision.

[a] Much of we have to say in this chapter is not, by any means, limited to macroeconomics. Similar problems appear in fields such as finance, industrial organization, international finance, etc.

The resource constraint of the economy is given by

$$c_t + k_{t+1} = e^{z_t} k_t^{\alpha} + (1-\delta)k_t \tag{3}$$

where δ is the depreciation rate and z_t is an AR(1) productivity process:

$$z_t = \rho z_{t-1} + \sigma \varepsilon_t, \varepsilon_t \sim N(0,1) \text{ and } |\rho| < 1. \tag{4}$$

Since both fundamental welfare theorems hold in this economy, we can jump between the social planner's problem and the competitive equilibrium according to which approach is more convenient in each moment. In general, this would not be possible, and some care is required to stay on either the equilibrium problem or the social planner's problem according to the goals of the exercise.

3.2 A Value Function

Under standard technical conditions (Stokey et al., 1989), we can transform the sequential problem defined by Eqs. (2)–(4) into a recursive problem in terms of a value function $V(k_t, z_t)$ for the social planner that depends on the two state variables of the economy, capital, k_t, and productivity, z_t. More concretely, $V(k_t, z_t)$ is defined by the Bellman operator:

$$V(k_t, z_t) = \max_{k_{t+1}} \left[u\left(e^{z_t} k_t^{\alpha} + (1-\delta)k_t - k_{t+1}\right) + \beta \mathbb{E}_t V(k_{t+1}, z_{t+1}) \right] \tag{5}$$

where we have used the resource constraint (3) to substitute for c_t in the utility function and the expectation in (5) is taken with respect to (4). This value function has an associated decision rule $g: \mathbb{R}_+ \times \mathbb{R} \rightarrow \mathbb{R}_+$:

$$k_{t+1} = g(k_t, z_t)$$

that maps the states k_t and z_t into optimal choices of k_{t+1} (and, therefore, optimal choices of $c_t = e^{z_t} k_t^{\alpha} + (1-\delta)k_t - g(k_t, z_t)$).

Expressing the model as a value function problem is convenient for several reasons. First, we have many results about the properties of value functions and the decision rules associated with them (for example, regarding their differentiability). These results can be put to good use both in the economic analysis of the problem and in the design of numerical methods. The second reason is that, as a default, we can use value function iteration (as explained in Rust, 1996 and Cai and Judd, 2014), a solution method that is particularly reliable, although often slow.

We can rewrite the Bellman operator as:

$$V(k_t, z_t) - \max_{k_{t+1}} \left[u\left(e^{z_t} k_t^{\alpha} + (1-\delta)k_t - k_{t+1}\right) + \beta \mathbb{E}_t V\ (k_{t+1}, z_{t+1}) \right] = 0,$$

for all k_t and z_t. If we define:

$$\mathcal{H}(d) = V(k_t, z_t) - \max_{k_{t+1}} \left[u\left(e^{z_t}k_t^{\alpha} + (1-\delta)k_t - k_{t+1}\right) + \beta\mathbb{E}_t V(k_{t+1}, z_{t+1})\right] = 0, \tag{6}$$

for all k_t and z_t, where $d(\cdot,\cdot) = V(\cdot,\cdot)$, we see how the operator $\mathcal{H}$, a rewrite of the Bellman operator, takes the value function $V(\cdot,\cdot)$ and obtains a zero. More precisely, Eq. (6) is an integral equation given the presence of the expectation operator. This can lead to some nontrivial measure theory considerations that we leave aside.

3.3 Euler Equation

We have outlined several reasons why casting the problem in terms of a value function is attractive. Unfortunately, this formulation can be difficult. If the model does not satisfy the two fundamental welfare theorems, we cannot easily move between the social planner's problem and the competitive equilibrium. In that case, also, the value function of the household and firms will require laws of motion for individual and aggregate state variables that can be challenging to characterize.[b]

An alternative is to work directly with the set of equilibrium conditions of the model. These include the first-order conditions for households, firms, and, if specified, government, budget and resource constraints, market clearing conditions, and laws of motion for exogenous processes. Since, at the core of these equilibrium conditions, we will have the Euler equations for the agents in the model that encode optimal behavior (with the other conditions being somewhat mechanical), this approach is commonly known as the Euler equation method (sometimes also referred to as solving the equilibrium conditions of the models). This solution strategy is extremely general and it allows us to handle non-Pareto efficient economies without further complications.

In the case of the stochastic neoclassical growth model, the Euler equation for the sequential problem defined by Eqs. (2)–(4) is:

$$u'(c_t) = \beta\mathbb{E}_t\left[u'(c_{t+1})\left(\alpha e^{z_{t+1}}k_{t+1}^{\alpha-1} + 1 - \delta\right)\right]. \tag{7}$$

Again, under standard technical conditions, there is a decision rule $g: \mathbb{R}_+ \times \mathbb{R} \rightarrow \mathbb{R}_+^2$ for the social planner that gives the optimal choice of consumption ($g^1(k_t, z_t)$) and capital tomorrow ($g^2(k_t, z_t)$) given capital, k_t, and productivity, z_t, today. Then, we can rewrite the first-order condition as:

$$u'\left(g^1(k_t, z_t)\right) = \beta\mathbb{E}_t\left[u'\left(g^1\left(g^2(k_t, z_t), z_{t+1}\right)\right)\left(\alpha e^{\rho z_t + \sigma\varepsilon_{t+1}}\left(g^2(k_t, z_t)\right)^{\alpha-1} + 1 - \delta\right)\right],$$

[b] See Hansen and Prescott (1995), for examples of how to recast a non-Pareto optimal economy into the mold of an associated Pareto-optimal problem.

for all k_t and z_t, where we have used the law of motion for productivity (4) to substitute forz_{t+1} or, alternatively:

$$\left(\begin{array}{c} u'\left(g^1(k_t,z_t)\right) \\ -\beta\mathbb{E}_t\left[u'\left(g^1\left(g^2(k_t,z_t),z_{t+1}\right)\right)\left(\alpha e^{\rho z_t+\sigma\varepsilon_{t+1}}\left(g^2(k_t,z_t)\right)^{\alpha-1}+1-\delta\right)\right]\end{array}\right)=0, \tag{8}$$

for all k_t and z_t (note the composition of functions $g^1\left(g^2(k_t,z_t),z_{t+1}\right)$ when evaluating consumption at $t+1$). We also have the resource constraint:

$$g^1(k_t,z_t)+g^2(k_t,z_t)=e^{z_t}k_t^\alpha+(1-\delta)k_t \tag{9}$$

Then, we have a functional equation where the unknown object is the decision rule g. Mapping Eqs. (8) and (9) into our operator $\mathcal{H}$ is straightforward:

$$\mathcal{H}(d)=\left\{\begin{array}{c} u'\left(g^1(k_t,z_t)\right) \\ -\beta\mathbb{E}_t\left[u'\left(g^1\left(g^2(k_t,z_t),z_{t+1}\right)\right)\left(\alpha e^{\rho z_t+\sigma\varepsilon_{t+1}}\left(g^2(k_t,z_t)\right)^{\alpha-1}+1-\delta\right)\right] \\ g^1(k_t,z_t)+g^2(k_t,z_t)-e^{z_t}k_t^\alpha-(1-\delta)k_t\end{array}\right.=\mathbf{0},$$

for all k_t and z_t, where $d=g$.

In this simple model, we could also have substituted the resource constraint in Eq. (8) and solved for a one-dimensional decision rule, but by leaving Eqs. (8) and (9), we illustrate how to handle cases where this substitution is either infeasible or inadvisable.

An additional consideration that we need to take care of is that the Euler equation (7) is only a necessary condition. Thus, after finding $g(\cdot,\cdot)$, we would also need to ensure that a transversality condition of the form:

$$\lim_{t\to\infty}\beta^t\frac{u'(c_t)}{u'(c_0)}k_t=0$$

(or a related one) is satisfied. We will describe below how we build our solution methods to ensure that this is, indeed, the case.

3.4 Conditional Expectations

We have a considerable degree of flexibility in how we specify $\mathcal{H}$ and d. For instance, if we go back to the Euler equation (7):

$$u'(c_t)=\beta\mathbb{E}_t\left[u'(c_{t+1})\left(\alpha e^{z_{t+1}}k_{t+1}^{\alpha-1}+1-\delta\right)\right]$$

we may want to find the unknown conditional expectation:

$$\mathbb{E}_t\left[u'(c_{t+1})\left(\alpha e^{z_{t+1}}k_{t+1}^{\alpha-1}+1-\delta\right)\right].$$

This may be the case either because the conditional expectation is the object of interest in the analysis or because solving for the conditional expectation avoids problems associated with the decision rule. For example, we could enrich the stochastic neoclassical growth model with additional constraints (such as a nonnegative investment: $k_{t+1} \geq (1-\delta)k_t$) that induce kinks or other undesirable properties in the decision rules. Even when those features appear, the conditional expectation (since it smooths over different realizations of the productivity shock) may still have properties such as differentiability that the researcher can successfully exploit either in her numerical solution or later in the economic analysis.[c]

To see how this would work, we can define $g: \mathbb{R}_+ \times \mathbb{R} \rightarrow \mathbb{R}_+$:

$$g(k_t, z_t) = \mathbb{E}_t\left[u'(c_{t+1})\left(\alpha e^{z_{t+1}} k_{t+1}^{\alpha-1} + 1 - \delta\right)\right] \tag{10}$$

where we take advantage of $\mathbb{E}_t$ being a function of the states of the economy. Going back to our the Euler equation (7) and the resource constraint (3), if we have access to g, we can find:

$$c_t = u'(\beta g(k_t, z_t))^{-1} \tag{11}$$

and

$$k_{t+1} = e^{z_t} k_t^{\alpha} + (1-\delta)k_t - u'(\beta g(k_t, z_t))^{-1}.$$

Thus, knowledge of the conditional expectation allows us to recover all the other endogenous variables of interest in the model. To save on notation, we write $c_t = c_{g,t}$ and $k_{t+1} = k_{g,t}$ to denote the values of c_t and k_{t+1} implied by g. Similarly:

$$c_{t+1} = c_{g,t+1} = u'(\beta g(k_{t+1}, z_{t+1}))^{-1} = u'\left(\beta g\left(k_{g,t}, z_{t+1}\right)\right)^{-1}$$

is the value of c_{t+1} implied by the recursive application of g.

To solve for g, we use its definition in Eq. (10):

$$g(k_t, z_t) = \beta \mathbb{E}_t\left[u'\left(c_{g,t+1}\right)\left(\alpha e^{\rho z_t + \sigma \varepsilon_{t+1}} k_{g,t}^{\alpha-1} + 1 - \delta\right)\right]$$

and write:

$$\mathcal{H}(d) = g(k_t, z_t) - \beta \mathbb{E}_t\left[u'\left(c_{g,t+1}\right)\left(\alpha e^{\rho z_t + \sigma \varepsilon_{t+1}} k_{g,t}^{\alpha-1} + 1 - \delta\right)\right] = \mathbf{0}$$

where $d = g$.

[c] See Fernández-Villaverde et al. (2015a) for an example. The paper is interested in solving a New Keynesian business cycle model with a zero lower bound (ZLB) on the nominal interest rate. This ZLB creates a kink on the function that maps states of the model into nominal interest rates. The paper gets around this problem by solving for consumption, inflation, and an auxiliary variable that encodes information similar to that of a conditional expectation. Once these functions have been found, the rest of the endogenous variables of the model, including the nominal interest rate, can be derived without additional approximations. In particular, the ZLB is always satisfied.

3.5 The Way Forward

We have argued that a large number of problems in macroeconomics can be expressed in terms of a functional equation problem

$$\mathcal{H}(d) = \mathbf{0}$$

and we have illustrated our assertion by building the operator $\mathcal{H}$ for a value function, for an Euler equation problem, and for a conditional expectation problem. Our examples, though, do not constitute an exhaustive list. Dozens of other cases can be constructed following the same ideas.

We will move now to study the two main families of solution methods for functional equation problems: perturbation and projection methods. Both families replace the unknown function d for an approximation $d^j(\mathbf{x}, \theta)$ in terms of the state variables of the model $\mathbf{x}$ and a vector of coefficients θ and a degree of approximation j (we are deliberately being ambiguous about the interpretation of that degree). We will use the terminology "parameters" to refer to objects describing the preferences, technology, and information sets of the model. The discount factor, risk aversion, the depreciation rate, or the persistence of the productivity shock are examples of parameters. We will call the numerical terms "coefficients" in the numerical solution. While the "parameters" usually have a clear economic interpretation associated with them, the "coefficients" will, most of the time, lack such interpretation.

Remark 3 (Structural parameters?) We are carefully avoiding the adjective "structural" when we discuss the parameters of the model. Here we follow Hurwicz (1962), who defined a "structural parameter" as a parameter that was invariant to a class of policy interventions the researcher is interested in analyzing. Many parameters of interest may not be "structural" in Hurwicz's sense. For example, the persistence of a technology shock may depend on the barriers to entry/exit in the goods and services industries and how quickly technological innovations can diffuse. These barriers may change with variations in competition policy. See a more detailed discussion on the "structural" character of parameters in DSGE models as well as empirical evidence in Fernández-Villaverde and Rubio-Ramírez (2008).

The states of the model will be determined by the structure of the model. Even if, in the words of Thomas Sargent, "finding the states is an art" (meaning both that there is no constructive algorithm to do so and that the researcher may be able to find different sets of states that accomplish the goal of fully describing the situation of the model, some of which may be more useful than the others in one context but less so in another one), determining the states is a step previous to the numerical solution of the model and, therefore, outside the purview of this chapter.

4. PERTURBATION

Perturbation methods build approximate solutions to a DSGE economy by starting from the exact solution of a particular case of the model or from the solution of a nearby model whose solution we have access to. Perturbation methods are also known as asymptotic methods, although we will avoid such a name because it risks confusion with related techniques regarding the large sample properties of estimators as the ones we will introduce in Part II of the chapter. In their more common incarnation in macroeconomics, perturbation algorithms build Taylor series approximations to the solution of a DSGE model around its deterministic steady state using implicit-function theorems. However, other perturbation approaches are possible, and we should always talk about *a* perturbation of the model instead of *the* perturbation. With a long tradition in physics and other natural sciences, perturbation theory was popularized in economics by Judd and Guu (1993) and it has been authoritatively presented by Judd (1998), Judd and Guu (2001), and Jin and Judd (2002).[d] Since there is much relevant material about perturbation problems in economics (including a formal mathematical background regarding solvability conditions, and more advanced perturbation techniques such as gauges and Padé approximants) that we cannot cover in this chapter, we refer the interested reader to these sources.

Over the last two decades, perturbation methods have gained much popularity among researchers for four reasons. First, perturbation solutions are accurate around an approximation point. Perturbation methods find an approximate solution that is inherently local. In other words, the approximated solution is extremely close to the exact, yet unknown, solution around the point where we take the Taylor series expansion. However, researchers have documented that perturbation often displays good global properties along a wide range of state variable values. See the evidence in Judd (1998); Aruoba et al. (2006) and Caldara et al. (2012). Also, as we will discuss below, the perturbed solution can be employed as an input for other solution methods, such as value function iteration. Second, the structure of the approximate solution is intuitive and easily interpretable. For example, a second-order expansion of a DSGE model includes a term that corrects for the standard deviation of the shocks that drive the stochastic dynamics of the economy. This term, which captures precautionary behavior, breaks the certainty equivalence of linear approximations that makes the discussion of welfare and risk in a linearized world challenging. Third, as we will explain below, a traditional linearization is nothing but a first-order perturbation. Hence, economists can import into perturbation theory much of their knowledge and practical experience while, simultaneously, being able to incorporate the formal results developed in applied mathematics. Fourth, thanks

[d] Perturbation approaches were already widely used in physics in the 19th century. They became a central tool in the natural sciences with the development of quantum mechanics in the first half of the 20th century. Good general references on perturbation methods are Simmonds and Mann (1997) and Bender and Orszag (1999).

to open-source software such as Dynare and Dynare++ (developed by Stéphane Adjemian, Michel Juillard, and their team of collaborators), or Perturbation AIM (developed by Eric Swanson, Gary Anderson, and Andrew Levin) higher-order perturbations are easy to compute even for practitioners less familiar with numerical methods.[e]

4.1 The Framework

Perturbation methods solve the functional equation problem:

$$\mathcal{H}(d) = \mathbf{0}$$

by specifying a Taylor series expansion to the unknown function $d : \boldsymbol{\Omega} \rightarrow \mathbb{R}^m$ in terms of the n state variables of the model $\mathbf{x}$ and some coefficients θ. For example, a second-order Taylor expansion has the form:

$$d_i^2(\mathbf{x},\theta) = \theta_{i,0} + \theta_{i,1}(\mathbf{x}-\mathbf{x}_0)' + (\mathbf{x}-\mathbf{x}_0)\theta_{i,2}(\mathbf{x}-\mathbf{x}_0)', \text{ for } i = 1,\ldots,m \tag{12}$$

where $\mathbf{x}'$ is the transpose of $\mathbf{x}$, $\mathbf{x}_0$ is the point around which we build our perturbation solution, $\theta_{i,0}$ is a scalar, $\theta_{i,1}$ is an n-dimensional vector, $\theta_{i,2}$ is a $n \times n$ matrix, and where $\theta_{i,0}$, $\theta_{i,1}$, and $\theta_{i,2}$ depend on the derivatives of d that we will find using implicit-function theorems.[f]

In comparison, the traditional linearization approach popularized by King et al. (2002) delivers a solution of the form:

$$d_i^1(\mathbf{x},\theta) = \widetilde{\theta}_{i,0} + \theta_{i,1}(\mathbf{x}-\mathbf{x}_0)'$$

where the vector $\theta_{i,1}$ is the same as in Eq. (12) and $\widetilde{\theta}_{i,0} = \theta_{i,0}$ if $j = 1$. In other words, linearization is nothing more than a first-order perturbation. Higher-order approximations generalize the structure of the linearized solution by including additional terms. Instead of being an *ad hoc* procedure (as it was sometimes understood in the 1980s and 1990s), linearization can borrow from a large set of well-established results in perturbation theory. But the direction of influence also goes in the opposite direction: we can use much of our accumulated understanding on linearized DSGE models (such as how to efficiently solve for the coefficients $\theta_{i,0}$ and $\theta_{i,1}$ and how to interpret their economic meaning) in perturbation.

[e] Dynare (a toolbox for Matlab) and Dynare++ (a stand-alone application) allow the researcher to write, in a concise and transparent language, the equilibrium conditions of a DSGE model and find a perturbation solution to it, up to the third order in Dynare and an arbitrary order in Dynare++. See http://www.dynare.org/. Perturbation AIM follows a similar philosophy, but with the additional advantage of being able to rely on Mathematica and its efficient use of arbitrary-precision arithmetic. This is important, for example, in models with extreme curvature such as those with Epstein–Zin preferences or habit persistence. See http://www.ericswanson.us/perturbation.html.

[f] Strictly speaking, the order of the approximation is given by the first nonzero or dominant term, but since in DSGE models the $\theta_{i,1}$ are typically different from zero, we can proceed without further qualifications.

Remark 4 (Linearization vs loglinearization) Linearization and, more generally, perturbation, can be performed in the level of the state variables or after applying some change of variables to any (or all) the variables of the model. Loglinearization, for example, approximates the solution of the model in terms of the log-deviations of the variables with respect to their steady state. That is, for a variable $x \in \mathbf{x}$, we define:

$$\hat{x} = \log \frac{x}{\bar{x}}$$

where $\bar{x}$ is its steady-state value, and then we find a second-order approximation:

$$d_i^2(\hat{\mathbf{x}}, \theta) = \theta_{i,0} + \theta_{i,1}(\hat{\mathbf{x}} - \hat{\mathbf{x}}_0)' + (\hat{\mathbf{x}} - \hat{\mathbf{x}}_0)\theta_{i,2}(\hat{\mathbf{x}} - \hat{\mathbf{x}}_0)', \text{ for } i = 1, \ldots, m.$$

If $\mathbf{x}_0$ is the deterministic steady state (this is more often than not the case), $\hat{\mathbf{x}}_0 = \mathbf{0}$, since for all variables $x \in \mathbf{x}$

$$\hat{x}_0 = \log \frac{x}{\bar{x}} = 0.$$

This result provides a compact representation:

$$d_i^2(\hat{\mathbf{x}}, \theta) = \theta_{i,0} + \theta_{i,1}\hat{\mathbf{x}}' + \hat{\mathbf{x}}\theta_{i,2}\hat{\mathbf{x}}', \text{ for } i = 1, \ldots, m.$$

Loglinear solutions are easy to read (the loglinear deviation is an approximation of the percentage deviation with respect to the steady state) and, in some circumstances, they can improve the accuracy of the solution. We will revisit the change of variables later in the chapter.

Before getting into technical details of how to implement perturbation methods, we will briefly distinguish between regular and singular perturbations. A regular perturbation is a situation where a *small* change in the problem induces a *small* change in the solution. An example is a standard New Keynesian model (Woodford, 2003). A small change in the standard deviation of the monetary policy shock will lead to a small change in the properties of the equilibrium dynamics (ie, the standard deviation and autocorrelation of variables such as output or inflation). A singular perturbation is a situation where a *small* change in the problem induces a *large* change in the solution. An example can be an excess demand function. A small change in the excess demand function may lead to an arbitrarily large change in the price that clears the market.

Many problems involving DSGE models will result in regular perturbations. Thus, we will concentrate on them. But this is not necessarily the case. For instance, introducing a new asset in an incomplete market model can lead to large changes in the solution. As researchers pay more attention to models with financial frictions and/or market incompleteness, this class of problems may become common. Researchers will need to learn more about how to apply singular perturbations. See, for pioneering work, Judd and Guu (1993), and a presentation of bifurcation methods for singular problems in Judd (1998).

4.2 The General Case

We are now ready to deal with the details of how to implement a perturbation. We present first the general case of how to find a perturbation solution of a DSGE model by (1) using the equilibrium conditions of the model and (2) by finding a higher-order Taylor series approximation. Once we have mastered this task, it would be straightforward to extend the results to other problems, such as the solution of a value function, and to conceive other possible perturbation schemes. This section follows much of the structure and notation of section 3 in Schmitt-Grohé and Uribe (2004).

We start by writing the equilibrium conditions of the model as

$$\mathbb{E}_t \mathcal{H}(\mathbf{y}, \mathbf{y}', \mathbf{x}, \mathbf{x}') = 0, \tag{13}$$

where $\mathbf{y}$ is an $n_y \times 1$ vector of controls, $\mathbf{x}$ is an $n_x \times 1$ vector of states, and $n = n_x + n_y$. The operator $\mathcal{H} : \mathbb{R}^{n_y} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_x} \times \mathbb{R}^{n_x} \to \mathbb{R}^n$ stacks all the equilibrium conditions, some of which will have expectational terms, some of which will not. Without loss of generality, and with a slight change of notation with respect to Section 3, we place the conditional expectation operator outside $\mathcal{H}$: for those equilibrium conditions without expectations, the conditional expectation operator will not have any impact. Moving $\mathbb{E}_t$ outside $\mathcal{H}$ will make some of the derivations below easier to follow. Also, to save on space, when there is no ambiguity, we will employ the recursive notation where x represents a variable at period t and x' a variable at period $t + 1$.

It will also be convenient to separate the endogenous state variables (capital, asset positions, etc.) from the exogenous state variables (productivity shocks, preference shocks, etc.). In that way, it will be easier to see the variables on which the perturbation parameter that we will introduce below will have a direct effect. Thus, we partition the state vector $\mathbf{x}$ (and taking transposes) as

$$\mathbf{x} = [\mathbf{x}_1'; \mathbf{x}_2']'.$$

where $\mathbf{x}_1$ is an $(n_x - n_\epsilon) \times 1$ vector of endogenous state variables and $\mathbf{x}_2$ is an $n_\epsilon \times 1$ vector of exogenous state variables. Let $\tilde{n} = n_x - n_\epsilon$.

4.2.1 Steady State

If we suppress the stochastic component of the model (more details below), we can define the deterministic steady-state of the model as vectors $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$ such that:

$$\mathcal{H}(\bar{\mathbf{y}}, \bar{\mathbf{y}}, \bar{\mathbf{x}}, \bar{\mathbf{x}}) = 0. \tag{14}$$

The solution $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$ of this problem can often be found analytically. When this cannot be done, it is possible to resort to a standard nonlinear equation solver.

The previous paragraph glossed over the possibility that the model we are dealing with either does not have a steady state or that it has several of them (in fact, we can even have a continuum of steady states). Given our level of abstraction with the definition of Eq. (13), we cannot rule out any of these possibilities. Galor (2007) discusses in detail the existence and stability (local and global) of steady states in discrete time dynamic models.

A case of interest is when the model, instead of having a steady state, has a balanced growth path (BGP): that is, when the variables of the model (with possibly some exceptions such as labor) grow at the same rate (either deterministic or stochastic). Given that perturbation is an inherently local solution method, we cannot deal directly with solving such a model. However, on many occasions, we can rescale the variables x_t in the model by the trend μ_t:

$$\hat{x}_t = \frac{x_t}{\mu_t}$$

to render them stationary (the trend itself may be a complicated function of some technological processes in the economy, as when we have both neutral and investment-specific technological change; see Fernández-Villaverde and Rubio-Ramírez, 2007). Then, we can undertake the perturbation in the rescaled variable $\hat{x}_t$ and undo the rescaling when using the approximated solution for analysis and simulation.[g]

Remark 5 (Simplifying the solution of $(\bar{x}, \bar{y})$***)*** Finding the solution $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$ can often be made much easier by using two "tricks." One is to substitute some of the variables away from the operator $\mathcal{H}(\cdot)$ and reduce the system from being one of n equations in n unknowns into a system of $n' < n$ equations in n' unknowns. For example, if we have a law of motion for capital involving capital next period, capital next period, and investment:

$$k_{t+1} = (1-\delta)k_t + i_t$$

we can substitute out investment throughout the whole system just by writing:

$$i_t = k_{t+1} - (1-\delta)k_t.$$

Since the complexity of solving a nonlinear system of equations grows exponentially in the dimension of the problem (see Sikorski, 1985, for classic results on computational complexity), even a few substitutions can produce considerable improvements.

A second possibility is to select parameter values to pin down one or more variables of the model and then to solve all the other variables as a function of the fixed variables. To illustrate this point, let us consider a simple stochastic neoclassical growth model with a representative household with utility function:

[g] This rescaling is also useful with projection methods since they need a bounded domain of the state variables.

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \left(\log c_t - \psi \frac{l_t^{1+\eta}}{1+\eta} \right)$$

where the notation is the same as in Section 3 and a production function:

$$output_t = A_t k_t^{\alpha} l_t^{1-\alpha}$$

where A_t is the productivity level and a law of motion for capital:

$$k_{t+1} = output_t + (1-\delta) k_t - c_t.$$

This model has a static optimality condition for labor supply of the form:

$$\psi c_t l_t^{\eta} = w_t$$

where w_t is the wage. Since with the log-CRRA utility function that we selected l_t does not have a natural unit, we can fix its deterministic steady-state value, for example, $\bar{l} = 1$. This normalization is as good as any other and the researcher can pick the normalization that best suits her needs.

Then, we can analytically solve the rest of the equilibrium conditions of the model for all other endogenous variables as a function of $\bar{l} = 1$. After doing so, we return to the static optimality condition to obtain the value of the parameter ψ as:

$$\psi = \frac{\bar{w}}{\bar{c}\bar{l}^{\eta}} = \frac{\bar{w}}{\bar{c}}$$

where $\bar{c}$ and $\bar{w}$ are the deterministic steady-state values of consumption and wage, respectively. An alternative way to think about this procedure is to realize that it is often easier to find parameter values that imply a particular endogenous variable value than to solve for those endogenous variable values as a function of an arbitrary parameter value.

Although not strictly needed to find $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$, other good practices include picking units that make algebraic and numerical computations convenient to handle. For example, we can pick units to make $\overline{output} = 1$. Again, in the context of the stochastic neoclassical growth model, we will have:

$$\overline{output} = 1 = \overline{Ak}^{\alpha} \bar{l}^{1-\alpha} = \overline{Ak}^{\alpha}.$$

Then, we can find:

$$\bar{A} = \frac{1}{\bar{k}^{\alpha}}$$

and wages:

$$\bar{w} = (1-\alpha) \frac{\overline{output}}{\bar{l}} = 1 - \alpha.$$

Going back to the intertemporal Euler equation:

$$\frac{1}{\bar{c}}=\frac{1}{\bar{c}}\beta(1+\bar{r}-\delta)$$

where r is the rental rate of capital and δ is depreciation, we find:

$$\bar{r}=\frac{1}{\beta}-1+\delta.$$

Since:

$$\bar{r}=\alpha\frac{\overline{output}}{\bar{k}}=\frac{\alpha}{\bar{k}}$$

we get:

$$\bar{k}=\frac{\alpha}{\frac{1}{\beta}-1+\delta}$$

and:

$$\bar{c}=\overline{output}-\delta\bar{k}=1-\delta\frac{\alpha}{\frac{1}{\beta}-1+\delta},$$

from which:

$$\psi=\frac{\overline{w}}{\bar{c}}=\frac{1-\alpha}{1-\delta\frac{\alpha}{\frac{1}{\beta}-1+\delta}}$$

In this example, two judicious choices of units ($\bar{l}=\overline{output}=1$) render the solution of the deterministic steady state a straightforward exercise. While the deterministic steady state of more complicated models would be harder to solve, experience suggests that following the advice in this remark dramatically simplifies the task in many situations.

The deterministic steady state $(\bar{\mathbf{x}},\bar{\mathbf{y}})$ is different from a fixed point $(\hat{\mathbf{x}},\hat{\mathbf{y}})$ of (13):

$$\mathbb{E}_t\mathcal{H}(\hat{\mathbf{y}},\hat{\mathbf{y}},\hat{\mathbf{x}},\hat{\mathbf{x}})=0,$$

because in the former case we eliminate the conditional expectation operator while in the latter we do not. The vector $(\hat{\mathbf{x}},\hat{\mathbf{y}})$ is sometimes known as the stochastic steady state (although, since we find the idea of mixing the words "stochastic" and "steady state" in the same term confusing, we will avoid that terminology).

4.2.2 Exogenous Stochastic Process

For the exogenous stochastic variables, we specify a stochastic process of the form:

$$\mathbf{x}_2'=\mathbf{C}(\mathbf{x}_2)+\sigma\eta_\epsilon\epsilon' \tag{15}$$

where $\mathbf{C}$ is a potentially nonlinear function. At our current level of abstraction, we are not imposing much structure on $\mathbf{C}$, but in concrete applications, we will need to add more constraints. For example, researchers often assume that all the eigenvalues of the Hessian matrix of $\mathbf{C}$ evaluated at the steady state $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$ lie within the unit circle. The vector ϵ' contains the n_ϵ exogenous zero-mean innovations. Initially, we only assume that ϵ' is independent and identically distributed with finite second moments, meaning that we do not rely on any distributional assumption. Thus, the innovations may be non-Gaussian. This is denoted by $\epsilon' \sim iid(\mathbf{0}, \mathbf{I})$. Additional moment restrictions will be introduced as needed in each concrete application. Finally, η_ϵ is an $n_\epsilon \times n_\epsilon$ matrix that determines the variances-covariances of the innovations, and $\sigma \geq 0$ is a perturbation parameter that scales η_ϵ.

Often, it will be the case that $\mathbf{C}$ is linear:

$$x_2' = Cx_2 + \sigma\eta_\epsilon\epsilon'$$

where C is an $n_\epsilon \times n_\epsilon$ matrix, with all its eigenvalues with modulus less than one.

Remark 6 (Linearity of innovations) The assumption that innovations enter linearly in Eq. (15) may appear restrictive, but it is without loss of generality. Imagine that instead of Eq. (15), we have:

$$\mathbf{x}_{2,t} = \mathbf{D}(\mathbf{x}_{2,t-1}, \sigma\eta_\epsilon\epsilon_t).$$

This richer structure can be handled by extending the state vector by incorporating the innovations ϵ in the state vector. In particular, let

$$\tilde{\mathbf{x}}_{2,t} = \begin{bmatrix} \mathbf{x}_{2,t-1} \\ \epsilon_t \end{bmatrix}$$

and

$$\tilde{\epsilon}_{t+1} = \begin{bmatrix} \mathbf{0}_{n_\epsilon \times 1} \\ \epsilon_{t+1} \end{bmatrix}$$

Then, we can write

$$\mathbf{x}_{2,t} = \tilde{\mathbf{D}}\ (\tilde{\mathbf{x}}_{2,t}, \sigma\eta_\epsilon).$$

The new stochastic process is given by:

$$\begin{bmatrix} \mathbf{x}_{2,t} \\ \epsilon_{t+1} \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{D}}\ (\tilde{\mathbf{x}}_{2,t}, \sigma\eta_\epsilon) \\ 0 \end{bmatrix} + \begin{bmatrix} \mathbf{0}_{n_\epsilon \times 1} \\ \epsilon_{t+1} \end{bmatrix}$$

where $\mathbf{u}_{t+1} \sim iid(\mathbf{0}, \mathbf{I})$ or, switching back to the recursive notation:

$$\tilde{\mathbf{x}}_2' = \mathbf{C}(\tilde{\mathbf{x}}_2) + \tilde{\epsilon}'$$

To illustrate this point, we use the popular case of time-varying volatility, which, it has been argued, is of considerable importance to understand the dynamics of aggregate variables (see Bloom, 2009 and Fernández-Villaverde et al., 2011). Imagine that we have a stochastic volatility process for productivity a_t:

$$\log a_t = \rho_a \log a_{t-1} + \lambda_t \upsilon_t, \upsilon_t \sim N(0,1)$$

where λ_t is the standard deviation of the innovation υ_t. The standard deviation follows another autoregressive process:

$$\log \lambda_t = \overline{\lambda} + \rho_\lambda \log \lambda_{t-1} + \psi \eta_t, \eta_t \sim N(0,1).$$

To fit this system into our notation, we only need to define:

$$\tilde{\mathbf{x}}_{2,t} = \begin{bmatrix} \log a_{t-1} \\ \log \lambda_{t-1} \\ \upsilon_t \\ \eta_t \end{bmatrix}$$

and

$$\tilde{\epsilon}_{t+1} = \begin{bmatrix} \mathbf{0}_{2\times 1} \\ \epsilon_{t+1} \end{bmatrix}.$$

Note, also, how the perturbation parameter controls both the innovation υ_t and its standard deviation λ_t.

Perturbation methods are well suited to the solution of models with time-varying volatility because these models have a richness of state variables: for each stochastic process, we need to keep track of the level of the process and its variance. The projection methods that we will describe in the next section will have problems dealing with this large number of state variables.

Only one perturbation parameter appears in Eq. (15), even if we have a model with many innovations. The matrix η_ϵ takes account of relative sizes (and comovements) of the different innovations. If we set $\sigma = 0$, we have a deterministic model.

Remark 7 (Perturbation parameter) In the main text, we introduced the perturbation parameter as controlling the standard deviation of the stochastic process:

$$\mathbf{x}_2' = \mathbf{C}(\mathbf{x}_2) + \sigma \eta_\epsilon \epsilon'.$$

However, we should not hew too closely to this choice. First, there may be occasions where placing the perturbation in another parameter could offer better accuracy and/or deeper insights into the behavior of the model. For example, in models with Epstein–Zin preferences, Hansen et al. (2008) perform a perturbation around an elasticity of intertemporal substitution equal to 1. Also, the choice of perturbation would be different in a continuous time model, where it is usually more convenient to control the variance.

We depart from Samuelson (1970) and Jin and Judd (2002), who impose a bounded support for the innovations of the model. By doing so, these authors avoid problems with the stability of the simulations coming from the perturbation solution that we will discuss below. Instead, we will introduce pruning as an alternative strategy to fix these problems.

4.2.3 Solution of the Model

The solution of the model will be given by a set of decision rules for the control variables

$$\mathbf{y} = \mathbf{g}(\mathbf{x}; \sigma), \tag{16}$$

and for the state variables

$$\mathbf{x}' = \mathbf{h}(\mathbf{x}; \sigma) + \sigma \eta \epsilon', \tag{17}$$

where $\mathbf{g}$ maps $\mathbb{R}^{n_x} \times \mathbb{R}^+$ into R^{n_y} and $\mathbf{h}$ maps $\mathbb{R}^{n_x} \times \mathbb{R}^+$ into $\mathbb{R}^{n_x}$. Note our timing convention: controls depend on current states, while states next period depend on states today and the innovations tomorrow. By defining additional state variables that store the information of states with leads and lags, this structure is sufficiently flexible to capture rich dynamics. Also, we separate states $\mathbf{x}$ and the perturbation parameter σ by a semicolon to emphasize the difference between both elements.

The $n_x \times n_\epsilon$ matrix η is:

$$\eta = \begin{bmatrix} \emptyset \\ \eta_\epsilon \end{bmatrix}$$

where the first n_x rows come from the states today determining the endogenous states tomorrow and the last n_ϵ rows come from the exogenous states tomorrow depending on the states today and the innovations tomorrow.

The goal of perturbation is to find a Taylor series expansion of the functions $\mathbf{g}$ and $\mathbf{h}$ around an appropriate point. A natural candidate for this point is the deterministic steady state, $\mathbf{x}_t = \bar{\mathbf{x}}$ and $\sigma = 0$. As we argued above, we know how to compute this steady state and, consequently, how to evaluate the derivatives of the operator $\mathcal{H}(\cdot)$ that we will require.

First, note by the definition of the deterministic steady state (14) we have that

$$\bar{\mathbf{y}} = \mathbf{g}(\bar{\mathbf{x}}; 0) \tag{18}$$

and

$$\bar{\mathbf{x}} = \mathbf{h}(\bar{\mathbf{x}}; 0). \tag{19}$$

Second, we plug-in the unknown solution on the operator $\mathcal{H}$ and define the new operator $F : \mathbb{R}^{n_x+1} \rightarrow \mathbb{R}^n$:

$$F(\mathbf{x};\sigma) \equiv \mathbb{E}_t \mathcal{H}(\mathbf{g}(\mathbf{x};\sigma), \mathbf{g}(\mathbf{h}(\mathbf{x};\sigma) + \sigma\eta\epsilon', \sigma), \mathbf{x}, \mathbf{h}(\mathbf{x};\sigma) + \sigma\eta\epsilon') = \mathbf{0}.$$

Since $F(\mathbf{x};\sigma) = 0$ for any values of $\mathbf{x}$ and σ , any derivatives of F must also be zero:

$$F_{x_i^k \sigma^j}(\mathbf{x};\sigma) = 0, \forall \mathbf{x}, \sigma, i, k, j,$$

where $F_{x_i^k \sigma^j}(\mathbf{x};\sigma)$ is the derivative of F with respect to the i-th component x_i of $\mathbf{x}$ taken k times and with respect to σ taken j times evaluated at $(\mathbf{x};\sigma)$. Intuitively, the solution of the model must satisfy the equilibrium conditions for all possible values of the states and σ. Thus, any change in the values of the states or of σ must still keep the operator F exactly at $\mathbf{0}$. We will exploit this important fact repeatedly.

Remark 8 (Existence of derivatives) We will assume, without further discussion, that all the relevant derivatives of the operator F exist in a neighborhood of $\bar{\mathbf{x}}$. These differentiability assumptions may be hard to check in concrete applications and more research in the area would be welcomed (see the classic work of Santos, 1992). However, the components that enter into F (utility functions, production functions, etc.) are usually smooth when we deal with DSGE models, which suggest that the existence of these derivatives is a heroic assumption (although the examples in Santos, 1993 are a cautionary sign). Judd (1998, p. 463) indicates, also, that if the derivative conditions were violated, our computations would display telltale signs that would alert the researcher to the underlying problems.

The derivative assumption, however, traces the frontiers of problems suitable for perturbation: if, for example, some variables are discrete or the relevant equilibrium conditions are nondifferentiable, perturbation cannot be applied. Two caveats about the previous statement are, nevertheless, worthwhile to highlight. First, the presence of expectations often transforms problems that appear discrete into continuous ones. For example, deciding whether or not to go to college can be "smoothed out" by a stochastic shock to college costs or by an effort variable that controls how hard the prospective student is applying to college or searching for funding. Second, even if the derivative assumption breaks down and the perturbation solution is not valid, it may still be an excellent guess for another solution method.

Remark 9 (Taking derivatives) The previous exposition demonstrates the central role of derivatives in perturbation methods. Except for simple examples, manually calculating these derivatives is too onerous. Thus, researchers need to rely on computers. A first possibility, numerical derivatives, is inadvisable Judd (1998, chapter 7). The errors created by numerical derivatives quickly accumulate and, after the second or third derivative, the perturbation solution is too contaminated by them to be of any real use. A second possibility is to exploit software that takes analytic derivatives, such as Mathematica or the symbolic toolbox of Matlab. This route is usually straightforward, but it may slow down the computation and require an inordinate amount of memory. A third final alternative is to employ automatic differentiation, a technique that takes advantage of the application of the chain rule to a series of elementary arithmetic operations and functions (for how automatic differentiation can be applied to DSGE models, see Bastani and Guerrieri, 2008).

4.2.4 First-Order Perturbation

A first-order perturbation approximates $\mathbf{g}$ and $\mathbf{h}$ around $(\mathbf{x};\sigma)=(\bar{\mathbf{x}};0)$ as:

$$\begin{aligned}\mathbf{g}(\mathbf{x};\sigma) &= \mathbf{g}(\bar{\mathbf{x}};0)+\mathbf{g}_{\mathbf{x}}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'+\mathbf{g}_{\sigma}(\bar{\mathbf{x}};0)\sigma\\ \mathbf{h}(\mathbf{x};\sigma) &= \mathbf{h}(\bar{\mathbf{x}};0)+\mathbf{h}_{\mathbf{x}}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'+\mathbf{h}_{\sigma}(\bar{\mathbf{x}};0)\sigma\end{aligned}$$

where $\mathbf{g}_{\mathbf{x}}$ and $\mathbf{h}_{\mathbf{x}}$ are the gradients of $\mathbf{g}$ and $\mathbf{h}$, respectively (including only the partial derivatives with respect to components of $\mathbf{x}$) and $\mathbf{g}_{\sigma}$ and $\mathbf{h}_{\sigma}$ the derivatives of $\mathbf{g}$ and $\mathbf{h}$ with respect to the perturbation parameter σ.

Using Eqs. (18) and (19), we can write

$$\begin{aligned}\mathbf{g}(\mathbf{x};\sigma)-\bar{\mathbf{y}} &= \mathbf{g}_{\mathbf{x}}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'+\mathbf{g}_{\sigma}(\bar{\mathbf{x}};0)\sigma\\ \mathbf{h}(\mathbf{x};\sigma)-\bar{\mathbf{x}} &= \mathbf{h}_{\mathbf{x}}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'+\mathbf{h}_{\sigma}(\bar{\mathbf{x}};0)\sigma.\end{aligned}$$

Since we know $(\bar{\mathbf{x}},\bar{\mathbf{y}})$, we only need to find $\mathbf{g}_{\mathbf{x}}(\bar{\mathbf{x}};0)$, $\mathbf{g}_{\sigma}(\bar{\mathbf{x}};0)$, $\mathbf{h}_{\mathbf{x}}(\bar{\mathbf{x}};0)$, and $\mathbf{h}_{\sigma}(\bar{\mathbf{x}};0)$ to evaluate the approximation at any arbitrary point $(\mathbf{x},\sigma)$. We are searching for $n\times(n_x+1)$ coefficients (the $n_x \times n_y$ terms in $\mathbf{g}_{\mathbf{x}}(\bar{\mathbf{x}};0)$, the $n_x \times n_x$ terms in $\mathbf{h}_{\mathbf{x}}(\bar{\mathbf{x}};0)$, the n_y terms in $\mathbf{g}_{\sigma}(\bar{\mathbf{x}};0)$, and the n_x terms in $\mathbf{h}_{\sigma}(\bar{\mathbf{x}};0)$).

These coefficients can be found by using:

$$F_{x_i}(\bar{\mathbf{x}};0)=0, \forall i,$$

which gives us $n \times n_x$ equations and

$$F_{\sigma}(\bar{\mathbf{x}};0)=0,$$

which gives us n equations.

But before doing so, and to avoid runaway notation, we need to introduce the use of tensors.

Remark 10 (Tensor notation) Tensor notation (or Einstein summation notation), commonly used in physics, keeps the algebra required to perform a perturbation at a manageable level by eliminating $\sum$ and ∂ signs. To further reduce clutter, the points of evaluation of a derivative are skipped when they are unambiguous from context. An n^{th}-rank tensor in an m-dimensional space is an operator that has n indices and m^n components and obeys certain transformation rules. In our environment, $[\mathcal{H}_y]^i_\alpha$ is the (i, α) element of the derivative of $\mathcal{H}$ with respect to y:

1. The derivative of $\mathcal{H}$ with respect to y is an $n \times n_y$ matrix.
2. Thus, $[\mathcal{H}_y]^i_\alpha$ is the i-th row and α-th column element of this matrix.

3. When a subindex appears as a superindex in the next term, we are omitting a sum operator. For example,

$$[\mathcal{H}_y]^i_\alpha [\mathbf{g}_x]^\alpha_\beta [\mathbf{h}_x]^\beta_j = \sum_{\alpha=1}^{n_y} \sum_{\beta=1}^{n_x} \frac{\partial \mathcal{H}^i}{\partial y^\alpha} \frac{\partial \mathbf{g}^\alpha}{\partial x^\beta} \frac{\partial \mathbf{h}^\beta}{\partial x^j}.$$

4. The generalization to higher derivatives is direct. If we have $[\mathcal{H}_{y'y'}]^i_{\alpha\gamma}$:
   (a) $\mathcal{H}_{y'y'}$ is a three-dimensional array with n rows, n_y columns, and n_y pages.
   (b) Thus, $[\mathcal{H}_{y'y'}]^i_{\alpha\gamma}$ denotes the i-th row, α-th column element, and γ-th page of this matrix.

With the tensor notation, we can get into solving the system. First, $\mathbf{g_x}(\bar{\mathbf{x}};0)$ and $\mathbf{h_x}(\bar{\mathbf{x}};0)$ are the solution to:

$$[F_x(\bar{\mathbf{x}};0)]^i_j = [\mathcal{H}_{y'}]^i_\alpha [\mathbf{g}_x]^\alpha_\beta [\mathbf{h}_x]^\beta_j + [\mathcal{H}_y]^i_\alpha [\mathbf{g}_x]^\alpha_j + [\mathcal{H}_{x'}]^i_\beta [\mathbf{h}_x]^\beta_j + [\mathcal{H}_x]^i_j = \mathbf{0}; \\ i=1,\ldots,n;\ \ j,\beta=1,\ldots,n_x;\ \ \alpha=1,\ldots,n_y. \tag{20}$$

The derivatives of $\mathcal{H}$ evaluated at $(\mathbf{y},\mathbf{y}',\mathbf{x},\mathbf{x}') = (\bar{\mathbf{y}},\bar{\mathbf{y}},\bar{\mathbf{x}},\bar{\mathbf{x}})$ are known. Therefore, we have a system of $n \times n_x$ quadratic equations in the $n \times n_x$ unknowns given by the elements of $\mathbf{g_x}(\bar{\mathbf{x}};0)$ and $\mathbf{h_x}(\bar{\mathbf{x}};0)$. After some algebra, the system (20) can be written as:

$$AP^2 - BP - C = \mathbf{0}$$

where the $\tilde{n} \times \tilde{n}$ matrix A, the $\tilde{n} \times \tilde{n}$ matrix B and the $\tilde{n} \times \tilde{n}$ matrix C involve terms from $[\mathcal{H}_{y'}]^i_\alpha$, $[\mathcal{H}_y]^i_\alpha$, $[\mathcal{H}_{x'}]^i_\beta$, and $[\mathcal{H}_x]^i_j$ and the $\tilde{n} \times \tilde{n}$ matrix P the terms $[\mathbf{h}_x]^\beta_j$ related to the law of motion of $\mathbf{x}_1$ (in our worked-out example of the next subsection, we will make this algebra explicit). We can solve this system with a standard quadratic matrix equation solver.

Remark 11** **(Quadratic equation solvers) The literature has proposed several procedures to solve quadratic systems. Without being exhaustive, we can list Blanchard and Kahn (1980), King and Watson (1998), Uhlig (1999), Klein (2000), and Sims (2002). These different approaches vary in the details of how the solution to the system is found and how general they are (regarding the regularity conditions they require). But, conditional on applicability, all methods find the same policy functions since the linear space approximating a nonlinear space is unique.

For concision, we will only present one of the simplest of these procedures, as discussed by Uhlig (1999, pp. 43–45). Given

$$AP^2 - BP - C = \mathbf{0},$$

define the $2\tilde{n} \times 2\tilde{n}$ matrix:

$$D = \begin{bmatrix} A & \mathbf{0}_{\tilde{n}} \\ \mathbf{0}_{\tilde{n}} & I_{\tilde{n}} \end{bmatrix}$$

where $I_{\tilde{n}}$ is the $\tilde{n} \times \tilde{n}$ identity matrix and $\mathbf{0}_{\tilde{n}}$ the $\tilde{n} \times \tilde{n}$ zero matrix, and the $2\tilde{n} \times 2\tilde{n}$ matrix:

$$F = \begin{bmatrix} B & C \\ I_n & \mathbf{0}_n \end{bmatrix}$$

Let Q and Z be unitary matrices (ie, $Q^H Q = Z^H Z = I_{2\tilde{n}}$ where H is the complex Hermitian transposition operator). Let Φ and Σ be upper triangular matrices with diagonal elements ϕ_{ii} and σ_{ii}. Then, we find the generalized Schur decomposition (QZ) of D and F:

$$Q'\Sigma Z = D$$
$$Q'\Phi Z = F$$

such that Σ and Φ are diagonal and the ratios of diagonal elements $|\phi_{ii}/\sigma_{ii}|$ are in increasing order (there exists a QZ decomposition for every ordering of these ratios). In such a way, the stable (smaller than one) generalized eigenvalues of F with respect to D would come first and the unstable generalized eigenvalues (exceeding one and infinite) would come last. QZ decompositions are performed by standard numerical software such as Matlab and many programs exist to achieve the QZ decomposition with the desired ordering of ratios.

Then, if we partition:

$$Z = \begin{bmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{bmatrix}$$

where each submatrix Z_{ii} has a size $\tilde{n} \times \tilde{n}$, we can find:

$$P = -Z_{21}^{-1} Z_{22}.$$

If the number of ratios of diagonal elements with absolute value less than 1 (ie, we have enough stable generalized eigenvalues of F with respect to D), then we can select a P such that $P^m x \rightarrow \mathbf{0}$ as $m \rightarrow \infty$ for any $\tilde{n}$-dimensional vector. If the number of ratios of diagonal elements with absolute value less than 1 is larger than $\tilde{n}$, there may be more than one possible choice of P such that $P^m x \rightarrow \mathbf{0}$ as $m \rightarrow \infty$ for any $\tilde{n}$-dimensional vector.

The reason a quadratic system appears is that, in general, we will have multiple possible paths for the endogenous variables of the model that would satisfy the equilibrium conditions (Uhlig, 1999 and Galor, 2007). Some of these paths (the stable manifolds) will be stable and satisfy appropriate transversality conditions (although they might imply limit cycles). The other paths (the unstable manifolds) will not. We will need to select the right eigenvalues that induce stability. For many DSGE models, we will have exactly $\tilde{n}$ stable generalized eigenvalues and the stable solution would also be unique. If we have too few stable generalized eigenvalues, the equilibrium dynamics will be inherently unstable. If we have too many, we can have sunspots (Lubik and Schorfheide, 2003). Suffice it to note here that all these issues would depend only on the first-order approximation and that going to higher-order approximations would not change the issues at hand. If we have uniqueness of equilibrium in the first-order approximation, we will also have uniqueness in the second-order approximation. And if we have multiplicity of equilibria in the first-order approximation, we will also have multiplicity in the second-order approximation.

Remark 12 (Partitioning the quadratic system) The quadratic system (20) can be further divided into two parts to get a recursive solution. The system:

$$\begin{gathered}[F_x(\bar{\mathbf{x}};0)]^i_j = [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_x]^\beta_j + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_x]^\alpha_j + [\mathcal{H}_{x'}]^i_\beta[\mathbf{h}_x]^\beta_j + [\mathcal{H}_x]^i_j = \mathbf{0}; \\ i = 1,\ldots,n;\;\; j,\beta = 1,\ldots,\tilde{n};\;\; \alpha = 1,\ldots,n_y.\end{gathered} \tag{21}$$

only involves the $\tilde{n} \times n_y$ elements of $\mathbf{g}_\mathbf{x}(\bar{\mathbf{x}};0)$ and the $\tilde{n} \times n_x$ elements of $\mathbf{h}_\mathbf{x}(\bar{\mathbf{x}};0)$ related to the $\tilde{n}$ endogenous state variables $\mathbf{x}_1$. Once we have solved the $\tilde{n} \times \left(n_y + n_x\right)$ unknowns in this system, we can plug them into the system:

$$\begin{gathered}[F_x(\bar{\mathbf{x}};0)]^i_j = [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_x]^\beta_j + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_x]^\alpha_j + [\mathcal{H}_{x'}]^i_\beta[\mathbf{h}_x]^\beta_j + [\mathcal{H}_x]^i_j = \mathbf{0}; \\ i = 1,\ldots,n;\;\; j,\beta = \tilde{n}+1,\ldots,n_x;\;\; \alpha = 1,\ldots,n_y.\end{gathered} \tag{22}$$

and solve for the $n_\epsilon \times n_y$ elements of $\mathbf{g}_\mathbf{x}(\bar{\mathbf{x}};0)$ and the $n_\epsilon \times n_x$ elements of $\mathbf{h}_\mathbf{x}((\bar{\mathbf{x}};0)$ related to the n_ϵ stochastic variables $\mathbf{x}_2$.

This recursive solution has three advantages. The first, and most obvious, is that it simplifies computations. The system (20) has $n_x \times \left(n_y + n_x\right)$ unknowns, while the system (21) has $\tilde{n} \times \left(n_y + n_x\right)$. The difference, $n_\epsilon \times \left(n_y + n_x\right)$, makes the second system considerably smaller. Think, for instance, about the medium-scale New Keynesian model in Fernández-Villaverde and Rubio-Ramírez (2008). In the notation of this chapter, the model has $n_x = 20$, $n_y = 1$, and $n_\epsilon = 5$. Thus, by partitioning the system, we go from solving for 420 unknowns to solve a first system of 315 unknowns and, later, a second system of 105 unknowns. The second advantage, which is not obvious in our compact notation, is that system (22) is linear and, therefore, much faster to solve and with a unique solution. In the next subsection, with our worked-out example, we will see this more clearly. The third advantage is that, in some cases, we may only care about the coefficients associated with the $\tilde{n}$ endogenous state variables $\mathbf{x}_1$. This occurs, for example, when we are interested in computing the deterministic transitional path of the model toward a steady state given some initial conditions or when we are plotting impulse response functions generated by the first-order approximation.

The coefficients $\mathbf{g}_\sigma(\bar{\mathbf{x}};0)$ and $\mathbf{h}_\sigma(\bar{\mathbf{x}};0)$ are the solution to the n equations:

$$\begin{gathered}[F_\sigma(\bar{\mathbf{x}};0)]^i = \mathbb{E}_t\{[\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_\sigma]^\beta + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\eta]^\beta_\phi[\epsilon']^\phi + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_\sigma]^\alpha \\ + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_\sigma]^\alpha + [\mathcal{H}_{x'}]^i_\beta[\mathbf{h}_\sigma]^\beta + [\mathcal{H}_{x'}]^i_\beta[\eta]^\beta_\phi[\epsilon']^\phi\} \\ i = 1,\ldots,n;\;\; \alpha = 1,\ldots,n_y;\;\; \beta = 1,\ldots,n_x;\;\; \phi = 1,\ldots,n_\epsilon.\end{gathered}$$

Then:

$$[F_\sigma(\bar{\mathbf{x}};0)]^i = [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_\sigma]^\beta + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_\sigma]^\alpha + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_\sigma]^\alpha + [f_{x'}]^i_\beta[\mathbf{h}_\sigma]^\beta = 0;$$
$$i=1,\ldots,n;\quad \alpha=1,\ldots,n_y;\quad \beta=1,\ldots,n_x;\quad \phi=1,\ldots,n_\epsilon.$$

Inspection of the previous equations shows that they are linear and homogeneous equations in $\mathbf{g}_\sigma$ and $\mathbf{h}_\sigma$. Thus, if a unique solution exists, it satisfies:

$$\mathbf{g}_\sigma = \mathbf{0}$$
$$\mathbf{h}_\sigma = \mathbf{0}$$

In other words, the coefficients associated with the perturbation parameter are zero and the first-order approximation is

$$\mathbf{g}(\mathbf{x};\sigma) - \bar{\mathbf{y}} = \mathbf{g}_\mathbf{x}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'$$
$$\mathbf{h}(\mathbf{x};\sigma) - \bar{\mathbf{x}} = \mathbf{h}_\mathbf{x}(\bar{\mathbf{x}};0)(\mathbf{x}-\bar{\mathbf{x}})'.$$

These equations embody certainty equivalence as defined by Simon (1956) and Theil (1957). Under certainty equivalence, the solution of the model, up to first-order, is identical to the solution of the same model under perfect foresight (or under the assumption that $\sigma = 0$). Certainty equivalence does not preclude the realization of the shock from appearing in the decision rule. What certainty equivalence precludes is that the standard deviation of it appears as an argument by itself, regardless of the realization of the shock.

The intuition for the presence of certainty equivalence is simple. Risk-aversion depends on the second derivative of the utility function (concave utility). However, Leland (1968) and Sandmo (1970) showed that precautionary behavior depends on the third derivative of the utility function. But a first-order perturbation involves the equilibrium conditions of the model (which includes first derivatives of the utility function, for example, in the Euler equation that equates marginal utilities over time) and first derivatives of these equilibrium conditions (and, therefore, second derivatives of the utility function), but not higher-order derivatives.

Certainty equivalence has several drawbacks. First, it makes it difficult to talk about the welfare effects of uncertainty. Although the dynamics of the model are still partially driven by the variance of the innovations (the realizations of the innovations depend on it), the agents in the model do not take any precautionary behavior to protect themselves from that variance, biasing any welfare computation. Second, related to the first point, the approximated solution generated under certainty equivalence cannot generate any risk premia for assets, a strongly counterfactual prediction.[h] Third, certainty equivalence prevents researchers from analyzing the consequences of changes in volatility.

[h] In general equilibrium, there is an intimate link between welfare computations and asset pricing. An exercise on the former is always implicitly an exercise on the latter (see Alvarez and Jermann, 2004).

Remark 13 (Perturbation and LQ approximations) Kydland and Prescott (1982)—and many papers after them—took a different route to solving DSGE models. Imagine that we have an optimal control problem that depends on n_x states $\mathbf{x}_t$ and n_u control variables $\mathbf{u}_t$. To save on notation, let us also define the column vector $\mathbf{w}_t = [\mathbf{x}_t, \mathbf{u}_t]'$ of dimension $n_w = n_x + n_u$. Then, we can write the optimal control problem as:

$$\max \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t r(\mathbf{w}_t)$$
$$\text{s.t. } \mathbf{x}_{t+1} = A(\mathbf{w}_t, \varepsilon_t)$$

where r is a return function, ε_t a vector of n_ε innovations with zero mean and finite variance, and A summarizes all the constraints and laws of motion of the economy. By appropriately enlarging the state space, this notation can accommodate the innovations having an impact on the period return function and some variables being both controls and states.

In the case where the return function r is quadratic, ie,

$$r(\mathbf{w}_t) = B_0 + B_1 \mathbf{w}_t + \mathbf{w}_t' Q \mathbf{w}_t$$

(where B_0 is a constant, B_1 a row vector $1 \times n_w$, and B_2 is an $n_w \times n_w$ matrix) and the function A is linear:

$$\mathbf{x}_{t+1} = B_3 \mathbf{w}_t + B_4 \varepsilon_t$$

(where B_3 is an $n_x \times n_w$ matrix and B_4 is an $n_x \times n_\varepsilon$ matrix), we are facing a stochastic discounted linear-quadratic regulator (LQR) problem. There is a large and well-developed research area on LQR problems. This literature is summarized by Anderson et al. (1996) and Hansen and Sargent (2013). In particular, we know that the optimal decision rule in this environment is a linear function of the states and the innovations:

$$\mathbf{u}_t = F_w \mathbf{w}_t + F_\varepsilon \varepsilon_t$$

where F_w can be found by solving a Ricatti equation Anderson et al. (1996, pp. 182–183) and F_ε by solving a Sylvester equation Anderson et al. (1996, pp. 202–205). Interestingly, F_w is independent of the variance of ε_t. That is, if ε_t has a zero variance, then the optimal decision rule is simply:

$$\mathbf{u}_t = F_w \mathbf{w}_t.$$

This neat separation between the computation of F_w and of F_ε allows the researcher to deal with large problems with ease. However, it also implies certainty equivalence.

Kydland and Prescott (1982) setup the social planner's problem of their economy, which fits into an optimal regulator problem, and they were able to write a function A that was linear in $\mathbf{w}_t$, but they did not have a quadratic return function. Instead, they took a quadratic approximation to the objective function of the social planner. Most of the literature that followed them used a Taylor series approximation of the objective function around the deterministic steady state, sometimes called the approximated LQR problem (Kydland and Prescott also employed a slightly different point of approximation that attempted to control for uncertainty; this did not make much quantitative difference). Furthermore, Kydland and Prescott worked with the value function representation of the problem. See Díaz-Giménez (1999) for an explanation of how to deal with the LQ approximation to the value function.

The result of solving the approximated LQR when the function A is linear is equivalent to the result of a first-order perturbation of the equilibrium conditions of the model. The intuition is simple. Derivatives are unique, and since both approaches search for a linear approximation to the solution of the model, they have to yield identical results.

However, approximated LQR have lost their popularity for three reasons. First, it is often hard to write the function A in a linear form. Second, it is challenging to set up a social planner's problem when the economy is not Pareto efficient. And even when it is possible to have a modified social planner's problem that incorporates additional constraints that incorporate non-optimalities (see, for instance, Benigno and Woodford, 2004), the same task is usually easier to accomplish by perturbing the equilibrium conditions of the model. Third, and perhaps most important, perturbations can easily go to higher-order terms and incorporate nonlinearities that break certainty equivalence.

4.2.5 Second-Order Perturbation

Once we have finished the first-order perturbation, we can iterate on the steps before to generate higher-order solutions. More concretely, the second-order approximations to $\mathbf{g}$ around $(\mathbf{x};\sigma)=(\bar{\mathbf{x}};0)$ are:

$$\begin{aligned}
[\mathbf{g}(\mathbf{x};\sigma)]^i = {} & [\mathbf{g}(\bar{\mathbf{x}};0)]^i + [\mathbf{g}_x(\bar{\mathbf{x}};0)]^i_a[(\mathbf{x}-\mathbf{x})]_a + [\mathbf{g}_\sigma(\bar{\mathbf{x}};0)]^i[\sigma] \\
& + \frac{1}{2}[\mathbf{g}_{xx}(\bar{\mathbf{x}};0)]^i_{ab}[(\mathbf{x}-\bar{\mathbf{x}})]_a[(\mathbf{x}-\bar{\mathbf{x}})]_b \\
& + \frac{1}{2}[\mathbf{g}_{x\sigma}(\bar{\mathbf{x}};0)]^i_a[(\mathbf{x}-\bar{\mathbf{x}})]_a[\sigma] \\
& + \frac{1}{2}[\mathbf{g}_{\sigma x}(\bar{\mathbf{x}};0)]^i_a[(\mathbf{x}-\bar{\mathbf{x}})]_a[\sigma] \\
& + \frac{1}{2}[\mathbf{g}_{\sigma\sigma}(\bar{\mathbf{x}};0)]^i[\sigma][\sigma]
\end{aligned}$$

where $i=1,\ldots,n_y$, $a,b=1,\ldots,n_x$, and $j=1,\ldots,n_x$.

Similarly, the second-order approximations to $\mathbf{h}$ around $(\mathbf{x};\sigma)=(\bar{\mathbf{x}};0)$ are:

$$
\begin{aligned}
[\mathbf{h}(\mathbf{x};\sigma)]^{j} = {} & [\mathbf{h}(\bar{\mathbf{x}};0)]^{j} + [\mathbf{h}_{x}(\bar{\mathbf{x}};0)]^{j}_{a}[(\mathbf{x}-\mathbf{x})]_{a} + [\mathbf{h}_{\sigma}(\bar{\mathbf{x}};0)]^{j}[\sigma] \\
& + \frac{1}{2}[\mathbf{h}_{xx}(\bar{\mathbf{x}};0)]^{j}_{ab}[(\mathbf{x}-\bar{\mathbf{x}})]_{a}[(\mathbf{x}-\bar{\mathbf{x}})]_{b} \\
& + \frac{1}{2}[\mathbf{h}_{x\sigma}(\bar{\mathbf{x}};0)]^{j}_{a}[(\mathbf{x}-\bar{\mathbf{x}})]_{a}[\sigma] \\
& + \frac{1}{2}[\mathbf{h}_{\sigma x}(\bar{\mathbf{x}};0)]^{j}_{a}[(\mathbf{x}-\bar{\mathbf{x}})]_{a}[\sigma] \\
& + \frac{1}{2}[\mathbf{h}_{\sigma\sigma}(\bar{\mathbf{x}};0)]^{j}[\sigma][\sigma],
\end{aligned}
$$

where $i=1,\ldots,n_y$, $a,b=1,\ldots,n_x$, and $j=1,\ldots,n_x$.

The unknown coefficients in these approximations are $[\mathbf{g}_{xx}]^{i}_{ab}$, $[\mathbf{g}_{x\sigma}]^{i}_{a}$, $[\mathbf{g}_{\sigma x}]^{i}_{a}$, $[\mathbf{g}_{\sigma\sigma}]^{i}$, $[\mathbf{h}_{xx}]^{j}_{ab}$, $[\mathbf{h}_{x\sigma}]^{j}_{a}$, $[\mathbf{h}_{\sigma x}]^{j}_{a}$, $[\mathbf{h}_{\sigma\sigma}]^{j}$. As before, we solve for these coefficients by taking the second derivatives of $F(\mathbf{x};\sigma)$ with respect to x and σ, making them equal to zero, and evaluating them at $(\bar{\mathbf{x}};0)$.

How do we solve the system? First, we exploit $F_{xx}(\bar{\mathbf{x}};0)$ to solve for $\mathbf{g}_{xx}(\bar{\mathbf{x}};0)$ and $h_{xx}(\bar{\mathbf{x}};0)$:

$$
\begin{aligned}
& [F_{xx}(\bar{\mathbf{x}};0)]^{i}_{jk} = \\
& \left([\mathcal{H}_{y'y'}]^{i}_{\alpha\gamma}[\mathbf{g}_{x}]^{\gamma}_{\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{y'y}]^{i}_{\alpha\gamma}[\mathbf{g}_{x}]^{\gamma}_{k} + [\mathcal{H}_{y'x'}]^{i}_{\alpha\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{y'x}]^{i}_{\alpha k}\right)[\mathbf{g}_{x}]^{\alpha}_{\beta}[\mathbf{h}_{x}]^{\beta}_{j} \\
& +[\mathcal{H}_{y'}]^{i}_{\alpha}[\mathbf{g}_{xx}]^{\alpha}_{\beta\delta}[\mathbf{h}_{x}]^{\delta}_{k}[\mathbf{h}_{x}]^{\beta}_{j} + [\mathcal{H}_{y'}]^{i}_{\alpha}[\mathbf{g}_{x}]^{\alpha}_{\beta}[\mathbf{h}_{xx}]^{\beta}_{jk} \\
& +\left([\mathcal{H}_{yy'}]^{i}_{\alpha\gamma}[\mathbf{g}_{x}]^{\gamma}_{\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{yy}]^{i}_{\alpha\gamma}[\mathbf{g}_{x}]^{\gamma}_{k} + [\mathcal{H}_{yx'}]^{i}_{\alpha\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{yx}]^{i}_{\alpha k}\right)[\mathbf{g}_{x}]^{\alpha}_{j} + [\mathcal{H}_{y}]^{i}_{\alpha}[\mathbf{g}_{xx}]^{\alpha}_{jk} \\
& +\left([\mathcal{H}_{x'y'}]^{i}_{\beta\gamma}[\mathbf{g}_{x}]^{\gamma}_{\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{x'y}]^{i}_{\beta\gamma}[\mathbf{g}_{x}]^{\gamma}_{k} + [\mathcal{H}_{x'x'}]^{i}_{\beta\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{x'x}]^{i}_{\beta k}\right)[\mathbf{h}_{x}]^{\beta}_{j} + [\mathcal{H}_{x'}]^{i}_{\beta}[\mathbf{h}_{xx}]^{\beta}_{jk} \\
& +[\mathcal{H}_{xy'}]^{i}_{j\gamma}[\mathbf{g}_{x}]^{\gamma}_{\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{xy}]^{i}_{j\gamma}[\mathbf{g}_{x}]^{\gamma}_{k} + [\mathcal{H}_{xx'}]^{i}_{j\delta}[\mathbf{h}_{x}]^{\delta}_{k} + [\mathcal{H}_{xx}]^{i}_{jk} = 0; \\
& \qquad i=1,\ldots n, \quad j,k,\beta,\delta=1,\ldots n_x; \quad \alpha,\gamma=1,\ldots n_y.
\end{aligned}
$$

But we know the derivatives of $\mathcal{H}$. We also know the first derivatives of **g** and **h** evaluated at $(\bar{\mathbf{x}}, 0)$. Hence, the above expression is a system of $n \times n_x \times n_x$ linear equations in the $n \times n_x \times n_x$ unknown elements of $\mathbf{g}_{xx}$ and $\mathbf{h}_{xx}$. This point is crucial: linear solvers are fast and efficient. In the first-order approximation we had to solve a quadratic system to select between stable and unstable solutions. But once we are already in the stable manifold, there are no further additional solutions that we need to rule out. These quadratic terms involve the endogenous state vector x_1. Those terms capture nonlinear behavior and induce nonsymmetries. We will discuss those in more detail in our worked-out example below.

The coefficients in $\mathbf{g}_{\sigma\sigma}$ and $\mathbf{h}_{\sigma\sigma}$ come from solving the system of n linear equations in the n unknowns:

$$\begin{aligned}[F_{\sigma\sigma}(\bar{\mathbf{x}};0)]^i = {} & [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_{\sigma\sigma}]^\beta \\ & + [\mathcal{H}_{y'y'}]^i_{\alpha\gamma}[\mathbf{g}_x]^\gamma_\delta[\eta]^\delta_\xi[\mathbf{g}_x]^\alpha_\beta[\eta]^\beta_\phi[I]^\phi_\xi + [\mathcal{H}_{y'x'}]^i_{\alpha\delta}[\eta]^\delta_\xi[\mathbf{g}_x]^\alpha_\beta[\eta]^\beta_\phi[I]^\phi_\xi \\ & + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_{xx}]^\alpha_{\beta\delta}[\eta]^\delta_\xi[\eta]^\beta_\phi[I]^\phi_\xi + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_{\sigma\sigma}]^\alpha \\ & + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_{\sigma\sigma}]^\alpha + [\mathcal{H}_{x'}]^i_\beta[\mathbf{h}_{\sigma\sigma}]^\beta \\ & + [\mathcal{H}_{x'y'}]^i_{\beta\gamma}[\mathbf{g}_x]^\gamma_\delta[\eta]^\delta_\xi[\eta]^\beta_\phi[I]^\phi_\xi + [\mathcal{H}_{x'x'}]^i_{\beta\delta}[\eta]^\delta_\xi[\eta]^\beta_\phi[I]^\phi_\xi = 0; \\ & = 1,\ldots,n; \alpha,\gamma = 1,\ldots,n_y; \beta,\ \delta = 1,\ldots,n_x; \phi,\ \xi = 1,\ldots,n_\epsilon.\end{aligned}$$

The coefficients $\mathbf{g}_{\sigma\sigma}$ and $\mathbf{h}_{\sigma\sigma}$ capture the correction for risk that breaks certainty equivalence. In addition, the cross derivatives $\mathbf{g}_{x\sigma}$ and $\mathbf{h}_{x\sigma}$ are zero when evaluated at $(\bar{\mathbf{x}};0)$. To see this, write the system $F_{\sigma x}(\bar{\mathbf{x}};0)=0$, taking into account that all terms containing either g_σ or $\mathbf{h}_\sigma$ are zero at $(\bar{\mathbf{x}};0)$. Then, we have a homogeneous system of $n \times n_x$ equations in the $n \times n_x$ elements of $\mathbf{g}_{\sigma x}$ and $\mathbf{h}_{\sigma x}$:

$$\begin{gathered}[F_{\sigma x}(\bar{\mathbf{x}};0)]^i_j = [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_x]^\alpha_\beta[\mathbf{h}_{\sigma x}]^\beta_j + [\mathcal{H}_{y'}]^i_\alpha[\mathbf{g}_{\sigma x}]^\alpha_\gamma[\mathbf{h}_x]^\gamma_j + [\mathcal{H}_y]^i_\alpha[\mathbf{g}_{\sigma x}]^\alpha_j + [\mathcal{H}_{x'}]^i_\beta[\mathbf{h}_{\sigma x}]^\beta_j = 0; \\ i = 1,\ldots n; \quad \alpha = 1,\ldots,n_y; \quad \beta,\gamma,j = 1,\ldots,n_x.\end{gathered}$$

Hence, the last component of the second-order perturbation is given by:[i]

$$\begin{aligned}\mathbf{g}_{\sigma x} &= \mathbf{0} \\ \mathbf{h}_{\sigma x} &= \mathbf{0}.\end{aligned}$$

4.2.6 Higher-Order Perturbations

We can iterate the previous procedure (taking higher-order derivatives, plugging in the already found terms, and solving for the remaining ones) as many times as we want to obtain n-th order approximations. All the associated systems of equations that we would need to solve are linear, which keeps the computational complexity manageable. The only additional point to remember is that we will need to make assumptions about the higher moments of the innovations, as we will have expectational terms involving these higher moments.

If the functions $\mathbf{g}$ and $\mathbf{h}$ are analytic in a neighborhood of $\bar{\mathbf{x}}$, then the series we are building by taking higher-order approximations has an infinite number of terms and is convergent. Convergence will occur in a radius of convergence centered around $\bar{\mathbf{x}}$, (ie, the r such that for all state values with a distance with respect to $\bar{\mathbf{x}}$ smaller then r). This radius can be infinite. In that case, the series is guaranteed to converge uniformly everywhere. However, the radius can also be finite and there exist a nonremovable

[i] We conjecture (and we have checked up to as high an order of a perturbation as computer memory allows) that all terms involving odd derivatives of σ are zero. Unfortunately, we do not have a formal proof.

singularity on its boundary. Disappointingly, for most DSGE models, the radius of convergence is unknown (for more details and examples, see Swanson et al., 2006 and Aldrich and Kung, 2011). More research on this topic is sorely needed. Also, even when the series is convergent, there are two potential problems. First, at a j-th order approximation, we may lose the "right" shape of $\mathbf{g}$ and $\mathbf{h}$. For example, Aruoba et al. (2006) document how the decision rules for consumption and capital of the stochastic neoclassical growth model approximated with a fifth-order perturbation are no longer globally concave, as implied by economic theory. Instead, the approximated functions present oscillating patterns. Second, the convergence to the exact solution may not be monotone: it is easy to build examples where the errors a bit away from $\bar{\mathbf{x}}$ are worse for a $j+1$-th order approximation than for a j-th order approximation. Neither of these two problems is fatal, but the researcher needs to be aware of them and undertake the necessary tests to minimize their impact (for instance, checking the solution for different approximation orders).

Later, we will discuss how to gauge the accuracy of a solution and how to decide whether a higher-order approximation is required. For example, to deal with models with time-varying volatility, we would need at least a third-order approximation. Levintal (2015a) has argued that to approximate well models with disaster risk, we need a fifth-order approximation. The drawback of higher-order approximations is that we will run into problems of computational cost and memory use.

4.3 A Worked-Out Example

The previous derivations were somewhat abstract and the notation, even using tensors, burdensome. Consequently, it is useful to show how perturbation works in a concrete example. For that, we come back to our example of the neoclassical growth model defined by Eqs. (2)–(4), except that, to make the algebra easier, we assume $u(c) = \log c$ and $\delta = 1$.

The equilibrium conditions of the model are then:

$$\frac{1}{c_t} = \beta \mathbb{E}_t \frac{\alpha e^{z_{t+1}} k_{t+1}^{\alpha-1}}{c_{t+1}}$$

$$c_t + k_{t+1} = e^{z_t} k_t^{\alpha}$$

$$z_t = \rho z_{t-1} + \eta \varepsilon_t$$

While this parameterization is unrealistic for periods of time such as a quarter or a year typically employed in business cycle analysis, it has the enormous advantage of implying that the model has a closed-form solution. With $\delta = 1$, the income and the substitution effect from a productivity shock cancel each other, and consumption and investment are constant fractions of income:

$$c_t = (1 - \alpha\beta) e^{z_t} k_t^{\alpha}$$

$$k_{t+1} = \alpha\beta e^{z_t} k_t^{\alpha}$$

(these optimal decision rules can be verified by plugging them into the equilibrium conditions and checking that indeed these conditions are satisfied).

Imagine, however, that we do not know this exact solution and that we are searching a decision rule for consumption:

$$c_t = c(k_t, z_t)$$

and another one for capital:

$$k_{t+1} = k(k_t, z_t)$$

In our general notation, d would just be the stack of $c(k_t, z_t)$ and $k(k_t, z_t)$. We substitute these decision rules in the equilibrium conditions above (and, to reduce the dimensionality of the problem, we substitute out the budget constraint and the law of motion for technology) to get:

$$\frac{1}{c(k_t, z_t)} = \beta \mathbb{E}_t \frac{\alpha e^{\rho z_t + \sigma \varepsilon_{t+1}} k(k_t, z_t)^{\alpha-1}}{c(k(k_t, z_t), \rho z_t + \eta \varepsilon_{t+1})} \tag{23}$$

$$c(k_t, z_t) + k(k_t, z_t) = e^{z_t} k_t^{\alpha} \tag{24}$$

The decision rules are approximated by perturbation solutions on the two state variables plus the perturbation parameter σ:

$$\begin{aligned} c_t &= c(k_t, z_t; \sigma) \\ k_{t+1} &= k(k_t, z_t; \sigma). \end{aligned}$$

We introduce σ in the law of motion for technology:

$$z_t = \rho z_{t-1} + \sigma \eta \varepsilon_t.$$

In that way, if we set $\sigma = 0$, we recover a deterministic model. If $z_t = 0$ (either because $z_0 = 0$ or because t is sufficiently large such that $z_t \rightarrow 0$), we can find the steady state k by solving the system of equilibrium conditions:

$$\begin{aligned} \frac{1}{c} &= \beta \frac{\alpha k^{\alpha-1}}{c} \\ c + k &= k^{\alpha} \end{aligned}$$

which has a unique solution $k = k(k, 0; 0) = (\alpha\beta)^{\frac{1}{1-\alpha}}$ and $c = c(k, 0; 0) = (\alpha\beta)^{\frac{\alpha}{1-\alpha}} - (\alpha\beta)^{\frac{1}{1-\alpha}}$.

The second-order expansion for the consumption decision rule is given by:

$$\begin{aligned} c_t = {} & c + c_k(k_t - k) + c_z z_t + c_\sigma \sigma \\ & + \frac{1}{2} c_{kk}(k_t - k)^2 + c_{kz}(k_t - k) z_t + c_{k\sigma}(k_t - k)\sigma \\ & + \frac{1}{2} c_{zz} z_t^2 + c_{z\sigma} z_t \sigma + \frac{1}{2} c_{\sigma^2} \sigma^2 \end{aligned} \tag{25}$$

and for the capital decision rule:

$$\begin{aligned}k_{t+1} = k + k_k(k_t - k) + k_z z_t + k_\sigma \sigma \\ + \frac{1}{2}k_{kk}(k_t - k)^2 + k_{kz}(k_t - k)z_t + k_{k\sigma}(k_t - k)\sigma \\ + \frac{1}{2}k_{zz}z_t^2 + \frac{1}{2}k_{\sigma z}\sigma z_t + \frac{1}{2}k_{\sigma^2}\sigma^2\end{aligned} \tag{26}$$

(where we have already used the symmetry of second derivatives and assumed that all terms are evaluated at $(k, 0; 0)$). Higher-order approximations can be written in a similar way, but, for this example, a second-order approximation is all we need.

Beyond the correction for risk $\frac{1}{2}c_{\sigma^2}\sigma^2$ and $\frac{1}{2}k_{\sigma^2}\sigma^2$ that we discussed above, the additional terms in Eqs. (25) and (26) introduce dynamics that cannot be captured by a first-order perturbation. In the linear solution, the terms $c_z z_t$ and $k_\sigma \sigma$ imply that the effects of positive and negative shocks are mirrors of each other. That is why, for instance, researchers using linearized models only report impulse response functions to a positive or a negative shock: the other impulse response functions are the same but inverted. In comparison, in the second-order perturbation, the terms $\frac{1}{2}c_{zz}z_t^2$ and $\frac{1}{2}k_{zz}z_t^2$ mean that positive and negative shocks have divergent effects: z_t^2 is always positive and the impulse response functions are asymmetric. The terms $c_{kz}(k_t - k)z_t$ and $k_{kz}(k_t - k)z_t$ cause the effect of a shock to also depend on how much capital the economy has at period t, a mechanism missed in the first-order approximation since z_t enters linearly. This might be of importance in many applications. For example, the effects of a financial shock may depend on the household asset level.

To find the unknown coefficients in Eqs. (25) and (26), we come back to the equilibrium conditions (23) and (24), we substitute the decision rules with the approximated decision rules $c(k_t, z_t; \sigma)$ and $k(k_t, z_t; \sigma)$, and we rearrange terms to get:

$$F(k_t, z_t; \sigma) = \mathbb{E}_t \begin{bmatrix} \frac{1}{c(k_t, z_t; \sigma)} - \beta \frac{\alpha e^{\rho z_t + \sigma\eta\varepsilon_{t+1}} k(k_t, z_t; \sigma)^{\alpha - 1}}{c(k(k_t, z_t; \sigma), \rho z_t + \sigma\eta\varepsilon_{t+1}; \sigma)} \\ c(k_t, z_t; \sigma) + k(k_t, z_t; \sigma) - e^{z_t}k_t^\alpha \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

More compactly:

$$F(k_t, z_t; \sigma) = \mathcal{H}(c(k_t, z_t; \sigma), c(k(k_t, z_t; \sigma), z_{t+1}; \sigma), k_t, k(k_t, z_t; \sigma), z_t; \sigma)$$

We will use $\mathcal{H}_i$ to represent the partial derivative of $\mathcal{H}$ with respect to the i component and drop the evaluation at the steady state of the functions when we do not need it.

We start with the first-order terms. We take derivatives of $F(k_t, z_t; \sigma)$ with respect to k_t, z_t, and σ and we equate them to zero:

$$\begin{aligned}F_k &= \mathcal{H}_1 c_k + \mathcal{H}_2 c_k k_k + \mathcal{H}_3 + \mathcal{H}_4 k_k = \mathbf{0}\\ F_z &= \mathcal{H}_1 c_z + \mathcal{H}_2 (c_k k_z + c_k \rho) + \mathcal{H}_4 k_z + \mathcal{H}_5 = \mathbf{0}\\ F_\sigma &= \mathcal{H}_1 c_\sigma + \mathcal{H}_2 (c_k k_\sigma + c_\sigma) + \mathcal{H}_4 k_\sigma + \mathcal{H}_6 = \mathbf{0}\end{aligned}$$

Note that:

$$\begin{aligned}F_k &= \mathcal{H}_1 c_k + \mathcal{H}_2 c_k k_k + \mathcal{H}_3 + \mathcal{H}_4 k_k = \mathbf{0}\\ F_z &= \mathcal{H}_1 c_z + \mathcal{H}_2 (c_k k_z + c_k \rho) + \mathcal{H}_4 k_z + \mathcal{H}_5 = \mathbf{0}\end{aligned}$$

is a quadratic system of four equations in four unknowns: c_k, c_z, k_k, and k_z (the operator F has two dimensions). As we mentioned above, the system can be solved recursively. The first two equations:

$$F_k = \mathcal{H}_1 c_k + \mathcal{H}_2 c_k k_k + \mathcal{H}_3 + \mathcal{H}_4 k_k = \mathbf{0}$$

only involve c_k and k_k (the terms affecting the deterministic variables).

Remark 14 (Quadratic problem, again) The first two equations:

$$F_k = \mathcal{H}_1 c_k + \mathcal{H}_2 c_k k_k + \mathcal{H}_3 + \mathcal{H}_4 k_k = \mathbf{0}$$

can easily be written in the form of a quadratic matrix system as follows. First, we write the two equations as:

$$\begin{pmatrix}\mathcal{H}_1^1\\ \mathcal{H}_1^2\end{pmatrix} c_k + \begin{pmatrix}\mathcal{H}_2^1\\ \mathcal{H}_2^2\end{pmatrix} c_k k_k + \begin{pmatrix}\mathcal{H}_3^1\\ \mathcal{H}_3^2\end{pmatrix} + \begin{pmatrix}\mathcal{H}_4^1\\ \mathcal{H}_4^2\end{pmatrix} k_k = \begin{pmatrix}0\\ 0\end{pmatrix}$$

where $\mathcal{H}_i^j$ is the j-th dimension of $\mathcal{H}_i$. But $\mathcal{H}_2^2 = 0$ and $\mathcal{H}_3^1 = 0$, then

$$\begin{pmatrix}\mathcal{H}_1^1\\ \mathcal{H}_1^2\end{pmatrix} c_k + \begin{pmatrix}\mathcal{H}_2^1\\ 0\end{pmatrix} c_k k_k + \begin{pmatrix}0\\ \mathcal{H}_3^2\end{pmatrix} + \begin{pmatrix}\mathcal{H}_4^1\\ \mathcal{H}_4^2\end{pmatrix} k_k = \begin{pmatrix}0\\ 0\end{pmatrix}.$$

We can use the second equation to eliminate c_k from the first equation. Then, rearranging the terms and calling $P = k_k$ we have the equation:

$$AP^2 - BP - C = 0$$

that we presented in the previous subsection. Note that, in this example, instead of a complicated matrix equation, we have a much simpler quadratic scalar equation.

Our quadratic system will have two solutions. One solution will imply that $k_k > 1$ and the other solution $k_k < 1$. The first solution is unstable. Remember that the first elements of the decision rule are

$$k_{t+1} = k + k_k (k_t - k) + \dots$$

If $k_k > 1$, a deviation of k_t with respect to k will imply an even bigger deviation of k_{t+1} with respect to k, leading to explosive behavior. In comparison, when $k_k < 1$, deviations of k_t with respect to k will, in the absence of additional shocks, dissipate over time. Once we know c_k and k_k, we can come back to

$$F_z = \mathcal{H}_1 c_z + \mathcal{H}_2(c_k k_z + c_k \rho) + \mathcal{H}_4 k_z + \mathcal{H}_5 = 0$$

and solve for c_z and k_z. As emphasized in Remark 12, this system is linear.

Finally, as in the general case, the last two equations

$$F_\sigma = \mathcal{H}_1 c_\sigma + \mathcal{H}_2(c_k k_\sigma + c_\sigma) + \mathcal{H}_4 k_\sigma + \mathcal{H}_6 = 0$$

form a linear, and homogeneous system in c_σ and k_σ. Hence, $c_\sigma = k_\sigma = 0$ and we obtain the certainty equivalence of first-order approximations.

To find the second-order approximation, we take second derivatives of $F(k_t, z_t; \sigma)$ around k, 0, and 0:

$$\begin{aligned} F_{kk} &= 0 \\ F_{kz} &= 0 \\ F_{k\sigma} &= 0 \\ F_{zz} &= 0 \\ F_{z\sigma} &= 0 \\ F_{\sigma\sigma} &= 0 \end{aligned}$$

(where we have already eliminated symmetric second derivatives). We substitute the coefficients that we already know from the first-order approximation and we get a linear system of 12 equations in 12 unknowns. Again, we get that all cross-terms on $k\sigma$ and $z\sigma$ are zero.

Imposing the results concerning the coefficients that are equal to zero, we can rewrite Eqs. (25) and (26) up to second-order as:

$$\begin{aligned} c_t = {} & c + c_k(k_t - k) + c_z z_t \\ & + \frac{1}{2} c_{kk}(k_t - k)^2 + c_{kz}(k_t - k) z_t + \frac{1}{2} c_{zz} z_t^2 + \frac{1}{2} c_{\sigma^2} \sigma^2 \end{aligned} \tag{27}$$

and

$$\begin{aligned} k_{t+1} = {} & k + k_k(k_t - k) + k_z z_t \\ & + \frac{1}{2} k_{kk}(k_t - k)^2 + k_{kz}(k_t - k) z_t + \frac{1}{2} k_{zz} z_t^2 + \frac{1}{2} k_{\sigma^2} \sigma^2. \end{aligned} \tag{28}$$

Since even with this simple neoclassical growth model the previous systems of equations are too involved to be written explicitly, we illustrate the procedure numerically. In Table 1, we summarize the parameter values for the four parameters of the model. We do not pretend to be selecting a realistic calibration (our choice of $\delta = 1$ precludes any attempt at matching observed data). Instead, we pick standard parameter values in the

Table 1 Calibration

Parameter	**Value**
β	0.99
α	0.33
ρ	0.95
η	0.01

literature. The discount factor, β, is 0.99, the elasticity of output with respect to capital, α, is 0.33, the persistence of the autoregressive process, ρ, is 0.95, and the standard deviation of the innovation, η, is 0.01. With this calibration, the steady state is $c = 0.388$ and $k = 0.188$.

The first-order components of the solution are (already selecting the stable solution):

$$\begin{aligned} c_k &= 0.680 \quad c_z = 0.388 \\ k_k &= 0.330 \quad k_z = 0.188 \end{aligned}$$

and the second-order components:

$$\begin{aligned} c_{kk} &= -2.420 \quad c_{kz} = 0.680 \quad c_{zz} = 0.388 \quad c_{\sigma\sigma} = 0 \\ k_{kk} &= -1.174 \quad k_{kz} = 0.330 \quad k_{zz} = 0.188 \quad k_{\sigma\sigma} = 0 \end{aligned}$$

In addition, recall that we have the theoretical results: $c_\sigma = k_\sigma = c_{k\sigma} = k_{k\sigma} = c_{z\sigma} = k_{z\sigma} = 0$. Thus, we get our second-order approximated solutions for the consumption decision rule:

$$\begin{aligned} c_t = {} & 0.388 + 0.680(k_t - 0.188) + 0.388 z_t \\ & - 1.210(k_t - 0.188)^2 + 0.680(k_t - 0.188) z_t + 0.194 z_t^2 \end{aligned}$$

and for the capital decision rule:

$$\begin{aligned} k_{t+1} = {} & 0.188 + 0.330\,(k_t - 0.188) + 0.188 z_t \\ & - 0.587(k_t - 0.188)^2 + 0.330\,(k_t - 0.188)\, z_t + 0.094 z_t^2. \end{aligned}$$

In this case, the correction for risk is zero. This should not be a surprise. In the neoclassical growth model, risk is production risk driven by technology shocks. This production risk is brought about by capital: the more capital the representative household accumulates, the more it exposes itself to production risk. At the same time, the only asset available for net saving in this economy is capital. Thus, any increment in risk (ie, a rise in the standard deviation of the technology shock) generates two counterbalancing mechanisms: a desire to accumulate more capital to buffer future negative shocks and a desire to accumulate less capital to avoid the additional production risk. For low values of risk aversion, both mechanisms nearly cancel each other (with a log utility function, they perfectly compensate each other: in the exact solution, the standard deviation of the innovation to the shock does not appear, only the realization of z_t). For higher values of risk aversion or for models with different assets (for instance, a model where the representative household can save in the form of an international bond whose payments are not perfectly correlated with the productivity shock within the country), the correction for risk can be quite different from zero.

The next step is to compare the exact and the approximated decision rules. With our calibration, the exact solution is given by:

$$c_t = 0.673 e^{z_t} k_t^{0.33}$$
$$k_{t+1} = 0.327 e^{z_t} k_t^{0.33}.$$

To gauge how close these two solutions are, we plot in Fig. 1 the exact decision rule for capital (continuous line in the top and bottom panels), the first-order approximation (discontinuous line in the top panel), and the second-order approximation (discontinuous line in the bottom panel). In both panels, we plot the decision rule for capital when $z_t = 0$ and for values of capital that are ± 25% of the value of capital in the steady state. The first-order approximation is nearly identical to the exact solution close to the steady state. Only farther away, do both solutions diverge. At the start of the grid (with $k = 0.1412$),

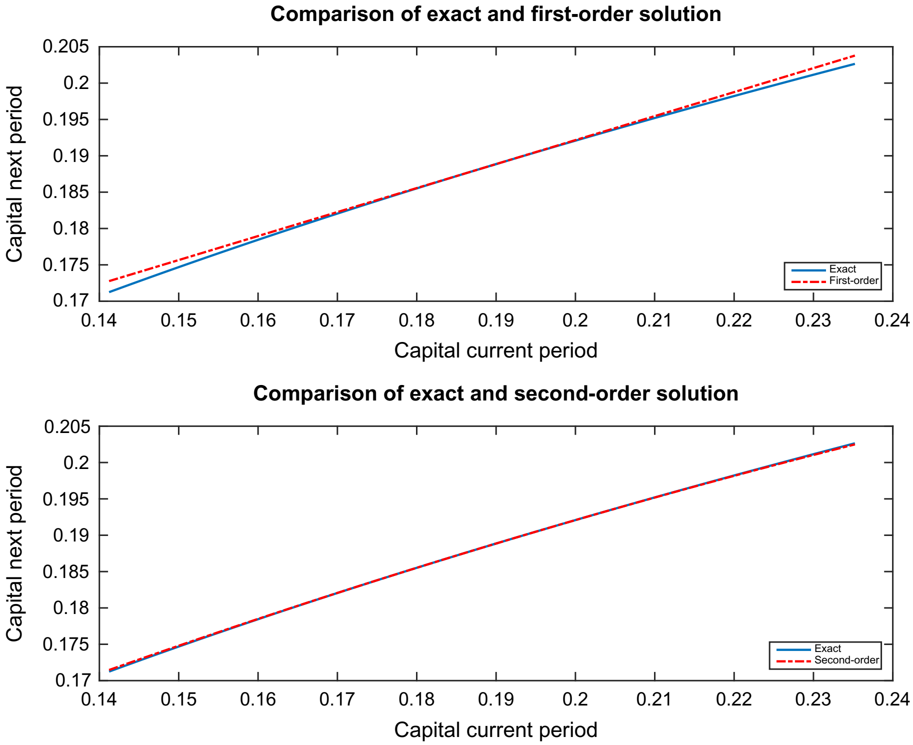

Fig. 1 Comparison of exact and perturbation solution.

the exact decision rule and the first-order approximation diverge by nearly 1%. The second-order approximation, in comparison, is more accurate along the whole range of values of capital. Even at $k = 0.1412$, the difference between both solutions is only 0.13%. This result shows the often good global properties of perturbation solutions.

We will revisit below how to assess the accuracy of a solution. Suffice it to say at this moment that whether 0.13% is too large or accurate enough is application dependent. For instance, for the computation of business cycle moments, we often need less accuracy than for welfare evaluations. The reason is that while errors in the approximation of a moment of the model, such as the mean or variance of consumption, tend to cancel each other, welfare is a nonlinear function of the allocation and small errors in computing an allocation can translate into large errors in computing welfare.

4.4 Pruning

Although the higher-order perturbations that we described are intuitive and straightforward to compute, they often generate explosive sample paths even when the corresponding linear approximation is stable. These explosive sample paths arise because the higher-order terms induce additional fixed points for the system, around which the approximated solution is unstable (see Kim et al., 2008 and Den Haan and De Wind, 2012). A simple example clarifies this point. Imagine that we have an approximated decision rule for capital (where, for simplicity, we have eliminated the persistence on the productivity process z_t) that has the form:

$$k_{t+1} = a_0 + a_1 k_t + a_2 k_t^2 + \ldots + b_1 \varepsilon_t + \ldots$$

If we substitute recursively, we find:

$$k_{t+1} = a_1 k_t + a_2 \left(a_1 k_{t-1} + a_2 k_{t-1}^2\right)^2 + \ldots + b_1 \varepsilon_t + \ldots,$$

an expression that involves terms in k_{t-1}^3 and k_{t-1}^4. If the support of ε_t is not bounded, sooner or later, we will have, in a simulation, an innovation large enough such that k_{t+1} is far away from its steady-state value. As the simulation progresses over time, that value of k_{t+1} will be raised to cubic and higher-order powers, and trigger an explosive path. The presence of this explosive behavior complicates any model evaluation because no unconditional moments would exist based on this approximation. It also means that any unconditional moment-matching estimation methods, such as the generalized method of moments (GMM) or the simulated method of moments (SMM), are inapplicable in this context as they rely on finite moments from stationary and ergodic probability distributions.

For second-order approximations, Kim et al. (2008) propose pruning the approximation. Loosely speaking, pruning means to eliminate, in the recursions, all terms that are of a higher order than the order of the solution (ie, if we are dealing with a second-order perturbation, all terms involving states or innovations raised to powers higher than 2). Kim et al. (2008) prove that the pruned approximation does not explode.

Andreasen et al. (2013) extend Kim et al. (2008)'s approach by showing how to apply pruning to an approximation of any arbitrary order by exploiting what the authors refer to as the pruned state-space system. Under general technical conditions, Andreasen et al. (2013) show that first and second unconditional moments for a pruned state-space system exist. Then, they provide closed-form expressions for first and second unconditional moments and impulse response functions. This is important because these expressions let researchers avoid the use of numerical simulations to compute these moments. These numerical simulations have often been shown to be unreliable, in particular, when solving for the generalized impulse response functions of DSGE models (for the definition of generalized impulse response functions, see Koop et al., 1996). Andreasen et al. (2013) also derive conditions for the existence of higher unconditional moments, such as skewness and kurtosis.

4.5 Change of Variables

In Remark 4, we discussed the possibility of performing the perturbation of a DSGE model in logs of the variables of interest, instead of doing it in levels. In a creative contribution, Judd (2003) argues that loglinearization is a particular case of the more general idea of a change of variables and shows how this technique could be efficiently implemented. In this subsection, we explain Judd's contribution by following Fernández-Villaverde and Rubio-Ramírez (2006).

The point of departure is to note that if we have a Taylor expansion of a variable x around a point a:

$$d(x) \simeq d(a) + \frac{\partial d(a)}{\partial a}(x-a) + H.O.T.,$$

(where $H.O.T.$ stands for higher-order terms), we can rewrite the expansion in terms of a transformed variable $Y(x)$:

$$g(y) = h(d(X(y))) = g(b) + \frac{\partial g(b)}{\partial b}(Y(x)-b) + H.O.T.$$

where $b = Y(a)$ and $X(y)$ is the inverse of $Y(x)$. Since with a perturbation we find a Taylor series approximation of the unknown function d that solves the operator $\mathcal{H}(\cdot)$ as a function of the states x, the change of variables means we can find an alternative Taylor series in terms of $Y(x)$.

Why do we want to perform this change of variables? The famous British meteorologist Eric Eady (1915–1966) remarked once that: "It is not the process of linearization that limits insight. It is the nature of the state that we choose to linearize about."

By picking the right change of variables, we can reshape a highly nonlinear problem into a much more linear one and, therefore, significantly increase the accuracy of the perturbation.[j]

4.5.1 A Simple Example

Imagine that our aim is to approximate the decision rule for capital in our workhorse stochastic neoclassical growth model with a first-order perturbation (the same ideas would apply if we are trying to approximate other decision rules, expectations, value functions, etc.). Remember that we derived that such an approximation had the form:

$$k_{t+1} = k + a_1(k_t - k) + b_1 z_t$$

where a and b are the coefficients that we find by taking derivatives of $F(k_t, z_t; \sigma)$ and k is the steady-state value of capital. In this section, it is more convenient to rewrite the decision rule as:

$$(k_{t+1} - k) = a_1(k_t - k) + b_1 z_t.$$

Analogously a loglinear approximation of the policy function will take the form:

$$\log k_{t+1} - \log k = a_2(\log k_t - \log k) + b_2 z$$

or in equivalent notation:

$$\hat{k}_{t+1} = a_2 \hat{k}_t + b_2 z_t$$

where $\hat{x} = \log x - \log x_0$ is the percentage deviation of the variable x with respect to its steady state.

How do we go from one approximation to the second one? First, we write the linear system in levels as:

$$k_{t+1} = d(k_t, z_t; \sigma) = d(k, 0; 0) + d_1(k, 0; 0)(k_t - k) + d_2(k, 0; 0) z_t$$

where $d(k, 0; 0) = k$, $d_1(k, 0; 0) = a_1$, $d_2(k, 0; 0) = b_1$. Second, we propose the changes of variables $h = \log d$, where $Y(x) = \log x$ and $Y(x) = \log x$. Third, we apply Judd (2003)'s formulae for this example:

$$\log k_{t+1} - \log k = d_1(k, 0, 0)(\log k_t - \log k) + \frac{1}{k} d_2(k, 0, 0) z$$

Finally, by equating coefficients, we obtain a simple closed-form relation between the parameters of both representations: $a_2 = a_1$ and $b_2 = \frac{1}{k} b_1$.

[j] An idea related to the change of variables is the use of gauges, where the perturbation is undertaken not in terms of powers of the perturbation parameter, σ, but of a series of gauge functions $\{\delta_n(\sigma)\}_{n=1}^{\infty}$ such that: $\lim_{n \to \infty} \frac{\delta_{n+1}(\sigma)}{\delta_n(\sigma)} = 0$. See Judd (1998) for details.

Three points are important. First, moving from a_1 and b_1 to a_2 and b_2 is an operation that only involves k, a value that we already know from the computation of the first-order perturbation in levels. Therefore, once the researcher has access to the linear solution, obtaining the loglinear one is immediate.[k] Second, we have not used any assumption on the utility or production functions except that they satisfy the general technical conditions of the stochastic neoclassical growth model. Third, the change of variables can be applied to a perturbation of an arbitrary order. We only presented the case for a first-order approximation to keep the exposition succinct.

4.5.2 A More General Case

We can now present a more general case of change of variables. The first-order solution of a model is:

$$d(x) \simeq d(a) + \frac{\partial d(a)}{\partial a}(x-a).$$

If we expand $g(y) = h(d(X(y)))$ around $b = Y(a)$, where $X(y)$ is the inverse of $Y(x)$, we can write:

$$g(y) = h(d(X(y))) = g(b) + g_\alpha(b)(Y^\alpha(x) - b^\alpha)$$

where $g_\alpha = h_A d_i^A X_\alpha^i$ comes from the application of the chain rule.

Following Judd (2003), we use this approach to encompass any power function approximation of the form:

$$k_{t+1}(k,z;\gamma,\zeta,\varphi)^\gamma - k^\gamma = a_3\left(k_t^\zeta - k^\zeta\right) + b_3 z^\varphi$$

where we impose $\varphi \geq 1$ to ensure that we have real values for the power z^φ. Power functions are attractive because, with only three free parameters (γ,ζ,φ), we can capture many nonlinear structures and nest the log transformation as the limit case when the coefficients γ and ζ tend to zero and $\varphi = 1$. The changes of variables for this family of functions are given by $h = d^\gamma$, $Y = x^\zeta$, and $X = y^{\frac{1}{\zeta}}$. Following the same reasoning as before, we derive:

$$k_{t+1}(k,z;\gamma,\zeta,\varphi)^\gamma - k^\gamma = \frac{\gamma}{\zeta}k^{\gamma-\zeta}a_1\left(k_t^\zeta - k^\zeta\right) + \frac{\gamma}{\varphi}k^{\gamma-1}b_1 z^\varphi.$$

The relation between the new and the old coefficients is again easy to compute: $a_3 = \frac{\gamma}{\zeta}k^{\gamma-\zeta}a_1$ and $b_3 = \frac{\gamma}{\varphi}k^{\gamma-1}b_1$.

[k] A heuristic argument that delivers the same result takes: $(k_{t+1} - k) = a_1(k_t - k) + b_1 z_t$ and divides on both sides by k: $\frac{k_{t+1}-k}{k} = a_1\frac{k_t - k}{k} + \frac{1}{k}b_1 z$. Noticing that $\frac{x_t - x}{x} \simeq \log x_t - \log x$, we get back the same relation as the one above. Our argument in the main text is more general and does not depend on an additional approximation.

A slightly more restrictive case is to impose that $\gamma = \zeta$ and $z = 1$. Then, we get a power function with only one free parameter γ:

$$k_{t+1}(k, z; \gamma)^{\gamma} - k^{\gamma} = a_4\left(k_t^{\zeta} - k^{\zeta}\right) + b_4 z$$

or, by defining $\widetilde{k}_t = k_t^{\gamma} - k^{\gamma}$, we get:

$$\widetilde{k}_{t+1} = a_4 \widetilde{k}_t + b_4 z$$

with $a_4 = a_1$ and $b_4 = k^{\gamma - 1} b_1$. This representation has the enormous advantage of being a linear system, which makes it suitable for analytic study and, as we will see in Section 10, for estimation with a Kalman filter.

4.5.3 The Optimal Change of Variables

The previous subsection showed how to go from a first-order approximation to the solution of a DSGE model to a more general representation indexed by some parameters. The remaining question is how to select the optimal value of these parameters.[1]

Fernández-Villaverde and Rubio-Ramírez (2006) argue that a reasonable criterion (and part of the motivation for the change of variables) is to select these parameters to improve the accuracy of the solution of the model. More concretely, the authors propose to minimize the Euler error function with respect to some metric. Since we have not introduced the measures of accuracy of the solution to a DSGE model, we will skip the details of how to do so. Suffice it to say that Fernández-Villaverde and Rubio-Ramírez (2006) find that the optimal change of variables improves the average accuracy of the solution by a factor of around three. This improvement makes a first-order approximation competitive in terms of accuracy with much more involved methods. Fernández-Villaverde and Rubio-Ramírez (2006) also report that the optimal parameter values depend on the standard deviation of the exogenous shocks to the economy. This is a significant result: the change of variables corrects by the level of uncertainty existing in the economy and breaks certainty equivalence.

Remark 15 (Loglinearization v. lognormal–loglinear approximation) A different solution technique, called lognormal–loglinear approximation, is popular in finance. Its relation with standard loglinearization (as a particular case of first-order perturbation with a change of variables in logs) often causes confusion among researchers and students. Thus, once we have understood the change of variables technique, it is worthwhile to dedicate this remark to clarifying the similarities and differences between the first-order

[1] We do not even need to find the optimal value of these parameters. It may be the case that a direct but not optimal choice of parameter values already delivers substantial improvements in accuracy at a very low computational cost. When one is maximizing, for example, a likelihood function, being at the true maximum matters. When one is finding parameters that improve accuracy, optimality is desirable but not essential, and it can be traded off against computational cost.

perturbation in logs and the lognormal–loglinear approximation. The best way to illustrate this point is with a concrete example. Imagine that we have a household with utility function

$$\max \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t \log C_t$$

and budget constraint:

$$W_{t+1} = R_{t+1}(W_t - C_t)$$

where W_t is total wealth and W_0 is given. Then, the optimality conditions are:

$$1 = \beta \mathbb{E}_t \frac{C_t}{C_{t+1}} R_{t+1}$$
$$W_{t+1} = R_{t+1}(W_t - C_t)$$

with steady state $R = \frac{1}{\beta}$ and $W = R(W - C)$.

Under a standard first-order perturbation in logs (loglinearization) around the previous steady state, and after some algebra:

$$\mathbb{E}_t \Delta \hat{c}_{t+1} = \mathbb{E}_t \hat{r}_{t+1}$$
$$\hat{w}_{t+1} = \hat{r}_{t+1} + \frac{1}{\rho}\hat{w}_t + \left(1 - \frac{1}{\rho}\right)\hat{c}_t$$

where, for a variable X_t,

$$\hat{x}_t = x_t - x = \log X_t - \log X$$

and $\rho = \frac{W - C}{W}$. Subtracting $\hat{w}_t$ from the second equation:

$$\Delta \hat{w}_{t+1} = \hat{r}_{t+1} + \left(1 - \frac{1}{\rho}\right)(\hat{c}_t - \hat{w}_t)$$

If we want to express these two equations in logs, instead of log-deviations (and using the fact that $r = -\log\beta$):

$$\mathbb{E}_t \Delta c_{t+1} = \log\beta + \mathbb{E}_t r_{t+1} \tag{29}$$

$$\Delta w_{t+1} = r_{t+1} + k + \left(1 - \frac{1}{\rho}\right)(c_t - w_t) \tag{30}$$

where

$$k = -r - \left(1 - \frac{1}{\rho}\right)(c - w).$$

In comparison, a lognormal–loglinearization still uses the approximation of the budget constraint (30), but it assumes that $\frac{C_t}{C_{t+1}}R_{t+1}$ is distributed as a lognormal random variable. Since, for an arbitrary variable:

$$\log \mathbb{E}_t X_t = \mathbb{E}_t \log X_t + \frac{1}{2} Var_t \log X_t,$$

we can go back to the Euler equation

$$1 = \beta \mathbb{E}_t \frac{C_t}{C_{t+1}} R_{t+1}$$

and rewrite it as:

$$\begin{aligned} 0 &= \log\beta + \log \mathbb{E}_t \frac{C_t}{C_{t+1}} R_{t+1} \\ &= \log\beta + \mathbb{E}_t \log \frac{C_t}{C_{t+1}} R_{t+1} + \frac{1}{2} Var_t \log \frac{C_t}{C_{t+1}} R_{t+1} \end{aligned}$$

or, rearranging terms:

$$\mathbb{E}_t \Delta c_{t+1} = \log\beta + \mathbb{E}_t r_{t+1} + \frac{1}{2}\left[Var_t \Delta c_{t+1} + Var_t r_{t+1} - 2cov_t(\Delta c_{t+1}, r_{t+1})\right] \tag{31}$$

More in general, in a lognormal–loglinearization, we approximate the nonexpectational equations with a standard loglinearization and we develop the expectational ones (or at least the ones with returns on them) using a lognormal assumption. In particular, we do not approximate the Euler equation. Once we have assumed that $\frac{C_t}{C_{t+1}}R_{t+1}$ is lognormal, all the results are exact.

If we compare the two equations for the first difference of consumption, (29) and (31), we see that the lognormal–loglinear approximation introduces an additional term

$$\frac{1}{2}\left[Var_t \Delta c_{t+1} + Var_t r_{t+1} - 2cov_t(\Delta c_{t+1}, r_{t+1})\right]$$

that breaks certainty equivalence. This novel feature has important advantages. For example, for a pricing kernel M_t and an asset i, we have the pricing equation:

$$1 = \mathbb{E}_t M_{t+1} R_{i,t+1}.$$

Then:

$$0 = \mathbb{E}_t \log M_{t+1} R_{i,t+1} + \frac{1}{2} Var_t \log M_{t+1} R_{i,t+1}$$

or:

$$\mathbb{E}_t r_{i,t+1} = -\mathbb{E}_t m_{t+1} - \frac{1}{2} Var_t m_{t+1} - \frac{1}{2} Var_t r_{i,t+1} - cov_t\left(m_{t+1}, r_{i,t+1}\right)$$

If we look at the same expression for the risk-free bond:

$$1 = \mathbb{E}_t M_{t+1} R_{f,t+1}$$

we get:

$$r_{f,t+1} = -\mathbb{E}_t m_{t+1} - \frac{1}{2} Var_t m_{t+1}$$

and we can find that the excess return is:

$$\mathbb{E}_t r_{i,t+1} - r_{f,t+1} = -\frac{1}{2} Var_t r_{i,t+1} - cov_t\left(m_{t+1}, r_{i,t+1}\right),$$

an expression that it is easy to interpret.

On the other hand, this expression also embodies several problems. First, it is often unclear to what extent, in a general equilibrium economy, $\frac{C_t}{C_{t+1}} R_{t+1}$ is close to lognormality. Second, in lognormal–loglinear approximation, we are mixing two approaches, a lognormal assumption with a loglinearization. This is not necessarily coherent from the perspective of perturbation theory and we may lack theoretical foundations for the approach (including an absence of convergence theorems). Third, in the loglinearization, we can compute all the coefficients by solving a quadratic matrix system. In the lognormal–loglinear approximation, we need to compute second moments and, in many applications, how to do so may not be straightforward. Finally, it is not obvious how to get higher-order approximations with the lognormal–loglinear approximation, while perturbation theory can easily handle higher-order solutions.

4.6 Perturbing the Value Function

In some applications, it is necessary to perturb the value function of a DSGE model, for example, when we are dealing with recursive preferences or when we want to evaluate welfare. Furthermore, a perturbed value function can be an outstanding initial guess for value function iteration, making it possible to deal with high-dimensional problems that could be otherwise too slow to converge. Given the importance of perturbing the value function, this section illustrates in some detail how to do so.

Since all that we learned in the general case subsection will still apply by just changing the operator $\mathcal{H}$ from the equilibrium conditions to the Bellman operator, we can go directly to a concrete application. Consider a value function problem (following the same notation as above).

$$V(k_t, z_t) = \max_{c_t} \left[(1-\beta)\log c_t + \beta \mathbb{E}_t V(k_{t+1}, z_{t+1})\right]$$
$$\text{s.t. } c_t + k_{t+1} = e^{z_t} k_t^{\alpha} + (1-\delta)k_t$$
$$z_t = \rho z_{t-1} + \eta \varepsilon_t,\ \varepsilon_t \sim N(0,1)$$

where we have "normalized" $\log c_t$ by $(1-\beta)$ to make the value function and the utility function have the same order of magnitude (thanks to normalization, $V_{ss} = \log c$, where V_{ss} is the steady-state value function and c is the steady-state consumption).

We can rewrite the problem in terms of a perturbation parameter σ:

$$V(k_t, z_t; \sigma) = \max_{c_t} \left[\log c_t + \beta \mathbb{E}_t V\left(e^{z_t} k_t^{\alpha} + (1-\delta)k_t - c_t, \rho z_t + \sigma \eta \varepsilon_{t+1}; \sigma\right)\right].$$

Note that we have made explicit the dependencies in the next period states from the current period state. The perturbation solution of this problem is a value function $V(k_t, z_t; \sigma)$ and a policy function for consumption $c(k_t, z_t; \sigma)$. For example, the second-order Taylor approximation of the value function around the deterministic steady state $(k, 0; 0)$ is:

$$\begin{aligned} V(k_t, z_t; \sigma) = {} & V_{ss} + V_{1,ss}\,(k_t - k) + V_{2,ss} z_t + V_{3,ss}\sigma \\ & + \frac{1}{2} V_{11,ss}(k_t - k)^2 + V_{12,ss}(k_t - k) z_t + V_{13,ss}(k_t - k)\sigma \\ & + \frac{1}{2} V_{22,ss} z_t^2 + V_{23,ss} z_t \sigma + \frac{1}{2} V_{33,ss}\sigma^2 \end{aligned}$$

where:

$$V_{ss} = V(k, 0; 0)$$
$$V_{i,ss} = V_i(k, 0; 0) \text{ for } i = \{1,2,3\}$$
$$V_{ij,ss} = V_{ij}(k, 0; 0) \text{ for } i, j = \{1,2,3\}$$

By certainty equivalence:

$$V_{3,ss} = V_{13,ss} = V_{23,ss} = 0$$

and then:

$$\begin{aligned} V(k_t, z_t; 1) = {} & V_{ss} + V_{1,ss}\,(k_t - k) + V_{2,ss} z_t \\ & + \frac{1}{2} V_{11,ss}\,(k_t - k)^2 + \frac{1}{2} V_{22,ss} z_{tt}^2 + V_{12,ss}\,(k_t - k) z + \frac{1}{2} V_{33,ss}\sigma^2 \end{aligned}$$

Note that $V_{33,ss} \neq s0$, a difference from the LQ approximation to the utility function that we discussed in Remark 13.

Similarly, the policy function for consumption can be expanded as:

$$c_t = c(k_t, z_t; \sigma) = c_{ss} + c_{1,ss}(k_t - k) + c_{2,ss} z_t + c_{3,ss}\sigma$$

where $c_{i,ss} = c_1(k, 0; 0)$ for $i = \{1,2,3\}$. Since the first derivatives of the consumption function only depend on the first and second derivatives of the value function, we must have that $c_{3,ss} = 0$ (remember that precautionary consumption depends on the third derivative of the value function; Kimball, 1990).

To find the linear components of our approximation to the value function, we take derivatives of the value function with respect to controls (c_t), states (k_t, z_t), and the perturbation parameter σ and solve the associated system of equations when $\sigma = 0$. We can find the quadratic components of the value function by taking second derivatives, plugging in the known components from the previous step, and solving the system when $\sigma = 0$.

We are ready now to show some of the advantages of perturbing the value function. First, we have an evaluation of the welfare cost of business cycle fluctuations readily available. At the deterministic steady state $k_t = k$ and $z_t = 0$, we have:

$$V(k, 0; \sigma) = V_{ss} + \frac{1}{2} V_{33,ss}\sigma^2.$$

Hence $\frac{1}{2} V_{33,ss}\sigma^2$ is a measure of the welfare cost of the business cycle: it is the difference, up to second-order, between the value function evaluated at the steady-state value of the state variables $(k, 0)$ and the steady-state value function (where not only are we at the steady state, but where we know that in future periods we will be at that point as well). Note that this last quantity is not necessarily negative. Indeed, it may well be positive in many models, such as in a stochastic neoclassical growth model with leisure choice. For an explanation and quantitative evidence, see Cho et al. (2015).[m]

It is easier to interpret $V_{33,ss}$ if we can transform it into consumption units. To do so, we compute the decrease in consumption τ that will make the household indifferent between consuming $(1-\tau)c$ units per period with certainty or c_t units with uncertainty. That is, τ satisfies:

$$\log(1-\tau)c = \log c + \frac{1}{2} V_{33,ss}\sigma^2$$

where we have used $V_{ss} = \log c$. Then,

$$\tau = 1 - e^{\frac{1}{2} V_{33,ss}\sigma^2}.$$

[m] In his classical calculation about the welfare cost of the business cycle, Lucas Jr. (1987) assumed an endowment economy, where the representative household faces the same consumption process as the one observed for the US economy. Thus, for any utility function with risk aversion, the welfare cost of the business cycle must be positive (although Lucas' point, of course, was that it was rather small). When consumption and labor supply are endogenous, agents can take advantage of uncertainty to increase their welfare. A direct utility function that is concave in allocations can generate a convex indirect utility function on prices and those prices change in general equilibrium as a consequence of the agents' responses to uncertainty.

We close this section with a numerical application. To do so, we pick the same calibration as in Table 1. We get:

$$V(k_t, z_t; 1) = -0.54000 + 0.026(k_t - 0.188) + 0.250z_t - 0.069(k_t - 0.188)^2 \tag{32}$$

(where, for this calibration, $V_{kz} = V_{z^2} = V_{\sigma^2} = 0$) and:

$$c(k_t, z_t; \chi) = 0.388 + 0.680(k_t - 0.188) + 0.388z_t,$$

which is the same approximation to the consumption decision rule we found when we tackled the equilibrium conditions of the model. For this calibration, the welfare cost of the business cycle is zero.[n]

We can also use Eq. (32) as an initial guess for value function iteration. Thanks to it, instead of having to iterate hundreds of times, as if we were starting from a blind initial guess, value function iteration can converge after only a few dozen interactions.

Finally, a mixed strategy is to stack both the equilibrium conditions of the model and the value function evaluated at the optimal decision rules:

$$V(k_t, z_t) = (1-\beta)\log c_t + \beta\mathbb{E}_t V(k_{t+1}, z_{t+1}).$$

in the operator $\mathcal{H}$. This strategy delivers an approximation to the value function and the decision rules with a trivial cost.[o]

5. PROJECTION

Projection methods (also known as weighted residual methods) handle DSGE models by building a function indexed by some coefficients that approximately solves the operator $\mathcal{H}$. The coefficients are selected to minimize a residual function that evaluates how far away the solution is from generating a zero in $\mathcal{H}$. More concretely, projection methods solve:

$$\mathcal{H}(d) = \mathbf{0}$$

[n] Recall that the exact consumption decision rule is $c_t = 0.673e^{z_t}k_t^{0.33}$. Since the utility function is log, the period utility from this decision rule is $\log c_t = z_t + \log 0.673 + 0.33\log k_t$. The unconditional mean of z_t is 0 and the capital decision rule is certainty equivalent in logs. Thus, there is no (unconditional) welfare cost of changing the variance of z_t.

[o] We could also stack derivatives of the value function, such as:

$$(1-\beta)c_t^{-1} - \beta\mathbb{E}_t V_{1,t+1} = 0$$

and find the perturbation approximation to the derivative of the value function (which can be of interest in itself or employed in finding higher-order approximations of the value function).

by specifying a linear combination:

$$d^j(\mathbf{x}|\theta) = \sum_{i=0}^{j} \theta_i \Psi_i(\mathbf{x}) \tag{33}$$

of basis function $\Psi_i(\mathbf{x})$ given coefficients $\theta = \{\theta_0, \ldots, \theta_j\}$. Then, we define a residual function:

$$R(\mathbf{x}|\theta) = \mathcal{H}\left(d^j(\mathbf{x}|\theta)\right)$$

and we select the values of the coefficients θ that minimize the residual given some metric. This last step is known as "projecting" $\mathcal{H}$ against that basis to find the components of θ (and hence the name of the method).

Inspection of Eq. (33) reveals that to build the function $d^j(\mathbf{x}|\theta)$, we need to pick a basis $\{\Psi_i(\mathbf{x})\}_{i=0}^{\infty}$ and decide which inner product we will use to "project" $\mathcal{H}$ against that basis to compute θ. Different choices of bases and of the projection algorithm will imply different projection methods. These alternative projections are often called in the literature by their own particular names, which can be sometimes bewildering.

Projection theory, which has been applied in *ad hoc* ways by economists over the years, was popularized as a rigorous approach in economics by Judd (1992) and Gaspar and Judd (1997) and, as in the case of perturbation, it has been authoritatively presented by Judd (1998).[p]

Remark 16 (Linear v. nonlinear combinations) Instead of linear combinations of basis functions, we could deal with more general nonlinear combinations:

$$d^j(\mathbf{x}|\theta) = f\left(\{\Psi_i(\mathbf{x})\}_{i=0}^{j} | \theta\right)$$

for a known function f. However, the theory for nonlinear combinations is less well developed, and we can already capture a full range of nonlinearities in d^j with the appropriate choice of basis functions Ψ_i. In any case, it is more pedagogical to start with the linear combination case. Most of the ideas in the next pages carry over the case of nonlinear combinations. The fact that we are working with linear combinations of basis functions also means that, in general, we will have the same number of coefficients θ as the number of basis functions Ψ_i times the dimensionality of d^j.

[p] Projection theory is more modern than perturbation. Nevertheless, projection methods have been used for many decades in the natural sciences and engineering. Spectral methods go back, at least, to Lanczos (1938). Alexander Hrennikoff and Richard Courant developed the finite elements method in the 1940s, although the method was christened by Clough (1960), who made pioneering contributions while working at Boeing. See Clough and Wilson (1999) for a history of the early research on finite elements.

5.1 A Basic Projection Algorithm

Conceptually, projection is easier to present than perturbation (although its computational implementation is harder). We can start directly by outlining a projection algorithm:

Algorithm 1 (Projection Algorithm)

1. Define $j+1$ known linearly independent functions $\psi_i : \Omega \rightarrow \mathbb{R}$ where $j < \infty$. We call the $\psi_0, \psi_1, \ldots, \psi_j$ the *basis functions*. These basis functions depend on the vector of state variables x.
2. Define a vector of coefficients $\theta^l = [\theta^l_0, \theta^l_1, \ldots, \theta^l_j]$ for $l = 1, \ldots, m$ (where recall that m is the dimension that the function d of interest maps into). Stack all coefficients on a $m \times (j+1)$ matrix $\theta = [\theta^1; \theta^2; \ldots; \theta^l]$.
3. Define a combination of the basis functions and the θ's:

$$d^{l,j}(\cdot|\theta^l) = \sum_{i=0}^{j} \theta^l_i \psi_i(\cdot)$$

for $l = 1, \ldots, m$. Then:

$$d^j(\cdot|\theta) = \left[d^{1,j}(\cdot|\theta^l); d^{2,j}(\cdot|\theta^l); \ldots; d^{m,j}(\cdot|\theta^l)\right].$$

4. Plug $d^j(\cdot|\theta)$ into the operator H(·) to find the *residual equation*:

$$R(\cdot|\theta) = \mathcal{H}\left(d^j(\cdot|\theta)\right).$$

5. Find the value of θˆthat makes the residual equation as close to $\mathbf{0}$ as possible given some objective function $\rho : J^2 \times J^2 \rightarrow \mathbb{R}$:

$$\hat{\theta} = \arg \min_{\theta \in \mathbb{R}^{m \times (j+1)}} \rho(R(\cdot|\theta), \mathbf{0}).$$

To ease notation, we have made two simplifications on the previous algorithm. First, we assumed that, along each dimension of d, we used the same basis functions ψ_i and the same number $j+1$ of them. Nothing forces us to do so. At the mere cost of cumbersome notation, we could have different basis functions for each dimension and a different number of them (ie, different j's). While the former is not too common in practice, the latter is standard, since some variables' influence on the function d can be harder to approximate than others'.[q]

We specify a metric function ρ to gauge how close the residual function is to zero over the domain of the state variables. For example, in Fig. 2, we plot two different residual

[q] For the nonlinear combination case, $f\left(\{\Psi_i(\mathbf{x})\}_{i=0}^{j}|\theta\right)$, we would just write the residual function:

$$R(\cdot|\theta) = \mathcal{H}\left(f\left(\{\Psi_i(\mathbf{x})\}_{i=0}^{j}|\theta\right)\right)$$

and find the θ's that minimize a given metric. Besides the possible computational complexities of dealing with arbitrary functions $f\left(\{\Psi_i(\mathbf{x})\}_{i=0}^{j}|\theta\right)$, the conceptual steps are the same.

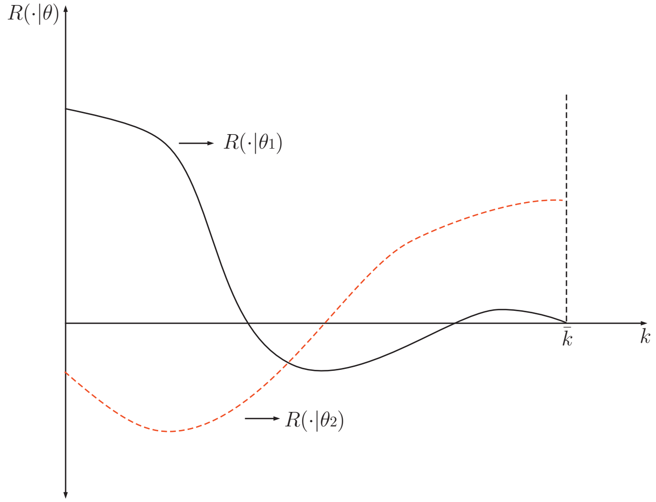

Fig. 2 Residual functions.

functions for a problem with only one state variable k_t (think, for instance, of a deterministic neoclassical growth model) that belongs to the interval $[0, \bar{k}]$, one for coefficients θ_1 (continuous line) and one for coefficients θ_2 (discontinuous line). $R(\cdot|\theta_1)$ has large values for low values of k_t, but has small values for high levels of k_t. $R(\cdot|\theta_2)$ has larger values on average, but it never gets as large as $R(\cdot|\theta_1)$. Which of the two residual functions is closer to zero over the interval? Obviously, different choices of ρ will yield different answers. We will discuss below how to select a good ρ.

A small example illustrates the previous steps. Remember that we had, for the stochastic neoclassical growth model, the system built by the Euler equation and the resource constraint of the economy:

$$\mathcal{H}(d) = \left\{ \begin{array}{c} u'\left(d^1(k_t, z_t)\right) \\ -\beta \mathbb{E}_t \left[u'\left(d^1\left(d^2(k_t, z_t), z_{t+1}\right)\right)\left(\alpha e^{\rho z_t + \sigma \varepsilon_{t+1}}\left(d^2(k_t, z_t)\right)^{\alpha-1} + 1 - \delta\right)\right] \\ d^1(k_t, z_t) + d^2(k_t, z_t) - e^{z_t} k_t^{\alpha} - (1-\delta)k_t \end{array} \right. = \mathbf{0},$$

for all k_t and z_t and where:

$$c_t = d^1(k_t, z_t)$$
$$k_{t+1} = d^2(k_t, z_t)$$

and we have already recursively substituted k_{t+1} in the decision rule of consumption evaluated at $t + 1$. Then, we can define

$$c_t = d^{1,j}\left(k_t, z_t | \theta^1\right) = \sum_{i=0}^{j} \theta_i^1 \psi_i(k_t, z_t)$$

and

$$k_{t+1} = d^{2,j}\left(k_t, z_t|\theta^2\right) = \sum_{i=0}^{j} \theta_i^2 \psi_i(k_t, z_t)$$

for some $\psi_0(k_t,z_t), \psi_1(k_t,z_t), \ldots, \psi_j(k_t,z_t)$. Below we will discuss which basis functions we can select for this role.

The next step is to write the residual function:

$$R(k_t, z_t|\theta) = \left\{ \begin{array}{c} u'\left(\sum_{i=0}^{j} \theta_i^1 \psi_i(k_t, z_t)\right) \\ -\beta \mathbb{E}_t \left[\begin{array}{c} u'\left(\sum_{i=0}^{j} \theta_i^1 \psi_i\left(\sum_{i=0}^{j} \theta_i^2 \psi_n(k_t, z_t), \rho z_t + \sigma \varepsilon_{t+1}\right)\right) \\ \times \left(\alpha e^{\rho z_t + \sigma \varepsilon_{t+1}} \left(\sum_{i=0}^{j} \theta_i^2 \psi_i(k_t, z_t)\right)^{\alpha - 1} + 1 - \delta\right) \end{array} \right] \\ \sum_{i=0}^{j} \theta_i^1 \psi_i(k_t, z_t) + \sum_{i=0}^{j} \theta_i^2 \psi_i(k_t, z_t) - e^{z_t} k_t^{\alpha} - (1-\delta) k_t \end{array} \right. ,$$

for all k_t and z_t, $\theta = \left[\theta^1; \theta^2\right]$.

The final step is to find $\hat{\theta} = \arg\min_{\theta \in \mathbb{R}^{m \times (j+1)}} \rho(R(\cdot|\theta), \mathbf{0})$. Again, we will discuss these choices below in detail, but just for concreteness, let us imagine that we pick $m \times (j+1)$ points (k_l, z_l) and select the metric function to be zero at each of these $m \times (j+1)$ points and one everywhere else. Such a metric is trivially minimized if we make the residual function equal to zero exactly on those points. This is equivalent to solving the system of $m \times (j+1)$ equations:

$$R(k_l, z_l|\theta) = \mathbf{0}, \text{ for } l = 1, \ldots, m \times (j+1)$$

with $m \times (j+1)$ unknowns (we avoid here the discussion about the existence and uniqueness of such a solution).

Remark 17 (Relation to econometrics) Many readers will be familiar with the use of the word "projection" in econometrics. This is not a coincidence. A common way to present linear regression is to think about the problem of searching for the unknown conditional expectation function:

$$\mathbb{E}(Y|X)$$

for some variables Y and X. Given that this conditional expectation is unknown, we can approximate it with the first two monomials on X, 1 (a constant) and X (a linear function), and associated coefficients θ_0 and θ_1:

$$\mathbb{E}(Y|X) \simeq \theta_0 + \theta_1 X.$$

These two monomials are the first two elements of a basis composed by the monomials (and also of the Chebyshev polynomials, a basis of choice later in this section). The residual function is then:

$$R(Y,X|\theta_0,\theta_1) = Y - \theta_0 - \theta_1 X.$$

The most common metric in statistical work is to minimize the square of this residual:

$$R(Y,X|\theta_{0},\theta_1)^2$$

by plugging in the observed series $\{Y,X\}_{t=1:T}$. The difference, thus, between ordinary least squares and the projection algorithm is that while in the former we use observed data, in the latter we use the operator $\mathcal{H}(d)$ imposed by economic theory. This link is even clearer when we study the econometrics of semi-nonparametric methods, such as sieves (Chen, 2007), which look for flexible basis functions indexed by a low number of coefficients and that, nevertheless, impose fewer restrictions than a linear regression.

Remark 18 (Comparison with other methods) From our short description of projection methods, we can already see that other algorithms in economics are particular cases of it. Think, for example, about the parameterized expectations approach (Marcet and Lorenzoni, 1999). This approach consists of four steps.

First, the conditional expectations that appear in the equilibrium conditions of the model are written as a flexible function of the state variables of the model and some coefficients. Second, the coefficients are initialized at an arbitrary value. Third, the values of the coefficients are updated by running a nonlinear regression that minimizes the distance between the conditional expectations forecasted by the function guessed in step 1 and the actual realization of the model along a sufficiently long simulation. Step 3 is repeated until the coefficient values used to simulate the model and the coefficient values that come out of the nonlinear regression are close enough.

Step 1 is the same as in any other projection method: the function of interest (in this case the conditional expectation) is approximated by a flexible combination of basis functions. Often the parameterized expectations approach relies on monomials to do so (or functions of the monomials), which, as we will argue below, is rarely an optimal choice. But this is not an inherent property of the approach. Christiano and Fisher (2000) propose to use functions of Chebyshev polynomials, which will yield better results. More important is the iterative procedure outlined by steps 2–4. Finding the fixed point of the values of the coefficients by simulation and a quadratic distances is rarely the best option. Even if, under certain technical conditions (Marcet and Marshall, 1994) the algorithm converges, such convergence can be slow and fragile. In the main text, we will explain that a collocation approach can achieve the same goal much more efficiently and without having to resort to simulation (although there may be concrete cases where simulation is a superior strategy).

Value function iteration and policy function iteration can also be understood as particular forms of projection, where the basis functions are linear functions (or higher-order interpolating functions such as splines). Since in this chapter we are not dealing with these methods, we skip further details.

5.2 Choice of Basis and Metric Functions

The previous subsection highlighted the two issues ahead of us: how to decide which basis $\psi_0, \psi_1, \ldots, \psi_j$ to select and which metric function ρ to use. Different choices in each of these issues will result in slightly different projection methods, each with its weaknesses and strengths.

Regarding the first issue, we can pick a global basis (ie, basis functions that are nonzero and smooth for most of the domain of the state variable Ω) or a local basis (ie, basis functions that are zero for most of the domain of the state variable, and nonzero and smooth for only a small portion of the domain Ω). Projection methods with a global basis are often known as spectral methods. Projection methods with a local basis are also known as finite elements methods.

5.3 Spectral Bases

Spectral techniques were introduced in economics by Judd (1992). The main advantage of this class of global basis functions is their simplicity: building and working with the approximation will be straightforward. The main disadvantage of spectral bases is that they have a hard time dealing with local behavior. Think, for instance, about Fig. 3, which plots the decision rule $k_{t+1} = d(k_t)$ that determines capital tomorrow given capital today for some model that implies a nonmonotone, local behavior represented by the hump in the middle of the capital range (perhaps due to a complicated incentive constraint). The change in the coefficients θ required to capture that local shape of d would leak into the approximation for the whole domain Ω. Similar local behavior appears when we deal with occasionally binding constraints, kinks, or singularities.

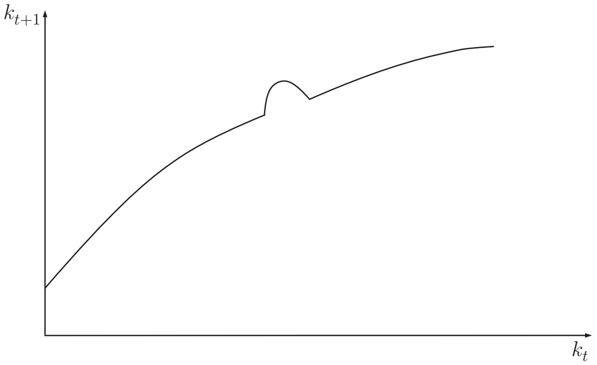

Fig. 3 Decision rule for capital.

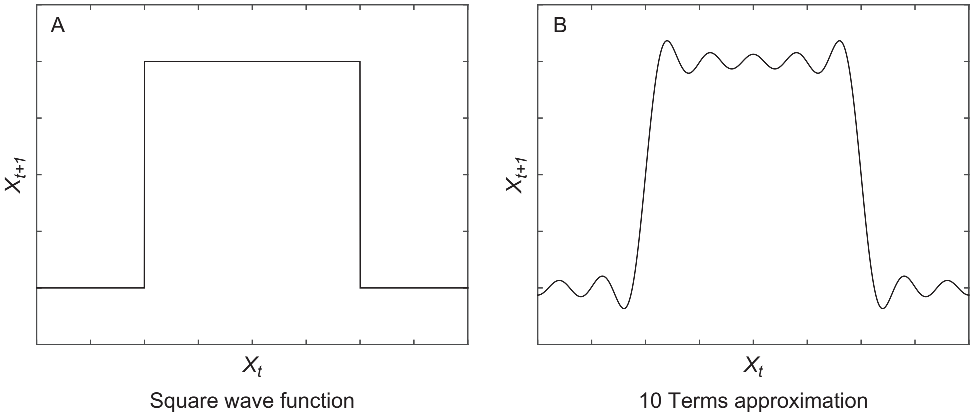

Fig. 4 Gibbs phenomenon.

A well-known example of this problem is the Gibbs phenomenon. Imagine that we are trying to approximate a piecewise continuously differentiable periodic function with a jump discontinuity, such as a square wave function (Fig. 4, panel A):

$$f(x) = \begin{cases} \frac{\pi}{4}, \text{ if } x \in [2j\pi, 2(j+1)\pi] \text{ and for } \forall j \in \mathbb{N} \\ -\frac{\pi}{4}, \text{ otherwise.} \end{cases}$$

Given that the function is periodic, a sensible choice for a basis is a trigonometric series $\sin(x)$, $\sin(2x)$, $\sin(3x)$, … The optimal approximation is:

$$\sin(x) + \frac{1}{3}\sin(3x) + \frac{1}{5}\sin(5x) + \ldots$$

The approximation behaves poorly at a jump discontinuity. As shown in Fig. 4, panel B, even after using 10 terms, the approximation shows large fluctuations around all the discontinuity points $2j\pi$ and $2(j+1)\pi$. These fluctuations will exist even if we keep adding many more terms to the approximation. In fact, the rate of convergence to the true solution as $n \to \infty$ is only $O(n)$.

5.3.1 Unidimensional Bases

We will introduce in this subsection some of the most common spectral bases. First, we will deal with the unidimensional case where there is only one state variable. This will allow us to present most of the relevant information in a succinct fashion. It would be important to remember, however, that our exposition of unidimensional bases cannot be exhaustive (for instance, in the interest of space, we will skip splines) and that the researcher may find herself tackling a problem that requires a specific basis. One of the great advantages of projection methods is their flexibility to accommodate unexpected requirements. In the next subsection, we will deal with the case of an arbitrary number of state variables and we will discuss how to address the biggest challenge of projection methods: the curse of dimensionality.

5.3.1.1 Monomials

A first basis is the monomials 1, x, x^2, x^3, … Monomials are simple and intuitive. Furthermore, even if this basis is not composed by orthogonal functions, if J_1 is the space of bounded measurable functions on a compact set, the Stone–Weierstrass theorem tells us that we can uniformly approximate any continuous function defined on a closed interval with linear combinations of these monomials.

Rudin (1976, p. 162) provides a formal statement of the theorem:

Theorem 1 (Stone–Weierstrass) *Let $\mathcal{A}$ be an algebra of real continuous functions on a compact set* K. *If $\mathcal{A}$ separates points on* K *and if $\mathcal{A}$ vanishes at no point of* K, *then the uniform closure $\mathcal{B}$ of $\mathcal{A}$ consists of all real continuous functions on* K.

A consequence of this theorem is that if we have a real function f that is continuous on K, we can find another function $h \in \mathcal{B}$ such that for $\varepsilon > 0$:

$$|f(x) - h(x)| < \varepsilon,$$

for all $x \in K$.

Unfortunately, monomials suffer from two severe problems. First, monomials are (nearly) multicollinear. Fig. 5 plots the graphs of x^{10} (continuous line) and x^{11} (discontinuous line) for $x \in [0.5, 1.5]$. Both functions have a very similar shape. As we add higher monomials, the new components of the solution do not allow the distance between the exact function we want to approximate and the computed approximation to diminish sufficiently fast.[r]

Second, monomials vary considerably in size, leading to scaling problems and the accumulation of numerical errors. We can also see this point in Fig. 5: x^{11} goes from $4.8828e^{-04}$ to 86.4976 just by moving x from 0.5 to 1.5.

The challenges presented by the use of monomials motivate the search for an orthogonal basis in a natural inner product that has a bounded variation in range. Orthogonality will imply that when we add more one element of the basis (ie, when we go from order j

[r] A sharp case of this problem is when $\mathcal{H}(\cdot)$ is linear. In that situation, the solution of the projection involves the inversion of matrices. When the basis functions are similar, the condition numbers of these matrices (the ratio of the largest and smallest absolute eigenvalues) are too high. Just the first six monomials can generate condition numbers of 10^{10}. In fact, the matrix of the least squares problem of fitting a polynomial of degree 6 to a function (the *Hilbert Matrix*) is a popular test of numerical accuracy since it maximizes rounding errors. The problem of the multicollinearity of monomials is also well appreciated in econometrics.

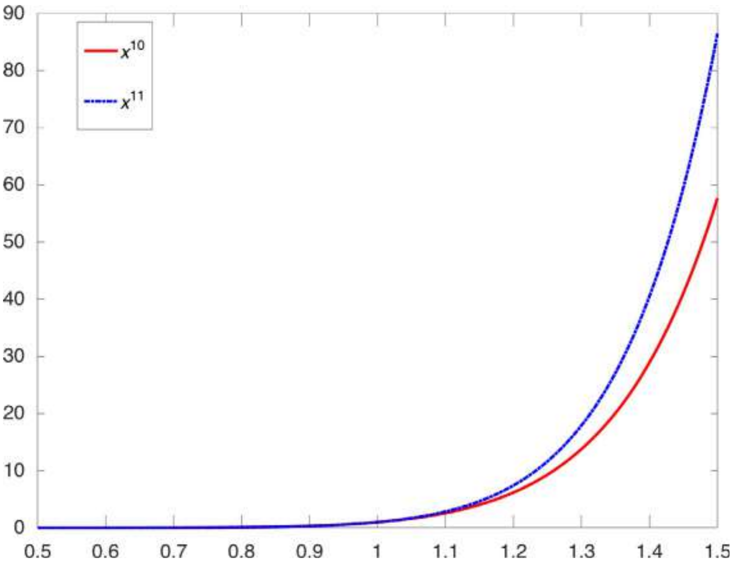

Fig. 5 Graphs of x^{10} and x^{11}.

to order $j + 1$), the newest element brings a sufficiently different behavior so as to capture features of the unknown function d not well approximated by the previous elements of the basis.

5.3.1.2 Trigonometric Series

A second basis is a trigonometric series

$$1/(2\pi)^{0.5}, \cos x/(2\pi)^{0.5}, \sin x/(2\pi)^{0.5}, \ldots,$$
$$\cos kx/(2\pi)^{0.5}, \sin kx/(2\pi)^{0.5}, \ldots$$

Trigonometric series are well suited to approximate periodic functions (recall our example before of the square wave function). Trigonometric series are, therefore, quite popular in the natural sciences and engineering, where periodic problems are common. Furthermore, they are easy to manipulate as we have plenty of results involving the transformation of trigonometric functions and we can bring to the table the powerful tools of Fourier analysis. Sadly, economic problems are rarely periodic (except in the frequency analysis of time series) and periodic approximations to nonperiodic functions are highly inefficient.

5.3.1.3 Orthogonal Polynomials of the Jacobi Type

We motivated before the need to use a basis of orthogonal functions. Orthogonal polynomials of the Jacobi (also known as hypergeometric) type are a flexible class of polynomials well suited for our needs.

The Jacobi polynomial of degree n, $P_n^{\alpha,\beta}(x)$ for $\alpha, \beta > -1$, is defined by the orthogonality condition:

$$\int_{-1}^{1} (1-x)^{\alpha}(1+x)^{\beta} P_n^{\alpha,\beta}(x) P_m^{\alpha,\beta}(x) dx = 0 \text{ for } m \neq n$$

One advantage of this class of polynomials is that we have a large number of alternative expressions for them. The orthogonality condition implies, with the normalizations:

$$P_n^{\alpha,\beta}(1) = \binom{n+\alpha}{n},$$

that the general n term is given by:

$$2^{-n} \sum_{k=0}^{n} \binom{n+\alpha}{k} \binom{n+\beta}{n-k} (x-1)^{n-k}(x+1)^{k}$$

Recursively:

$$\begin{gathered} 2(n+1)(n+\alpha+\beta+1)(2n+\alpha+\beta)P_{n+1} = \\ \left(\begin{gathered} (2n+\alpha+\beta+1)\left(\alpha^2-\beta^2\right) \\ +(2n+\alpha+\beta)(2n+\alpha+\beta+1)(2n+\alpha+\beta+2)x \end{gathered} \right) P_n \\ -2(n+\alpha)(n+\beta)(2n+\alpha+\beta+2)P_{n-1} \end{gathered}$$

Two important cases of Jacobi polynomials are the Legendre polynomials, where $\alpha = \beta = -\frac{1}{2}$, and the Chebyshev polynomials, where $\alpha = \beta = 0$. There is a generalization of Legendre and Chebyshev polynomials, still within the Jacobi family, known as the Gegenbauer polynomials, which set $\alpha = \beta = \upsilon - \frac{1}{2}$ for a parameter υ.

Boyd and Petschek (2014) compare the performance of Gegenbauer, Legendre, and Chebyshev polynomials. Their table 1 is particularly informative. We read it as suggesting that, except for some exceptions that we find of less relevance in the solution of DSGE models, Chebyshev polynomials are the most convenient of the three classes of polynomials. Thus, from now on, we focus on Chebyshev polynomials.

5.3.1.4 Chebyshev Polynomials

Chebyshev polynomials are one of the most common tools of applied mathematics. See, for example, Boyd (2000) and Fornberg (1996) for references and background material. The popularity of Chebyshev polynomials is easily explained if we consider some of their advantages.

First, numerous simple closed-form expressions for the Chebyshev polynomials are available. Thus, the researcher can easily move from one representation to another according to her convenience. Second, the change between the coefficients of a Chebyshev expansion of a function and the values of the function at the Chebyshev nodes is quickly performed by the cosine transform. Third, Chebyshev polynomials are more robust than their alternatives for interpolation. Fourth, Chebyshev polynomials are smooth and bounded between $[-1,1]$. Finally, several theorems bound the errors for Chebyshev polynomials' interpolations.

The most common definition of the Chebyshev polynomials is recursive, with $T_0(x)=1$, $T_1(x)=x$, and the general $n+1$-th order polynomial given by:

$$T_{n+1}(x)=2xT_n(x)-T_{n-1}(x)$$

Applying this recursive definition, the first few polynomials are 1, x, $2x^2-1$, $4x^3-3x$, $8x^4-8x^2+1$,... Thus, the approximation of a function with Chebyshev polynomials is not different from an approximation with monomials (and, thus, we can rely on appropriate versions of the Stone–Weierstrass theorem), except that the orthogonality properties of how Chebyshev polynomials group the monomials make the approximation better conditioned.

Fig. 6 plots the Chebyshev polynomials of order 0–5. The first two polynomials coincide with the first two monomials, a constant and the 45-degree line. The Chebyshev polynomial of order two is a parabola. Higher-order Chebyshev polynomials accumulate several waves. Fig. 6 shows that the Chebyshev polynomials of order n has n zeros, given by

$$x_k=\cos\left(\frac{2k-1}{2n}\pi\right), k=1,\ldots,n.$$

This property will be useful when we describe collocation in a few pages. Also, these zeros are quadratically clustered toward ±1.

Other explicit and equivalent definitions for the Chebyshev polynomials include

$$\begin{aligned}
T_n(x) &= \cos(n \arccos x)\\
&= \frac{1}{2}\left(z^n+\frac{1}{z^n}\right) \text{ where } \frac{1}{2}\left(z+\frac{1}{z}\right)=x\\
&= \frac{1}{2}\left(\left(x+\left(x^2-1\right)^{0.5}\right)^n+\left(x-\left(x^2-1\right)^{0.5}\right)^n\right)\\
&= \frac{1}{2}\sum_{k=0}^{[n/2]}(-1)^k\frac{(n-k-1)!}{k!(n-2k)!}(2x)^{n-2k}\\
&= \frac{(-1)^n\pi^{0.5}}{2^n\Gamma\left(n+\frac{1}{2}\right)}\left(1-x^2\right)^{0.5}\frac{d^n}{dx^n}\left(\left(1-x^2\right)^{n-\frac{1}{2}}\right).
\end{aligned}$$

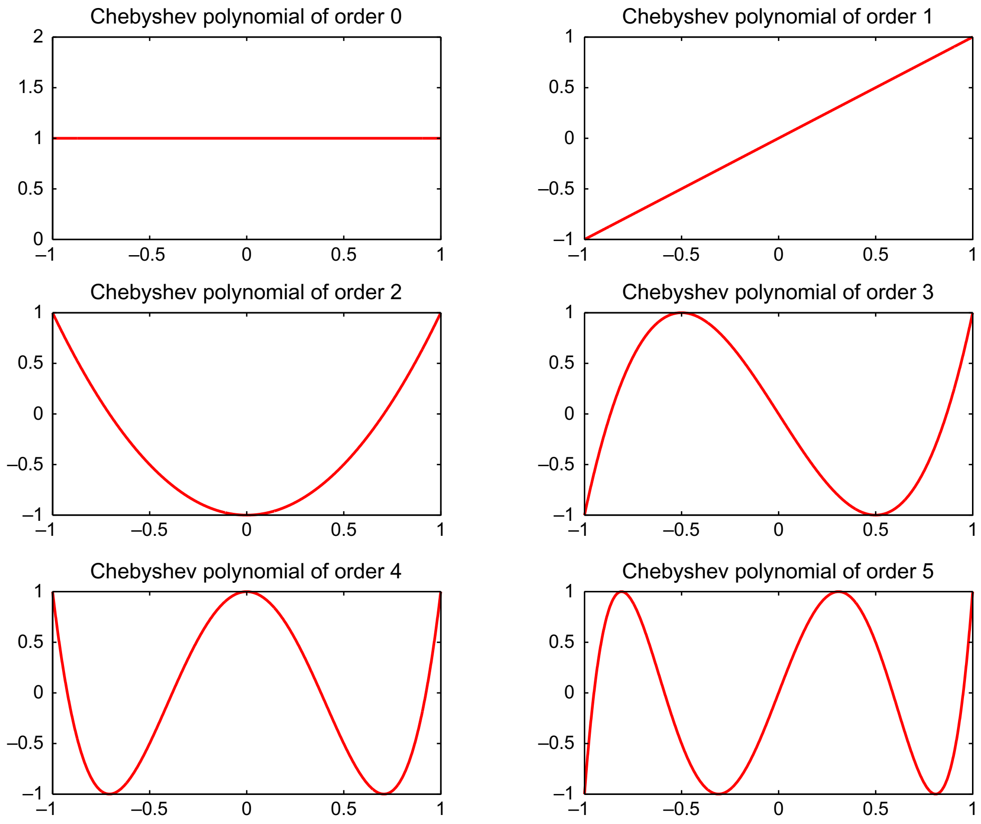

Fig. 6 First six Chebyshev polynomials.

Perhaps the most interesting of these definitions is the first one, since it tells us that Chebyshev polynomials are a trigonometric series in disguise (Boyd, 2000).

A few additional facts about Chebyshev polynomials deserve to be highlighted. First, the $n + 1$ extrema of the polynomial $T_n(x_k)$ $(n > 0)$ are given by:

$$x_k = cos\left(\frac{k}{n}\pi\right), \quad k = 0, \ldots, n. \tag{34}$$

All these extrema are either -1 or 1. Furthermore, two of the extrema are at the endpoints of the domain: $T_n(-1) = (-1)^n$ and $T_n(1) = 1$. Second, the domain of the Chebyshev polynomials is $[-1, 1]$. Since the domain of a state variable x in a DSGE model would be, in general, different from $[-1, 1]$, we can use a linear translation from $[a, b]$ into $[-1, 1]$:

$$2\frac{x-a}{b-a} - 1.$$

Third, the Chebyshev polynomials are orthogonal with respect to the weight function:

$$w(x) = \frac{1}{(1-x^2)^{0.5}}.$$

We conclude the presentation of Chebyshev polynomials with two remarkable results, which we will use below. The first result, due to Erdös and Turán (1937),[s] tells us that if an approximating function is exact at the roots of the n_1^{th} order Chebyshev polynomial, then, as $n_1 \to \infty$, the approximation error becomes arbitrarily small. The *Chebyshev interpolation theorem* will motivate, in a few pages, the use of orthogonal collocation where we pick as collocation points the zeros of a Chebyshev polynomial (there are also related, less used, results when the extrema of the polynomials are chosen instead of the zeros).

Theorem 2 (Chebyshev interpolation theorem) *If $d(x) \in \mathcal{C}[a,b]$, if $\{\phi_i(x), i=0,\ldots\}$ is a system of polynomials (where $\phi_i(x)$ is of exact degree* i*) orthogonal to with respect to $w(x)$ on $[a,b]$ and if $p_j = \sum_{i=0}^{j} \theta_i \phi_i(x)$ interpolates $f(x)$ in the zeros of $\phi_{n+1}(x)$, then:*

$$\lim_{j\to\infty} \left(\left\| d - p_j \right\|_2 \right)^2 = \lim_{n\to\infty} \int_a^b w(x) \left(d(x) - p_j \right)^2 dx = 0$$

We stated a version of the theorem that shows $\mathcal{L}_2$ convergence (a natural norm in economics), but the result holds for $\mathcal{L}_p$ convergence for any $p > 1$. Even if we called this result the *Chebyshev interpolation theorem*, its statement is more general, as it will apply to other polynomials that satisfy an orthogonality condition. The reason we used *Chebyshev* in the theorem's name is that the results are even stronger if the function $d(x)$ satisfies a Dini–Lipschitz condition and the polynomials $\phi_i(x)$ are Chebyshev to uniform convergence, a much more reassuring finding.[t]

But the previous result requires that $j \to \infty$, which is impossible in real applications. The second result will give a sense of how big is the error we are accepting by truncating the approximation of $d(\cdot)$ after a finite (and often relatively low) j.

[s] We reproduce the statement of the theorem, with only minor notational changes, from Mason and Handscomb (2003), chapter 3, where the interested reader can find related results and all the relevant details. This class of theorems is usually derived in the context of interpolating functions.

[t] A function f satisfies a Dini–Lipschitz condition if

$$\lim_{\delta\to 0^+} \omega(\delta) \log \delta = 0$$

where $\omega(\delta)$ is a modulus of continuity of f with respect to δ such that:

$$|f(x+\delta) - f(x)| \leq \omega(\delta).$$

Theorem 3 (Chebyshev truncation theorem, Boyd (Boyd (2000), p. 47)) *The error in approximating* d *is bounded by the sum of the absolute values of all the neglected coefficients. In other words, if we have*

$$d^j(\cdot|\theta) = \sum_{i=0}^{j} \theta_i \psi_i(\cdot)$$

then

$$\left|d(x) - d^j(x|\theta)\right| \leq \sum_{i=j+1}^{\infty} |\theta_i|$$

for any $x \in [-1, 1]$ *and any* j.

We can make the last result even stronger. Under certain technical conditions, we will have a geometric convergence of the Chebyshev approximation to the exact unknown function.[u] And when we have geometric convergence,

$$\left|d(x) - d^j(x|\theta)\right| \sim O(\theta_j)$$

that is, the truncation error created by stopping at the polynomial j is of the same order of magnitude as the coefficient θ_j of the last polynomial. This result also provides us with a simple numerical test: we can check the coefficient θ_j from our approximation: if θ_j is not close enough to zero, we probably need to increase j. We will revisit the evaluation of the accuracy of an approximation in Section 7.

Remark 19 (Change of variables) We mentioned above that, since a state variable x_t in a DSGE model would have, in general, a domain different from $[-1, 1]$, we can use a linear translation from $[a, b]$ into $[-1, 1]$:

$$2\frac{x_t - a}{b - a} - 1.$$

This transformation points to a more general idea: the change of variables as a way to improve the accuracy of an approximation (see also Section 4.5 for the application of the same idea in perturbation). Imagine that we are solving the stochastic neoclassical growth model. Instead of searching for

$$c_t = d^1(k_t, z_t)$$

and

$$k_{t+1} = d^2(k_t, z_t),$$

[u] Convergence of the coefficients is geometric if $\lim_{j\to\infty} \log(|\theta_j|)/j = \text{constant}$. If the lim is infinity, convergence is supergeometric; if the lim is zero, convergence is subgeometric.

we could, instead, search for

$$\log c_t = d^1(\log k_t, z_t)$$

and

$$\log k_{t+1} = d^2(\log k_t, z_t),$$

by defining

$$\log c_t = d^{1,j}\left(\log k_t, z_t|\theta^1\right) = \sum_{i=0}^{j} \theta_i^1 \psi_i(\log k_t, z_t)$$

and

$$\log k_{t+1} = d^{2,j}\left(\log k_t, z_t|\theta^2\right) = \sum_{i=0}^{j} \theta_i^2 \psi_i(\log k_t, z_t).$$

In fact, even in the basic projection example above, we already have a taste of this idea, as we used z_t as a state variable, despite the fact that it appears in the production function as e^{z_t}. An alternative yet equivalent reparameterization writes $A_t = e^{z_t}$ and $z_t = \log A_t$. The researcher can use her a priori knowledge of the model (or preliminary computational results) to search for an appropriate change of variables in her problem. We have changed both state and control variables, but nothing forced us to do so: we could have just changed one variable but not the other or employed different changes of variables.

Remark 20 (Boyd's moral principle)

All of the conveniences of Chebyshev polynomials we just presented are not just theoretical. Decades of real-life applications have repeatedly shown how well Chebyshev polynomials work in a wide variety of applications. In the case of DSGE models, the outstanding performance of Chebyshev polynomial has been shown by Aruoba et al. (2006) and Caldara et al. (2012). Boyd (2000, p. 10), only half-jokingly, has summarized these decades of experience in what he has named his Moral Principle 1:

1. When in doubt, use Chebyshev polynomials unless the solution is spatially periodic, in which case an ordinary Fourier series is better.
2. Unless you are sure another set of basis functions is better, use Chebyshev polynomials.
3. Unless you are really, really sure another set of basis functions is better, use Chebyshev polynomials.

5.3.2 Multidimensional Bases

All of the previous discussion presented unidimensional basis functions. This was useful to introduce the topic. However, most problems in economics are multidimensional: nearly all DSGE models involve several state variables. How do we generalize our basis functions?

The answer to this question is surprisingly important. Projection methods suffer from an acute curse of dimensionality. While solving DSGE models with one or two state variables and projection methods is relatively straightforward, solving DSGE models with 20 state variables and projection methods is a challenging task due to the curse of dimensionality. The key to tackling this class of problems is to intelligently select the multidimensional basis.

5.3.2.1 Discrete State Variables

The idea that the state variables are continuous was implicit in our previous discussion. However, there are many DSGE models where either some state variable is discrete (ie, the government can be in default or not, as in Bocola (2015), or monetary policy can be either active or passive in the sense of Leeper, 1991) or where we can discretize one continuous state variable without losing much accuracy. The best example of the latter is the discretization of exogenous stochastic processes for productivity or preference shocks. Such discretization can be done with the procedures proposed by Tauchen (1986) or Kopecky and Suen (2010), who find a finite state Markov chain that generates the same population moments as the continuous process. Experience suggests that, in most applications, a Markov chain with 5 or 7 states suffices to capture nearly all the implications of the stochastic process for quantitative analysis.

A problem with discrete state variables can be thought of as one where we search for a different decision rule for each value of that state variable. For instance, in the stochastic neoclassical growth model with state variables k_t and z_t, we can discretize the productivity level z_t into a Markov chain with n points

$$z_t \in \{z_1, .., z_n\}$$

and transition matrix:

$$P_{z,z'} = \left\{ \begin{array}{ccc} p_{11} & \cdots & p_{1n} \\ \vdots\ddots & \vdots & \\ p_{n1} & \cdots & p_{nn} \end{array} \right\} \tag{35}$$

where entry p_{ij} is the probability that the chain will move from position i in the current period to position j in the next period.

Remark 21 (Discretization methods) Tauchen (1986) procedure to discretize an AR(1) stochastic process

$$z_t = \rho z_{t-1} + \epsilon_t$$

with stationary distribution $N(0, \sigma_z^2)$, where $\sigma_z = \frac{\sigma_\epsilon}{\sqrt{1-\rho^2}}$, works as follows:

Algorithm 2 (AR(1) Discretization)

1. Set n, the number of potential realizations of the process z.
2. Set the upper ($\bar{z}$) and lower ($\underline{z}$) bounds for the process. An intuitive way to set the bounds is to pick m such that:

$$\bar{z} = m\sigma_z$$
$$\underline{z} = -m\sigma_z$$

   The latter alternative is appealing given the symmetry of the normal distribution around 0. Usual values of m are between 2 and 3.
3. Set $\{z_i\}_{i=1}^{n}$ such that:

$$z_i = \underline{z} + \frac{\bar{z} - \underline{z}}{n-1}(i-1)$$

   and construct the midpoints $\{\tilde{z}_i\}_{i=1}^{n-1}$, which are given by:

$$\tilde{z}_i = \frac{z_{i+1} + z_i}{2}$$

4. The transition probability $p_{ij} \in P_{z,z'}$ (the probability of going to state z_j conditional on being on state z_i), is computed according to:

$$p_{ij} = \Phi\left(\frac{\tilde{z}_j - \rho z_i}{\sigma}\right) - \Phi\left(\frac{\tilde{z}_{j-1} - \rho z_i}{\sigma}\right) \qquad j = 2,3,\ldots,n-1$$

$$p_{i1} = \Phi\left(\frac{\tilde{z}_1 - \rho z_i}{\sigma}\right)$$

$$p_{in} = 1 - \Phi\left(\frac{\tilde{z}_{n-1} - \rho z_i}{\sigma}\right)$$

   where $\Phi(\cdot)$ denotes a CDF of a $N(0,1)$.

To illustrate Tauchen's procedure, let us assume we have a stochastic process:

$$z_t = 0.95 z_{t-1} + \epsilon_t$$

with $N(0,0.007^2)$ (this is a standard quarterly calibration for the productivity process for the US economy; using data after 1984 the standard deviation is around 0.0035) and we want to approximate it with a 5-point Markov chain and $m = 3$. Tauchen's procedure gives us:

$$z_t \in \{-0.0673, -0.03360, 0.0336, 0.0673\} \tag{36}$$

and transition matrix:

$$P_{z,z'} = \left\{ \begin{array}{ccccc} 0.9727 & 0.0273 & 0 & 0 & 0 \\ 0.0041 & 0.9806 & 0.0153 & 0 & 0 \\ 0 & 0.0082 & 0.9837 & 0.0082 & 0 \\ 0 & 0 & 0.0153 & 0.9806 & 0.0041 \\ 0 & 0 & 0 & 0.0273 & 0.9727 \end{array} \right\} \tag{37}$$

Note how the entries in the diagonal are close to 1 (the persistence of the continuous stochastic process is high) and that the probability of moving two or more positions is zero. It would take at least 4 quarters for the Markov chain to travel from z_1 to z_5 (and vice versa).

Tauchen's procedure can be extended to VAR processes instead of an AR process. This is convenient because we can always rewrite a general ARMA(p,q) process as a VAR(1) (and a VAR(p) as a VAR(1)) by changing the definition of the state variables. Furthermore, open source implementations of the procedure exist for all major programming languages.

Kopecky and Suen (2010) show that an alternative procedure proposed by Rouwenhorst (1995) is superior to Tauchen's method when ρ, the persistence of the stochastic process, is close to 1. The steps of Rouwenhorst (1995)'s procedure are:

Algorithm 3 (Alternative AR(1) Discretization)

1. Set n, the number of potential realizations of the process z.

2. Set the upper ($\bar{z}$) and lower ($\underline{z}$) bounds for the process. Let $\underline{z} = -\lambda$ and $\bar{z} = \lambda$. λ can be set to be $\lambda = \sqrt{n-1}\sigma_z$.

3. Set $\{z_i\}_{i=1}^{n}$ such that:

$$z_i = \underline{z} + \frac{\bar{z} - \underline{z}}{n-1}(i-1)$$

4. When $n = 2$, let P_2 be given by:

$$P_2 = \begin{bmatrix} p & 1-p \\ 1-q & q \end{bmatrix}$$

p, q can be set to be $p = q = \dfrac{1+\rho}{2}$.

5. For $n \geq 3$, construct recursively the transition matrix:

$$P_n = p\begin{bmatrix} P_{n-1} & \mathbf{0} \\ \mathbf{0}' & 0 \end{bmatrix} + (1-p)\begin{bmatrix} \mathbf{0} & P_{n-1} \\ 0 & \mathbf{0}' \end{bmatrix} + (1-q)\begin{bmatrix} \mathbf{0}' & 0 \\ P_{n-1} & \mathbf{0} \end{bmatrix} + q\begin{bmatrix} 0 & \mathbf{0}' \\ \mathbf{0} & P_{n-1} \end{bmatrix}$$

where $\mathbf{0}$ is an $(n-1) \times 1$ column vector of zeros. Divide all but the top and bottom rows by 2 so that the sum of the elements of each row is equal to 1. The final outcome is $P_{z,z'}$.

Once productivity has been discretized, we can search for

$$\begin{aligned} c(k,z_m) &= d^{c,m,j}(k|\theta^{m,c}) = \sum_{i=0}^{j} \theta_i^{m,c}\psi_i(k) \\ k(k,z_m) &= d^{k,m,j}\left(k|\theta^{m,k}\right) = \sum_{i=0}^{j} \theta_i^{m,k}\psi_i(k) \end{aligned}$$

where $m = 1,\ldots,n$. That is, we search for decision rules for capital and consumption when productivity is z_1 today, decision rules for capital and consumption when productivity is z_2 today, and so on, for a total of $2 \times n$ decision rules. Since n is usually a small number (we mentioned above 5 or 7), the complexity of the problem is not exploding.

Note that since we substitute these decision rules in the Euler equation:

$$u'(c_t) = \beta\mathbb{E}_t\left[u'(c_{t+1})\left(\alpha e^{z_{t+1}}k_{t+1}^{\alpha-1} + 1 - \delta\right)\right]. \tag{38}$$

to get:

$$u'\left(d^{c,m,j}(k|\theta^{m,c})\right) = \\ \beta\sum_{l=0}^{n} p_{ml}\left[u'\left(d^{c,l,j}\left(d^{k,m,j}\left(k|\theta^{m,k}\right)\big|\theta^{l,c}\right)\right)\left(\alpha e^{z_{t+1}}\left(d^{k,m,j}\left(k|\theta^{m,k}\right)\right)_{t+1}^{\alpha-1} + 1 - \delta\right)\right]$$

we are still taking account of the fact that productivity can change in the next period (and hence, consumption and capital accumulation will be determined by the decision rule for the next period level of productivity). Also, since now the stochastic process is discrete, we can substitute the integral on the right-hand side of Eq. (38) for the much simpler sum operator with the probabilities from the transition matrix (35). Otherwise, we would need to use a quadrature method to evaluate the integral (see Judd, 1998 for the relevant formulae and the proposal in Judd et al., 2011a).

Thus, discretization of state variables such as the productivity shock is more often than not an excellent strategy to deal with multidimensional problems: simple, transparent, and not too burdensome computationally. Furthermore, we can discretize some of the state variables and apply the methods in the next paragraphs to deal with the remaining continuous state variables. In computation, mixing of strategies is often welcomed.

5.3.2.2 Tensors

Tensors build multidimensional basis functions by finding the Kronecker product of all unidimensional basis functions.[v] Imagine, for example, that we have two state variables,

[v] One should not confuse the tensors presented here with the tensor notation used for perturbation methods. While both situations deal with closely related mathematical objects, the key when we were dealing with perturbation was the convenience that tensor notation offered.

physical capital k_t and human capital h_t. We have three Chebyshev polynomials for each of these two state variables:

$$\psi_0^k(k_t), \psi_1^k(k_t), \text{ and } \psi_2^k(k_t)$$

and

$$\psi_0^h(h_t), \psi_1^h(h_t), \text{ and } \psi_2^h(h_t).$$

Then, the tensor is given by:

$$\begin{aligned}&\psi_0^k(k_t)\psi_0^h(h_t), \psi_0^k(k_t)\psi_1^h(h_t), \psi_0^k(k_t)\psi_2^h(h_t),\\&\psi_1^k(k_t)\psi_0^h(h_t), \psi_1^k(k_t)\psi_1^h(h_t), \psi_1^k(k_t)\psi_2^h(h_t),\\&\psi_2^k(k_t)\psi_2^h(h_t), \psi_2^k(k_t)\psi_1^h(h_t), \text{ and } \psi_2^k(k_t)\psi_2^h(h_t).\end{aligned}$$

More formally, imagine that we want to approximate a function of n state variables $d:[-1,1]^n \rightarrow \mathbb{R}$ with Chebyshev polynomial of degree j. We build the sum:

$$d^j(\cdot|\theta) = \sum_{i_1=0}^{j} \cdots \sum_{i_n=0}^{j} \theta_{i_1,\ldots,i_n} \psi_{i_1}^1(\cdot) * \ldots * \psi_{i_n}^n(\cdot)$$

where $\psi_{i_\kappa}^\kappa$ is the Chebyshev polynomials of degree i_κ on the state variable κ and θ is the vector of coefficients $\theta_{i_1,\ldots,i_n}$. To make the presentation concise, we have made three simplifying assumptions. First, we are dealing with the case that d is one dimensional. Second, we are using the same number of Chebyshev polynomials for each state variable. Three, the functions $\psi_{i_\kappa}^\kappa$ could be different from the Chebyshev polynomials and belong to any basis we want (there can even be a different basis for each state variable). Eliminating these simplifications is straightforward, but notationally cumbersome.

There are two main advantages of a tensor basis. First, it is trivial to build. Second, if the one-dimensional basis is orthogonal, then the tensor basis is orthogonal in the product norm. The main disadvantage is the exponential growth in the number of coefficients $\theta_{i_1,\ldots,i_n}$: $(j+1)^n$. In the example above, even using only three Chebyshev polynomials (ie, $j = 2$) for each of these two state variables, we end up having to solve for nine coefficients. This curse of dimensionality is acute: with five state variables and three Chebyshev polynomials, we end up with 243 coefficients. With ten Chebyshev polynomials, we end up with 100,000 coefficients.

5.3.2.3 Complete Polynomials

In practice, it is infeasible to use tensors when we are dealing with models with more than 3 continuous state variables and a moderate j. A solution is to eliminate some elements of the tensor in a way that avoids much numerical degradation. In particular, Gaspar and Judd (1997) propose using the complete polynomials:

$$\mathcal{P}_\kappa^n \equiv \left\{\psi_{i_1}^1 * \ldots * \psi_{i_n}^n \text{ with } |\mathbf{i}| \leq \kappa\right\}$$

where

$$|\mathbf{i}| = \sum_{l=1}^{n} i_l, 0 \leq i_1, \ldots, i_n.$$

Complete polynomials, instead of employing all the elements of the tensor, keep only those such that the sum of the order of the basis functions is less than a prefixed κ. The intuition is that the elements of the tensor $\psi_{i_1}^{1} * \ldots * \psi_{i_n}^{n}, |\mathbf{i}| > \kappa$ add little additional information to the basis: most of the flexibility required to capture the behavior of d is already in the complete polynomials. For instance, if we are dealing with three state variables and Chebyshev polynomials $j = 4$, we can keep the complete polynomials of order 6:

$$\mathcal{P}_6^3 \equiv \left\{ \psi_{i_1}^{1} * \ldots * \psi_{i_n}^{n} \text{ with } |\mathbf{i}| \leq 6 \right\}.$$

Complete polynomials eliminate many coefficients: in our example, instead of $(4 + 1)^3 = 125$ coefficients of the tensor, when $\kappa = 6$ we only need to approximate 87 coefficients. Unfortunately, we still need too many coefficients. In Section 5.7, we will present an alternative: Smolyak's algorithm. However, since the method requires the introduction of a fair amount of new notation and the presentation of the notion of interpolating polynomials, we postpone the discussion and, instead, start analyzing the finite element methods.

5.4 Finite Elements

Finite elements techniques, based on local basis functions, were popularized in economics by McGrattan (1996) (see, also, Hughes (2000), for more background, and Brenner and Scott (2008), for all the mathematical details that we are forced to skip in a handbook chapter). The main advantage of this class of basis functions is they can easily capture local behavior and achieve a tremendous level of accuracy even in the most challenging problems. That is why finite element methods are often used in mission-critical design in industry, such as in aerospace or nuclear power plant engineering. The main disadvantage of finite elements methods is that they are hard to code and expensive to compute. Therefore, we should choose this strategy when accuracy is more important than speed of computation or when we are dealing with complicated, irregular problems.

Finite elements start by bounding the domain $\mathbf{\Omega}$ of the state variables. Some of the bounds would be natural (ie, $k_t > 0$). Other bounds are not ($k_t < \bar{k}$) and we need some care in picking them. For example, we can guess a $\bar{k}$ sufficiently large such that, in the simulations of the model, k_t never reaches $\bar{k}$. This needs, however, to be verified and some iterative fine-tuning may be required.[w]

[w] Even if the simulation rarely reaches $\bar{k}$, it may be useful to repeat the computation with a slightly higher bound $\omega\bar{k}$, with $\omega > 1$, to check that we still do not get to $\bar{k}$. In some rare cases, the first simulation might not have reached $\bar{k}$ because the approximation of the function $d(\cdot)$ precluded traveling into that region.

The second step in the finite elements method is to partition Ω into small, nonintersecting elements. These small sections are called elements (hence the name, "finite elements"). The boundaries of the elements are called nodes. The researcher enjoys a fantastic laxity in selecting the partition. One natural partition is to divide Ω into equal elements: simple and direct. But elements can be of unequal size. More concretely, we can have small elements in the areas of Ω where the economy will spend most of the time, while just a few large elements will cover areas of Ω infrequently visited (these areas can be guessed based on the theoretical properties of the model, or they can be verified by an iterative procedure of element partition; we will come back to this point below). Or we can have small elements in the areas of Ω where the function $d(\cdot)$ we are looking for changes quickly in shape, while we reserve large elements for areas of Ω where the function d is close to linear. Thanks to this flexibility in the element partition, we can handle kinks or constraints, which are harder to tackle with spectral methods (or next to impossible to do with perturbation, as they violate differentiability conditions).[x]

An illustration of such capability appears in Fig. 7, where we plot the domain Ω of a dynamic model of a firm with two state variables, bonds b_t on the x-axis (values to the right denote positive bond holdings by the firm and values to the left negative bond holdings), and capital k_t on the y-axis. The domain Ω does not include an area in the lower left corner, of combinations of negative bond holdings (ie, debt) and low capital. This area is excluded because of a financial constraint: firms cannot take large amounts of debt when

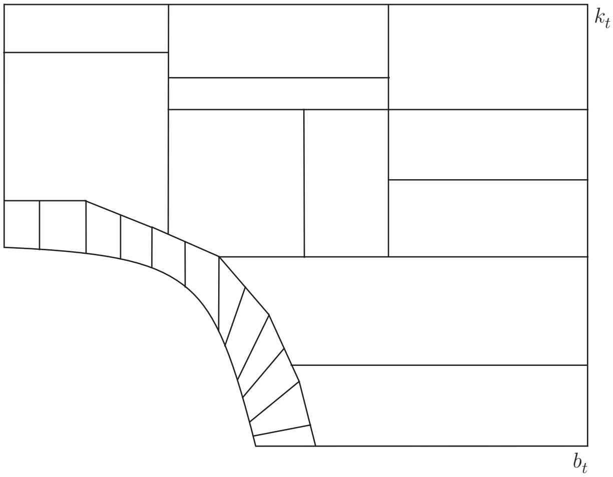

Fig. 7 Two-dimensional element grid.

[x] This flexibility in the definition of the elements is a main reason why finite elements methods are appreciated in industry, where applications often do not conform to the regularity technical conditions required by perturbation or spectral techniques.

they do not have enough capital to use as collateral (the concrete details of this financial constraint or why the shape of the restricted area is the one we draw are immaterial for the argument). In Fig. 7, the researcher has divided the domain Ω into unequal elements: there are many of them, of small size, close to the lower left corner boundary. One can suspect that the decision rule for the firm for b_t and k_t may change rapidly close to the frontier or, simply, the researcher wants to ensure the accuracy of the solution in that area. Farther away from the frontier, elements become larger. But even in those other regions, the researcher can partition the domain Ω with very different elements, some smaller (high levels of debt and k_t), some larger (high levels of b_t and k_t), depending on what the researcher knows about the shape of the decision rule.

There is a whole area of research concentrated on the optimal generation of an element grid that we do not have space to review. The interested reader can check Thompson et al. (1985). For a concrete application of unequal finite elements to the stochastic neoclassical growth model to reduce computational time, see Fernández-Villaverde and Rubio-Ramírez (2004).

The third step in the finite elements method is to choose a basis for the policy functions in each element. Since the elements of the partition of Ω are usually small, a linear basis is often good enough. For instance, letting $\{k_0, k_1, \ldots, k_j\}$ be the nodes of a partition of Ω into elements, we can define the tent functions for $i \in \{1, j-1\}$

$$\psi_i(k) = \begin{cases} \dfrac{k - k_{i-1}}{k_i - k_{i-1}}, \text{ if } x \in [k_{i-1}, k_i] \\ \dfrac{k_{i+1} - k}{k_{i+1} - k_i}, \text{ if } k \in [k_i, k_{i+1}] \\ 0 \quad \text{elsewhere} \end{cases}$$

and the corresponding adjustments for the first function:

$$\psi_0(k) = \begin{cases} \dfrac{k_0 - k}{k_1 - k_0}, \text{ if } x \in [k_0, k_1] \\ 0 \quad \text{elsewhere} \end{cases}$$

and the last one

$$\psi_j(k) = \begin{cases} \dfrac{k - k_{j-1}}{k_j - k_{j-1}}, \quad \text{if } k \in [k_i, k_{i+1}] \\ 0 \quad \text{elsewhere.} \end{cases}$$

We plot examples of these tent functions in Fig. 8.

We can extend this basis to higher dimensions by either discretizing some of the state variables (as we did when we talked about spectral bases) or by building tensors of them. Below, we will also see how to use Smolyak's algorithm with finite elements.

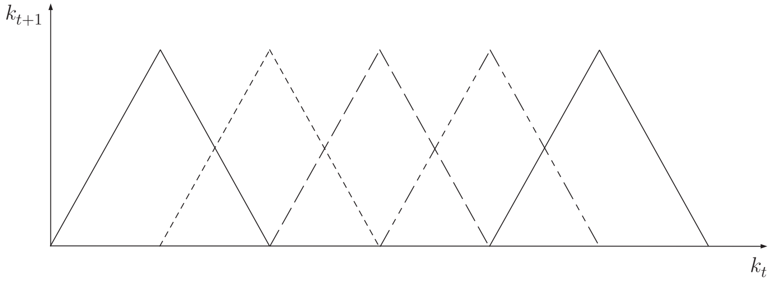

Fig. 8 Five basis functions.

The fourth step in the finite elements method is the same as for any other projection method: we build

$$d^{n,j}(\cdot|\theta^n) = \sum_{i=0}^{j} \theta_i^n \psi_i(\cdot)$$

and we plug them into the operator $\mathcal{H}$. Then, we find the unknown coefficients as we would do with Chebyshev polynomials.

By construction, the different parts of the approximating function will be pasted together to ensure continuity. For example, in our Fig. 8, there are two basis functions in the element defined by the nodes k_i and k_{i+1}

$$\psi_i(k) = \frac{k_{i+1} - k}{k_{i+1} - k_i}$$

$$\psi_{i+1}(k) = \frac{k - k_i}{k_{i+1} - k_i}$$

and their linear combination (ie, the value of $d^{n,j}(\cdot|\theta^n)$ in that element) is:

$$\hat{d}\left(k|k_{i+1}, k_i, \theta_{i+1}^n, \theta_i^n\right) = \theta_i^n \frac{k_{i+1} - k}{k_{i+1} - k_i} + \theta_{i+1}^n \frac{k - k_i}{k_{i+1} - k_i} = \frac{\left(\theta_{i+1}^n - \theta_i^n\right)k + \theta_i^n k_{i+1} - \theta_{i+1}^n k_i}{k_{i+1} - k_i},$$

which is a linear function, with positive or negative slope depending on the sign of $\theta_{i+1}^n - \theta_i^n$. Also note that the value of $d^{n,j}(\cdot|\theta^n)$ in the previous element is the linear function:

$$\hat{d}\left(k|k_i, k_{i-1}, \theta_i^n, \theta_{i-1}^n\right) = \frac{\left(\theta_i^n - \theta_{i-1}^n\right)k + \theta_{i-1}^n k_i - \theta_i^n k_{i-1}}{k_i - k_{i-1}}.$$

When we evaluate both linear functions at k_i

$$\hat{d}\left(k_i|k_i, k_{i-1}, \theta_i^n, \theta_{i-1}^n\right) = \theta_i^n$$

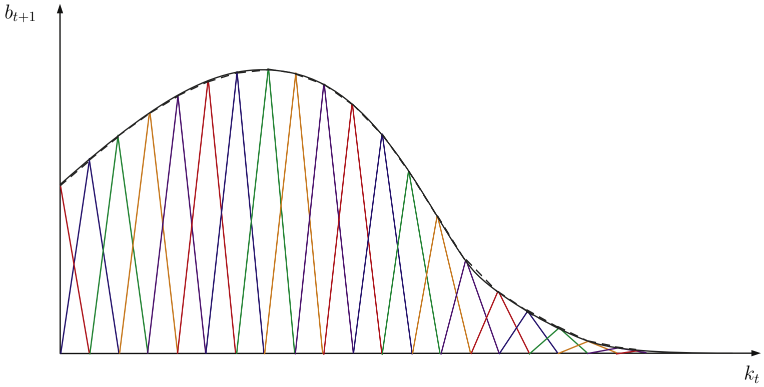

Fig. 9 Finite element approximation.

and

$$\hat{d}\left(k_i|k_{i+1},k_i,\theta^n_{i+1},\theta^n_i\right)=\theta^n_i$$

that is, both functions have the same value equal to the coefficient θ^n_i, which ensures continuity (although, with only tent functions, we cannot deliver differentiability).

The previous derivation also shows why finite elements are a smart strategy. Imagine that our metric ρ is such that we want to make the residual function equal to zero in the nodes of the elements (below we will present a metric like this one). With our tent functions, this amounts to picking, at each k_i, the coefficient θ^n_i such that the approximating and exact function coincide:

$$d^{n,j}(\cdot|\theta^n)=d^n(\cdot).$$

This implies that the value of d^n outside k_i are irrelevant for our choice of θ^n_i. An example of such piecewise linear approximation to a decision rule for the level of debt tomorrow, b_{t+1}, given capital today, k_t, in a model of financial frictions, is drawn in Fig. 9. The discontinuous line is the approximated decision rule and the continuous line the exact one. The tent functions are multiplied by the coefficients to make the approximation and the exact solution equal at the node points. We can appreciate an already high level of accuracy. As the elements become smaller and smaller, the approximation will become even more accurate (ie, smooth functions are locally linear).

This is a stark example of a more general point: the large system of nonlinear equations that we will need to solve in a finite element method will be sparse, a property that can be suitably exploited by modern nonlinear solvers.

Remark 22 (Finite elements method refinements) An advantage of the finite elements method is that we can refine the solution that we obtain as much as we desire (with only the constraints of computational time and memory). The literature distinguishes among three different refinements. First, we have the *h-refinement*. This scheme subdivides each element into smaller elements to improve resolution uniformly over the domain. That is, once we have obtained a first solution, we check whether this solution achieves the desired level of accuracy. If it does not, we go back to our partition, and we subdivide the elements. We can iterate in this procedure as often as we need. Second, we have *r-refinement*: This scheme subdivides each element only in those regions where there are high nonlinearities. Third, we have the *p-refinement*: This scheme increases the order of the approximation in each element, that is, it adds more basis functions (for example, several Chebyshev polynomials). If the order of the expansion is high enough, we generate a hybrid of finite and spectral methods known as spectral elements. This approach has gained much popularity in the natural sciences and engineering. See, for example, Solín et al. (2004).

Sometimes, *h-refinements* and *p-refinements* are mixed in what is known as the hp-finite element method, which delivers exponential convergence to the exact solution. Although difficult to code and computationally expensive, an hp-finite element method is, perhaps, the most powerful solution technique available for DSGE models, as it can tackle even the most challenging problems.[y]

The three refinements can be automatically implemented: we can code the finite element algorithm to identify the regions of Ω where, according to some goal of interest (for example, how tightly a Euler equation is satisfied), we refine the approximation without further input from the researcher. See Demkowicz (2007).

5.5 Objective Functions

Our second choice is to select a metric function ρ to determine how we "project." The most common answer to this question is given by a *weighted residual*: we select θ to get the residual close to 0 in the weighted integral sense. Since we did not impose much structure on the operator $\mathcal{H}$ and therefore, on the residual function $R(\cdot|\theta)$, we will deal with the simplest case where $R(\cdot|\theta)$ is unidimensional. More general cases can be dealt with at the cost of heavier notation. Given some weight functions $\phi_i : \Omega \to \mathbb{R}$, we define the metric:

$$\rho(R(\cdot|\theta),0)=\begin{cases}0 & \text{if } \int_\Omega \phi_i(\mathbf{x})R(\cdot|\theta)d\mathbf{x}=0,\, i=1,..,j+1\\ 1 & \text{otherwise}\end{cases}$$

[y] An additional, new refinement is the extended finite element method (x-fem), which adds to the basis discontinuous functions that can help in capturing irregularities in the solution. We are not aware of applications of the x-fem in economics.

Hence, the problem is to choose the θ that solves the system of integral equations:

$$\int_{\Omega} \phi_i(\mathbf{x}) R(\cdot|\theta) d\mathbf{x} = 0, i = 1,..,j+1. \tag{39}$$

Note that, for the system to have a solution, we need $j + 1$ weight functions. Thanks to the combination of approximating the function d by basis functions ψ_i and the definition of weight functions ϕ_i, we have transformed a rather intractable functional equation problem into a standard nonlinear equations system. The solution of this system can be found using standard methods, such as a Newton algorithm for small problems or a Levenberg–Marquardt method for bigger ones.

However, the system (39) may have no solution or it may have multiple ones. We know very little about the theoretical properties of projection methods in economic applications. The literature in applied mathematics was developed for the natural sciences and engineering and many of the technical conditions required for existence and convergence theorems to work do not easily travel across disciplines. In fact, some care must be put into ensuring that the solution of the system (39) satisfies the transversality conditions of the DSGE model (ie, we are picking the stable manifold). This can usually be achieved with the right choice of an initial guess θ_0 or by adding boundary conditions to the solver.

As was the case with the bases, we will have plenty of choices for our weight functions. Instead of reviewing all possible alternatives, we will focus on the most popular ones in economics.

5.5.1 Weight Function I: Least Squares

Least squares use as weight functions the derivatives of the residual function:

$$\phi_i(\mathbf{x}) = \frac{\partial R(\mathbf{x}|\theta)}{\partial \theta_{i-1}}$$

for all $i \in 1,..,j + 1$. This choice is motivated by the variational problem:

$$\min_{\theta} \int_{\Omega} R^2(\cdot|\theta) d\mathbf{x}$$

with first-order condition:

$$\int_{\Omega} \frac{\partial R(\mathbf{x}|\theta)}{\partial \theta_{i-1}} R(\cdot|\theta) d\mathbf{x} = 0, i = 1,..,j+1.$$

This variational problem is mathematically equivalent to a standard regression problem in econometrics.

While least squares are intuitive and there are algorithms that exploit some of their structure to increase speed and decrease memory requirements, they require the computation of the derivative of the residual, which can be costly. Also, least squares problems are often ill-conditioned and complicated to solve numerically.

5.5.2 Weight Function II: Subdomain

The subdomain approach divides the domain $\boldsymbol{\Omega}$ into 1,..,j + 1 subdomains $\boldsymbol{\Omega}_i$ and define the j + 1 step functions:

$$\phi_i(\mathbf{x}) = \begin{cases} 1 & \text{if } \mathbf{x} \in \boldsymbol{\Omega}_i \\ 0 & \text{otherwise} \end{cases}$$

This choice is equivalent to solving the system:

$$\int_{\Omega_i} R(\cdot|\theta)d\mathbf{x} = 0, i = 1, .., j+1.$$

The researcher has plenty of flexibility to pick her subdomains as to satisfy her criteria of interest.

5.5.3 Weight Function III: Collocation

This method is also known as pseudospectral or the method of selected points. It defines the weight function as:

$$\phi_i(\mathbf{x}) = \delta(\mathbf{x} - \mathbf{x}_i)$$

where δ is the Dirac delta function and $\mathbf{x}_i$ are the j + 1 collocation points selected by the researcher.

This method implies that the residual function is zero at the n collocation points. Thus, instead of having to compute complicated integrals, we only need to solve the system:

$$R(\mathbf{x}_i|\theta) = 0, i = 1, .., j+1.$$

This is attractive when the operator $\mathcal{H}$ generates large nonlinearities.

A systematic way to pick collocation points is to use the zeros of the $(j+1)$-th-order Chebyshev polynomial in each dimension of the state variable (or the corresponding polynomials, if we are using different approximation orders along each dimension). This approach is known as orthogonal collocation. The Chebyshev interpolation theorem tells us that, with this choice of collocation points, we can achieve $\mathcal{L}_p$ convergence and sometimes even uniform convergence to the unknown function d. Another possibility is to pick, as collocation points, the extrema of the j-th-order Chebyshev polynomial in each dimension. Experience shows a surprisingly good performance of orthogonal collocation methods and it is one of our recommended approaches.

5.5.4 Weight Function IV: Galerkin or Rayleigh–Ritz

The last weight function we consider is the Galerkin (also called Rayleigh–Ritz when it satisfies some additional properties of less importance for economists). This approach takes as the weight function the basis functions used in the approximation:

$$\phi_i(\mathbf{x}) = \psi_{i-1}(\mathbf{x}).$$

Then we have:

$$\int_{\Omega} \psi_i(\mathbf{x}) R(\cdot|\theta) d\mathbf{x} = 0, i = 1, .., j+1.$$

The interpretation is that the residual has to be orthogonal to each of the basis functions.

The Galerkin approach is highly accurate and robust, but difficult to code. If the basis functions are complete over J_1 (they are indeed a basis of the space), then the Galerkin solution will converge pointwise to the true solution as n goes to infinity:

$$\lim_{j \to \infty} d^j(\cdot|\theta) = d(\cdot)$$

Also, practical experience suggests that a Galerkin approximation of order j is as accurate as a pseudospectral $j+1$ or $j+2$ expansion.

In the next two remarks, we provide some hints for a faster and more robust solution of the system of nonlinear equations:

$$\int_{\Omega} \phi_i(\mathbf{x}) R(\cdot|\theta) d\mathbf{x} = 0, i = 1, .., j+1, \tag{40}$$

a task that can be difficult if the number of coefficients is large and the researcher does not have a good initial guess θ_0 for the solver.

Remark 23 (Transformations of the problem) A bottleneck for the solution of (39) can be the presence of strong nonlinearities. Fortunately, it is often the case that simple changes in the problem can reduce these nonlinearities. For example, Judd (1992) proposes that if we have an Euler equation:

$$\frac{1}{c_t} = \beta \mathbb{E}_t \left\{ \frac{1}{c_{t+1}} R_{t+1} \right\}$$

where R_{t+1} is the gross return rate of capital, we can take its inverse:

$$\beta c_t = \left(\mathbb{E}_t \left\{ \frac{1}{c_{t+1}} R_{t+1} \right\} \right)^{-1},$$

which now is linear on the left-hand side and much closer to linear on the right-hand side. Thus, instead of computing the residual for some state variable x_t

$$R(\cdot|\theta) = \frac{1}{c(x_t|\theta)} - \beta \mathbb{E}_t \left\{ \frac{1}{c(x_t|\theta)} R_{t+1}(x_t|\theta) \right\},$$

we compute:

$$\widetilde{R}(\cdot|\theta) = \beta c(x_t|\theta) - \left(\mathbb{E}_t \left\{ \frac{1}{c(x_t|\theta)} R_{t+1}(x_t|\theta) \right\} \right)^{-1}.$$

Similar algebraic manipulations are possible in many DSGE models.

Remark 24 (Multistep schemes) The system (39) can involve a large number of coefficients. A natural strategy is to solve first a smaller system and to use that solution as an input for a larger system. This strategy, called a multistep scheme, often delivers excellent results, in particular when dealing with orthogonal bases such as Chebyshev polynomials.

More concretely, instead of solving the system for an approximation with $j+1$ basis functions, we can start by solving the system with only $j'+1 \ll j+1$ basis functions and use the solution to this first problem as a guess for the more complicated problem. For example, if we are searching for a solution with 10 Chebyshev polynomials and m dimensions, we first find the approximation with only 3 Chebyshev polynomials. Therefore, instead of solving a system of $10 \times m$ equations, we solve a system of $3 \times m$. Once we have the solution θ^3, we build the initial guess for the problem with 10 Chebyshev polynomials as:

$$\theta_0 = \left[\theta^3, \mathbf{0}_{1\times m}, \ldots, \mathbf{0}_{1\times m}\right],$$

that is, we use θ^3 for the first coefficients and zero for the additional new coefficients. Since the additional polynomials are orthogonal to the previous ones, the final values of the coefficients associated with the three first polynomials will change little with the addition of 7 more polynomials: the initial guess θ^3 is, thus, most splendid. Also, given the fast convergence of Chebyshev polynomials, the coefficients associated with higher-order polynomials will be close to zero. Therefore, our initial guess for those coefficients is also informative.

The researcher can use as many steps as she needs. By judiciously coding the projection solver, the researcher can write the program as depending on an abstract number of Chebyshev polynomials. Then, she can call the solver inside a loop and iteratively increase the level of approximation from j' to j as slow or as fast as required.

5.6 A Worked-Out Example

We present now a worked-out example of how to implement a projection method in a DSGE model. In particular, we will use Chebyshev polynomials and orthogonal collocation to solve the stochastic neoclassical growth model with endogenous labor supply.

In this economy, there is a representative household, whose preferences over consumption, c_t, and leisure, $1 - l_t$, are representable by the utility function:

$$\mathbb{E}_0 \sum_{t=1}^{\infty} \beta^{t-1} \frac{\left(c_t^{\tau}(1-l_t)^{1-\tau}\right)^{1-\eta}}{1-\eta}$$

where $\beta \in (0,1)$ is the discount factor, η controls the elasticity of intertemporal substitution and risk aversion, τ controls labor supply, and $\mathbb{E}_0$ is the conditional expectation operator.

There is one good in the economy, produced according to the aggregate production function:

$$y_t = e^{z_t} k_t^{\alpha} l_t^{1-\alpha}$$

where k_t is the aggregate capital stock, l_t is aggregate labor, and z_t is a stochastic process for technology:

$$z_t = \rho z_{t-1} + \epsilon_t$$

with $|\rho| < 1$ and $\epsilon_t \sim N(0, \sigma^2)$. Capital evolves according to:

$$k_{t+1} = (1-\delta)k_t + i_t$$

and the economy must satisfy the resource constraint $y_t = c_t + i_t$.

Since both welfare theorems hold in this economy, we solve directly for the social planner's problem:

$$\begin{gathered} V(k_t, z_t) = \max_{c_t, l_t} \frac{\left(c_t^{\tau}(1-l_t)^{1-\tau}\right)^{1-\eta}}{1-\eta} + \beta \mathbb{E}_t V(k_{t+1}, z_{t+1}) \\ \text{s.t. } k_{t+1} = e^{z_t} k_t^{\alpha} l_t^{1-\alpha} + (1-\delta)k_t - c_t \\ z_t = \rho z_{t-1} + \epsilon_t \end{gathered}$$

given some initial conditions k_0 and z_0. Tackling the social planner's problem is only done for convenience, and we could also solve for the competitive equilibrium. In fact, one key advantage of projection methods is that they easily handle non-Pareto efficient economies.

We calibrate the model with standard parameter values to match US quarterly data (see Table 2). The only exception is η, for which we pick a value of 5, in the higher range of empirical estimates. Such high-risk aversion induces, through precautionary behavior, more curvature in the decision rules. This curvature would present a more challenging test bed for the projection method.

We discretize z_t into a 5-point Markov chain $\{z_1, \ldots, z_5\}$ using Tauchen's procedure and covering ±3 unconditional standard deviations of z_t (this is the same Markov chain as

Table 2 Calibration

Parameter	Value
β	0.991
η	5.000
τ	0.357
α	0.300
δ	.0196
ρ	0.950
σ	0.007

the example in Remark 21, see (36) and (37) for the concrete values of the discretization). We will use p_{mn} to denote the generic entry of the transition matrix $P_{z,z'}$ generated by Tauchen's procedure for z_m today moving to z_n next period.

Then, we approximate the value function $V^j(k_t)$ and the decision rule for labor, $l^j(k_t)$, for $j = 1,\ldots,5$ using 11 Chebyshev polynomials as:

$$V^j\left(k_t|\theta^{V,j}\right) = \sum_{i=0}^{10}\theta_i^{V,j}T_i(k_t) \tag{41}$$

$$l^j\left(k_t|\theta^{l,j}\right) = \sum_{i=0}^{10}\theta_i^{l,k}T_i(k_t) \tag{42}$$

Once we have the decision rule for labor, we can find output:

$$y^j(k_t) = e^{z_t}k_t^{\alpha}\left(l^j\left(k_t|\theta^{l,j}\right)\right)^{1-\alpha},$$

With output, from the first-order condition that relates the marginal utility consumption and the marginal productivity of labor, we can find consumption:

$$c^j(k_t) = \frac{\tau}{1-\tau}(1-\alpha)e^{z_t}k_t^{\alpha}\left(l^j\left(k_t|\theta^{l,j}\right)\right)^{-\alpha}\left(1-l^j\left(k_t|\theta^{l,j}\right)\right) \tag{43}$$

and, from the resource constraint, capital next period:

$$k^j(k_t) = e^{z_t}k_t^{\alpha}\left(l^j\left(k_t|\theta^{l,j}\right)\right)^{1-\alpha} + (1-\delta)k_t - c^j(k_t) \tag{44}$$

Our notations $y^j(k_t)$, $c^j(k_t)$, and $k^j(k_t)$ emphasize the exact dependence of these three variables on capital and the productivity level: once we have approximated $l^j\left(k_t|\theta^{l,j}\right)$, simple algebra with the equilibrium conditions allows us to avoid further approximation.

We decided to approximate the value function and the decision rule for labor and use them to derive the other variables of interest to illustrate how flexible projection methods are. We could, as well, have decided to approximate the decision rules for consumption and capital and find labor and the value function using the equilibrium conditions. The researcher should pick the approximating functions that are more convenient, either for algebraic reasons or her particular goals.

To solve for the unknown coefficients θ^V and θ^l, we plug the functions (41), (42), (43), and (44) into the Bellman equation to get:

$$\sum_{i=0}^{10}\theta_i^{V,j}T_i(k_t) = \frac{\left(\left(c^j(k_t)\right)^{\theta}\left(1-\sum_{i=0}^{10}\theta_i^l T_i(k_t)\right)^{1-\theta}\right)^{1-\tau}}{1-\tau} + \beta\sum_{m=1}^{5}p_{jm}\sum_{i=0}^{10}\theta_i^{V,j}T_i\left(k^j(k_t)\right) \tag{45}$$

where, since we are already using the optimal decision rules, we can drop the max operator. Also, we have substituted the expectation by the sum operator and the transition probabilities p_{jm}. We plug the same functions (41), (42), (43), and (44) into the Euler equation to get:

$$\frac{\left(c_t^{\theta}\left(1-\sum_{i=0}^{10}\theta_i^{l,k}T_i(k_t)\right)^{1-\theta}\right)^{1-\tau}}{c_t}=\beta\mathbb{E}_t\sum_{m=1}^{5}p_{jm}\sum_{i=0}^{10}\theta_i^{V,j}T_i\left(k^j(k_t)\right)\prime, \tag{46}$$

where $T_i(k^j(k_t))\prime$ is the derivative of the Chebyshev polynomial with respect to its argument.

The residual equation groups Eqs. (45) and (46):

$$R\left(k_t, z_j\middle|\theta\right)=\begin{cases}\sum_{i=0}^{10}\theta_i^{V,j}T_i(k_t)-\dfrac{\left(\left(c^j(k_t)\right)^{\theta}\left(1-\sum_{i=0}^{10}\theta_i^{l}T_i(k_t)\right)^{1-\theta}\right)^{1-\tau}}{1-\tau}\\ -\beta\sum_{m=1}^{5}p_{jm}\sum_{i=0}^{10}\theta_i^{V,j}T_i\left(k^j(k_t)\right)\\ \dfrac{\left(c_t^{\theta}\left(1-\sum_{i=0}^{10}\theta_i^{l,k}T_i(k_t)\right)^{1-\theta}\right)^{1-\tau}}{c_t}-\beta\mathbb{E}_t\sum_{m=1}^{5}p_{jm}\sum_{i=0}^{10}\theta_i^{V,j}T_i\left(k^j(k_t)\right)\prime\end{cases}$$

where θ stacks $\theta^{V,j}$ and $\theta^{l,k}$. Given that we use 11 Chebyshev polynomials for the value function and another 11 for the decision rule for labor for each of the 5 levels of z_j, θ has 110 elements ($110 = 11 \times 2 \times 5$). If we evaluate the residual function at each of the 11 zeros of the Chebyshev of order 11 for capital and the 5 levels of z_j, we will have the 110 equations required to solve for those 110 coefficients. A Newton solver can easily deal with this system (although, as explained in Remark 24, using a multistep approach simplifies the computation: we used 3 Chebyshev polynomials in the first step and 11 Chebyshev polynomials in the second one).

We plot the main components of the solution in Fig. 10. The top left panel draws the value function, with one line for each of the five values of productivity and capital on the x-axis. As predicted by theory, the value function is increasing and concave in both state variables, k_t and z_t. We follow the same convention for the decision rules for consumption (top right panel), labor supply (bottom left panel), and capital next period, k_{t+1} (bottom right panel). The most noticeable pattern is the near linearity of the capital decision rule. Once the researcher has found the value function and all the decision rules, she can easily simulate the model, compute impulse response functions, and evaluate welfare.

The accuracy of the solution is impressive, with Euler equation errors below -13 in the log_{10} scale. Section 7 discusses how to interpret these errors. Suffice it to say here that, for practical purposes, the solution plotted in Fig. 10 can be used instead of the exact solution of the stochastic neoclassical growth model with a discrete productivity level.

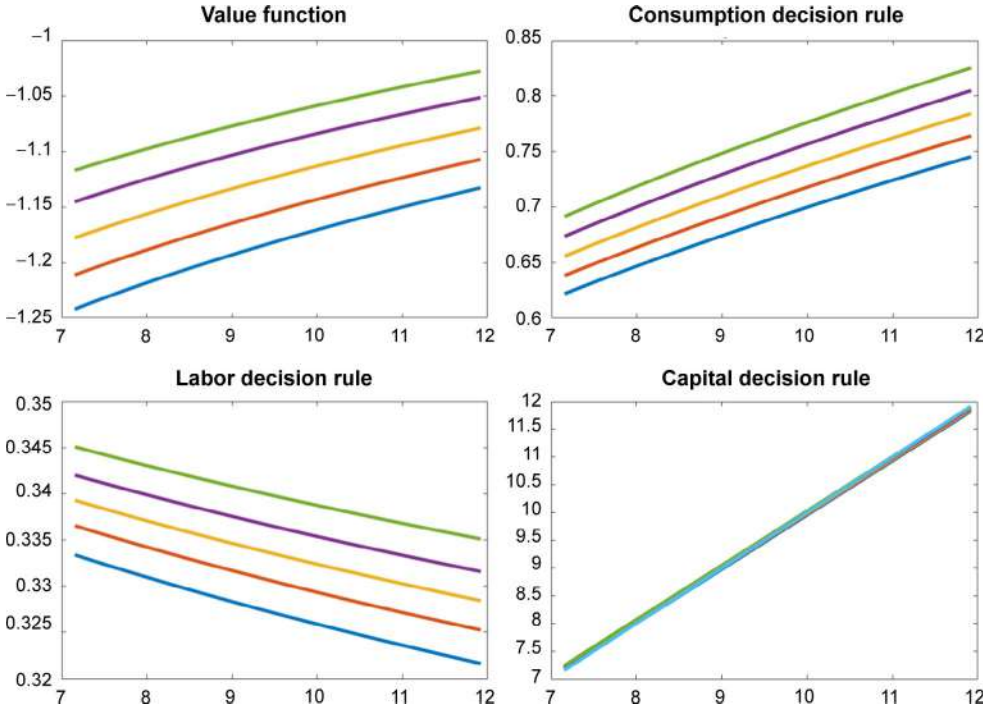

Fig. 10 Solution, stochastic neoclassical growth model.

5.7 Smolyak's Algorithm

An alternative to complete polynomials that can handle the curse of dimensionality better than other methods is Smolyak's algorithm. See Smolyak (1963), Delvos (1982), Barthelmann et al. (2000), and, especially, Bungartz and Griebel (2004) for a summary of the literature. Krüger and Kubler (2004) and Malin et al. (2011) introduced the algorithm in economics as a solution method for DSGE models. Subsequently, Smolyak's algorithm has been applied by many researchers. For example, Fernández-Villaverde et al. (2015a) rely on Smolyak's algorithm to solve a New Keynesian model with a ZLB (a model with 5 state variables), Fernández-Villaverde and Levintal (2016) exploit it to solve a New Keynesian model with big disasters risk (a model with 12 state variables), and Gordon (2011) uses it to solve a model with heterogeneous agents. Malin et al. (2011) can accurately compute a model with 20 continuous state variables and a considerable deal of curvature in the production and utility functions. In the next pages, we closely follow the explanations in Krüger and Kubler (2004) and Malin et al. (2011) and invite the reader to check those papers for further details.[z]

[z] There is also a promising line of research based on the use of ergodic sets to solve highly dimensional models (Judd et al., 2011b; Maliar et al., 2011; and Maliar and Maliar, 2015). Maliar and Maliar (2014) cover the material better than we could.

As before, we want to approximate a function (decision rule, value function, expectation, etc.) on n state variables, $d:[-1,1]^n \rightarrow \mathbb{R}$ (the generalization to the case $d:[-1,1]^n \rightarrow \mathbb{R}^m$ is straightforward, but tedious). The idea of Smolyak's algorithm is to find a grid of points $\mathbb{G}(q,n) \in [-1,1]^n$ where $q > n$ and an approximating function $d(x|\theta,\ q,\ n):[-1,1]^n \rightarrow \mathbb{R}$ indexed by some coefficients θ such that, at the points $x_i \in \mathbb{G}(q,n)$, the unknown function $d(\cdot)$ and $d(\cdot|\theta,\ q,\ n)$ are equal:

$$d(x_i) = d(x_i|\theta,\ q,\ n)$$

and, at the points $x_i \notin \mathbb{G}(q,n)$, $d(\cdot|\theta, q, n)$ is close to the unknown function $d(\cdot)$. In other words, at the points $x_i \in \mathbb{G}(q,\ n)$, the operator $\mathcal{H}(\cdot)$ would be exactly satisfied and, at other points, the residual function would be close to zero. The integer q indexes the size of the grid and, with it, the precision of the approximation.

The challenge is to judiciously select grid points $\mathbb{G}(q,n)$ in such a way that the number of coefficients θ does not explode with n. Smolyak's algorithm is (almost) optimal for that task within the set of polynomial approximations (Barthelmann et al., 2000). Also, the method is universal, that is, almost optimal for many different function spaces.

5.7.1 Implementing Smolyak's Algorithm

Our search of a grid of points $\mathbb{G}(q,n)$ and a function $d(x|\theta,q,n)$ will proceed in several steps.

5.7.1.1 First Step: Transform the Domain of the State Variables

For any state variable $\tilde{x}_l$, $l = 1,\ldots,n$ that has a domain $[a,b]$, we use a linear translation from $[a,b]$ into $[-1,1]$:

$$x_l = 2\frac{\tilde{x}_l - a}{b-a} - 1.$$

5.7.1.2 Second Step: Setting the Order of the Polynomial

We define $m_1 = 1$ and $m_i = 2^{i-1} + 1$, $i = 2,\ldots,$ where $m_i - 1$ will be the order of the polynomial that we will use to approximate $d(\cdot)$.

5.7.1.3 Third Step: Building the Gauss–Lobotto Nodes

We build the sets:

$$\mathcal{G}^i = \{\zeta_1^i,\ldots,\zeta_{m_i}^i\} \subset [-1,1]$$

that contain the Gauss–Lobotto nodes (also known as the Clenshaw–Curtis points), that is, the extrema of the Chebyshev polynomials:

$$\zeta_j^i = -cos\left(\frac{j-1}{m_i - 1}\pi\right), j = 1, \ldots, m_i$$

with the initial set $\mathcal{G}^1 = \{0\}$ (with a change of notation, this formula for the extrema is the same as the one in Eq. (34)). For instance, the first three sets are given by:

$$\mathcal{G}^1 = \{0\}, \text{ where } i = 1, m_1 = 1.$$
$$\mathcal{G}^2 = \{-1, 0, 1\}, \text{ where } i = 2, m_3 = 3.$$
$$\mathcal{G}^3 = \left\{-1, -\cos\left(\frac{\pi}{4}\right), 0, -\cos\left(\frac{3\pi}{4}\right), 1\right\}, \text{ where } i = 3, m_5 = 5.$$

Since, in the construction of the sets, we impose that $m_i = 2^{i-1} + 1$, we generate sets that are nested, that is, $\mathcal{G}^i \subset \mathcal{G}^{i+1}, \forall i = 1, 2, \ldots$. This result is crucial for the success of the algorithm.

5.7.1.4 Fourth Step: Building a Sparse Grid

For any integer q bigger than the number of state variables n, $q > n$, we define a sparse grid as the union of the Cartesian products:

$$\mathbb{G}(q, n) = \bigcup_{q-n+1 \le |\mathbf{i}| \le q} \left(\mathcal{G}^{i_1} \times \ldots \times \mathcal{G}^{i_n}\right),$$

where $|\mathbf{i}| = \sum_{l=1}^{n} i_l$.

To illustrate how this sparse grid works, imagine that we are dealing with a DSGE model with two continuous state variables. If we pick $q = 2 + 1 = 3$, we have the sparse grid

$$\begin{aligned}\mathbb{G}(3, 2) &= \bigcup_{2 \le |\mathbf{i}| \le 3} \left(\mathcal{G}^{i_1} \times \mathcal{G}^{i_2}\right) \\ &= \left(\mathcal{G}^1 \times \mathcal{G}^1\right) \cup \left(\mathcal{G}^1 \times \mathcal{G}^2\right) \cup \left(\mathcal{G}^2 \times \mathcal{G}^1\right) \\ &= \{(-1, 0), (0, 1), (0, 0), (0, -1), (1, 0)\}\end{aligned}$$

We plot this grid in the top left panel of Fig. 11, which reproduces fig. 1 in Krüger and Kubler (2004).

If we pick $q = 2 + 2 = 4$, we have the sparse grid

$$\begin{aligned}\mathbb{G}(4, 2) &= \bigcup_{3 \le |\mathbf{i}| \le 4} \left(\mathcal{G}^{i_1} \times \mathcal{G}^{i_2}\right) \\ &= \left(\mathcal{G}^1 \times \mathcal{G}^2\right) \cup \left(\mathcal{G}^1 \times \mathcal{G}^3\right) \cup \left(\mathcal{G}^2 \times \mathcal{G}^2\right) \cup \left(\mathcal{G}^3 \times \mathcal{G}^1\right) \\ &= \left\{\begin{array}{c} (-1, 1), (-1, 0), (-1, -1), \left(-\cos\left(\frac{\pi}{4}\right), 0\right), \\ (0, 1), \left(0, -\cos\left(\frac{3\pi}{4}\right)\right), (0, 0), \left(0, -\cos\left(\frac{\pi}{4}\right)\right), \\ (0, -1), \left(-\cos\left(\frac{3\pi}{4}\right), 0\right), (1, 1), (1, 0), (1, -1) \end{array}\right\}\end{aligned}$$

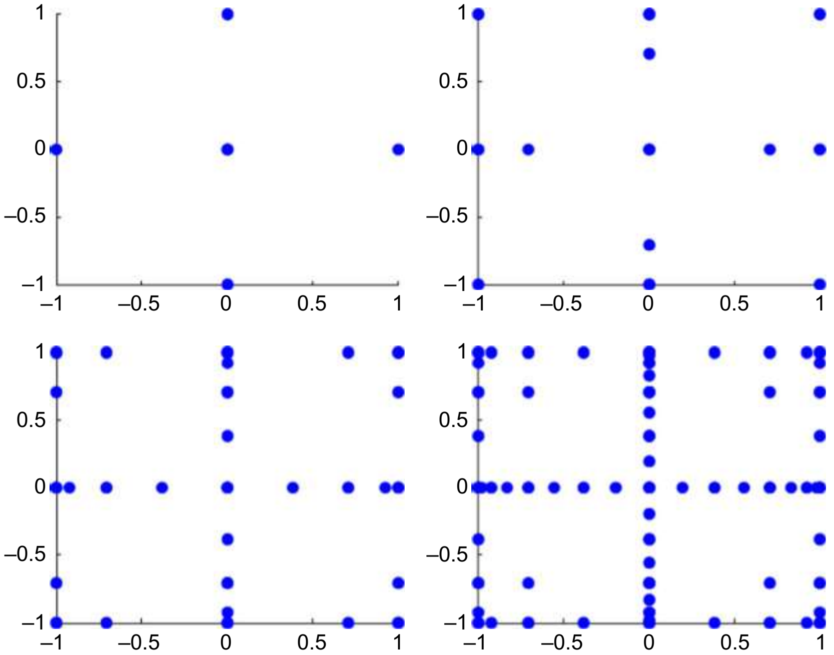

Fig. 11 Four sparse grids

We plot this grid in the top right panel of Fig. 11. Note that the sparse grids have a hierarchical structure, where $\mathbb{G}(3,2) \in \mathbb{G}(4,2)$ or, more generally, $\mathbb{G}(q,n) \in \mathbb{G}(q+1,n)$.

Following the same strategy, we can build $\mathbb{G}(5,2)$, plotted in the bottom left panel of Fig. 11, and $\mathbb{G}(6,2)$, plotted in the bottom right panel of Fig. 11 (in the interest of concision, we skip the explicit enumeration of the points of these two additional grids). In Fig. 12, we plot a grid for a problem with 3 state variables, $\mathbb{G}(5,3)$.

The sparse grid has two important properties. First, the grid points cluster around the corners of the domain of the Chebyshev polynomials and the central cross. Second, the number of points in a sparse grid when $q = n + 2$ is given by $1 + 4n + 2n(n - 1)$. The cardinality of this grid grows polynomially on n^2. Similar formulae hold for other $q > n$. For example, the cardinality of the grid grows polynomially on n^3 when $q = n + 3$. In fact, the computational burden of the method notably increases as we keep n fixed and a rise q. Fortunately, experience suggests that $q = n + 2$ and $q = n + 3$ are usually enough to deliver the desired accuracy in DSGE models.

The nestedness of the sets of the Gauss–Lobotto nodes plays a central role in controlling the cardinality of $\mathbb{G}(q,n)$. In comparison, the number of points in a rectangular grid is 5^n, an integer that grows exponentially on n. If $n = 2$, this would correspond, in the top right panel of Fig. 11, to having all possible tensors of

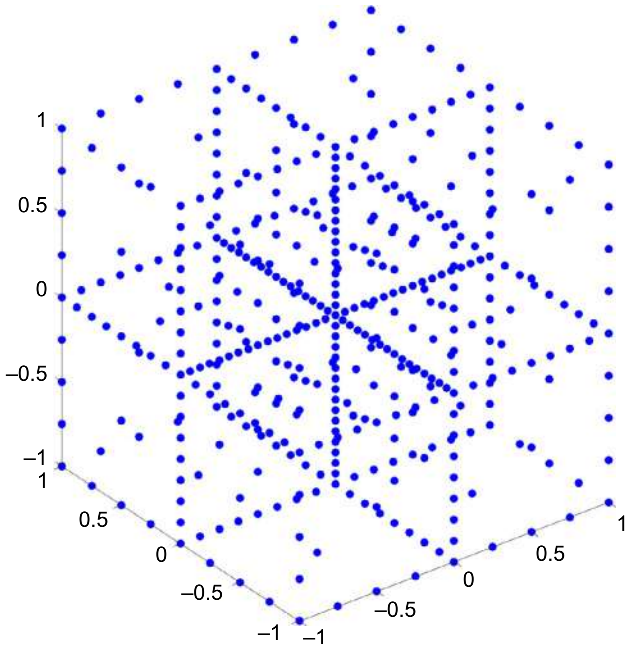

Fig. 12 A sparse grid, 3 state variables.

Table 3 Size of the grid for $q = n + 2$

n	$\mathbb{G}(q,n)$	5^n
2	13	25
3	25	125
4	41	625
5	61	3125
12	313	244,140,625

$\left\{-1, -\cos\left(\frac{\pi}{4}\right), 0, -\cos\left(\frac{3\pi}{4}\right), 1\right\}$ and $\left\{-1, -\cos\left(\frac{\pi}{4}\right), 0, -\cos\left(\frac{3\pi}{4}\right), 1\right\}$ covering the whole of the $[-1,1]^2$ square. Instead of keeping these 25 points, Smolyak's algorithm eliminates 12 of them and only keeps 13. To illustrate how dramatic is the difference between polynomial and exponential growth, Table 3 shows the cardinality of both grids as we move from 2 state variables to 12.

5.7.1.5 Fifth Step: Building Tensor Products

We use the Chebyshev polynomials $\psi_i(x_i) = T_{i-1}(x_i)$ to build the tensor-product multivariate polynomial:

$$p^{|\mathbf{i}|}(x|\theta) = \sum_{l_1=1}^{m_{i_1}} \dots \sum_{l_n=1}^{m_{i_n}} \theta_{l_1 \dots l_n} \psi_{l_1}(x_1) \dots \psi_{l_n}(x_n)$$

where $|\mathbf{i}| = \sum_{l=1}^{n} i_l$, $x_i \in [-1,1]$, $x = \{x_1, \dots, x_n\}$, and θ stacks all the coefficients $\theta_{l_1 \dots l_n}$. So, for example, for a DSGE model with two continuous state variables and $q = 3$, we will have:

$$\begin{aligned}
p^{\mathbf{1},\mathbf{1}}(x|\theta) &= \sum_{l_1=1}^{m_1} \sum_{l_n=1}^{m_1} \theta_{l_1 l_2} \psi_{l_1}(x_1) \psi_{l_2}(x_2) = \theta_{11} \\
p^{\mathbf{1},\mathbf{2}}(x|\theta) &= \sum_{l_1=1}^{m_1} \sum_{l_n=1}^{m_2} \theta_{l_1 l_2} \psi_{l_1}(x_1) \psi_{l_2}(x_2) = \theta_{11} + \theta_{12} T_1(x_2) + \theta_{13} T_2(x_2) \\
p^{2,\mathbf{1}}(x|\theta) &= \sum_{l_1=1}^{m_2} \sum_{l_n=1}^{m_1} \theta_{l_1 l_2} \psi_{l_1}(x_1) \psi_{l_2}(x_2) = \theta_{11} + \theta_{21} T_1(x_1) + \theta_{31} T_2(x_1)
\end{aligned}$$

where we have already used $T_0(x_i) = 1$. Therefore, for $x = \{x_1, x_2\}$:

$$\begin{aligned}
p^{|\mathbf{2}|}(x|\theta) &= p^{\mathbf{1},\mathbf{1}}(x|\theta) \\
p^{|\mathbf{3}|}(x|\theta) &= p^{\mathbf{1},\mathbf{2}}(x|\theta) + p^{2,\mathbf{1}}(x|\theta).
\end{aligned}$$

Most conveniently, for an arbitrary grid with points $k_1, \dots, k_n > 1$ along each dimension, these coefficients are given by:

$$\theta_{l_1 \dots l_n} = \frac{2^n}{(k_1 - 1) \dots (k_n - 1)} \frac{1}{c_{l_1} \dots c_{l_n}} \sum_{j_1=1}^{k_1} \dots \sum_{j_n=1}^{k_n} \frac{1}{c_{j_1} \dots c_{j_n}} \psi_{l_1}(\zeta_1) \dots \psi_{l_d}(\zeta_n) d(\zeta_1, \dots, \zeta_n) \quad (47)$$

where $c_j = 1$ for all j, except for the cases $c_1 = c_{k_d} = 2$, and $\zeta_k \in \mathcal{G}^i$ are the Gauss–Lobotto nodes. This approximation is exact in the Gauss–Lobotto nodes and interpolates among them.

There is nothing special about the use of Chebyshev polynomials as the basis functions $\psi_j(x)$ and we could rely, if required, on other basis functions. For instance, one can implement a finite element method with the Smolyak algorithm by partitioning $\mathbf{\Omega}$ into elements and defining local basis functions as in Nobile et al. (2008). We use Chebyshev polynomials just because they have been popular in the applications of the Smolyak algorithm in macroeconomics.

5.7.1.6 Sixth Step: Building the Interpolating Function in n Dimensions

The Smolyak function that interpolates on $\mathbb{G}(q,n)$ is:

$$d(x|\theta, q, n) = \sum_{\max(n, q-n+1) \leq |\mathbf{i}| \leq q} (-1)^{q-|\mathbf{i}|} \binom{n-1}{q-|\mathbf{i}|} p^{|\mathbf{i}|}(x|\theta),$$

which is nothing more than the weighted sum of the tensors. In our previous example, a DSGE model with two continuous state variables and $q=3$, we will have the sparse grid:

$$\mathbb{G}(3,2)=\{(-1,0),(0,1),(0,0),(0,-1),(1,0)\}$$

(this sparse grid was drawn in the top left panel of Fig. 11) and:

$$\begin{aligned} d(x|\theta,q,n) &= \sum_{2\leq|\mathbf{i}|\leq 3}(-1)^{3-|\mathbf{i}|}\binom{1}{3-|\mathbf{i}|}p^{|\mathbf{i}|}(x|\theta) \\ &= (-1)\binom{1}{1}p^{|\mathbf{2}|}(x|\theta)+(-1)^{0}\binom{1}{0}p^{|\mathbf{3}|}(x|\theta) \\ &= p^{\mathbf{1},\mathbf{2}}(x|\theta)+p^{2,\mathbf{1}}(x|\theta)-p^{\mathbf{1},\mathbf{1}}(x|\theta) \\ &= \theta_{11}+\theta_{21}T_1(x_1)+\theta_{31}T_2(x_1)+\theta_{12}T_1(x_2)+\theta_{13}T_2(x_2). \end{aligned}$$

Each of the coefficients in this approximation is given by the formula in Eq. (47):

$$\begin{aligned} \theta_{21} &= \frac{1}{2}(d(1,0)-d(-1,0)) \\ \theta_{12} &= \frac{1}{2}(d(0,1)-d(0,-1)) \\ \theta_{31} &= \frac{1}{4}(d(1,0)+d(-1,0))-\frac{1}{2}d(0,0) \\ \theta_{13} &= \frac{1}{4}(d(0,1)+d(0,-1))-\frac{1}{2}d(0,0) \end{aligned}$$

except the constant term:

$$\theta_{11}=\frac{1}{4}(d(0,1)+d(0,-1)+d(1,0)+d(-1,0)),$$

which instead ensures that the interpolating function satisfies $d(0,0)=d(x|\theta,q,n)$. It is easy to check that we indeed satisfy the condition that the approximating function equates the unknown function at the points of the sparse grid. For example, at $(-1,0)$:

$$\begin{aligned} d((-1,0)|\theta,q,n) &= \theta_{11}+\theta_{21}T_1(-1)+\theta_{31}T_2(-1)+\theta_{12}T_1(0)+\theta_{13}T_2(0) \\ &= \theta_{11}-\theta_{21}+\theta_{31}-\theta_{13} \\ &= \frac{1}{4}(d(0,1)+d(0,-1)+d(1,0)+d(-1,0)) \\ &\quad -\frac{1}{2}(d(1,0)-d(-1,0)) \\ &\quad +\frac{1}{4}(d(1,0)+d(-1,0))-\frac{1}{2}d(0,0) \\ &\quad -\frac{1}{4}(d(0,1)+d(0,-1))+\frac{1}{2}d(0,0) \\ &= d(-1,0). \end{aligned}$$

An interesting property of this construction of $d(x|\theta,q,n)$ is that the cardinality of $\mathbb{G}(q,n)$ and the number of coefficients on θ coincide. In our previous example, $\mathbb{G}(3,2)=5$ and $\theta=\{\theta_{11},\theta_{21},\theta_{31},\theta_{12},\theta_{13}\}$. A second relevant property is that $d(x|\theta,q,n)$ exactly replicates any polynomial function built with monomials of degree less than or equal to $q-n$.

5.7.1.7 Seventh Step: Solving for the Polynomial Coefficients

We plug $d(x|\theta,q,n)$ into the operator $\mathcal{H}(\cdot)$ for all $x_i\in\mathbb{G}(q,n)$. At this point the operator needs to be exactly zero:

$$\mathcal{H}(d(x_i|\theta,q,n))=0$$

and we solve for the unknown coefficients on θ. In our previous example, we had $\mathbb{G}(3,2)=\{(-1,0),(0,1),(0,0),(0,-1),(1,0)\}$ and, therefore:

$$d((-1,0)|\theta,q,n)=\theta_{11}+\theta_{21}T_1(-1)+\theta_{31}T_2(-1)+\theta_{12}T_1(0)+\theta_{13}T_2(0)=\theta_{11}-\theta_{21}+\theta_{31}-\theta_{13}$$

$$d((0,1)|\theta,q,n)=\theta_{11}+\theta_{21}T_1(0)+\theta_{31}T_2(0)+\theta_{12}T_1(1)+\theta_{13}T_2(1)=\theta_{11}-\theta_{31}+\theta_{12}+\theta_{13}$$

$$d((0,0)|\theta,q,n)=\theta_{11}+\theta_{21}T_1(0)+\theta_{31}T_2(0)+\theta_{12}T_1(0)+\theta_{13}T_2(0)=\theta_{11}-\theta_{31}-\theta_{13}$$

$$d((0,-1)|\theta,q,n)=\theta_{11}+\theta_{21}T_1(0)+\theta_{31}T_2(0)+\theta_{12}T_1(-1)+\theta_{13}T_2(-1)=\theta_{11}-\theta_{31}-\theta_{12}+\theta_{13}$$

$$d((1,0)|\theta,q,n)=\theta_{11}+\theta_{21}T_1(1)+\theta_{31}T_2(1)+\theta_{12}T_1(0)+\theta_{13}T_2(0)=\theta_{11}+\theta_{21}+\theta_{31}-\theta_{13}$$

The system of equations:

$$\mathcal{H}(d(x_i|\theta,q,n))=0,\, x_i\in\mathbb{G}(q,n)$$

can be solved with a standard nonlinear solver. Krüger and Kubler (2004) and Malin et al. (2011) suggest a time-iteration method that starts, as an initial guess, from the first-order perturbation of the model. This choice is, nevertheless, not essential to the method.

5.7.2 Extensions

Recently, Judd et al. (2014b) have proposed an important improvement of Smolyak's algorithm. More concretely, the authors first present a more efficient implementation of Smolyak's algorithm that uses disjoint-set generators that are equivalent to the sets $\mathcal{G}^i$. Second, the authors use a Lagrange interpolation scheme. Third, the authors build an anisotropic grid, which allows having a different number of grid points and basis functions for different state variables. This may be important to capture the fact that, often, it is harder to approximate the decision rules of agents along some dimensions than along others. Finally, the authors argue that it is much more efficient to employ a derivative-free fixed-point iteration method instead of the time-iteration scheme proposed by Krüger and Kubler (2004) and Malin et al. (2011).

In comparison, Brumm and Scheidegger (2015) keep a time-iteration procedure, but they embed on it an adaptive sparse grid. This grid is refined locally in an automatic fashion, which allows the capture of steep gradients and some nondifferentiabilities. The authors provide a fully hybrid parallel implementation of the method, which takes advantage of the fast improvements in massively parallel processing.

6. COMPARISON OF PERTURBATION AND PROJECTION METHODS

After our description of perturbation and projection methods, we can offer some brief comments on their relative strengths and weaknesses.

Perturbation methods have one great advantage: their computational efficiency. We can compute, using a standard laptop computer, a third-order approximation to DSGE models with dozens of state variables in a few seconds. Perturbation methods have one great disadvantage: they only provide a local solution. The Taylor series expansion is accurate around the point at which we perform the perturbation and deteriorates as we move away from that point. Although perturbation methods often yield good global results (see Aruoba et al., 2006; Caldara et al., 2012; and Swanson et al., 2006), such performance needs to be assessed in each concrete application and even a wide range of accuracy may not be sufficient for some quantitative experiments. Furthermore, perturbation relies on differentiability conditions that are often violated by models of interest, such as those that present kinks or occasionally binding constraints.[aa]

Projection methods are nearly the mirror image of perturbation. Projection methods have one great advantage: Chebyshev and finite elements produce solutions that are of high accuracy over the whole range of state variable values. See, again, Aruoba et al. (2006) and Caldara et al. (2012). And projection methods can attack even the most complex problems with occasionally binding constraints, irregular shapes, and local behavior. But power and flexibility come at a cost: computational effort. Projection methods are harder to code, take longer to run, and suffer, as we have repeatedly pointed out, from an acute curse of dimensionality.[ab]

Thus, which method to use in real life? The answer, not unsurprisingly, is "it depends." Solution methods for DSGE models provide a menu of options. If we are dealing, for example, with a standard middle-sized New Keynesian model with

[aa] Researchers have proposed getting around these problems with different devices, such as the use of penalty functions. See, for example, Preston and Roca (2007). In fact, the recent experience of several central banks pushing their target interest rates below zero suggests that many constraints such as the ZLB may be closer to such a penalty function than to a traditional kink.

[ab] The real bottleneck for most research projects involving DSGE models is coding time, not running time. Moving from a few seconds of running time with perturbation to a few minutes of running time with projection is a minuscule fraction of the cost of coding a finite elements method in comparison with the cost of employing Dynare to find a perturbation.

25 state variables, perturbation methods are likely to be the best option. The New Keynesian model is sufficiently well behaved that a local approximation would be good enough for most purposes. A first-order approximation will deliver accurate estimates of the business cycle statistics such as variances and covariances, and a second- or third-order approximation is likely to generate good welfare estimates (although one should always be careful when performing welfare evaluations). If we are dealing, in contrast, with a DSGE model with financial constraints, large risk aversion, and only a few state variables, a projection method is likely to be a superior option. An experienced researcher may even want to have two different solutions to check one against the other, perhaps of a simplified version of the model, and decide which one provides her with a superior compromise between coding time, running time, and accuracy.

Remark 25 (Hybrid methods) The stark comparison between perturbation and projection methods hints at the possibility of developing hybrid methods that combine the best of both approaches. Judd (1998, section 15.6), proposes the following hybrid algorithm:

Algorithm 4 (Hybrid algorithm)

1. Use perturbation to build a basis tailored to the DSGE model we need to solve.
2. Apply a Gram-Schmidt process to build an orthogonal basis from the basis obtained in 1.
3. Employ a projection method with the basis from 2.

While this algorithm is promising (see the example provided by Judd, 1998), we are unaware of further explorations of this proposal.

More recently, Levintal (2015b) and Fernández-Villaverde and Levintal (2016) have proposed the use of Taylor-based approximations that also have the flavor of a hybrid method. The latter paper shows the high accuracy of this hybrid method in comparison with pure perturbation and projection methods when computing a DSGE model with disaster risk and a dozen state variables. Other hybrid proposals include Maliar et al. (2013).

7. ERROR ANALYSIS

A final step in every numerical solution of a DSGE model is to assess the error created by the approximation, that is, the difference between the exact and the approximated solution. This may seem challenging since the exact solution of the model is unknown. However, the literature has presented different methods to evaluate the errors.[ac] We will concentrate on the two most popular procedures to assess error: χ^2 −test proposed by

[ac] Here we follow much of the presentation of Aruoba et al. (2006), where the interested reader can find more details.

Den Haan and Marcet (1994) and the Euler equation error proposed by Judd (1992). Throughout this section, we will use the superscript j to index the perturbation order, the number of basis functions, or another characteristic of the solution method. For example, $c^j(k_t, z_t)$ will be the approximation to the decision rule for consumption $c(k_t, z_t)$ in a model with state variables k_t and z_t.

Remark 26 (Theoretical bounds) There are (limited) theoretical results bounding the approximation errors and their consequences. Santos and Vigo-Aguiar (1998) derive upper bounds for the error in models computed with value function iteration. Santos and Rust (2004) extend the exercise for policy function iteration. Santos and Peralta-Alva (2005) propose regularity conditions under which the error from the simulated moments of the model converge to zero as the approximated equilibrium function approaches the exact, but unknown, equilibrium function. Fernández-Villaverde et al. (2006) explore similar conditions for likelihood functions and Stachurski and Martin (2008) perform related work for the computation of densities of ergodic distributions of variables of interest. Judd et al. (2014a) have argued for the importance of constructing lower bounds on the size of approximation errors and propose a methodology to do so. Kogan and Mitra (2014) have studied the information relaxation method of Brown et al. (2010) to measure the welfare cost of using approximated decision rules. Santos and Peralta-Alva (2014) review the existing literature. But, despite all this notable work, this is an area in dire need of further investigation.

Remark 27 (Preliminary assessments) Before performing a formal error analysis, researchers should undertake several preliminary assessments. First, we need to check that the computed solution satisfies theoretical properties, such as concavity or monotonicity of the decision rules. Second, we need to check the shape and structure of decision rules, impulse response functions, and basic statistics of the model. Third, we need to check how the solution varies as we change the calibration of the model.

These steps often tell us more about the (lack of) accuracy of an approximated solution than any formal method. Obviously, the researcher should also take aggressive steps to verify that her code is correct and that she is, in fact, computing what she is supposed to compute. The use of modern, industry-tested software engineering techniques is crucial in ensuring code quality.

7.1 A χ^2 Accuracy Test

Den Haan and Marcet (1994) noted that, if some of the equilibrium conditions of the model are given by:

$$f(y_t) = \mathbb{E}_t(\phi(y_{t+1}, y_{t+2}, ..))$$

where the vector y_t contains n variables of interest at time t, $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and $\phi : \mathbb{R}^n \times \mathbb{R}^\infty \rightarrow \mathbb{R}^m$ are known functions, then:

$$\mathbb{E}_t(u_{t+1} \otimes h(x_t)) = 0 \tag{48}$$

for any vector x_t measurable with respect to t with $u_{t+1} = \phi(y_{t+1}, y_{t+2}, ..) - f(y_t)$ and $h : \mathbb{R}^k \rightarrow \mathbb{R}^q$ being an arbitrary function.

If we simulate a series of length T from the DSGE model using a given solution method, $\left\{y_t^j\right\}_{t=1:T}$, we can find $\left\{u_{t+1}^j, x_t^j\right\}_{t=1:T}$ and compute the sample analog of (48):

$$B_T^j = \frac{1}{T}\sum_{t=1}^{T} u_{t+1}^j \otimes h\left(x_t^j\right). \tag{49}$$

The moment (49) would converge to zero as N increases almost surely if we were using the exact solution to the model. When, instead, we are using an approximation, the statistic $B\left(B_T^j\right)' \left(A_T^j\right)^{-1} B_T^j$ where A_T^j is a consistent estimate of the matrix:

$$\sum_{t=-\infty}^{\infty} \mathbb{E}_t\left[(u_{t+1} \otimes h(x_t))(u_{t+1} \otimes h(x_t))'\right]$$

converges to a χ^2 distribution with qm degrees of freedom under the null that the population moment (48) holds. Values of the test above the critical value can be interpreted as evidence against the accuracy of the solution. Since any solution method is an approximation, as T grows we will eventually reject the null. To control for this problem, Den Haan and Marcet (1990) suggest repeating the test for many simulations and report the percentage of statistics in the upper and lower critical 5% of the distribution. If the solution provides a good approximation, both percentages should be close to 5%.

This χ^2−test helps the researcher to assess how the errors of the approximated solution accumulate over time. Its main disadvantage is that rejections of accuracy may be difficult to interpret.

7.2 Euler Equation Errors

Judd (1992) proposed determining the quality of the solution method by defining normalized Euler equation errors. The idea is to measure how close the Euler equation at the core of nearly DSGE models is to be satisfied when we use the approximated solution.

The best way to understand how to implement this idea is with an example. We can go back to the stochastic neoclassical growth model that we solved in Section 5.6. This model generates an Euler equation:

$$u_{c'}(c_t, l_t) = \beta\mathbb{E}_t\{u_{c'}(c_{t+1}, l_{t+1})R_{t+1}\} \tag{50}$$

where

$$u_c\prime(c_t,l_t)=\frac{\left(c_t^{\tau}(1-l_t)^{1-\tau}\right)^{1-\eta}}{c_t}$$

is the marginal utility of consumption and $R_{t+1}=\left(1+\alpha e^{z_{t+1}}k_t^{\alpha-1}l_{t+1}^{1-\alpha}-\delta\right)$ is the gross return rate of capital. If we take the inverse of the marginal utility of consumption and do some algebra manipulations, we get:

$$1-\frac{u_c'\left(\beta\mathbb{E}_t\left\{u_c'(c_{t+1},l_{t+1})R_{t+1}\right\},l_t\right)^{-1}}{c_t}=0 \tag{51}$$

If we plug into Eq. (51) the exact decision rules for consumption:

$$c_t=c(k_t,z_t),$$

labor

$$l_t=l(k_t,z_t)$$

and capital:

$$k_{t+1}=k(k_t,z_t)$$

we get:

$$1-\frac{u_c'\left(\beta\mathbb{E}_t\left\{u_c'(c(k(k_t,z_t),z_{t+1}),l(k(k_t,z_t),z_{t+1}))R_{t+1}(k_t,z_t,z_{t+1})\right\},l(k_t,z_t)\right)^{-1}}{c(k_t,z_t)}=0 \tag{52}$$

where $R(k_t,z_t,z_{t+1})=\left(1+\alpha e^{z_{t+1}}k(k_t,z_t)^{\alpha-1}l(k(k_t,z_t),z_{t+1})^{1-\alpha}-\delta\right)$. Eq. (52) will hold exactly for any k_t and z_t.

If, instead, we plug into Eq. (52) the approximated decision rules $c^j(k_t,z_t)$, $l^j(k_t,z_t)$, and $k^j(k_t,z_t)$, we will have:

$$EEE(k_t,z_t)=\left\{\frac{1-}{u_c'\left(\beta\mathbb{E}_t\left\{u_c'\left(c^j\left(k^j\left(k_t^j,z_t\right),z_{t+1}\right),l^j(k^j(k_t,z_t),z_{t+1})\right)R_{t+1}^j(k_t,z_t,z_{t+1})\right\},l^j(k_t,z_t)\right)^{-1}}{c^j(k_t,z_t)}\right\} \tag{53}$$

where $R^j(k_t,z_t,z_{t+1})=\left(1+\alpha e^{z_{t+1}}k^j(k_t,z_t)^{\alpha-1}l^i\left(k^i(k_t,z_t),z_{t+1}\right)^{1-\alpha}-\delta\right)$. Eq. (53) defines a function, $EEE(k_t,z_t)$, that we call the Euler equation error.

We highlight three points about Eq. (53). First, the error in the Euler equation depends on the value of the state variables k_t and z_t. Perturbation methods will tend to have a small Euler equation error close to the point where the perturbation is undertaken and a larger Euler equation error farther from it. In contrast, projection methods will deliver a more uniform Euler equation error across Ω. Consequently, researchers have found it useful to summarize the Euler equation error. Proposals include the mean of the Euler equation error (either a simple average or using some estimate of the ergodic distribution of state variables[ad]) or the maximum of the Euler equation error in some region of Ω. Second, due to the algebraic transformation that we took on the Euler equation, $EEE(k_t, z_t)$ is expressed in consumption units, which have a meaningful economic interpretation as the relative optimization error incurred by the use of the approximated policy rule (Judd and Guu, 1997). For instance, if $EEE(k_t, z_t) = 0.01$, then the agent is making a $1 mistake for each $100 spent. In comparison, $EEE(k_t, z_t) = 1e^{-6}$ implies that the agent is making a 1 cent mistake for each 1 million spent. Third, the Euler equation error is also important because we know that, under certain conditions, the approximation error of the decision rule is of the same order of magnitude as the size of the Euler equation error. Correspondingly, the change in welfare is of the square order of the Euler equation error. Furthermore, the constants involved in these error bounds can be related to model primitives (Santos, 2000). Unfortunately, in some DSGE models it can be difficult to use algebraic transformations to achieve an expression for the Euler equation error that is interpretable as consumption units (or other natural economic unit).

Following the convention in the literature, we plot in Fig. 13, the $\log_{10}|EEE(k_t, z_t)|$ of the stochastic neoclassical growth model from Section 5.6. Taking the $\log_{10}$ eases reading: a value of -3 means $1 mistake for each $1000, a value of -4 a $1 mistake for each $10,000, and so on. Fig. 13 shows five lines, one for each value of productivity. As we hinted when we described the Chebyshev-collocation projection method, this accuracy is outstanding.

To compare this performance of Chebyshev-collocation with other solution methods, we reproduce, in Figs. 14 and 15, results from Aruoba et al. (2006). That paper uses the same stochastic neoclassical growth model with only a slightly different calibration (plus a few smaller details about how to handle z_t). Both figures display a transversal cut of the Euler equation errors when $z_t = 0$ and for values of capital between 70% and 130% of its steady-state value (23.14).

In Fig. 14, we plot the results for a first-order perturbation (in levels and in logs), a second-order perturbation, and a fifth-order perturbation. First, perturbations have smaller errors around the steady-state value of capital and deteriorate away from it. Second, there is a considerable improvement when we go from a first- to a second-order approximation. Third, a fifth-order approximation displays a great performance even 30% away from the steady state.

[ad] Using the ergodic distribution has the complication that we may not have access to it, since it is derived from the solution of the model, the object we are searching for. See Aruoba et al. (2006) for suggestions on how to handle this issue.

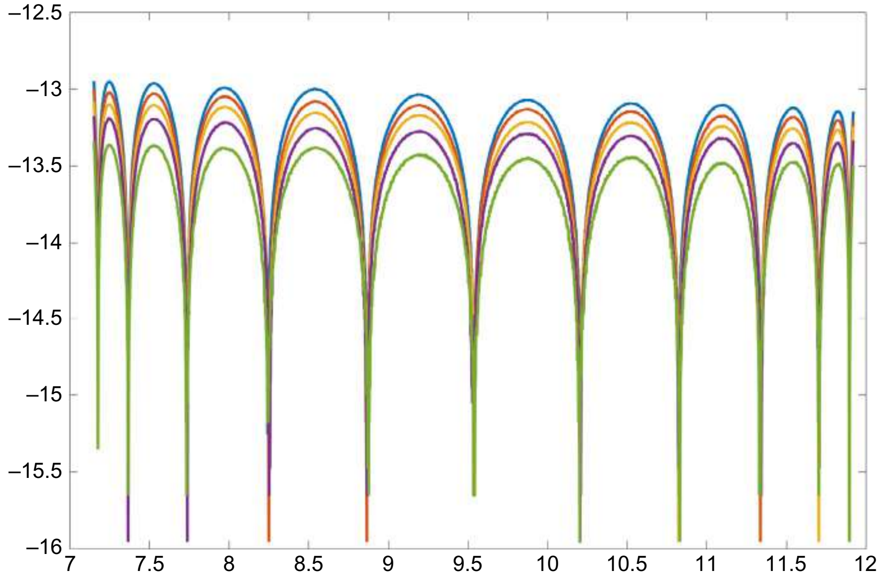

Fig. 13 *Log_{10}* of absolute value of Euler equation error.

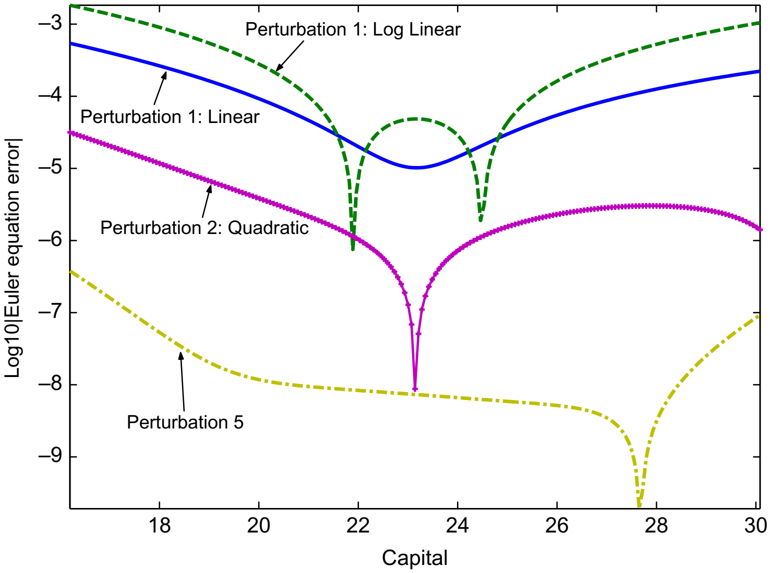

Fig. 14 *Log_{10}* of absolute value of Euler equation error.

In Fig. 15, we plot the results from the first-order perturbation (as a comparison with the previous graph), value function iteration (with a grid of one million points: 25,000 points for capital and 40 for the productivity level), finite elements (with 71 elements), and Chebyshev polynomials (as in Section 5.6, still with 11 polynomials). The main

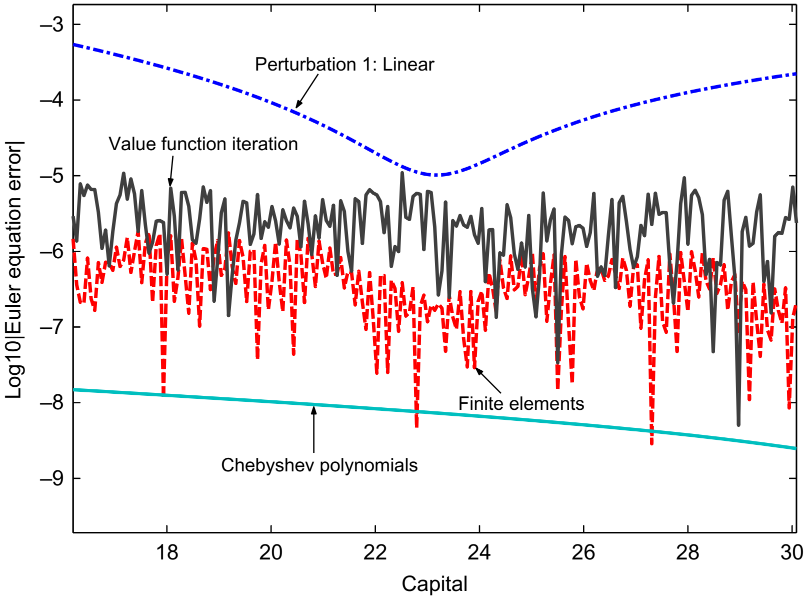

Fig. 15 *Log_{10}* of absolute value of Euler equation error.

lesson from this graph is that the Euler equation errors are much flatter for projection methods and value function iteration (another algorithm that delivers a global solution). The level of each of the three functions is harder to interpret, since it depends on the number of grid points (value function iteration), elements (finite elements), and Chebyshev polynomials. Nevertheless, the performance of Chebyshev is again excellent and its run time much lower than value function iteration and finite elements. This is not a surprise, since the decision rules for the stochastic neoclassical growth model are sufficiently well behaved for a spectral basis to do an extraordinary job.

Computing the Euler equation error has become standard in the literature because it often offers sharp assessments. However, Euler equation errors fail at giving a clear evaluation of how the errors of the approximated solution accumulate over time (see Santos and Peralta-Alva, 2005, for how to think about the impact of Euler equation errors on computed moments from the model). Thus, Euler equation errors should be understood as a complement to, not a substitute for, Den Haan and Marcet (1994)'s χ^2 −test.

7.3 Improving the Error

Once we have gauged the error in the solution to the DSGE, we can decide whether to improve the accuracy of the solution. Everything else equal, more accuracy is better than less accuracy. But, in real-life applications, everything else is rarely equal. More accuracy can come at the cost of more coding time and, in particular, longer running time. For example, in the exercise with the stochastic neoclassical growth model reported in Fig. 15, we could subdivide the finite elements as much as we want and use modern scientific libraries such as the *GNU multiple precision arithmetic library* to achieve any arbitrary level of accuracy, but at the cost of longer running times and more memory requirements. The researcher must look at her needs and resources and, once inferior solution methods are rejected, select those that best fit her goals.

But if the goal is indeed dependent on achieving additional accuracy, there are different possibilities available. If a perturbation is being used, we can increase the order of the perturbation. If a projection method is being used, we can increase the number of elements in the basis. The researcher can also explore changes of variables to make the problem more linear or switch the solution method.

Once the error of the model has been assessed, we are finally ready to move to Part II and see how the DSGE model can account for the observed data.

PART II. ESTIMATING DSGE MODELS

8. CONFRONTING DSGE MODELS WITH DATA

The preceding sections discussed how to compute an approximate solution for a DSGE model conditional on its parameterization. Part II focuses on determining the DSGE model parameters based on the empirical evidence and assessing the model's fit. More specifically, we ask four fundamental questions: (i) How can one estimate the DSGE model parameters from the observed macroeconomic time series? (ii) How well does the estimated DSGE model capture salient features of the data? (iii) What are the quantitative implications of the estimated DSGE models with respect to, for instance, sources of business cycle fluctuations, propagation of exogenous shocks, the effect of changes in macroeconomic policies, and the future path of macroeconomic time series? (iv) How should one construct measures of uncertainty for the parameters and the quantitative implications of the DSGE model? To answer these questions, we begin by analytically solving a stylized New Keynesian DSGE model in Section 8.1 and studying its properties in Section 8.2. DSGE model-implied population moments, autocovariances, spectra, and impulse response functions have sample analogs in the data, which are examined in Section 8.3. Macroeconomic time series exhibit trends that may or may not be captured by the DSGE model, which is discussed in Section 8.4.

Part II of this chapter assumes that the reader has some basic familiarity with econometrics, at the level of a first-year PhD sequence in a US graduate program. With the exception of Canova (2007) and DeJong and Dave (2007) there are no textbooks that focus on the estimation of DSGE models. The literature has progressed quickly since these two books were first written. The subsequent sections contain, in addition to a critical introduction to "standard methods," an overview of the most recent developments in the literature, which include identification conditions for DSGE models, identification-robust frequentist inference, and sequential Monte Carlo techniques for Bayesian analysis. Unlike the recent monograph by Herbst and Schorfheide (2015) which focuses on Bayesian computations, Part II of this chapter also contains extensive discussions of the consequences of misspecification for econometric inference and covers frequentist methods.

8.1 A Stylized DSGE Model

Throughout Part II we consider a stylized New Keynesian DSGE model in its loglinearized form.[ae] This model shares many of the features of its more realistic siblings that have been estimated in the literature. It is a stripped-down version of the model developed in the work by Christiano et al. (2005) and Smets and Wouters (2003). The specific version presented below is taken from Del Negro and Schorfheide (2008) and obtained by imposing several parameter restrictions. It is not suitable to be confronted with actual data, but it can be solved analytically, which is useful for the subsequent exposition. For brevity, we refer to this model as the stylized DSGE model in the remainder of this chapter.

The model economy consists of households, intermediate goods producers, final goods producers, a monetary policy authority, and a fiscal authority. Macroeconomic fluctuations are generated by four exogenous processes: a technology growth shock, z_t, a shock that generates shifts in the preference for leisure, ϕ_t, a price markup shock, λ_t, and a monetary policy shock $\epsilon_{R,t}$. We assume that the level of productivity Z_t in the economy is evolving exogenously according to a random walk with drift:

$$\log Z_t = \log \gamma + \log Z_{t-1} + z_t, \quad z_t = \rho_z z_{t-1} + \sigma_z \epsilon_{z,t}. \tag{54}$$

The productivity process Z_t induces a stochastic trend in output X_t and real wages W_t. To facilitate the model solution, it is useful to detrend output and real wages by the level of technology, defining $x_t = X_t/Z_t$ and $w_t = W_t/Z_t$, respectively. In terms of the detrended variables, the model has the following steady state:

$$\bar{x} = x^*, \quad \bar{w} = \overline{lsh} = \frac{1}{1+\lambda}, \quad \bar{\pi} = \pi^*, \quad \bar{R} = \pi^* \frac{\gamma}{\beta}. \tag{55}$$

Here x^* and π^* are free parameters. The latter can be interpreted as the central bank's target inflation rate, whereas the former can in principle be derived from the weight on leisure in the households' utility function. The steady-state real wage $\bar{w}$ is equal to the steady-state labor share $\overline{lsh}$. The parameter λ can be interpreted as the steady-state markup charged by the monopolistically competitive intermediate goods producers, β is the discount factor of the households, and γ is the growth rate of technology. Under the assumption that the production technology is linear in labor and labor is the only

[ae] See Sections 4.1 and 4.5 for how to think about loglinearizations as a first-order perturbations.

factor of production, the steady state labor share equals the steady state of detrended wages. We also assume that all output is consumed, which means that x can be interpreted as aggregate consumption.

8.1.1 Loglinearized Equilibrium Conditions

In terms of log-deviations from the steady state (denoted by ˆ), ie, $\hat{x} = \log(x_t/\bar{x})$, $\hat{w}_t = \log(w_t/\bar{w})$, $\hat{\pi}_t = \log(\pi_t/\bar{\pi})$, and $\hat{R}_t = \log(R_t/\bar{R})$, the equilibrium conditions of the model can be stated as follows. The consumption Euler equation of the households takes the form

$$\hat{x}_t = \mathbb{E}_{t+1}[\hat{x}_{t+1}] - \left(\hat{R}_t - \mathbb{E}[\hat{\pi}_{t+1}]\right) + \mathbb{E}_t[z_{t+1}]. \tag{56}$$

The expected technology growth rate arises because the Euler equation is written in terms of output in deviations from the stochastic trend induced by Z_t. Assuming the absence of nominal wage rigidities, the intratemporal Euler equation for the households leads to the following labor supply equation:

$$\hat{w}_t = (1+\nu)\hat{x}_t + \phi_t, \tag{57}$$

where $\hat{w}_t$ is the real wage, $1/(1+\nu)$ is the Frisch labor supply elasticity, $\hat{x}_t$ is proportional to hours worked, and ϕ_t is an exogenous labor supply shifter

$$\phi_t = \rho_\phi \phi_{t-1} + \sigma_\phi \epsilon_{\phi,t}. \tag{58}$$

We refer to ϕ_t as preference shock.

The intermediate goods producers hire labor from the households and produce differentiated products, indexed by j, using a linear technology of the form $X_t(j) = Z_t L_t(j)$. After detrending and loglinearization around steady-state aggregate output, the production function becomes

$$\hat{x}_t(j) = \hat{L}_t(j). \tag{59}$$

Nominal price rigidity is introduced via the Calvo mechanism. In each period, firm j is unable to reoptimize its nominal price with probability ζ_p. In this case, the firm simply adjusts its price from the previous period by the steady-state inflation rate. With probability $1 - \zeta_p$, the firm can choose its price to maximize the expected sum of future profits. The intermediate goods are purchased and converted into an aggregate good X_t by a collection of perfectly competitive final goods producers using a constant-elasticity-of-substitution aggregator.

The optimality conditions for the two types of firms can be combined into the so-called New Keynesian Phillips curve, which can be expressed as

$$\hat{\pi}_t = \beta \mathbb{E}_t[\hat{\pi}_{t+1}] + \kappa_p(\hat{w}_t + \lambda_t), \quad \kappa_p = \frac{(1-\zeta_p\beta)(1-\zeta_p)}{\zeta_p}, \tag{60}$$

where β is the households' discount factor and λ_t can be interpreted as a price mark-up shock, which exogenously evolves according to

$$\lambda_t = \rho_\lambda \lambda_{t-1} + \sigma_\lambda \epsilon_{\lambda,t}. \tag{61}$$

It is possible to derive an aggregate resource constraint that relates the total amount of labor L_t hired by the intermediate goods producers to the total aggregate output X_t produced in the economy. Based on this aggregate resource constraint, it is possible to compute the labor share of income, which, in terms of deviations from steady state is given by

$$\widehat{lsh}_t = \hat{w}_t. \tag{62}$$

Finally, the central bank sets the nominal interest rate according to the feedback rule

$$\hat{R}_t = \psi \hat{\pi}_t + \sigma_R \epsilon_{R,t} \quad \psi = 1/\beta. \tag{63}$$

We abstract from interest rate smoothing and the fact that central banks typically also react to some measure of real activity, eg, the gap between actual output and potential output. The shock $\epsilon_{R,t}$ is an unanticipated deviation from the systematic part of the interest rate feedback rule and is called a monetary policy shock. We assume that $\psi = 1/\beta$, which ensures the existence of a unique stable solution to the system of linear rational expectations difference equations and, as will become apparent below, simplifies the solution of the model considerably. The fiscal authority determines the level of debt and lump-sum taxes such that the government budget constraint is satisfied.

8.1.2 Model Solution

To solve the model, note that the economic state variables are ϕ_t, λ_t, z_t, and $\epsilon_{R,t}$. Due to the fairly simple loglinear structure of the model, the aggregate laws of motion $\hat{x}(\cdot)$, $\hat{l}sh(\cdot)$, $\hat{\pi}(\cdot)$, and $\hat{R}(\cdot)$ are linear in the states and can be determined sequentially. We first eliminate the nominal interest rate from the consumption Euler equation using (63):

$$\hat{x}_t = \mathbb{E}_{t+1}[\hat{x}_{t+1}] - \left(\frac{1}{\beta}\hat{\pi}_t + \sigma_R \epsilon_{R,t} - \mathbb{E}[\hat{\pi}_{t+1}] \right) + \mathbb{E}_t[z_{t+1}]. \tag{64}$$

Now notice that the New Keynesian Phillips curve can be rewritten as

$$\frac{1}{\beta}\hat{\pi}_t - \mathbb{E}_t[\hat{\pi}_{t+1}] = \frac{\kappa_p}{\beta}((1+\nu)\hat{x}_t + \phi_t + \lambda_t). \tag{65}$$

Here we replaced wages $\hat{w}_t$ with the right-hand side of (57). Substituting (65) into (64) and rearranging terms leads to the following expectational difference equation for output $\hat{x}_t$

$$\hat{x}_t = \psi_p \mathbb{E}_t[\hat{x}_{t+1}] - \frac{\kappa_p \psi_p}{\beta}(\phi_t + \lambda_t) + \psi_p \mathbb{E}_t[z_{t+1}] - \psi_p \sigma_R \epsilon_{R,t}, \tag{66}$$

where $0 \leq \psi_p \leq 1$ is given by

$$\psi_p = \left(1 + \frac{\kappa_p}{\beta}(1+\nu)\right)^{-1}.$$

We now need to find a law of motion for output (and, equivalently, consumption) of the form

$$\hat{x}_t = \hat{x}(\phi_t, \lambda_t, z_t, \epsilon_{R,t}) = x_\phi \phi_t + x_\lambda \lambda_t + x_z z_t + x_{\epsilon_R}\epsilon_{R,t} \tag{67}$$

that solves the functional equation

$$\begin{aligned} &\mathbb{E}_t \mathcal{H}(\hat{x}(\cdot)) \\ &\quad = \mathbb{E}_t \Big[\hat{x}(\phi_t, \lambda_t, z_t, \epsilon_{R,t}) - \psi_p \hat{x}\big(\rho_\phi \phi_t + \sigma_\phi \epsilon_{\phi,t+1}, \rho_\lambda \lambda_t + \sigma_\lambda \epsilon_{\lambda,t+1}, \rho z_t + \sigma_z \epsilon_{z,t+1}, \epsilon_{R,t+1}\big) \\ &\qquad + \frac{\kappa_p \psi_p}{\beta}(\phi_t + \lambda_t) - \psi_p z_{t+1} + \psi_p \sigma_R \epsilon_{R,t}\Big] = 0. \end{aligned} \tag{68}$$

Here, we used the laws of motion of the exogenous shock processes in (54), (58), and (61). Assuming that the innovations ϵ_t are Martingale difference sequences, it can be verified that the coefficients of the linear decision rule are given by

$$x_\phi = -\frac{\kappa_p \psi_p/\beta}{1-\psi_p\rho_\phi}, \quad x_\lambda = -\frac{\kappa_p \psi_p/\beta}{1-\psi_p\rho_\lambda}, \quad x_z = \frac{\rho_z \psi_p}{1-\psi_p\rho_z} z_t, \quad x_{\epsilon_R} = -\psi_p \sigma_R. \tag{69}$$

After having determined the law of motion for output, we now solve for the labor share, inflation, and nominal interest rates. Using (57) and (62) we immediately deduce that the labor share evolves according to

$$\widehat{lsh}_t = \left[1 + (1+\nu)x_\phi\right]\phi_t + (1+\nu)x_\lambda \lambda_t + (1+\nu)x_z z_t + (1+\nu)x_{\epsilon_R}\epsilon_{R,t}. \tag{70}$$

To obtain the law of motion of inflation, we have to solve the following functional equation derived from the New Keynesian Phillips curve (60):

$$\begin{aligned} &\mathbb{E}_t \mathcal{H}(\hat{\pi}(\cdot)) \\ &\quad = \mathbb{E}_t \big[\hat{\pi}(\phi_t, \lambda_t, z_t, \epsilon_{R,t}) - \beta \hat{\pi}\big(\rho_\phi \phi_t + \sigma_\phi \epsilon_{\phi,t+1}, \rho_\lambda \lambda_t + \sigma_\lambda \epsilon_{\lambda,t+1}, \rho z_t + \sigma_z \epsilon_{z,t+1}, \epsilon_{R,t+1}\big) \\ &\qquad - \kappa_p \widehat{lsh}(\phi_t, \lambda_t, z_t, \epsilon_{R,t}) - \kappa_p \lambda_t\big] = 0, \end{aligned} \tag{71}$$

where $\widehat{lsh}(\cdot)$ is given by (70). The solution takes the form

$$\begin{aligned} \hat{\pi}_t = {} & \frac{\kappa_p}{1-\beta\rho_\phi}\left[1 + (1+\nu)x_\phi\right]\phi_t + \frac{\kappa_p}{1-\beta\rho_\lambda}[1 + (1+\nu)x_\lambda]\lambda_t \\ & + \frac{\kappa_p}{(1-\beta\rho_z)}(1+\nu)x_z z_t + \kappa_p(1+\nu)x_{\epsilon_R}\epsilon_{R,t}. \end{aligned} \tag{72}$$

Finally, combining (72) with the monetary policy rule (63) yields the solution for the nominal interest rate

$$\begin{aligned}\hat{R}_t = & \frac{\kappa_p/\beta}{1-\beta\rho_\phi}\left[1+(1+\nu)x_\phi\right]\phi_t + \frac{\kappa_p/\beta}{1-\beta\rho_\lambda}[1+(1+\nu)x_\lambda]\lambda_t \\ & + \frac{\kappa_p/\beta}{1-\beta\rho_z}(1+\nu)x_z z_t + \left[\kappa_p(1+\nu)x_{\epsilon_R}/\beta + \sigma_R\right]\epsilon_{R,t}.\end{aligned} \tag{73}$$

8.1.3 State-Space Representation

To confront the model with data, one has to account for the presence of the model-implied stochastic trend in aggregate output and to add the steady states to all model variables. Measurement equations for output growth, the labor share, net inflation rates and net interest rates take the form

$$\begin{aligned}\log(X_t/X_{t-1}) &= \hat{x}_t - \hat{x}_{t-1} + z_t + \log\gamma \\ \log(lsh_t) &= \widehat{lsh}_t + \log(lsh) \\ \log\pi_t &= \hat{\pi}_t + \log\pi^* \\ \log R_t &= \hat{R}_t + \log(\pi^*\gamma/\beta).\end{aligned} \tag{74}$$

The DSGE model solution has the form of a generic state-space model. Define the $n_s \times 1$ vector of econometric state variables s_t as

$$s_t = [\phi_t, \lambda_t, z_t, \epsilon_{R,t}, \hat{x}_{t-1}]\prime$$

and the vector of DSGE model parameters[af]

$$\theta = [\beta, \gamma, \lambda, \pi^*, \zeta_p, \nu, \rho_\phi, \rho_\lambda, \rho_z, \sigma_\phi, \sigma_\lambda, \sigma_z, \sigma_R]'. \tag{75}$$

We omitted the steady-state output x^* from the list of parameters because it does not affect the law of motion of output growth. Using this notation, we can express the state transition equation as

$$s_t = \Phi_1(\theta)s_{t-1} + \Phi_\epsilon(\theta)\epsilon_t, \tag{76}$$

where the $n_\epsilon \times 1$ vector ϵ_t is defined as $\epsilon_t = [\epsilon_{\phi,t}, \epsilon_{\lambda,t}, \epsilon_{z,t}, \epsilon_{R,t}]'$. The coefficient matrices $\Phi_1(\theta)$ and $\Phi_\epsilon(\theta)$ are determined by (54), (58), (61), the identity $\epsilon_{R,t} = \epsilon_{R,t}$, and a lagged version of (69) to determine $\hat{x}_{t-1}$. If we define the $n_y \times 1$ vector of observables as

$$y_t = M_y'[\log(X_t/X_{t-1}), \log lsh_t, \log\pi_t, \log R_t]', \tag{77}$$

where M_y' is a matrix that selects rows of the vector $[\log(X_t/X_{t-1}), \log lsh_t, \log\pi_t, \log R_t]'$ then the measurement equation can be written as

$$y_t = \Psi_0(\theta) + \Psi_1(\theta)s_t. \tag{78}$$

[af] From now on, we will use θ to denote the parameters of the DSGE model as opposed to the coefficients of a decision rule conditional on a particular set of DSGE model parameters. Also, to reduce clutter, we no longer distinguish vectors and matrices from scalars by using boldfaced symbols.

The coefficient matrices $\Psi_0(\theta)$ and $\Psi_1(\theta)$ can be obtained from (74), the equilibrium law of motion for the detrended model variables given by (69), (70), (72), and (73). They are summarized in Table 4.

The state-space representation of the DSGE model given by (76) and (78) provides the basis for the subsequent econometric analysis. It characterizes the joint distribution of the observables y_t and the state variables s_t conditional on the DSGE model parameters θ

$$p(Y_{1:T}, S_{1:T}|\theta) = \int \left(\prod_{t=1}^{T} p(y_t|s_t,\theta) p(s_t|s_{t-1},\theta) \right) p(s_0|\theta) ds_0, \tag{79}$$

where $Y_{1:t} = \{y_1,\ldots,y_t\}$ and $S_{1:t} = \{s_1,\ldots,s_t\}$. Because the states are (at least partially) unobserved, we will often work with the marginal distribution of the observables defined as

$$p(Y_{1:T}|\theta) = \int p(Y_{1:T}, S_{1:T}|\theta) dS_{1:T}. \tag{80}$$

As a function of θ the density $p(Y_{1:T}|\theta)$ is called the likelihood function. It plays a central role in econometric inference and its evaluation will be discussed in detail in Section 10.

Remark 28 First, it is important to distinguish economic state variables, namely, ϕ_t, λ_t, z_t, and $\epsilon_{R,t}$, that are relevant for the agents' intertemporal optimization problems, from the econometric state variables s_t, which are used to cast the DSGE model solution into the state-space form given by (76) and (78). The economic state variables of our simple model are all exogenous. As we have seen in Section 4.3, the vector of state variables of a richer DSGE model also may include one or more endogenous variables, eg, the capital stock. Second, output growth in the measurement equation could be replaced by the level of output. This would require adding x^* to the parameter vector θ, eliminating $\hat{x}_{t-1}$ from s_t, adding $\log Z_t/\gamma^t$ to s_t, and accounting for the deterministic trend component $(\log\gamma)t$ in log output in the measurement equation. Third, the measurement Eq. (78) could be augmented by measurement errors. Fourth, if a DSGE model is solved with a higher-order perturbation or projection method, then, depending on how exactly the state vector s_t is defined, the state-transition Eq. (76), the measurement Eq. (78), or both are nonlinear.

8.2 Model Implications

Once we specify a distribution for the innovation vector ϵ_t the probability distribution of the DSGE model variables is fully determined. Recall that the innovation standard deviations were absorbed into the definition of the matrix $\Phi_\epsilon(\theta)$ in (76). For the sake of concreteness, we assume that

$$\epsilon_t \sim iidN(0, I), \tag{81}$$

where I denotes the identity matrix. Based on the probabilistic structure of the DSGE model, we can derive a number of implications from the DSGE model that will later

Table 4 System matrices for DSGE model

State-space representation:

$$y_t = \boldsymbol{\Psi}_0(\theta) + \boldsymbol{\Psi}_1(\theta) s_t$$
$$s_t = \boldsymbol{\Phi}_1(\theta) s_{t-1} + \boldsymbol{\Phi}_\epsilon(\theta)\epsilon_t$$

System matrices:

$$\boldsymbol{\Psi}_0(\theta) = M_y' \begin{bmatrix} \log\gamma \\ \log(lsh) \\ \log\pi^* \\ \log(\pi^*\gamma/\beta) \end{bmatrix}, \quad x_\phi = -\frac{\kappa_p\psi_p/\beta}{1-\psi_p\rho_\phi}, \quad x_\lambda = -\frac{\kappa_p\psi_p/\beta}{1-\psi_p\rho_\lambda}, \quad x_z = \frac{\rho_z\psi_p}{1-\psi_p\rho_z}, \quad x_{\epsilon_R} = -\psi_p\sigma_R$$

$$\boldsymbol{\Psi}_1(\theta) = M_y' \begin{bmatrix} x_\phi & x_\lambda & x_z + 1 & x_{\epsilon_R} & -1 \\ 1 + (1+\nu)x_\phi & (1+\nu)x_\lambda & (1+\nu)x_z & (1+\nu)x_{\epsilon_R} & 0 \\ \frac{\kappa_p}{1-\beta\rho_\phi}(1+(1+\nu)x_\phi) & \frac{\kappa_p}{1-\beta\rho_\lambda}(1+(1+\nu)x_\lambda) & \frac{\kappa_p}{1-\beta\rho_z}(1+\nu)x_z & +\kappa_p(1+\nu)x_{\epsilon_R} & 0 \\ \frac{\kappa_p/\beta}{1-\beta\rho_\phi}(1+(1+\nu)x_\phi) & \frac{\kappa_p/\beta}{1-\beta\rho_\lambda}(1+(1+\nu)x_\lambda) & \frac{\kappa_p/\beta}{1-\beta\rho_z}(1+\nu)x_z & (\kappa_p(1+\nu)x_{\epsilon_R}/\beta + \sigma_R) & 0 \end{bmatrix}$$

$$\boldsymbol{\Phi}_1(\theta) = \begin{bmatrix} \rho_\phi & 0 & 0 & 0 & 0 \\ 0 & \rho_\lambda & 0 & 0 & 0 \\ 0 & 0 & \rho_z & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ x_\phi & x_\lambda & x_z & x_{\epsilon_R} & 0 \end{bmatrix}, \quad \boldsymbol{\Phi}_\epsilon(\theta) = \begin{bmatrix} \sigma_\phi & 0 & 0 & 0 \\ 0 & \sigma_\lambda & 0 & 0 \\ 0 & 0 & \sigma_z & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

M_y' is an $n_y \times 4$ selection matrix that selects rows of $\boldsymbol{\Psi}_0$ and $\boldsymbol{\Psi}_1$.

Table 5 Parameter values for stylized DSGE model

Parameter	Value	Parameter	Value
β	$1/1.01$	γ	$\exp(0.005)$
λ	0.15	π^*	$\exp(0.005)$
ζ_p	0.65	ν	0
ρ_ϕ	0.94	ρ_λ	0.88
ρ_z	0.13		
σ_ϕ	0.01	σ_λ	0.01
σ_z	0.01	σ_R	0.01

be used to construct estimators of the parameter vector θ and evaluate the fit of the model. For now, we fix θ to the values listed in Table 5.

8.2.1 Autocovariances and Forecast Error Variances

DSGE models are widely used for business cycle analysis. In this regard, the model-implied variances, autocorrelations, and cross-correlations are important objects. For linear DSGE models it is straightforward to compute the autocovariance function from the state-space representation given by (76) and (78).[ag] Using the notation

$$\Gamma_{yy}(h) = \mathbb{E}[y_t y_{t-h}], \quad \Gamma_{ss}(h) = \mathbb{E}[s_t s_{t-h}], \quad \text{and} \quad \Gamma_{ys}(h) = \mathbb{E}[y_t s'_{t-h}]$$

and the assumption that $\mathbb{E}[\epsilon_t \epsilon_t']= I$, we can express the autocovariance matrix of s_t as the solution to the following Lyapunov equation:[ah]

$$\Gamma_{ss}(0) = \Phi_1 \Gamma_{ss}(0) \Phi_1' + \Phi_\epsilon \Phi_\epsilon'. \tag{82}$$

Once the covariance matrix of s_t has been determined, it is straightforward to compute the autocovariance matrices for $h \neq 0$ according to

$$\Gamma_{ss}(h) = \Phi_1^h \Gamma_{ss}(0). \tag{83}$$

Finally, using the measurement Eq. (78), we deduce that

$$\Gamma_{yy}(h) = \Psi_1 \Gamma_{ss}(h) \Psi_1', \quad \Gamma_{ys}(h) = \Psi_1 \Gamma_{ss}(h). \tag{84}$$

[ag] For the parameters in Table 5, the largest (in absolute value) eigenvalue of the matrix $\Phi_1(\theta)$ in (76) is less than one, which implies that the VAR(1) law of motion for s_t is covariance stationary.

[ah] Efficient numerical routines to solve Lyapunov equations are readily available in many software packages, eg, the function *dylap* in MATLAB.

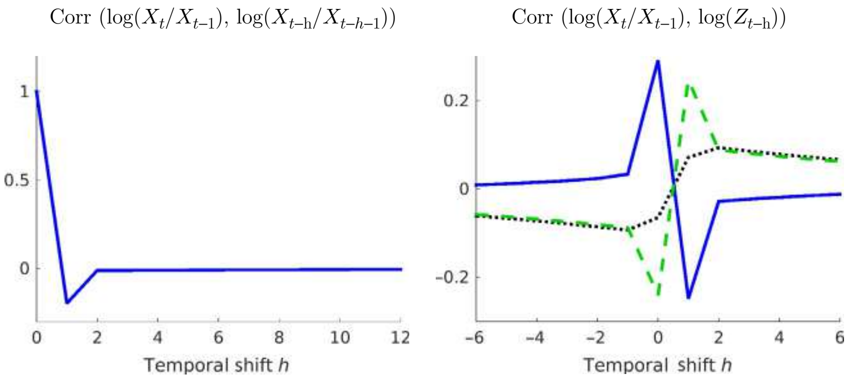

Fig. 16 Autocorrelations. *Notes*: *Right panel*: correlations of output growth with labor share (*solid*), inflation (*dotted*), and interest rates (*dashed*).

Correlations can be easily computed by normalizing the entries of the autocovariance matrices using the respective standard deviations. Fig. 16 shows the model-implied autocorrelation function of output growth and the cross-correlations of output growth with the labor share, inflation, and interest rates as a function of the temporal shift h.

The law of motion for the state vector s_t can also be expressed as the infinite-order vector moving average (MA) process

$$y_t = \Psi_0 + \Psi_1 \sum_{s=0}^{\infty} \Phi_1^s \Phi_\epsilon \epsilon_{t-s}. \tag{85}$$

Based on the moving average representation, it is straightforward to compute the h-step-ahead forecast error, which is given by

$$e_{t|t-h} = y_t - \mathbb{E}_{t-h}[y_t] = \Psi_1 \sum_{s=0}^{h-1} \Phi_1^s \Phi_\epsilon \epsilon_{t-s}. \tag{86}$$

The h-step-ahead forecast error covariance matrix is given by

$$\mathbb{E}[e_{t|t-h} e'_{t|t-h}] = \Psi_1 \left(\sum_{s=0}^{h-1} \Phi_1^s \Phi_\epsilon \Phi_\epsilon' \Phi_1^{s'} \right) \Psi_1' \quad \text{with} \quad \lim_{h\to\infty} \mathbb{E}[e_{t|t-h} e'_{t|t-h}] = \Gamma_{ss}(0). \tag{87}$$

Under the assumption that $\mathbb{E}[\epsilon_t \epsilon_t'] = I$, it is possible to decompose the forecast error covariance matrix as follows. Let $I^{(j)}$ be defined by setting all but the j-th diagonal element of the identity matrix I to zero. Then we can write

$$I = \sum_{j=1}^{n_\epsilon} I^{(j)}. \tag{88}$$

Moreover, we can express the contribution of shock j to the forecast error for y_t as

$$e^{(j)}_{t|t-h} = \Psi_1 \sum_{s=0}^{h-1} \Phi_1^s \Phi_\epsilon I^{(j)} \epsilon_{t-s}. \tag{89}$$

Thus, the contribution of shock j to the forecast error variance of observation $y_{i,t}$ is given by the ratio

$$\text{FEVD}(i,j,h) = \frac{\left[\Psi_1 \left(\sum_{s=0}^{h-1} \Phi_1^s \Phi_\epsilon I^{(j)} \Phi_\epsilon' \Phi_1^{s'}\right) \Psi_1'\right]_{ii}}{\left[\Psi_1 \left(\sum_{s=0}^{h-1} \Phi_1^s \Phi_\epsilon \Phi_\epsilon' \Phi_1^{s'}\right) \Psi_1'\right]_{ii}}, \tag{90}$$

where $[A]_{ij}$ denotes element (i,j) of a matrix A. Fig. 17 shows the contribution of the four shocks to the forecast error variance of output growth, the labor share, inflation, and interest rates in the stylized DSGE model. Given the choice of parameters θ in

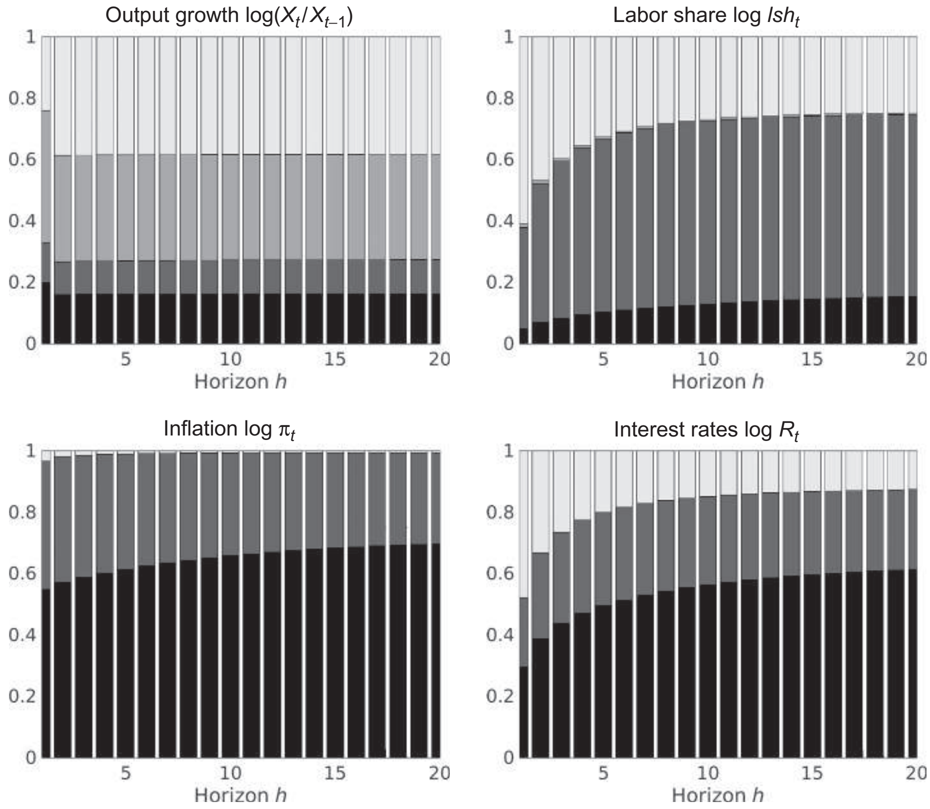

Fig. 17 Forecast error variance decomposition. *Notes*: The stacked bar plots represent the cumulative forecast error variance decomposition. The bars, from darkest to lightest, represent the contributions of ϕ_t, λ_t, z_t, and $\varepsilon_{R,t}$.

Table 5, most of the variation in output growth is due to the technology and the monetary policy shocks. The labor share fluctuations are dominated by the mark-up shock λ_t, in particular in the long run. Inflation and interest rate movements are strongly influenced by the preference shock ϕ_t and the mark-up shock λ_t.

8.2.2 Spectrum

Instead of studying DSGE model implications over different forecasting horizons, one can also consider different frequency bands. There is a long tradition of frequency domain analysis in the time series literature. A classic reference is Priestley (1981). We start with a brief discussion of the linear cyclical model, which will be useful for interpreting some of the formulas presented subsequently. Suppose that y_t is a scalar time series that follows the process

$$y_t = 2\sum_{j=1}^{m} a_j\big(\cos\theta_j \cos(\omega_j t) - \sin\theta_j \sin(\omega_j t)\big), \tag{91}$$

where $\theta_j \sim iidU[-\pi,\pi]$ and $0 \le \omega_j \le \omega_{j+1} \le \pi$. The random variables θ_j cause a phase shift of the cycle and are assumed to be determined in the infinite past. In a nutshell, the model in (91) expresses the variable y_t as the sum of sine and cosine waves that differ in their frequency. The interpretation of the ω_j's depends on the length of the period t. Suppose the model is designed for quarterly data and $\omega_j = (2\pi)/32$. This means that it takes 32 periods to complete the cycle. Business cycles typically comprise cycles that have a duration of 8–32 quarters, which would correspond to $\omega_j \in [0.196, 0.785]$ for quarterly t.

Using Euler's formula, we rewrite the cyclical model in terms of an exponential function:

$$y_t = \sum_{j=-m}^{m} A(\omega_j)e^{i\omega_j t}, \tag{92}$$

where $\omega_{-j} = -\omega_j$, $i = \sqrt{-1}$, and

$$A(\omega_j) = \begin{cases} a_j\big(\cos\theta_{|j|} + i\sin\theta_{|j|}\big) & \text{if } j > 0 \\ a_j\big(\cos\theta_{|j|} - i\sin\theta_{|j|}\big) & \text{if } j < 0 \end{cases} \tag{93}$$

It can be verified that expressions (91) and (92) are identical. The function $A(\omega_j)$ captures the amplitude of cycles with frequency ω_j.

The spectral distribution function of y_t on the interval $\omega \in (-\pi,\pi]$ is defined as

$$F_{yy}(\omega) = \sum_{j=-m}^{m} \mathbb{E}[A(\omega_j)\overline{A(\omega_j)}]\mathbb{I}\{\omega_j \le \omega\}, \tag{94}$$

where $\mathbb{I}\{\omega_j \le \omega\}$ denotes the indicator function that is one if $\omega_j \le \omega$ and $\bar{z} = x - iy$ is the complex conjugate of $z = x + iy$. If $F_{yy}(\omega)$ is differentiable with respect to ω, then we can define the spectral density function as

$$f_{yy}(\omega) = dF_{yy}(\omega)d\omega. \tag{95}$$

If a process has a spectral density function $f_{yy}(\omega)$, then the covariances can be expressed as

$$\Gamma_{yy}(h) = \int_{(-\pi,\pi]} e^{ih\omega} f_{yy}(\omega)d\omega. \tag{96}$$

For the linear cyclical model in (91) the autovariances are given by

$$\Gamma_{yy}(h) = \sum_{j=-m}^{m} \mathbb{E}[A(\omega_j)\overline{A(\omega_j)}]e^{i\omega_j h} = \sum_{j=-m}^{m} a_j^2 e^{i\omega_j h}. \tag{97}$$

The spectral density uniquely determines the entire sequence of autocovariances. Moreover, the converse is also true. The spectral density can be obtained from the autocovariances of y_t as follows:

$$f_{yy}(\omega) = \frac{1}{2\pi}\sum_{h=-\infty}^{\infty} \Gamma_{yy}(h)e^{-i\omega h}. \tag{98}$$

The formulas (96) and (98) imply that the spectral density function and the sequence of autocovariances contain the same information. Their validity is not restricted to the linear cyclical model and they extend to vector-valued y_t's. Recall that for the DSGE model defined by the state-space system (76) and (78) the autocovariance function for the state vector s_t was defined as $\Gamma_{ss}(h) = \Phi_1^h \Gamma_{ss}(0)$. Thus,

$$\begin{aligned} f_{ss}(\omega) &= \frac{1}{2\pi}\sum_{h=-\infty}^{\infty} \Phi_1^h \Gamma_{ss}(0)e^{-i\omega h} \\ &= \frac{1}{2\pi}\left(I - \Phi_1' e^{i\omega}\right)^{-1} \Phi_\epsilon \Phi_\epsilon' \left(I - \Phi_1 e^{-i\omega}\right)^{-1}. \end{aligned} \tag{99}$$

The contribution of shock j to the spectral density is given by

$$f_{ss}^{(j)}(\omega) = \frac{1}{2\pi}\left(I - \Phi_1' e^{i\omega}\right)^{-1} \Phi_\epsilon \mathcal{I}^{(j)} \Phi_\epsilon' \left(I - \Phi_1 e^{-i\omega}\right)^{-1}. \tag{100}$$

The spectral density for the observables y_t (and the contribution of shock j to the spectral density) can be easily obtained as

$$f_{yy}(\omega) = \Psi_1 f_{ss}(\omega)\Psi_1' \quad \text{and} \quad f_{yy}^{(j)}(\omega) = \Psi_1 f_{ss}^{(j)}(\omega)\Psi_1'. \tag{101}$$

Fig. 18 depicts the spectral density functions for output growth, the labor share, inflation, and interest rates for the stylized DSGE model conditional on the parameters in Table 5. Note that $f_{yy}(\omega)$ is a matrix valued function. The four panels correspond to the diagonal elements of this function, providing a summary of the univariate autocovariance properties of the four series. Each panel stacks the contributions of the four shocks to the spectral densities. Because the shocks are independent and evolve according to AR(1) processes, the spectral density peaks at the origin and then decays as the frequency increases.

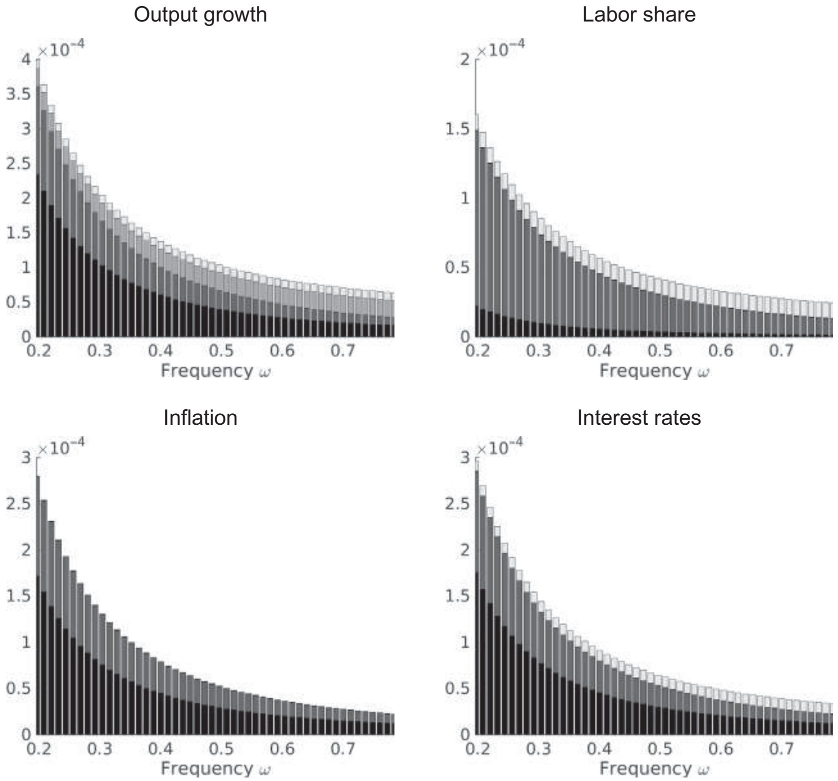

Fig. 18 Spectral decomposition. *Notes*: The stacked bar plots depict cumulative spectral densities. The bars, from darkest to lightest, represent the contributions of ϕ_t, λ_t, z_t, and $\varepsilon_{R,t}$.

8.2.3 Impulse Response Functions

An important tool for studying the dynamic effects of exogenous shocks are impulse response functions (IRFs). Formally, impulse responses in a DSGE model can be defined as the difference between two conditional expectations:

$$\mathrm{IRF}(i,j,h|s_{t-1}) = \mathbb{E}\big[y_{i,t+h} \mid s_{t-1}, \epsilon_{j,t} = 1\big] - \mathbb{E}[y_{i,t+h}| \, s_{t-1}]. \tag{102}$$

Both expectations are conditional on the initial state s_{t-1} and integrate over current and future realizations of the shocks ϵ_t. However, the first term also conditions on $\epsilon_{j,t} = 1$, whereas the second term averages of $\epsilon_{j,t}$. In a linearized DSGE model with a state-space representation of the form (76) and (78), we can use the linearity and the property that $\mathbb{E}[\epsilon_{t+h}|s_{t-1}] = 0$ for $h = 0,1,\ldots$ to deduce that

$$\mathrm{IRF}(.,j,h) = \Psi_1 \frac{\partial}{\partial \epsilon_{j,t}} s_{t+h} = \Psi_1 \Phi_1^h [\Phi_\epsilon]_{.j}, \tag{103}$$

where $[A]_{.j}$ is the j-th column of a matrix A. We dropped s_{t-1} from the conditioning set to simplify the notation.

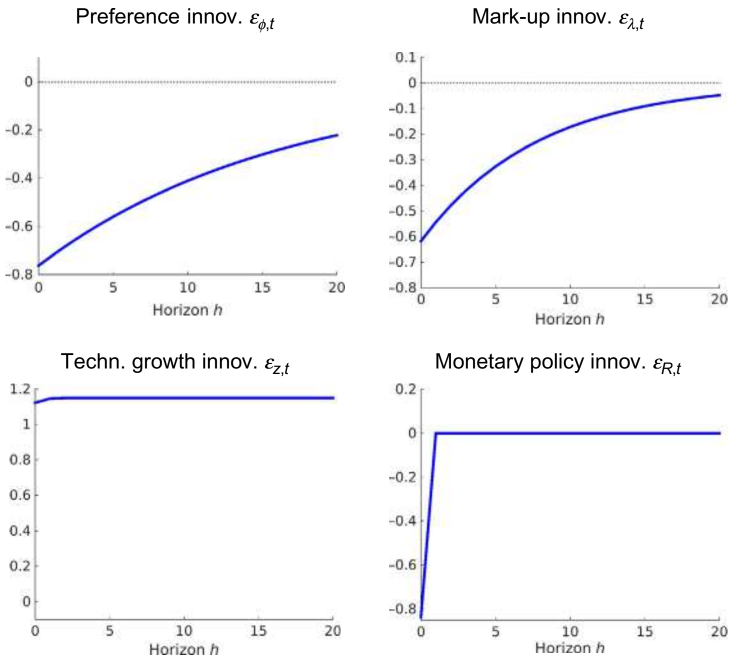

Fig. 19 Impulse responses of log output $100\log(X_{t+h}/X_t)$.

Fig. 19 depicts the impulse response functions for the stylized DSGE model of log output to the four structural shocks, which can be easily obtained from (69) and the laws of motion of the exogenous shock processes. The preference and mark-up shocks lower output upon impact. Subsequently, output reverts back to its steady state. The speed of the reversion is determined by the autoregressive coefficient associated with the exogenous shock process. The technology growth shock raises the log level of output permanently, whereas a monetary policy shock has only a one-period effect on output.

8.2.4 Conditional Moment Restrictions

The intertemporal optimality conditions take the form of conditional moment restrictions. For instance, rearranging the terms in the New Keynesian Phillips (60) curve, we can write

$$\mathbb{E}_{t-1}\left[\hat{\pi}_{t-1}-\beta\hat{\pi}_t-\kappa_p\left(\widehat{lsh}_{t-1}+\lambda_{t-1}\right)\right]=0. \tag{104}$$

The conditional moment condition can be converted into a vector of unconditional moment conditions as follows. Let $\mathcal{F}_t$ denote the sigma algebra generated by the infinite histories of $\{y_\tau, s_\tau, \epsilon_\tau\}_{\tau=-\infty}^{t}$ and let $\tilde{Z}_t$ be a vector of random variables that is measurable with respect to $\mathcal{F}_t$, meaning that its value is determined based on information on current and past (y_t, s_t, ϵ_t). Then for every such vector $\tilde{Z}_{t-1}$,

$$\begin{aligned}&\mathbb{E}\left[\widetilde{Z}_{t-1}\left(\hat{\pi}_{t-1}-\beta\hat{\pi}_t-\kappa_p(\widehat{lsh}_{t-1}+\lambda_{t-1})\right)\right]\\&\quad=\mathbb{E}\left[\widetilde{Z}_{t-1}\mathbb{E}_{t-1}\left[\hat{\pi}_{t-1}-\beta\hat{\pi}_t-\kappa_p(\widehat{lsh}_{t-1}+\lambda_{t-1})\right]\right]=0,\end{aligned} \tag{105}$$

where $\mathbb{E}_{t-1}[\cdot]=\mathbb{E}[\cdot|\mathcal{F}_{t-1}]$.

The moment conditions derived from the New Keynesian Phillips curve involve the latent price mark-up shock λ_t, which will cause difficulties if one tries to use (105) in an estimation objective function. Now consider the consumption Euler equation (56) instead. Recall that the measurement equations imply that

$$\hat{x}_t-\hat{x}_{t-1}+z_t=\log X_t-\log X_{t-1}-\log\gamma \quad\text{and}\quad \hat{R}_t=\log R_t-\log(\pi^*\gamma/\beta).$$

Thus, we can write

$$\mathbb{E}_{t-1}[-\log(X_t/X_{t-1})+\log R_{t-1}-\log\pi_t-\log(1/\beta)]=0. \tag{106}$$

The terms γ and $\log\pi^*$ that appear in the steady-state formulas for the nominal interest rate and inflation cancel and the conditional moment condition only depends on observables and the model parameters, but not on latent variables. Finally, as long as the monetary policy shock satisfies the martingale difference sequences property $\mathbb{E}_{t-1}[\epsilon_{R,t}]=0$, we obtain from the monetary policy rule the condition that

$$\mathbb{E}_{t-1}[\log R_t-\log(\gamma/\beta)-\psi\log\pi_t-(1-\psi)\log\pi^*]=0. \tag{107}$$

Both (106) and (107) can be converted into an unconditional moment condition using an $\mathcal{F}_{t-1}$ measurable random vector $\mathcal{Z}_{t-1}$ as in (105).

8.2.5 Analytical Calculation of Moments vs Simulation Approximations

As previously shown, formulas for autocovariance functions, spectra, and impulse response functions for a linearized DSGE model can be derived analytically from the state-space representation. These analytical expressions can then be numerically evaluated for different vectors of parameter values θ. For DSGE models solved with perturbation methods, there are also analytical formulas available that exploit a conditionally linear structure of some perturbation solutions; see Andreasen et al. (2013). For a general nonlinear DSGE model, the implied moments have to be computed using Monte Carlo simulation. For instance, let $Y^*_{1:T}$ denote a sequence of observations simulated from the state-space representation of the DSGE model by drawing an initial state vector s_0 and innovations ϵ_t from their model-implied distributions, then

$$\frac{1}{T}\sum_{t=1}^{T}y_t^*\xrightarrow{a.s.}\mathbb{E}[y_t], \tag{108}$$

provided that the DSGE model-implied y_t is strictly stationary and ergodic.[ai] The downside of Monte Carlo approximations is that they are associated with a simulation error. We will come back to this problem in Section 11.2, when we use simulation approximations of moments to construct estimators of θ.

8.3 Empirical Analogs

We now examine sample analogs of the population moments derived from the state-space representation of the DSGE model using US data. The time series were downloaded from the FRED database maintained by the Federal Reserve Bank of St. Louis and we report the series labels in parentheses. For real aggregate output, we use quarterly, seasonally adjusted GDP at the annual rate that has been pegged to 2009 dollars (GDPC96). We turn GDP into growth rates by taking logs and then differencing. The labor share is defined as Compensation of Employees (COE) divided by nominal GDP (GDP). Both series are quarterly and seasonally adjusted at the annual rate. We use the log labor share as the observable. Inflation rates are computed from the implicit price deflator (GDPDEF) by taking log differences. Lastly, for the interest rate, we use the Effective Federal Funds Rate (FEDFUNDS), which is monthly, and not seasonally adjusted. Quarterly interest rates are obtained by taking averages of the monthly rates. Throughout this section we focus on the post-Great Moderation and pre-Great Recession period and restrict our sample from 1984:Q1 to 2007:Q4.

8.3.1 *Autocovariances*

The sample analog of the population autocovariance $\Gamma_{yy}(h)$ is defined as

$$\hat{\Gamma}_{yy}(h) = \frac{1}{T}\sum_{t=h}^{T}(y_t - \hat{\mu}_y)(y_{t-h} - \hat{\mu}_y)', \quad \text{where} \quad \hat{\mu}_y = \frac{1}{T}\sum_{t=1}^{T} y_t. \tag{109}$$

Under suitable regularity conditions, eg, covariance stationarity of the vector process y_t, a sufficiently fast decay of the serial correlation in y_t, and some bounds on higher-order moments of y_t, the sample autocovariance $\hat{\Gamma}_{yy}(h)$ converges to the population autocovariance $\Gamma_{yy}(h)$, satisfying a strong law of large numbers (SLLN) and a central limit theorem (CLT).

If the object of interest is a sequence of autocovariance matrices, then it might be more efficient to first estimate an auxiliary model and then convert the parameter estimates of the auxiliary model into estimates of the autocovariance sequence. A natural class of auxiliary models is provided by linear vector autoregressions (VARs). For illustrative purposes consider the following VAR(1):

[ai] A sequence of random variables X_T converges to a limit random variable X almost surely (a.s.) if the set of trajectories for which $X_T \not\to X$ has probability zero.

$$y_t = \Phi_1 y_{t-1} + \Phi_0 + u_t, \quad u_t \sim iid(0, \Sigma). \tag{110}$$

The OLS estimator of Φ_1 can be approximated by

$$\hat{\Phi}_1 = \hat{\Gamma}_{yy}(1)\hat{\Gamma}_{yy}^{-1}(0) + O_p(T^{-1}), \quad \hat{\Sigma} = \hat{\Gamma}_{yy}(0) - \hat{\Gamma}_{yy}(1)\hat{\Gamma}_{yy}^{-1}(0)\hat{\Gamma}'_{yy}(1) + O_p(T^{-1}) \tag{111}$$

The $O_p(T^{-1})$ terms arise because the range of the summations in the definition of the sample autocovariances in (109) and the definition of the OLS estimator are not exactly the same.[aj] Suppose that now we plug the OLS estimator into the autocovariance formulas associated with the VAR(1) (see (82) and (83)), then:

$$\hat{\Gamma}_{yy}^V(0) = \hat{\Gamma}_{yy}(0) + O_p(T^{-1}), \quad \hat{\Gamma}_{yy}^V(h) = \left(\hat{\Gamma}_{yy}(1)\hat{\Gamma}_{yy}^{-1}(0)\right)^h \hat{\Gamma}_{yy}(0) + O_p(T^{-1}). \tag{112}$$

Note that for $h = 0,1$ we obtain $\hat{\Gamma}_{yy}^V(1) = \hat{\Gamma}_{yy}(1) + O_p(T^{-1})$. For $h > 1$ the VAR(1) plug-in estimate of the autocovariance matrix differs from the sample autocovariance matrix. If the actual time series are well approximated by a VAR(1), then the plug-in autocovariance estimate tends to be more efficient than the sample autocovariance estimate $\hat{\Gamma}_{yy}(h)$; see, for instance, Schorfheide (2005b).

In practice, a VAR(1) may be insufficient to capture the dynamics of a time series y_t. In this case the autocovariances can be obtained from a VAR(p)

$$y_t = \Phi_1 y_{t-1} + \ldots + \Phi_p y_{t-p} + \Phi_0 + u_t, \quad u_t \sim iid(0, \Sigma). \tag{113}$$

The appropriate lag length p can be determined with a model selection criterion, eg, the Schwarz (1978) criterion, which is often called the Bayesian information criterion (BIC). The notationally easiest way (but not the computationally fastest way) is to rewrite the VAR(p) in companion form. This entails expressing the law of motion for the stacked vector $\tilde{y}_t = [y'_t, y'_{t-1}, \ldots, y'_{t-p+1}]$ as VAR(1):

$$\tilde{y}_t = \tilde{\Phi}_1 \tilde{y}_{t-1} + \tilde{\Phi}_0 + \tilde{u}_t, \quad \tilde{u}_t \sim iid(0, \tilde{\Sigma}), \tag{114}$$

where

$$\tilde{\Phi}_1 = \begin{bmatrix} \Phi_1 & \ldots & \Phi_{p-1} & \Phi_p \\ I_{n\times n} & \ldots & 0_{n\times n} & 0_{n\times n} \\ \vdots & \ddots & \vdots & \vdots \\ 0_{n\times n} & \ldots & I_{n\times n} & 0_{n\times n} \end{bmatrix}, \quad \tilde{\Phi}_0 = \begin{bmatrix} \Phi_0 \\ 0_{n(p-1)\times 1} \end{bmatrix},$$

$$\tilde{\epsilon}_t = \begin{bmatrix} \epsilon_t \\ 0_{n(p-1)\times 1} \end{bmatrix}, \quad \tilde{\Sigma} = \begin{bmatrix} \Sigma & 0_{n\times n(p-1)} \\ 0_{n(p-1)\times n} & 0_{n(p-1)\times n(p-1)} \end{bmatrix}.$$

[aj] We say that a sequence of random variables is $O_p(T^{-1})$ if TX_T is stochastically bounded as $T \to \infty$.

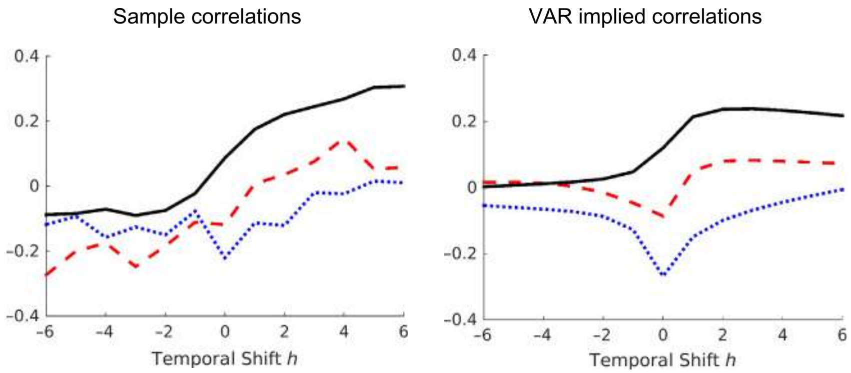

Fig. 20 Empirical cross-correlations $\text{Corr}(\log(X_t/X_{t-1}), \log Z_{t-h})$. *Notes*: Each plot shows the correlation of output growth $\log(X_t/X_{t-1})$ with interest rates (*solid*), inflation (*dashed*), and the labor share (*dotted*), respectively. *Left panel*: correlation functions are computed from sample autocovariance matrices $\hat{\Gamma}_{yy}(h)$. *Right panel*: correlation functions are computed from estimated VAR(1).

The autocovariances for $\widetilde{y}_t$ are then obtained by adjusting the VAR(1) formulas (112) to $\widetilde{y}_t$ and reading off the desired submatrices that correspond to the autocovariance matrices for y_t using the selection matrix $M' = [I_n, 0_{n\times n(p-1)}]$ such that $y_t = M'\widetilde{y}_t$.

We estimate a VAR for output growth, labor share, inflation, and interest rates. The lag length $p = 1$ is determined by the BIC. The left panel of Fig. 20 shows sample cross-correlations (obtained from $\hat{\Gamma}_{yy}(h)$ in (109)) between output growth and leads and lags of the labor share, inflation, and interest rates, respectively. The right panel depicts correlation functions derived from the estimated VAR(1). The two sets of correlation functions are qualitatively similar but quantitatively different. Because the VAR model is more parsimonious, the VAR-implied correlation functions are smoother.

8.3.2 Spectrum

An intuitively plausible estimate of the spectrum is the sample periodogram, defined as

$$\hat{f}_{yy}(\omega) = \frac{1}{2\pi}\sum_{h=-T+1}^{T-1}\hat{\Gamma}_{yy}(h)e^{-i\omega h} = \frac{1}{2\pi}\left(\hat{\Gamma}_{yy}(0) + \sum_{h=1}^{T-1}(\hat{\Gamma}_{yy}(h) + \hat{\Gamma}_{yy}(h)')\cos\omega h\right). \quad (115)$$

While the sample periodogram is an asymptotically unbiased estimator of the population spectral density, it is inconsistent because its variance does not vanish as the sample size $T \longrightarrow \infty$. A consistent estimator can be obtained by smoothing the sample periodogram across adjacent frequencies. Define the fundamental frequencies

$$\omega_j = j\frac{2\pi}{T}, \quad j = 1, \ldots, (T-1)/2$$

and let $K(x)$ denote a kernel function with the property that $\int K(x)dx = 1$. A smoothed periodogram can be defined as

$$\bar{f}_{yy}(\omega) = \frac{\pi}{\lambda(T-1)/2} \sum_{j=1}^{(T-1)/2} K\left(\frac{\omega_j - \omega}{\lambda}\right) \hat{f}_{yy}(\omega_j). \tag{116}$$

An example of a simple kernel function is

$$K\left(\frac{\omega_j - \omega}{\lambda}\right)\hat{f}_{yy}(\omega_j) = \mathbb{I}\left\{-\frac{1}{2} < \frac{\omega_j - \omega}{\lambda} < \frac{1}{2}\right\} = \mathbb{I}\{\omega_j \in B(\omega|\lambda)\},$$

where $B(\omega|\lambda)$ is a frequency band. The smoothed periodogram estimator $\bar{f}_{yy}(\omega)$ is consistent, provided that the bandwidth shrinks to zero, that is, $\lambda \longrightarrow 0$ as $T \longrightarrow \infty$, and the number of ω_j's in the band, given by $\lambda T(2\pi)$, tends to infinity. In the empirical application below we use a Gaussian kernel, meaning that $K(x)$ equals the probability density function of a standard normal random variable.

An estimate of the spectral density can also be obtained indirectly through the estimation of the VAR(p) in (113). Define

$$\Phi = [\Phi_1, \ldots, \Phi_p, \Phi_0]' \quad \text{and} \quad M(z) = [Iz, \ldots, Iz^p],$$

and let $\hat{\Phi}$ be an estimator of Φ. Then a VAR(p) plug-in estimator of the spectral density is given by

$$\hat{f}^{V}_{yy}(\omega) = \frac{1}{2\pi}[I - \hat{\Phi}'M'(e^{-i\omega})]^{-1}\hat{\Sigma}[I - M(e^{-i\omega})\hat{\Phi}]^{-1}. \tag{117}$$

This formula generalizes the VAR(1) spectral density in (99) to a spectral density for a VAR(p).

Estimates of the spectral densities of output growth, log labor share, inflation, and interest rates are reported in Fig. 21. The shaded areas highlight the business cycle frequencies. Because the autocorrelation of output growth is close to zero, the spectral density is fairly flat. The other three series have more spectral mass at the low frequency, which is a reflection of the higher persistence. The labor share has a pronounced hump-shaped spectral density, whereas the other spectral densities of interest and inflation rates are monotonically decreasing in the frequency ω. The smoothness of the periodogram estimates $\bar{f}_{yy}(\omega)$ depends on the choice of the bandwidth. The figure is based on a Gaussian kernel with standard deviation 0.15, which, roughly speaking, averages the sample periodogram over a frequency band of 0.6. While the shapes of the smoothed periodograms and the VAR-based spectral estimates are qualitatively similar, the spectral density is lower according to the estimated VAR.

8.3.3 Impulse Response Functions

The VAR(p) in (113) is a so-called reduced-form VAR because the innovations u_t do not have a specific structural interpretation—they are simply one-step-ahead forecast errors. The impulse responses that we constructed for the DSGE model are responses to

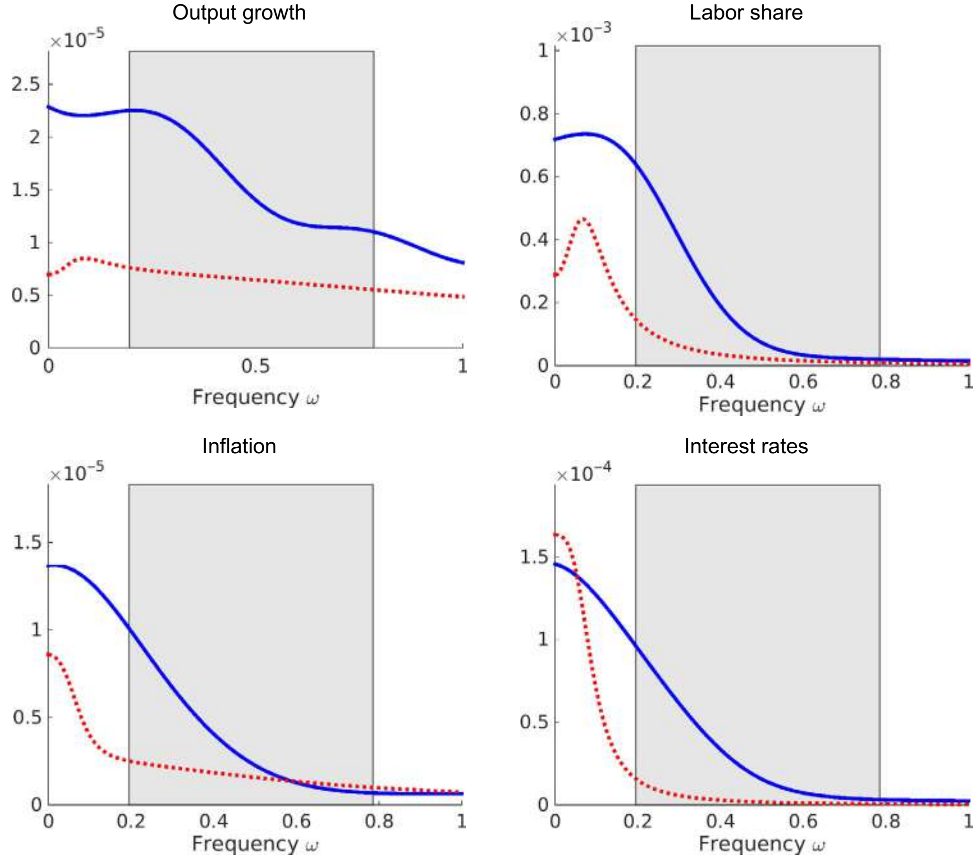

Fig. 21 Empirical spectrum. *Notes*: The *dotted lines* are spectra computed from an estimated VAR(1); the *solid lines* are smoothed periodograms based on a Gaussian kernel with standard deviation 0.15. The *shaded areas* indicate business cycle frequencies (0.196–0.785).

innovations in the structural shock innovations that contribute to the forecast error for several observables simultaneously. In order to connect VAR-based impulse responses to DSGE model-based responses, one has to link the one-step-ahead forecast errors to a vector of structural innovations ϵ_t. We assume that

$$u_t = \Phi_\epsilon \epsilon_t = \Sigma_{tr}\Omega\epsilon_t, \tag{118}$$

where Σ_{tr} is the unique lower-triangular Cholesky factor of Σ with nonnegative diagonal elements, and Ω is an $n \times n$ orthogonal matrix satisfying $\Omega\Omega' = I$. The second equality ensures that the covariance matrix of u_t is preserved in the sense that

$$\Phi_\epsilon \Phi_\epsilon' = \Sigma_{tr}\Omega\Omega'\Sigma_{tr}' = \Sigma. \tag{119}$$

By construction, the covariance matrix of the forecast error is invariant to the choice of Ω, which implies that it is not possible to identify Ω from the data. In turn, much of the literature on structural VARs reduces to arguments about an appropriate set of restrictions for the matrix Ω. Detailed surveys about the restrictions, or identification schemes, that have been used in the literature to identify innovations to technology, monetary policy, government spending, and other exogenous shocks can be found, for instance, in Cochrane (1994), Christiano et al. (1999), Stock and Watson (2001), and Ramey (2016). Conditional on an estimate of the reduced-form coefficient matrices Φ and Σ and an identification scheme for one or more columns of Ω, it is straightforward to express the impulse response as

$$\widehat{IRF}^{V}(.,j,h) = C_h(\hat{\Phi})\hat{\Sigma}_{tr}[\Omega]_{.j}, \tag{120}$$

where the moving average coefficient matrix $C_h(\hat{\Phi})$ can be obtained from the companion form representation of the VAR in (114): $C_h(\Phi) = M'\tilde{\Phi}_1^h M$ with $M' = [I_n, 0_{n\times n(p-1)}]$.

For illustrative purposes, rather than conditioning the computation of impulse response functions on a particular choice of Ω, we follow the recent literature on sign restrictions; see Faust (1998), Canova and De Nicoló (2002), and Uhlig (2005). The key idea of this literature is to restrict the matrices Ω to a set $\mathcal{O}(\Phi, \Sigma)$ such that the implied impulse response functions satisfy certain sign restrictions. This means that the magnitude of the impulse responses are only set-identified. Using our estimated VAR(1) in output growth, log labor share, inflation, and interest rates, we impose the condition that in response to a contractionary monetary policy shock interest rates increase and inflation is negative for four quarters. Without loss of generality, we can assume that the shocks are ordered such that the first column of Ω, denoted by q, captures the effect of the monetary policy shock. Conditional on the reduced-form VAR coefficient estimates $(\hat{\Phi}, \hat{\Sigma})$, we can determine the set of unit-length vectors q such that the implied impulse responses satisfy the sign restrictions. The bands depicted in Fig. 22 delimit the upper and lower bounds of the estimated identified sets for the pointwise impulse responses of output, labor share, inflation, and interest rates to a monetary policy shock. The sign restrictions that are imposed on the monetary policy shock are not sufficiently strong to determine the sign of the output and labor share responses to a monetary policy shock. Note that if a researcher selects a particular q (possibly as a function of the reduced-form parameters Φ and Σ), then the bands in the figure would reduce to a single line, which is exemplified by the solid line in Fig. 22.

8.3.4 Conditional Moment Restrictions

The unconditional moment restrictions derived from the equilibrium conditions of the DSGE model discussed in Section 8.2.4 have sample analogs in which the population expectations are replaced by sample averages. A complication arises if the moment

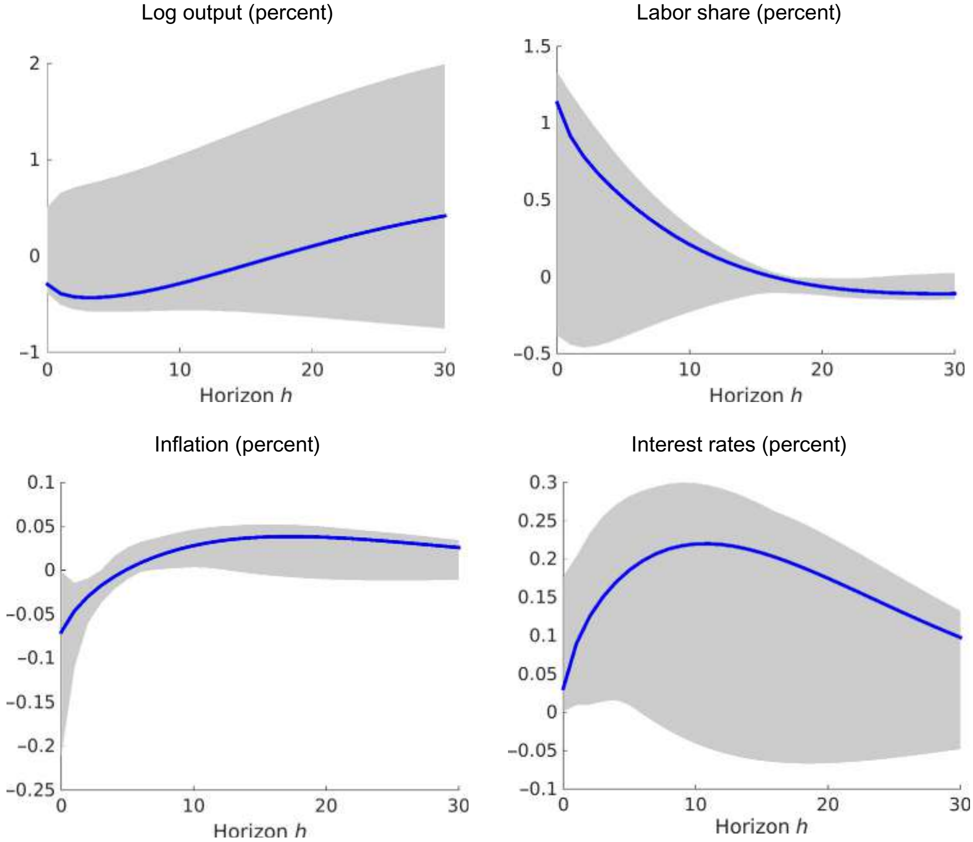

Fig. 22 Impulse responses to a monetary policy shock. *Notes*: Impulse responses to a one-standard-deviation monetary policy shock. Inflation and interest rate responses are not annualized. The bands indicate pointwise estimates of identified sets for the impulse responses based on the assumption that a contractionary monetary policy shock raises interest rates and lowers inflation for four quarters. The *solid line* represents a particular impulse response function contained in the identified set.

conditions contain latent variables, eg, the shock process λ_t in the moment condition (105) derived from the New Keynesian Phillips curve. Sample analogs of population moment conditions can be used to form generalized method of moments (GMM) estimators, which are discussed in Section 11.4.

8.4 Dealing with Trends

Trends are a salient feature of macroeconomic time series. The stylized DSGE model presented in Section 8.1 features a stochastic trend generated by the productivity process $\log Z_t$, which evolves according to a random walk with drift. While the trend in productivity induces a common trend in consumption, output, and real wages, the model

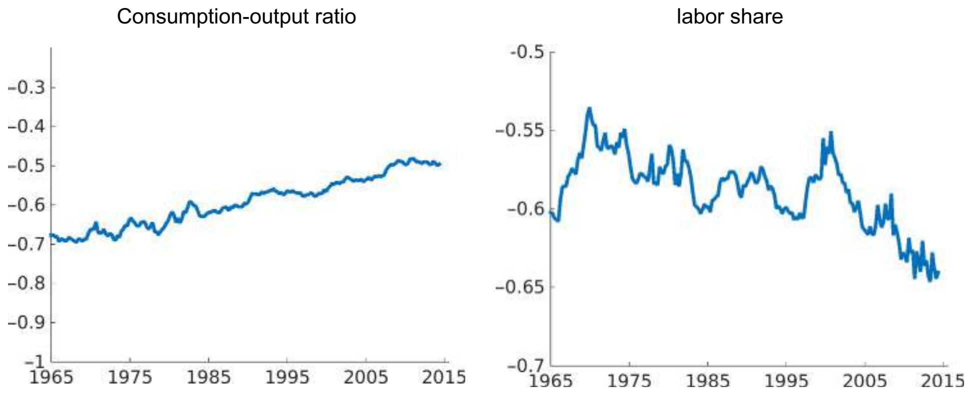

Fig. 23 Consumption-output ratio and Labor share (in logs).

specification implies that the log consumption-output ratio and the log labor share are stationary. Fig. 23 depicts time series of the US log consumption-output ratio and the log labor share for the United States from 1965 to 2014. Here the consumption-output ratio is defined as Personal Consumption Expenditure on Services (PCESV) plus Personal Consumption Expenditure on nondurable goods (PCND) divided by nominal GDP. The consumption-output ratio has a clear upward trend and the labor share has been falling since the late 1990s. Because these trends are not captured by the DSGE model, they lead to a first-order discrepancy between actual US and model-generated data.

Most DSGE models that are used in practice have counterfactual trend implications because they incorporate certain cotrending restrictions, eg, a balanced growth path along which output, consumption, investment, the capital stock, and real wages exhibit a common trend and hours worked and the return on capital are stationary, that are to some extent violated in the data as we have seen in the above example. Researchers have explored various remedies to address the mismatch between model and data, including: (i) detrending each time series separately and fitting the DSGE model to detrended data; (ii) applying an appropriate trend filter to both actual data and model-implied data when confronting the DSGE model with data; (iii) creating a hybrid model, eg, Canova (2014) that consists of a flexible, nonstructural trend component and uses the structural DSGE model to describe fluctuations around the reduced-form trend; and (iv) incorporating more realistic trends directly into the structure of the DSGE model. From a modeling perspective, option (i) is the least desirable and option (iv) is the most desirable choice.

9. STATISTICAL INFERENCE

DSGE models have a high degree of theoretical coherence. This means that the functional forms and parameters of equations that describe the behavior of macroeconomic aggregates are tightly restricted by optimality and equilibrium conditions. In turn, the family of probability distributions $p(Y|\theta)$, $\theta \in \Theta$, generated by a DSGE model tends to be more restrictive than the family of distributions associated with an atheoretical model, such as a reduced-form VAR as in (113). This may place the empirical researcher in a situation in which the data favor the atheoretical model and the atheoretical model generates more accurate forecasts, but a theoretically coherent model is required for the analysis of a particular economic policy. The subsequent discussion of statistical inference will devote special attention to this misspecification problem.

The goal of statistical inference is to infer an unknown parameter vector θ from observations Y; to provide a measure of uncertainty about θ; and to document the fit of the statistical model. The implementation of these tasks becomes more complicated if the statistical model suffers from misspecification. Confronting DSGE models with data can essentially take two forms. If it is reasonable to assume that the probabilistic structure of the DSGE model is well specified, then one can ask how far the observed data $Y^o_{1:T}$ or sample statistics $\mathcal{S}(Y^o_{1:T})$ computed from the observed data fall into the tails of the model-implied distribution derived from $p(Y_{1:T}|\theta)$. The parameter vector θ can be chosen to ensure that the density (likelihood) of $\mathcal{S}(Y^o_{1:T})$ is high under the distribution $p(Y_{1:T}|\theta)$. If, on the other hand, there is a strong belief (possibly supported by empirical evidence) that the probabilistic structure of the DSGE model is not rich enough to capture the salient features of the observed data, it is more sensible to consider a reference model with a well-specified probabilistic structure, use it to estimate some of the population objects introduced in Section 8.2, and compare these estimates to their model counterparts.

In Section 9.1 we ask the question whether the DSGE model parameters can be determined based on observations Y and review the recent literature on identification. We then proceed by reviewing two modes of statistical inference: frequentist and Bayesian.[ak] We pay special attention to the consequences of model misspecification. Frequentist inference, introduced in Section 9.2, takes a preexperimental perspective and focuses on the behavior of estimators and test statistics, which are functions of the observations Y, in repeated sampling under the distribution $\mathbb{P}^Y_\theta$. Frequentist inference is conditioned on a "true" but unknown parameter θ, or on a data-generating process (DGP), which is a hypothetical probability distribution under which the data are assumed to be generated. Frequentist procedures have to be well behaved for all values of $\theta \in \Theta$. Bayesian inference, introduced in Section 9.3, takes a postexperimental perspective by treating the unknown parameter θ as a random variable and updating a prior distribution $p(\theta)$ in view of the data Y using Bayes Theorem to obtain the posterior distribution $p(\theta|Y)$.

Estimation and inference requires that the model be solved many times for different parameter values θ. The subsequent numerical illustrations are based on the stylized

[ak] A comparison between econometric inference approaches and the calibration approach advocated by Kydland and Prescott (1982) can be found in Ríos-Rull et al. (2012).

DSGE model introduced in Section 8.1, for which we have a closed-form solution. However, such closed-form solutions are the exception and typically not available for models used in serious empirical applications. Thus, estimation methods, both frequentist and Bayesian, have to be closely linked to model solution procedures. This ultimately leads to a trade-off: given a fixed amount of computational resources, the more time is spent on solving a model conditional on a particular θ, eg, through the use of a sophisticated projection technique, the less often an estimation objective function can be evaluated. For this reason, much of the empirical work relies on first-order perturbation approximations of DSGE models, which can be obtained very quickly. The estimation of models solved with numerically sophisticated projection methods is relatively rare, because it requires a lot of computational resources. Moreover, as discussed in Part I, perturbation solutions are more easily applicable to models with a high-dimensional state vector and such models, in turn, are less prone to misspecification and are therefore more easily amenable to estimation. However, the recent emergence of low-cost parallel programming environments and cloud computing will make it feasible for a broad group of researchers to solve and estimate elaborate nonlinear DSGE models in the near future.

9.1 Identification

The question of whether a parameter vector θ is identifiable based on a sample Y is of fundamental importance for statistical inference because one of the main objectives is to infer the unknown θ based on the sample Y. Suppose that the DSGE model generates a family of probability distributions $p(Y|\theta)$, $\theta \in \Theta$. Moreover, imagine a stylized setting in which data are in fact generated from the DSGE model conditional on some "true" parameter θ_0. The parameter vector θ_0 is globally identifiable if

$$p(Y|\theta) = p(Y|\theta_0) \;\text{ implies }\; \theta = \theta_0. \tag{121}$$

The statement is somewhat delicate because it depends on the sample Y. From a preexperimental perspective, the sample is unobserved and it is required that (121) holds with probability one under the distribution $p(Y|\theta_0)$. From a postexperimental perspective, the parameter θ may be identifiable for some trajectories Y, but not for others. The following example highlights the subtle difference. Suppose that

$$y_{1,t}|(\theta, y_{2,t}) \sim iidN(\theta y_{2,t}, 1), \quad y_{2,t} = \begin{cases} 0 & \text{w.p. } 1/2 \\ \sim iidN(0,1) & \text{w.p. } 1/2 \end{cases}$$

Thus, with probability (w.p.) 1/2, one observes a trajectory along which θ is not identifiable because $y_{2,t} = 0$ for all t. If, on the other hand, $y_{2,t} \neq 0$, then θ is identifiable.

9.1.1 Local Identification

If condition (121) is only satisfied for values of θ in an open neighborhood of θ_0, then θ_0 is locally identified. Most of the literature has focused on devising procedures to check local identification in linearized DSGE models with Gaussian innovations. In this case the distribution of $Y|\theta$ is a joint normal distribution and can be characterized by a $Tn_y \times 1$ vector of means $\mu(\theta)$ (where n is the dimension of the vector y_t) and a $Tn_y \times Tn_y$ covariance matrix $\Sigma(\theta)$. Defining $m(\theta) = [\mu(\theta)', vech(\Sigma(\theta))']'$, where $vech(\cdot)$ vectorizes the nonredundant elements of a symmetric matrix, we can restate the identification condition as

$$m(\theta) = m(\theta_0) \text{ implies } \theta = \theta_0. \tag{122}$$

Thus, verifying the local identification condition is akin to checking whether the Jacobian

$$\mathcal{J}(\theta) = \frac{\partial}{\partial \theta'} m(\theta) \tag{123}$$

is of full rank. This approach was proposed and applied by Iskrev (2010) to examine the identification of linearized DSGE models. If the joint distribution of Y is not Gaussian, say because the DSGE model innovations ϵ_t are non-Gaussian or because the DSGE model is nonlinear, then it is possible that θ_0 is not identifiable based on the first and second moments $m(\theta)$, but that there are other moments that make it possible to distinguish θ_0 from $\tilde{\theta} \neq \theta_0$.

Local identification conditions are often stated in terms of the so-called information matrix. Using Jensen's inequality, it is straightforward to verify that the Kullback–Leibler discrepancy between $p(Y|\theta_0)$ and $p(Y|\theta)$ is nonnegative:

$$\Delta_{KL}(\theta|\theta_0) = -\int \log\left(\frac{p(Y|\theta)}{p(Y|\theta_0)}\right) p(Y|\theta_0) dY \geq 0. \tag{124}$$

Under a nondegenerate probability distribution for Y, the relationship holds with equality only if $p(Y|\theta) = p(Y|\theta_0)$. Thus, we deduce that the Kullback–Leibler distance is minimized at $\theta = \theta_0$ and that θ_0 is identified if θ_0 is the unique minimizer of $\Delta_{KL}(\theta|\theta_0)$. Let $\ell(\theta|Y) = \log p(Y|\theta)$ denote the log-likelihood function and $\nabla^2_\theta \ell(\theta|Y)$ denote the matrix of second derivatives of the log-likelihood function with respect to θ (Hessian), then (under suitable regularity conditions that allow the exchange of integration and differentiation)

$$\nabla_{\theta^2} \Delta_{KL}(\theta_0|\theta_0) = \int \nabla_{\theta^2} \ell(\theta_0|Y) p(Y|\theta_0) dY. \tag{125}$$

In turn, the model is locally identified at θ_0 if the expected Hessian matrix is nonsingular.

For linearized Gaussian DSGE models that can be written in the form $Y \sim N(\mu(\theta), \Sigma(\theta))$ we obtain

$$\int \nabla^2_\theta \ell(\theta_0|Y) p(Y|\theta_0) dY = \mathcal{J}(\theta)' \Omega \mathcal{J}(\theta), \tag{126}$$

where $\boldsymbol{\Omega}$ is the Hessian matrix associated with the unrestricted parameter vector $m = [\mu', vech(\Sigma)']'$ of a $N(\mu,\Sigma)$. Because $\boldsymbol{\Omega}$ is a symmetric full-rank matrix of dimension dim(m), we deduce that the Hessian is of full rank whenever the Jacobian matrix in (123) is of full rank.

Qu and Tkachenko (2012) focus on the spectral density matrix of the process y_t. Using a frequency domain approximation of the likelihood function and utilizing the information matrix equality, they express the Hessian as the outer product of the Jacobian matrix of derivatives of the spectral density with respect to θ

$$G(\theta_0) = \int_{-\pi}^{\pi} \left(\frac{\partial}{\partial \theta'} vec(f_{yy}(\omega)') \right)' \left(\frac{\partial}{\partial \theta'} vec(f_{yy}(\omega)) \right) d\omega \tag{127}$$

and propose to verify whether $G(\theta_0)$ is of full rank. The identification checks of Iskrev (2010) and Qu and Tkachenko (2012) have to be implemented numerically. For each conjectured θ_0 the user has to compute the rank of the matrices $\mathcal{J}(\theta_0)$ or $G(\theta_0)$, respectively. Because in a typical implementation the computation of the matrices relies on numerical differentiation (and integration), careful attention has be paid to the numerical tolerance level of the procedure that computes the matrix rank. Detailed discussions can be found in the two referenced papers.

Komunjer and Ng (2011) take a different route to assess the local identification of linearized DSGE models. They examine the relationship between the coefficients of the state-space representation of the DSGE model and the parameter vector θ. Recall that the state-space representation takes the form

$$y_t = \Psi_0(\theta) + \Psi_1(\theta), \quad s_t = \Phi_1(\theta) s_{t-1} + \Phi_\epsilon(\theta)\epsilon_t. \tag{128}$$

The notation highlights the dependence of the coefficient matrices on θ. Now stack the coefficients of the Ψ and Φ matrices in the vector ϕ:

$$\phi = \left[vec(\Psi_0)', vec(\Psi_1)', vec(\Phi_1)', vec(\Phi_\epsilon)' \right]'.$$

It is tempting to conjecture that θ is locally identifiable if the Jacobian matrix associated with the mapping from economic parameters θ to the reduced-form state-space parameters ϕ

$$\frac{\partial}{\partial \theta'} \phi(\theta) \tag{129}$$

has full column rank at θ_0. The problem with this conjecture is that the reduced-form parameters ϕ themselves are not identifiable. Let A be a nonsingular $n_s \times n_s$ matrix and $\boldsymbol{\Omega}$ an $n_\epsilon \times n_\epsilon$ orthogonal matrix, then we can define

$$\tilde{s}_t = A s_t, \quad \tilde{\epsilon}_t = \boldsymbol{\Omega} \epsilon_t, \quad \tilde{\Psi}_1 = \Psi_1 A^{-1}, \quad \tilde{\Phi}_1 = \Phi_1 A^{-1}, \quad \tilde{\Phi}_\epsilon = A \Phi_\epsilon \boldsymbol{\Omega}'$$

to obtain an observationally equivalent state-space system

$$y_t = \Psi_0 + \tilde{\Psi}_1 \tilde{s}_t, \quad s_t = \tilde{\Phi}_1 \tilde{s}_{t-1} + \tilde{\Phi}_\epsilon \epsilon_t \tag{130}$$

with $\phi \neq \tilde{\phi}$. Thus, the number of identifiable reduced-form parameters is smaller than the number of elements in the Ψ and Φ matrices. The main contribution in Komunjer and Ng (2011) is to account for the nonidentifiability of the reduced-form state-space parameters when formulating a rank condition along the lines of (129). In many DSGE models a subset of the state transitions are deterministic, which complicates the formal analysis.

Identification becomes generally more tenuous the fewer variables are included in the vector y_t. For instance, in the context of the stylized DSGE model, suppose y_t only includes the labor share. According to (70) the law of motion for the labor share is the sum of three AR(1) processes and an *iid* monetary policy shock. It can be rewritten as an ARMA(3,3) process and therefore has at most 8 identifiable reduced-form parameters. Thus, the upper bound on the number of reduced-form parameters is less than the number of DSGE model parameters, which is 13. In turn, it is not possible to identify the entire θ vector.

9.1.2 Global Identification

Global identification is more difficult to verify than local identification. Consider the following example from Schorfheide (2013):

$$y_t = [1 \quad 1]s_t, \quad s_t = \begin{bmatrix} \theta_1^2 & 0 \\ 1 - \theta_1^2 - \theta_1\theta_2 & (1-\theta_1^2) \end{bmatrix} s_{t-1} + \begin{bmatrix} 1 \\ 0 \end{bmatrix} \epsilon_t, \quad \epsilon_t \sim iidN(0,1). \tag{131}$$

Letting L denote the lag operator with the property that $Ly_t = y_{t-1}$, one can write the law of motion of y_t as an restricted ARMA(2,1) process:

$$\left(1-\theta_1^2 L\right)\left(1-(1-\theta_1^2)L\right)y_t = (1-\theta_1\theta_2 L)\epsilon_t. \tag{132}$$

It can be verified that given θ_1 and θ_2, an observationally equivalent process can be obtained by choosing $\tilde{\theta}_1$ and $\tilde{\theta}_2$ such that

$$\tilde{\theta}_1 = \sqrt{1-\theta_1^2}, \quad \tilde{\theta}_2 = \theta_1\theta_2/\tilde{\theta}_1.$$

Here we switched the values of the two roots of the autoregressive lag polynomial. Qu and Tkachenko (2014) propose to check for global identification by searching for solutions to the equation

$$0 = \triangle_{KL}(\theta|\theta_0), \quad \theta \in \Theta. \tag{133}$$

If θ_0 is the unique solution, then the DSGE model is globally identified. The authors evaluate the Kullback–Leibler discrepancy using a frequency domain transformation. The computational challenge is to find all the roots associated with (133). Kociecki and Kolasa (2015) follow a slightly different approach that is attractive because it requires the user to solve the DSGE model only at θ_0, but not at all the other values of $\theta \in \Theta$.

9.2 Frequentist Inference

The fundamental problem of statistical inference is to infer the parameter vector θ, in our case the DSGE model parameters, based on a random sample Y. Frequentist inference adopts a preexperimental perspective and examines the sampling distribution of estimators and test statistics, which are transformations of the random sample Y, conditional on a hypothetical DGP. We will distinguish between two cases. First, we consider the stylized case in which the DSGE model is correctly specified. Formally, this means that Y is sampled from $p(Y|\theta_0)$, where the density $p(Y|\theta_0)$ is derived from the DSGE model and θ is the "true" but unknown parameter vector.[al] Second, we consider the case of misspecification, meaning the DSGE model is too stylized to capture some of the key features of the data Y. As a consequence, the sampling distribution of Y has to be characterized by a reference model, for instance, a VAR or a linear process. In terms of notation, we will distinguish between the DSGE model, denoted by M_1, and the reference model M_0. To avoid confusion about which model generates the sampling distribution of Y, we add the model indicator to the conditioning set and write, eg, $p(Y|\theta,M_1)$ or $p(Y|M_0)$. We also use the notation $\|a\|_W = a'Wa$.

9.2.1 "Correct" Specification of DSGE Model

Under the assumption of correct specification, the DSGE model itself is the DGP and $p(Y|\theta_0,M_1)$ describes the sampling distribution of Y under which the behavior of estimators and test statistics is being analyzed. In this case it is desirable to let the model-implied probability distribution $p(Y|\theta_0,M_1)$ determine the choice of the objective function for estimators and test statistics to obtain a statistical procedure that is efficient (meaning that the estimator is close to θ_0 with high probability in repeated sampling). In this regard, the maximum likelihood (ML) estimator

$$\hat{\theta}_{ml} = \operatorname{argmax}_{\theta\in\Theta}\ \log p(Y|\theta,M_1) \tag{134}$$

plays a central role in frequentist inference, because it is efficient under fairly general regularity conditions. One of these conditions is that θ_0 is identifiable.

Alternative estimators can be obtained by constructing an objective function $Q_T(\theta|Y)$ that measures the discrepancy between sample statistics $\hat{m}_T(Y)$ (see Section 8.3) and model-implied population statistics $\mathbb{E}[\hat{m}_T(Y)|\theta,M_1]$ (see Section 8.2). Examples of the vector $\hat{m}_T(Y)$ are, for instance, vectorized sample autocovariances such as

[al] In reality, of course, the observed Y is never generated from a probabilistic mechanism. Instead it reflects measured macroeconomic activity. Thus, by "correct specification of a DSGE model" we mean that we believe that its probabilistic structure is rich enough to assign high probability to the salient features of macroeconomic time series.

$$\hat{m}_T(Y) = \left[vech(\hat{\Gamma}_{yy}(0))', vec(\hat{\Gamma}_{yy}(1))' \right] = \frac{1}{T}\sum_{t=1}^{T} m(y_{t-1:t})$$

or the OLS estimator of the coefficients of a VAR(1) (here without intercept)

$$\hat{m}_T(Y) = vec\left(\left(\frac{1}{T}\sum_{t=1}^{T} y_{t-1}y'_{t-1} \right)^{-1} \frac{1}{T}\sum_{t=1}^{T} y_{t-1}y'_t \right).$$

We write the estimation objective function as

$$Q_T(\theta|Y) = \|\hat{m}_T(Y) - \mathbb{E}[\hat{m}_T(Y)|\theta, M_1]\|_{W_T}, \tag{135}$$

where W_T is a symmetric positive-definite weight matrix. Under the assumption of a correctly specified DSGE model, the optimal choice of the weight matrix W_T is the inverse of the DSGE model-implied covariance matrix of $\hat{m}_T(Y)$. Thus, more weight is assigned to sample moments that accurately approximate the underlying population moment. The minimum distance (MD) estimator of θ is defined as

$$\hat{\theta}_{md} = \text{argmax}_{\theta \in \Theta}\ Q_T(\theta|Y). \tag{136}$$

Econometric inference is based on the sampling distribution of the estimator $\hat{\theta}_{md}$ and confidence sets and test statistics derived from $\hat{\theta}_{md}$ and $Q_T(\theta|Y)$ under the distribution $p(Y|\theta_0, M_1)$.

9.2.2 Misspecification and Incompleteness of DSGE Models

Model misspecification can be interpreted as a violation of the cross-coefficient restrictions embodied in the mapping from the DSGE model parameters θ into the system matrices Ψ_0, Ψ_1, Φ_1, and Φ_ϵ of the state-space representation in (76) and (78). An example of an incomplete model is a version of the stylized DSGE model in which we do not fully specify the law of motion for the exogenous shock processes and restrict our attention to certain moment conditions, such as the consumption Euler equation. In some cases, incompleteness and misspecification are two sides of the same coin. Consider a version of the stylized DSGE model with only one structural shock, namely, the monetary policy shock. This version does not contain sufficiently many shocks to explain the observed variability in output growth, the labor share, inflation, and the interest rate. More specifically, the one-shock DSGE model implies, for instance, that the linear combination

$$\frac{1}{\kappa_p(1+\nu)x_{\epsilon_R}/\beta + \sigma_R}\hat{R}_t - \frac{1}{\kappa_p(1+\nu)x_{\epsilon_R}}\hat{\pi}_t = 0$$

is perfectly predictable; see (72) and (73). This prediction is clearly counterfactual. We could regard the model as misspecified, in the sense that its predictions are at odds with the data; or as incomplete, in the sense that adding more structural shocks could reduce the gap between model and reality.

Regardless of whether the DSGE model is incomplete or misspecificed, it does not produce a sampling distribution for the data Y that can be used to determine the frequentist behavior of estimators and test statistics. In order to conduct a frequentist analysis, we require a reference model M_0 that determines the distribution of the data $p(Y|M_0)$ and can be treated as a DGP. The reference model could be a fully specified parametric model such as a VAR, $p(Y|\phi, M_0)$, where ϕ is a finite-dimensional parameter vector. Alternatively, the reference model could be a general stochastic process for $\{y_t\}$ that satisfies a set of regularity conditions necessary to establish large sample approximations of the sampling distributions of estimators and test statistics.

If the DSGE model is incompletely specified, it is still possible to uphold the notion of a "true" parameter vector θ_0, in the sense that one could imagine the DGP to be the incompletely specified DSGE model augmented by a set of equations (potentially with additional parameters). If the DSGE model is misspecified, then the concept of a "true" parameter value has to be replaced by the notion of a pseudo-true (or pseudo-optimal) parameter value. The definition of a pseudo-true parameter value requires a notion of discrepancy between the DGP $p(Y|M_0)$ and the DSGE model $p(Y|\theta, M_1)$. Different discrepancies lead to different pseudo-optimal values. Likelihood-based inference is associated with the Kullback–Leibler discrepancy and would lead to

$$\theta_0(KL) = \text{argmin}_{\theta\in\Theta} \; -\int \log\left(\frac{p(Y|\theta, M_1)}{p(Y|M_0)}\right) p(Y|M_0)dY. \tag{137}$$

Moment-based inference based on the sample objective function $Q_T(\theta|Y)$ is associated with a pseudo-optimal value

$$\theta_0(Q, W) = \text{argmin}_{\theta\in\Theta}\; Q(\theta|M_0), \tag{138}$$

where

$$Q(\theta|M_0) = \|\mathbb{E}[\hat{m}_T(Y)|M_0] - \mathbb{E}[\hat{m}(Y)|\theta, M_1]\|_W.$$

Ultimately, the sampling properties of estimators and test statistics have to be derived from the reference model M_0.

9.3 Bayesian Inference

Under the Bayesian paradigm, the calculus of probability is used not only to deal with uncertainty about shocks ϵ_t, states s_t, and observations y_t, but also to deal with uncertainty about the parameter vector θ. The initial state of knowledge (or ignorance) is summarized by a prior distribution with density $p(\theta)$. This prior is combined with the conditional distribution of the data given θ, ie, the likelihood function, to characterize the joint distribution of parameters and data. Bayes Theorem is applied to obtain the conditional distribution of the parameters given the observed data Y. This distribution is called the posterior distribution:

$$p(\theta|Y,M_1)=\frac{p(Y|\theta,M_1)p(\theta|M_1)}{p(Y|M_1)},\quad p(Y|M_1)=\int p(Y|\theta,M_1)p(\theta|M_1)d\theta. \tag{139}$$

The posterior distribution contains all the information about θ conditional on sample information Y. In a Bayesian setting a model comprises the likelihood function $p(Y|\theta, M_1)$ *and* the prior $p(\theta|M_1)$.

The posterior distribution of transformations of the DSGE model parameters θ, say, $h(\theta)$, eg, autocovariances and impulse response functions, can be derived from $p(\theta|Y, M_1)$. For instance,

$$\mathbb{P}_Y\{h(\theta)\leq\bar{h}\}=\int_{\theta\ |\ h(\theta)\leq\bar{h}}p(\theta|Y,M_1)d\theta. \tag{140}$$

Solutions to inference problems can generally be obtained by specifying a suitable loss function, stating the inference problem as a decision problem, and minimizing posterior expected loss. For instance, to obtain a point estimator for $h(\theta)$, let $L(h(\theta),\delta)$ describe the loss associated with reporting δ if $h(\theta)$ is correct. The optimal decision δ_* is obtained by minimizing the posterior expected loss:

$$\delta_*=\text{argmin}_{\delta\in\mathcal{D}}\int L(h(\theta),\delta)p(\theta|Y,M_1)d\theta. \tag{141}$$

If the loss function is quadratic, then the optimal point estimator is the posterior mean of $h(\theta)$.

The most difficult aspect of Bayesian inference is the characterization of the posterior moments of $h(\theta)$. Unfortunately, it is not possible to derive these moments analytically for DSGE models. Thus, researchers have to rely on numerical methods. The Bayesian literature has developed a sophisticated set of algorithms to generate draws θ^i from the posterior distribution, such that averages of these draws converge to posterior expectations:

$$\mathbb{E}[h(\theta)|Y,M_1]=\int h(\theta)p(\theta|Y,M_1)d\theta\approx\frac{1}{N}\sum_{i=1}^{N}h(\theta^i). \tag{142}$$

Several of these computational techniques are discussed in more detail in Section 12.

9.3.1 "Correct" Specification of DSGE Models

The use of Bayes Theorem to learn about the DSGE model parameters implicitly assumes that the researcher regards the probabilistic structure of the DSGE model as well specified in the sense that there are parameters θ in the support of the prior distribution conditional on which the salient features of the data Y are assigned a high probability. Of course, in practice there is always concern that an alternative DSGE model may deliver a better description of the data. The Bayesian framework is well suited to account for model uncertainty.

Suppose the researcher contemplates two model specifications M_1 and M_2, assuming that one of them is correct. It is natural to place prior probabilities on the two models, which we denote by $\pi_{j,0}$. Ratios of model probabilities are called model odds. The posterior odds of M_1 vs M_2 are given by

$$\frac{\pi_{1,T}}{\pi_{2,T}} = \frac{\pi_{1,0}}{\pi_{2,0}} \frac{p(Y|M_1)}{p(Y|M_2)}, \tag{143}$$

where the first factor on the right-hand side captures the prior odds and the second factor, called Bayes factor, is the ratio of marginal data densities. Note that $p(Y|M_i)$ appears in the denominator of Bayes Theorem (139). Posterior model odds and probabilities have been widely used in the DSGE model literature to compare model specification or to take averages across DSGE models. Prominent applications include Rabanal and Rubio-Ramírez (2005) and Smets and Wouters (2007).

9.3.2 Misspecification of DSGE Models

As in the frequentist case, model misspecification complicates inference. Several approaches have been developed in the literature to adapt Bayesian analysis to the potential misspecification of DSGE models. In general, the model space needs to be augmented by a more densely parameterized reference model, M_0, that provides a more realistic probabilistic representation of the data.

Schorfheide (2000) considers a setting in which a researcher is interested in the relative ability of two (or more) DSGE models, say, M_1 and M_2, to explain certain population characteristics φ, eg, autocovariances or impulse responses.[am] However, the DSGE models may be potentially misspecified and the researcher considers a reference model M_0. As long as it is possible to form a posterior distribution for φ based on the reference model, the overall posterior can be described by

$$p(\varphi|Y) = \sum_{j=0,1,2} \pi_{j,T} p(\varphi|Y, M_j). \tag{144}$$

If one of the DSGE models is well specified, this model receives high posterior probability and dominates the mixture. If both DSGE models are at odds with the data, the posterior probability of the reference model will be close to one. Given a loss function over predictions of φ, one can compute DSGE model-specific predictions:

$$\hat{\varphi}_{(j)} = \text{argmin}_{\tilde{\varphi}} \int L(\tilde{\varphi}, \varphi) p(\varphi|Y, M_j) d\varphi, \quad j = 1, 2. \tag{145}$$

[am] Frequentist versions of this approach have been developed in Hnatkosvaka et al. (2012) and Marmer and Otsu (2012).

Finally, the two DSGE models can be ranked based on the posterior risk

$$\int L(\hat{\varphi}_{(j)}, \varphi) p(\varphi | Y) d\varphi. \tag{146}$$

Geweke (2010) assumes that the researcher regards the DSGE models not as models of the data Y, but as models of some population moments φ. A reference model M_0, eg, a VAR, provides the model for Y, but also permits the computation of implied population moments. He shows that under these assumptions, one can define the posterior odds of DSGE models as

$$\frac{\pi_{1,T}}{\pi_{2,T}} = \frac{\pi_{1,0}}{\pi_{2,0}} \frac{\int p(\varphi | M_1) p(\varphi | Y, M_0) d\varphi}{\int p(\varphi | M_2) p(\varphi | Y, M_0) d\varphi}. \tag{147}$$

Roughly, if we were able to observe φ, then $p(\varphi | M_j)$ is the marginal likelihood. However, φ is unobservable and therefore replaced by a posterior predictive distribution obtained from a reference model M_0. The odds in favor of model M_1 are high if there is a lot of overlap between the preditive distribution for the population moments φ under the DSGE model, and the posterior distribution of φ obtained when estimating the reference model M_0.

Building on work by Ingram and Whiteman (1994); Del Negro and Schorfheide (2004) do not treat the DSGE model as a model of the data Y, but instead use it to construct a prior distribution for a VAR. Consider the companion form VAR in (114). Use the DSGE model to generate a prior distribution for $(\tilde{\Phi}_1, \tilde{\Phi}_0, \tilde{\Sigma})$ and combine this prior with the VAR likelihood function

$$p(Y, \tilde{\Phi}_0, \tilde{\Phi}_1, \tilde{\Sigma}, \theta | \lambda) = p(Y | \tilde{\Phi}_0, \tilde{\Phi}_1, \tilde{\Sigma}) p(\tilde{\Phi}_0, \tilde{\Phi}_1, \tilde{\Sigma} | \theta, \lambda) p(\theta). \tag{148}$$

The resulting hierarchical model is called a DSGE-VAR. The prior $p(\tilde{\Phi}_0, \tilde{\Phi}_1, \tilde{\Sigma} | \theta, \lambda)$ is centered on restriction functions

$$\tilde{\Phi}_0^*(\theta), \quad \tilde{\Phi}_1^*(\theta), \quad \tilde{\Sigma}^*(\theta),$$

but allows for deviations from these restriction functions to account for model misspecification. The parameter λ is a hyperparameter that controls the magnitude of the deviations (prior variance) from the restriction function. This framework can be used for forecasting, to assess the fit of DSGE models, eg, Del Negro et al. (2007), and to conduct policy analysis, eg, Del Negro and Schorfheide (2009).

In a setting in which the reference model M_0 plays a dominating role, Fernández-Villaverde and Rubio-Ramírez (2004) show that choosing the DSGE model that attains the highest posterior probability (among, say, competing DSGE models M_1 and M_2) leads asymptotically to the specification that is closest to M_0 in a Kullback–Leibler sense. Rather than using posterior probabilities to select among or average across two DSGE models, one can form a prediction pool, which is essentially a linear combination of two predictive densities:

$$\lambda p(y_t|Y_{1:t-1},M_1) + (1-\lambda)p(y_t|Y_{1:t-1},M_2).$$

The weight $\lambda \in [0,1]$ can be determined based on

$$\prod_{t=1}^{T} [\lambda p(y_t|Y_{1:t-1},M_1) + (1-\lambda)p(y_t|Y_{1:t-1},M_2)].$$

This objective function could either be maximized with respect to λ or it can be treated as a likelihood function for λ and embedded in a Bayesian inference procedure. This idea is developed in Geweke and Amisano (2011) and Geweke and Amisano (2012). Dynamic versions with λ depending on time t are provided by Waggoner and Zha (2012) and Del Negro et al. (2014).

10. THE LIKELIHOOD FUNCTION

The likelihood function plays a central role in both frequentist and Bayesian inference. The likelihood function treats the joint density of the observables conditional on the parameters, $p(Y_{1:T}|\theta)$, as a function of θ. The state-space representation of the DSGE model leads to a joint distribution $p(Y_{1:T},S_{1:T}|\theta)$; see (79). In order to obtain the likelihood function, one needs to integrate out the (hidden) states $S_{1:T}$. This can be done recursively, using an algorithm that is a called a *filter*.

This section focuses on the numerical evaluation of the likelihood function conditional on a particular parameterization θ through the use of linear and nonlinear filters. We assume that the DSGE model has the following, possibly nonlinear, state-space representation:

$$\begin{aligned} y_t &= \Psi(s_t, t;\theta) + u_t, \quad u_t \sim F_u(\cdot;\theta) \\ s_t &= \Phi(s_{t-1}, \epsilon_t;\theta), \quad \epsilon_t \sim F_\epsilon(\cdot;\theta). \end{aligned} \tag{149}$$

The state-space system is restricted in two dimensions. First, the errors in the measurement equation enter in an additively separable manner. This implies that the conditional density $p(y_t|s_t,\theta)$ is given by $p_u(y_t - \Psi(s_t,t;\theta)|\theta)$, where $p_u(\cdot|\theta)$ is the pdf associated with the measurement error distribution $F_u(\cdot;\theta)$. In the absence of measurement errors, the distribution $y_t|(s_t,\theta)$ is a pointmass at $\Psi(s_t,t;\theta)$. Second, the state-transition equation has a first-order Markov structure.[an] Owing to the first-order Markov structure of the state-transition equation, neither the states $s_{t-2},s_{t-3},\ldots$ nor the observations $y_{t-1},y_{t-2},\ldots$ provide any additional information about s_t conditional on s_{t-1}. Thus,

[an] Additional lags of the state vector could be easily incorporated using a companion form representation of the state vector as in (114).

$$p(s_t|s_{t-1},\theta)=p(s_t|s_{t-1},S_{1:t-2},\theta)=p(s_t|s_{t-1},S_{1:t-2},Y_{1:t-1},\theta). \tag{150}$$

For the linearized DSGE model of Section 8.1 with normally distributed measurement errors $u_t \sim N(0,\Sigma_u)$ the conditional distributions are given by $s_t|(s_{t-1},\theta) \sim N\left(\Phi_1 s_{t-1}, \Phi_\epsilon \Phi'_\epsilon\right)$ and $y_t|(s_t,\theta) \sim N(\Psi_0 + \Psi_1 s_t, \Sigma_u)$.

10.1 A Generic Filter

We now describe a generic filter that can be used to recursively compute the conditional distributions $p(s_t|Y_{1:t},\theta)$ and $p(y_t|Y_{1:t-1},\theta)$, starting from an initialization $p(s_0|\theta)$. The distributions $p(s_t|Y_{1:t},\theta)$ are a by-product of the algorithm and summarize the information about the state s_t conditional on the current and past observations $Y_{1:t}$, which may be of independent interest. The sequence of predictive distributions $p(y_t|Y_{1:t-1},\theta)$, $t=1,\ldots,T$, can be used to obtain the likelihood function, which can be factorized as follows

$$p(Y_{1:T}|\theta)=\prod_{t=1}^{T} p(y_t|Y_{1:t-1},\theta). \tag{151}$$

The filter is summarized in Algorithm 5. In the description of the filter we drop the parameter θ from the conditioning set to simplify the notation.

Algorithm 5 (Generic Filter). Let $p(s_0) = p(s_0|Y_{1:0})$ be the initial distribution of the state. For $t = 1$ to T:

1. Forecasting t given $t-1$:

(a) Transition equation:

$$p(s_t|Y_{1:t-1}) = \int p(s_t|s_{t-1}, Y_{1:t-1})p(s_{t-1}|Y_{1:t-1})ds_{t-1}$$

(b) Measurement equation:

$$p(y_t|Y_{1:t-1}) = \int p(y_t|s_t, Y_{1:t-1})p(s_t|Y_{1:t-1})ds_t$$

2. Updating with Bayes Theorem. Once y_t becomes available:

$$p(s_t|Y_{1:t}) = p(s_t|y_t, Y_{1:t-1}) = \frac{p(y_t|s_t, Y_{1:t-1})p(s_t|Y_{1:t-1})}{p(y_t|Y_{1:t-1})}.$$

10.2 Likelihood Function for a Linearized DSGE Model

For illustrative purposes, consider the prototypical DSGE model. Owing to the simple structure of the model, we can use (69), (70), (72), and (73) to solve for the latent shocks ϕ_t, λ_t, z_t, and $\epsilon_{R,t}$ as a function of $\hat{x}_t$, $\widehat{lsh}_t$, $\hat{\pi}_t$, and $\hat{R}_t$. Thus, we can deduce from (78) and the definition of s_t that conditional on $\hat{x}_0$, the states s_t can be uniquely inferred from the observables y_t in a recursive manner, meaning that the conditional distributions

$p(s_t|Y_{1:t}, \hat{x}_0)$ are degenerate. Thus, the only uncertainty about the state stems from the initial condition.

Suppose that we drop the labor share and the interest rates from the definition of y_t. In this case it is no longer possible to uniquely determine s_t as a function of y_t and $\hat{x}_0$, because we only have two equations, (69) and (72), and four unknowns. The filter in Algorithm 5 now essentially solves an underdetermined system of equations, taking into account the probability distribution of the four hidden processes. For our linearized DSGE model with Gaussian innovations, all the distributions that appear in Algorithm 5 are Gaussian. In this case the Kalman filter can be used to compute the means and covariance matrices of these distributions recursively. To complete the model specification, we make the following distributional assumptions about the initial state s_0:

$$s_0 \sim N\left(\bar{s}_{0|0}, P_{0|0}\right).$$

In stationary models it is common to set $\bar{s}_{0|0}$ and $P_{0|0}$ equal to the unconditional first and second moments of the invariant distribution associated with the law of motion of s_t in (76). The four conditional distributions in the description of Algorithm 5 for a linear Gaussian state-space model are summarized in Table 6. Detailed derivations can be found in textbook treatments of the Kalman filter and smoother, eg, Hamilton (1994) or Durbin and Koopman (2001).

To illustrate the Kalman filter algorithm, we simulate $T = 50$ observations from the stylized DSGE model conditional on the parameters in Table 5. The two left panels of Fig. 24 depict the filtered shock processes ϕ_t and z_t based on observations of only output growth, which are defined as $\mathbb{E}[s_t|Y_{1:t}]$. The bands delimit 90% credible intervals which are centered around the filtered estimates and based on the standard deviations $\sqrt{\mathbb{V}[s_t|Y_{1:t}]}$. The information in the output growth series is not sufficient to generate a precise estimate of the preference shock process ϕ_t, which, according to the forecast

Table 6 Conditional distributions for the Kalman filter

	Distribution	Mean and variance
$s_{t-1}\|Y_{1:t-1}$	$N\left(\bar{s}_{t-1\|t-1}, P_{t-1\|t-1}\right)$	Given from Iteration $t - 1$
$s_t\|Y_{1:t-1}$	$N\left(\bar{s}_{t\|t-1}, P_{t\|t-1}\right)$	$\bar{s}_{t\|t-1} = \Phi_1 \bar{s}_{t-1\|t-1}$ $P_{t\|t-1} = \Phi_1 P_{t-1\|t-1} \Phi_1' + \Phi_\epsilon \Sigma_\epsilon \Phi_\epsilon'$
$y_t\|Y_{1:t-1}$	$N\left(\bar{y}_{t\|t-1}, F_{t\|t-1}\right)$	$\bar{y}_{t\|t-1} = \Psi_0 + \Psi_1 \bar{s}_{t\|t-1}$ $F_{t\|t-1} = \Psi_1 P_{t\|t-1} \Psi_1' + \Sigma_u$
$s_t\|Y_{1:t}$	$N\left(\bar{s}_{t\|t}, P_{t\|t}\right)$	$\bar{s}_{t\|t} = \bar{s}_{t\|t-1} + P_{t\|t-1} \Psi_1' F_{t\|t-1}^{-1} (y_t - \bar{y}_{t\|t-1})$ $P_{t\|t} = P_{t\|t-1} - P_{t\|t-1} \Psi_1' F_{t\|t-1}^{-1} \Psi_1 P_{t\|t-1}$
$s_t\|(S_{t+1:T}, Y_{1:T})$	$N\left(\bar{s}_{t\|t+1}, P_{t\|t+1}\right)$	$\bar{s}_{t\|t+1} = \bar{s}_{t\|t} + P_{t\|t} \Phi_1' P_{t+1\|t}^{-1} (s_{t+1} - \Phi_1 \bar{s}_{t\|t})$ $P_{t\|t+1} = P_{t\|t} - P_{t\|t} \Phi_1' P_{t+1\|t}^{-1} \Phi_1 P_{t\|t}$

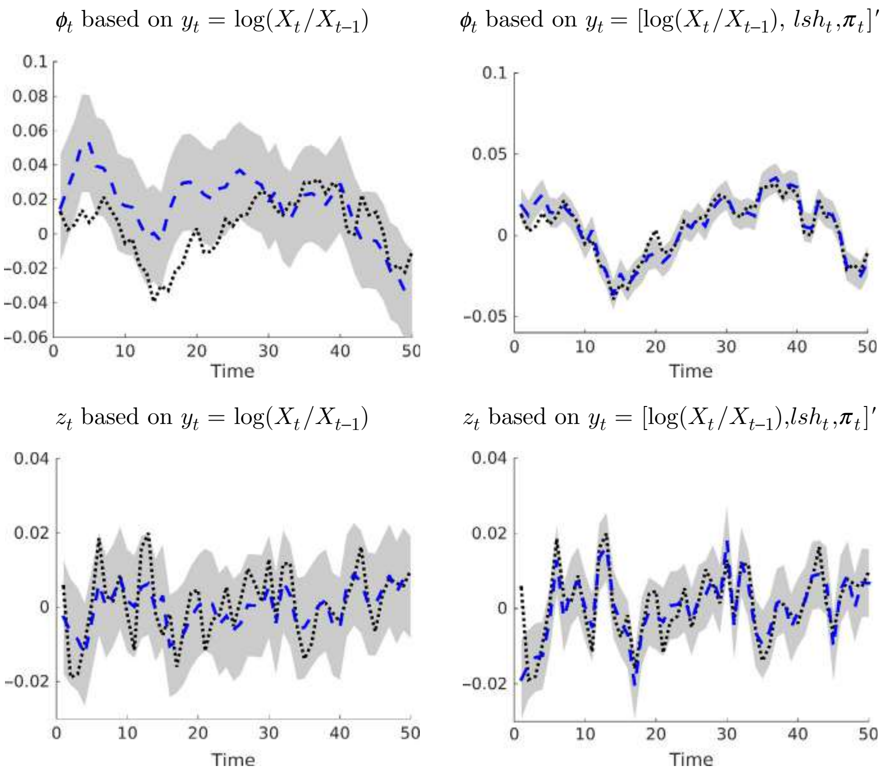

Fig. 24 Filtered states. *Notes*: The filtered states are based on a simulated sample of $T = 50$ observations. Each panel shows the true state s_t (*dotted*), the filtered state $\mathbb{E}[s_t|Y_{1:t}]$ (*dashed*), and 90% credible bands based on $p(s_t|Y_{1:t})$ (*grey area*).

error variance decomposition in Fig. 17, only explains a small fraction of the variation in output growth. The two right panels of Fig. 24 show what happens to the inference about the hidden states if inflation and labor share are added to the set of observables. Conditional on the three series, it is possible to obtain fairly sharp estimates of both the preference shock ϕ_t and the technology growth shock z_t.

Instead of using the Kalman filter, in a linearized DSGE model with Gaussian innovations it is possible to characterize the joint distribution of the observables directly. Let Y be a $T \times n_y$ matrix composed of rows y_t'. Then the joint distribution of Y is given by

$$vec(Y)|\theta \sim N\left(I \otimes \Phi_0(\theta),\ \begin{bmatrix} \Gamma_{yy}(0|\theta) & \Gamma_{yy}(1|\theta) & \ldots & \Gamma_{yy}(T-1|\theta) \\ \Gamma'_{yy}(1|\theta) & \Gamma_{yy}(0|\theta) & \ldots & \Gamma_{yy}(T-2|\theta) \\ \vdots & \vdots & \ddots & \vdots \\ \Gamma'_{yy}(T-1|\theta) & \Gamma'_{yy}(T-2|\theta) & \ldots & \Gamma_{yy}(0|\theta) \end{bmatrix} \right). \tag{152}$$

The evaluation of the likelihood function requires the calculation of the autocovariance sequence and the inversion of an $n_y T \times n_y T$ matrix. For large T the joint density can be approximated by the so-called Whittle likelihood function

$$p_W(Y|\theta) \propto \left(\prod_{j=0}^{T-1} \left| 2\pi f_{yy}^{-1}(\omega_j|\theta) \right| \right)^{1/2} \exp\left\{ -\frac{1}{2} \sum_{j=0}^{T-1} tr\left[f_{yy}^{-1}(\omega_j|\theta) \hat{f}_{yy}(\omega_j) \right] \right\} \tag{153}$$

where $f_{yy}(\omega|\theta)$ is the DSGE model-implied spectral density, $\hat{f}_{yy}(\omega)$ is the sample periodogram, and the ω_j's are the fundamental frequencies. The attractive feature of this likelihood function is that the researcher can introduce weights for the different frequencies, and, for instance, only consider business cycle frequencies in the construction of the likelihood function. For the estimation of DSGE models, the Whittle likelihood has been used, for instance, by Christiano and Vigfusson (2003), Qu and Tkachenko (2012), and Sala (2015).

10.3 Likelihood Function for Nonlinear DSGE Models

If the DSGE model is solved using a nonlinear approximation technique, then either the state-transition equation, or the measurement equation, or both become nonlinear. As a consequence, analytical representations of the densities $p(s_{t-1}|Y_{1:t-1})$, $p(s_t|Y_{1:t-1})$, and $p(y_t|Y_{1:t-1})$ that appear in Algorithm 5 are no longer available. While there exists a large literature on nonlinear filtering (see for instance Crisan and Rozovsky, 2011) we focus on the class of particle filters. Particle filters belong to the class of sequential Monte Carlo algorithms. The basic idea is to approximate the distribution $s_t|Y_{1:t}$ through a swarm of particles $\{s_t^j, W_t^j\}_{j=1}^M$ such that

$$\begin{aligned} \bar{h}_{t,M} &= \frac{1}{M}\sum_{j=1}^{M} h(s_t^j) W_t^j \xrightarrow{a.s.} \mathbb{E}[h(s_t)|Y_{1:t}], \\ \sqrt{M}(\bar{h}_{t,M} &- \mathbb{E}[h(s_t)|Y_{1:t}]) \Longrightarrow N(0, \Omega_t[h]), \end{aligned} \tag{154}$$

where $\Longrightarrow$ denotes convergence in distribution.[ao] Here the s_t^j's are particle values and the W_t^j's are the particle weights. The conditional expectation of $h(s_t)$ is approximated by a weighted average of the (transformed) particles $h(s_t^j)$. Under suitable regularity conditions, the Monte Carlo approximation satisfies an SLLN and a CLT. The covariance matrix $\Omega_t[h]$ characterizes the accuracy of the Monte Carlo approximation. Setting $h(s_t) = p(y_{t+1}|s_t)$ yields the particle filter approximation of the likelihood increment $p(y_{t+1}|Y_{1:t}) = \mathbb{E}[p(y_{t+1}|s_t)|Y_{1:t}]$. Each iteration of the filter manipulates the particle values and weights to recursively track the sequence of conditional distributions $s_t|Y_{1:t}$. The paper by Fernández-Villaverde and Rubio-Ramírez (2007) was the first to

[ao] A sequence of random variables X_T converges in distribution to a random variable X if for every measurable and bounded function $f(\cdot)$ that is continuous almost everywhere $\mathbb{E}[f(X_T)] \to \mathbb{E}[f(X)]$.

approximate the likelihood function of a nonlinear DSGE model using a particle filter and many authors have followed this approach.

Particle filters are widely used in engineering and statistics. Surveys and tutorials are provided, for instance, in Arulampalam et al. (2002), Cappé et al. (2007), Doucet and Johansen (2011), and Creal (2012). The basic bootstrap particle filter algorithm is remarkably straightforward, but may perform quite poorly in practice. Thus, much of the literature focuses on refinements of the bootstrap filter that increases the efficiency of the algorithm; see, for instance, Doucet et al. (2001). Textbook treatments of the statistical theory underlying particle filters can be found in Liu (2001), Cappé et al. (2005), and Del Moral (2013).

10.3.1 Generic Particle Filter

The subsequent exposition draws from Herbst and Schorfheide (2015), who provide a detailed presentation of particle filtering techniques in the context of DSGE model applications as well as a more extensive literature survey. In the basic version of the particle filter, the time t particles are generated based on the time $t-1$ particles by simulating the state-transition equation forward. The particle weights are then updated based on the likelihood of the observation y_t under the s_t^j particle, $p(y_t|s_t^j)$. The more accurate the prediction of y_t based on s_t^j, the larger the density $p(y_t|s_t^j)$, and the larger the relative weight that will be placed on particle j. However, the naive forward simulation ignores information contained in the current observation y_t and may lead to a very uneven distribution of particle weights, in particular, if the measurement error variance is small or if the model has difficulties explaining the period t observation in the sense that for most particles s_t^j the actual observation y_t lies far in the tails of the model-implied distribution of $y_t|s_t^j$. The particle filter can be generalized by allowing s_t^j in the forecasting step to be drawn from a generic importance sampling density $g_t(\cdot|s_{t-1}^j)$, which leads to the following algorithm:[ap]

Algorithm 6 (Generic Particle Filter).

1. **Initialization.** Draw the initial particles from the distribution $s_0^j \overset{iid}{\sim} p(s_0)$ and set $W_0^j = 1$, $j = 1,\ldots,M$.
2. **Recursion.** For $t = 1,\ldots,T$:
   (a) **Forecasting** s_t**.** Draw $\tilde{s}_t^j$ from density $g_t(\tilde{s}_t|s_{t-1}^j)$ and define the importance weights

$$\omega_t^j = \frac{p(\tilde{s}_t^j|s_{t-1}^j)}{g_t(\tilde{s}_t^j|s_{t-1}^j)}. \tag{155}$$

An approximation of $\mathrm{E}[h(s_t)|Y_{1:t-1}]$ is given by

[ap] To simplify the notation, we omit θ from the conditioning set.

$$\hat{h}_{t,M} = \frac{1}{M}\sum_{j=1}^{M} h(\tilde{s}_t^j)\omega_t^j W_{t-1}^j. \tag{156}$$

(b) Forecasting y_t. Define the incremental weights

$$\tilde{w}_t^j = p(y_t|\tilde{s}_t^j)\omega_t^j. \tag{157}$$

The predictive density $p(y_t|Y_{1:t-1})$ can be approximated by

$$\hat{p}(y_t|Y_{1:t-1}) = \frac{1}{M}\sum_{j=1}^{M} \tilde{w}_t^j W_{t-1}^j. \tag{158}$$

(c) Updating. Define the normalized weights

$$\tilde{W}_t^j = \frac{\tilde{w}_t^j W_{t-1}^j}{\frac{1}{M}\sum_{j=1}^{M} \tilde{w}_t^j W_{t-1}^j}. \tag{159}$$

An approximation of $\mathbb{E}[h(s_t)|Y_{1:t},\theta]$ is given by

$$\tilde{h}_{t,M} = \frac{1}{M}\sum_{j=1}^{M} h(\tilde{s}_t^j)\tilde{W}_t^j. \tag{160}$$

(d) Selection. Resample the particles via multinomial resampling. Let $\{s_t^j\}_{j=1}^M$ denote M *iid* draws from a multinomial distribution characterized by support points and weights $\{\tilde{s}_t^j, \tilde{W}_t^j\}$ and set $W_t^j = 1$ for $j =,1\ldots, M$. An approximation of $\mathbb{E}[h(s_t)|Y_{1:t},\theta]$ is given by

$$\bar{h}_{t,M} = \frac{1}{M}\sum_{j=1}^{M} h(s_t^j)W_t^j. \tag{161}$$

3. **Likelihood Approximation.** The approximation of the log likelihood function is given by

$$\log\hat{p}(Y_{1:T}|\theta) = \sum_{t=1}^{T}\log\left(\frac{1}{M}\sum_{j=1}^{M}\tilde{w}_t^j W_{t-1}^j\right). \tag{162}$$

Conditional on the stage $t-1$ weights W_{t-1}^j the accuracy of the approximation of the likelihood increment $p(y_t|Y_{1:t-1})$ depends on the variability of the incremental weights $\tilde{\omega}_t^j$ in (157). The larger the variance of the incremental weights, the less accurate the particle filter approximation of the likelihood function. In this regard, the most important choice for the implementation of the particle filter is the choice of the proposal distribution $g_t(\tilde{s}_t^j|s_{t-1}^j)$, which is discussed in more detail below.

The selection step is included in the filter to avoid a degeneracy of particle weights. While it adds additional noise to the Monte Carlo approximation, it simultaneously equalizes the particle weights, which increases the accuracy of subsequent approximations. In the absence of the selection step, the distribution of particle weights would become more uneven from iteration to iteration. The selection step does not have to be executed in every iteration. For instance, in practice, users often apply a threshold rule according to which the selection step is executed whenever the following measure falls below a threshold, eg, 25% or 50% of the nominal number of particles:

$$\widehat{ESS}_t = M \Big/ \left(\frac{1}{M} \sum_{j=1}^{M} (\tilde{W}_t^j)^2 \right). \tag{163}$$

The effective sample size $\widehat{ESS}_t$ (in terms of number of particles) captures the variance of the particle weights. It is equal to M if $\tilde{W}_t^j = 1$ for all j and equal to 1 if one of the particles has weight M and all others have weight 0. The resampling can be executed with a variety of algorithms. We mention multinomial resampling in the description of Algorithm 6. Multinomial resampling is easy to implement and satisfies a CLT. However, there are more efficient algorithms (meaning they are associated with a smaller Monte Carlo variance), such as stratified or systematic resampling. A detailed textbook treatment can be found in Liu (2001) and Cappé et al. (2005).

10.3.2 Bootstrap Particle Filter

The bootstrap particle filter draws $\tilde{s}_t^j$ from the state-transition equation and sets

$$g_t(\tilde{s}_t^j | s_{t-1}^j) = p(\tilde{s}_t^j | s_{t-1}^j). \tag{164}$$

This implies that $\omega_t^j = 1$ and the incremental weight is given by the likelihood $p(y_t | \tilde{s}_t^j)$, which unfortunately may be highly variable. Fig. 25 provides an illustration of the bootstrap particle filter with $M = 100$ particles using the same experimental design as for the Kalman filter in Section 10.2. The observables are output growth, labor share, and inflation and the observation equation is augmented with measurement errors. The measurement error variance amounts to 10% of the total variance of the simulated data. Because the stylized DSGE is loglinearized, the Kalman filter provides exact inference and any discrepancy between the Kalman and particle filter output reflects the approximation error of the particle filter. In this application the particle filter approximations are quite accurate even with a small number of particles. The particle filtered states z_t and $\epsilon_{R,t}$ appear to be more volatile than the exactly filtered states from the Kalman filter.

Fig. 26 illustrates the accuracy of the likelihood approximation. The left panel compares log-likelihood increments $\log p(y_t | Y_{1:t-1}, \theta)$ obtained from the Kalman filter and a single run of the particle filter. The left panel shows the distribution of the approximation errors of the log-likelihood function: $\log \hat{p}(Y_{1:T} | \theta) - \log p(Y_{1:T} | \theta)$. It has been shown,

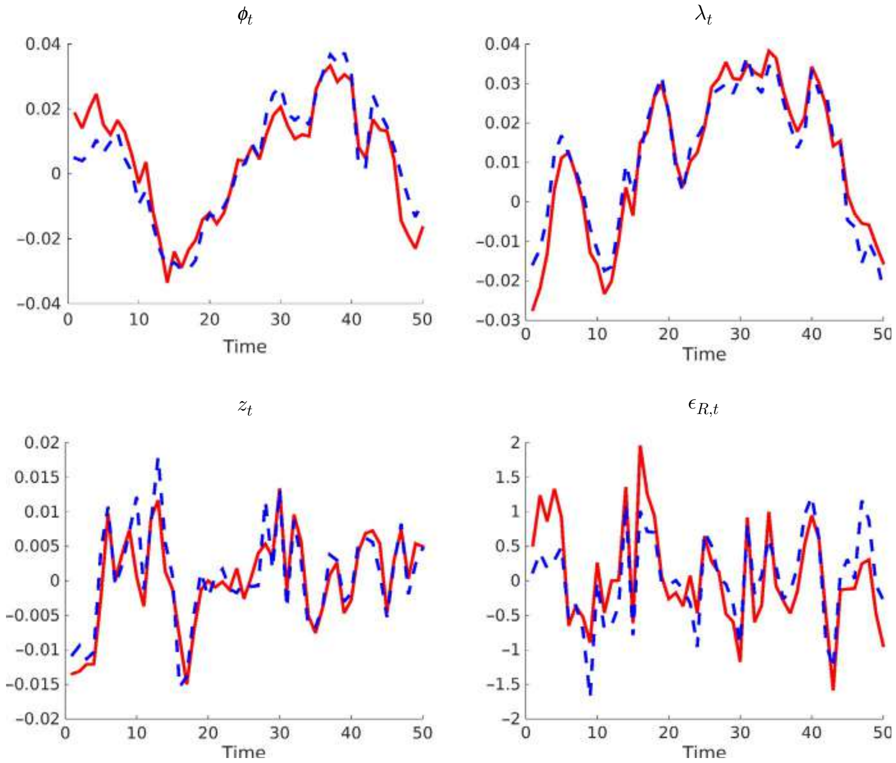

Fig. 25 Particle-filtered states. *Notes*: We simulate a sample of $T = 50$ observations y_t and states s_t from the stylized DSGE model. The four panels compare filtered states from the Kalman filter (*solid*) and a single run of the particle filter (*dashed*) with $M = 100$ particles. The observables used for filtering are output growth, labor share, and inflation. The measurement error variances are 10% of the total variance of the data.

eg, by Del Moral (2004) and Pitt et al. (2012), that the particle filter approximation of the likelihood function is unbiased, which implies that the approximation of the *log*-likelihood function has a downward bias, which is evident in the figure. Under suitable regularity conditions the particle filter approximations satisfy a CLT. The figure clearly indicates that the distribution of the approximation errors becomes more concentrated as the number of particles is increased from $M = 100$ to $M = 500$.

The accuracy of the bootstrap particle filter crucially depends on the quality of the fit of the DSGE model and the magnitude of the variance of the measurement errors u_t. Recall that for the bootstrap particle filter, the incremental weights $\tilde{w}_t^j = p(y_t|\tilde{s}_t^j)$. If the model fits poorly, then the one-step-ahead predictions conditional on the particles $\tilde{s}_t^j$ are inaccurate and the density of the actual observation y_t falls far in the tails of the predictive distribution. Because the density tends to decay quickly in the tails, the

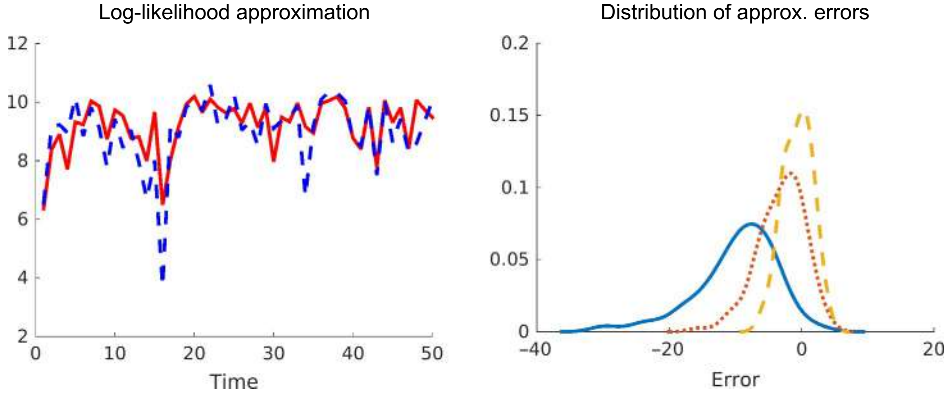

Fig. 26 Particle-filtered log-likelihood. *Notes*: We simulate a sample of $T = 50$ observations y_t and states s_t from the stylized DSGE model. The *left panel* compares log-likelihood increments from the Kalman filter (*solid*) and a single run of the particle filter (*dashed*) with $M = 100$ particles. The *right panel* shows a density plot for approximation errors of $\log \hat{p}(Y_{1:T}|\theta) - \log p(Y_{1:T}|\theta)$ based on $N_{run} = 100$ repetitions of the particle filter for $M = 100$ (*solid*), $M = 200$ (*dotted*), and $M = 500$ (*dashed*) particles. The measurement error variances are 10% of the total variance of the data.

incremental weights will have a high variability, which means that Monte Carlo approximations based on these incremental weights will be inaccurate.

The measurement error defines a metric between the observation y_t and the conditional mean prediction $\Psi(s_t,t;\theta)$. Consider the extreme case in which the measurement error is set to zero. This means that any particle that does not predict y_t exactly would get weight zero. In a model in which the error distribution is continuous, the probability of drawing a $\tilde{s}_t^j$ that receives a nonzero weight is zero, which means that the algorithm would fail in the first iteration. By continuity, the smaller the measurement error variance, the smaller the number of particles that would receive a nontrivial weight, and the larger the variance of the approximation error of particle filter approximations. In practice, it is often useful to start the filtering with a rather large measurement error variance, eg, 10% or 20% of the variance of the observables, and then observing the accuracy of the filter as the measurement error variance is reduced.

10.3.3 (Approximately) Conditionally Optimal Particle Filter

The conditionally optimal particle filter sets

$$g_t(\tilde{s}_t|s_{t-1}^j) = p(\tilde{s}_t|y_t, s_{t-1}^j), \tag{165}$$

that is, $\tilde{s}_t$ is sampled from the posterior distribution of the period t state given (y_t, s_{t-1}^j). In this case

$$\tilde{w}_t^j = \int p(y_t|s_t)p(s_t|s_{t-1}^j)ds_t = p(y_t|s_{t-1}^j). \tag{166}$$

Unfortunately, in a typical nonlinear DSGE model applications it is not possible to sample directly from $p(\tilde{s}_t|y_t, s^j_{t-1})$. In this case the researcher could try to approximate the conditionally optimal proposal density, which leads to an *approximately conditionally optimal particle filter*. For instance, if the DSGE model's nonlinearity arises from a higher-order perturbation solution and the nonlinearities are not too strong, then an approximately conditionally optimal importance distribution could be obtained by applying the one-step Kalman filter updating described in Table 6 to the first-order approximation of the DSGE model. More generally, as suggested in Guo et al. (2005), one could use the updating steps of a conventional nonlinear filter, such as an extended Kalman filter, unscented Kalman filter, or a Gaussian quadrature filter, to construct an efficient proposal distribution. Approximate filters for nonlinear DSGE models have been developed by Andreasen (2013) and Kollmann (2015).

Whenever one uses a proposal distribution that differs from $p(\tilde{s}^j_t|s^j_{t-1})$ it becomes necessary to evaluate the density $p(\tilde{s}^j_t|s^j_{t-1})$. In DSGE model applications, one typically does not have a closed-form representation for this density. It is implicitly determined by the distribution of ϵ_t and the state transition $\Phi(s_{t-1},\epsilon_t)$. The problem of having to evaluate the DSGE model-implied density of $\tilde{s}^j_t$ can be avoided by sampling an innovation from a proposal density $g^\epsilon(\tilde{\epsilon}_t|s^j_{t-1})$ and defining $\tilde{s}^j_t = \Phi(s^j_{t-1}, \tilde{\epsilon}_t)$. In this case the particle weights can be updated by the density ratio

$$\omega^j_t = \frac{p^\epsilon(\tilde{\epsilon}^j_t)}{g_t(\tilde{\epsilon}^j_t|s^j_{t-1})}, \tag{167}$$

where $p^\epsilon(\cdot)$ is the model-implied pdf of the innovation ϵ_t.

Sometimes, DSGE models have a specific structure that may simplify the particle-filter-based likelihood approximation. In models that are linear conditional on a subset of state variables, eg, volatility states or Markov-switching regimes, it is possible to use the Kalman filter to represent the uncertainty about a subset of states. In models in which the number of shocks ϵ_t equals the number of observables y_t, it might be possible (in the absence of measurement errors) conditional on an initial state vector s_0 to directly solve for ϵ_t based on y_t and s_{t-1}, which means that it may be possible to evaluate the likelihood function $p(Y_{1:T}|\theta,s_0)$ recursively. A more detailed discussion of these and other issues related to particle filtering for DSGE models is provided in Herbst and Schorfheide (2015).

11. FREQUENTIST ESTIMATION TECHNIQUES

We will now consider four frequentist inference techniques in more detail: likelihood-based estimation (Section 11.1), simulated method of moments estimation (Section 11.2), impulse response function matching (Section 11.3), and GMM estimation (Section 11.4). All of these econometric techniques, with the exception of the impulse response function matching approach, are widely used in other areas of economics and are associated with extensive literatures that we will not do justice to in this section. We will sketch the main idea behind each of the econometric procedures and then focus on adjustments that have been proposed to tailor the techniques to DSGE model applications. Each estimation method is associated with a model evaluation procedure that essentially assesses the extent to which the estimation objective has been achieved.

11.1 Likelihood-Based Estimation

Under the assumption that the econometric model is well specified, likelihood-based inference techniques enjoy many optimality properties. Because DSGE models deliver a joint distribution for the observables, maximum likelihood estimation of θ is very appealing. The maximum likelihood estimator $\hat{\theta}_{ml}$ was defined in (134). Altug (1989) and McGrattan (1994) are early examples of papers that estimated variants of a neoclassical stochastic growth model by maximum likelihood, whereas Leeper and Sims (1995) estimated a DSGE model meant to be usable for monetary policy analysis.

Even in a loglinearized DSGE model, the DSGE model parameters θ enter the coefficients of the state-space representation in a nonlinear manner, which can be seen in Table 4. Thus, a numerical technique is required to maximize the likelihood function. A textbook treatment of numerical optimization routines can be found, for instance, in Judd (1998) and Nocedal and Wright (2006). Some algorithms, eg, Quasi-Newton methods, rely on the evaluation of the gradient of the objective function (which requires differentiability), and other methods, such as simulated annealing, do not. This distinction is important if the likelihood function is evaluated with a particle filter. Without further adjustments, particle filter approximations of the likelihood function are nondifferentiable in θ even if the exact likelihood function is. This issue and possible solutions are discussed, for instance, in Malik and Pitt (2011) and Kantas et al. (2014).

11.1.1 Textbook Analysis of the ML Estimator

Under the assumption that θ is well identified and the log-likelihood function is sufficiently smooth with respect to θ, confidence intervals and test statistics for the DSGE model parameters can be based on a large sample approximation of the sampling distribution of the ML estimator. A formal analysis in the context of state-space models is provided, for instance, in the textbook by Cappé et al. (2005). We sketch the main steps of the approximation, assuming that the DSGE model is correctly specified and the data are generated by $p(Y|\theta_0,M_1)$. Of course, this analysis could be generalized to a setting in which the DSGE model is misspecified and the data are generated by a reference model $p(Y|M_0)$. In this case the resulting estimator is called quasi-maximum-likelihood estimator and the formula for the asymptotic covariance matrix presented below would have to be adjusted. A detailed treatment of quasi-likelihood inference is provided in White (1994).

Recall from Section 10 that the log-likelihood function can be decomposed as follows:

$$\ell_T(\theta|Y) = \sum_{t=1}^{T} \log p(y_t|Y_{1:t-1},\theta) = \sum_{t=1}^{T} \log \int p(y_t|s_t,\theta)p(s_t|Y_{1:t-1})ds_t. \tag{168}$$

Owing to the time-dependent conditioning information $Y_{1:t-1}$ the summands are not stationary. However, under the assumption that the sequence $\{s_t,y_t\}$ is stationary if initialized in the infinite past, one can approximate the log-likelihood function by

$$\ell^s_T(\theta|Y) = \sum_{t=1}^{T} \log \int p(y_t|s_t,\theta)p(s_t|Y_{-\infty:t-1})ds_t, \tag{169}$$

and show that the discrepancy $\left|\ell_T(\theta|Y) - \ell^s_T(\theta|Y)\right|$ becomes negligible as $T \to \infty$. The ML estimator is consistent if $T^{-1}\ell^s_T(\theta|Y) \xrightarrow{a.s.} \ell^s(\theta)$ uniformly almost surely (a.s.), where $\ell^s(\theta)$ is deterministic and maximized at the "true" θ_0. The consistency can be stated as

$$\hat{\theta}_{ml} \xrightarrow{a.s.} \theta_0. \tag{170}$$

Frequentist asymptotics rely on a second-order approximation of the log-likelihood function. Define the score (vector of first derivatives) $\nabla_\theta \ell^s_T(\theta|Y)$ and the matrix of second derivatives (Hessian, multiplied by minus one) $-\nabla^2_\theta \ell^s_T(\theta|Y)$ and let

$$\begin{aligned}\ell^s_T(\theta|Y) = {} & \ell^s_T(\theta_0|Y) + T^{-1/2}\nabla_\theta \ell^s_T(\theta_0|Y)\sqrt{T}(\theta-\theta_0) \\ & + \frac{1}{2}\sqrt{T}(\theta-\theta_0)'\left[\nabla^2_\theta \ell^s_T(\theta_0|Y)\right]\sqrt{T}(\theta-\theta_0) + \text{small}.\end{aligned}$$

If the maximum is attained in the interior of the parameter space Θ, the first-order conditions can be approximated by

$$\sqrt{T}(\hat{\theta}_{ml} - \theta_0) = \left[-\nabla^2_\theta \ell^s_T(\theta_0|Y)\right]^{-1} T^{-1/2}\nabla_\theta \ell^s_T(\theta_0|Y) + \text{small}. \tag{171}$$

Under suitable regularity conditions, the score process satisfies a CLT:

$$T^{-1/2}\nabla_\theta \ell_T(\theta|Y) \Longrightarrow N(0,\mathcal{I}(\theta_0)), \tag{172}$$

where $\mathcal{I}(\theta_0)$ is the Fisher information matrix.[aq] As long as the likelihood function is correctly specified, the term $\| -\nabla^2_\theta \ell_T(\theta|Y) - \mathcal{I}(\theta_0) \|$ converges to zero uniformly in a neighborhood around θ_0, which is a manifestation of the so-called information matrix equality. This leads to the following result

$$\sqrt{T}(\hat{\theta}_{ml} - \theta_0) \Longrightarrow N\left(0,\mathcal{I}^{-1}(\theta_0)\right). \tag{173}$$

[aq] The formal definition of the information matrix for this model is delicate and therefore omitted.

Thus, standard error estimates for t-tests and confidence intervals for elements of the parameter vector θ can be obtained from the diagonal elements of the inverse Hessian $[-\nabla^2_\theta \ell_T(\theta|Y)]^{-1}$ of the log-likelihood function evaluated at the ML estimator.[ar] Moreover, the maximized likelihood function can be used to construct textbook Wald, Lagrange-multiplier, and likelihood ratio statistics. Model selection could be based on a penalized likelihood function such as the Schwarz (1978) information criterion.

11.1.2 Illustration

To illustrate the behavior of the ML estimator we repeatedly generate data from the stylized DSGE model, treating the values listed in Table 5 as "true" parameters. We fix all parameters except for the Calvo parameter ζ_p at their "true" values and use the ML approach to estimate ζ_p. The likelihood function is based on output growth, labor share, inflation, and interest rate data. The left panel of Fig. 27 depicts the likelihood function for a single simulated data set Y. The right panel shows the sampling distribution of $\hat{\zeta}_{p,ml}$, which is approximated by repeatedly generating data and evaluating the ML estimator. The sampling distribution peaks near the "true" parameter value and becomes more concentrated as the sample size is increased from $T = 80$ to $T = 200$.

In practice, the ML estimator is rarely as well behaved as in this illustration, because the maximization is carried out over a high-dimensional parameter space and the log-likelihood function may be highly nonelliptical. In the remainder of this subsection, we focus on two obstacles that arise in the context of the ML estimation of DSGE models.

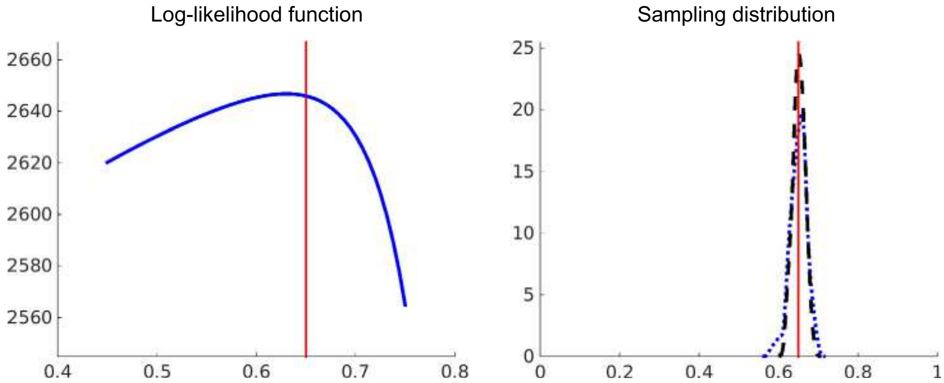

Fig. 27 Log-likelihood function and sampling distribution of $\hat{\zeta}_{p,ml}$. *Notes*: *Left panel*: log-likelihood function $\ell_T(\zeta_p|Y)$ for a single data set of size $T = 200$. *Right panel*: We simulate samples of size $T = 80$ (*dotted*) and $T = 200$ (*dashed*) and compute the ML estimator for the Calvo parameter ζ_p. All other parameters are fixed at their "true" value. The plot depicts densities of the sampling distribution of $\hat{\zeta}_p$. The vertical lines in the two panels indicate the "true" value of ζ_p.

[ar] Owing to the Information Matrix Equality, the standard error estimates can also be obtained from the outer product of the score: $\sum_{t=1}^T (\nabla_\theta \log p(y_t|Y_{1:t-1},\theta))(\nabla_\theta \log p(y_t|Y_{1:t-1},\theta))'$.

The first obstacle is the potential stochastic singularity of the DSGE model-implied conditional distribution of y_t given its past. The second obstacle is caused by a potential lack of identification of the DSGE model parameters.

11.1.3 Stochastic Singularity

Imagine removing all shocks except for the technology shock from the stylized DSGE model, while maintaining that y_t comprises output growth, the labor share, inflation, and the interest rate. In this case, we have one exogenous shock and four observables, which implies, among other things, that the DSGE model places probability one on the event that

$$\beta \log R_t - \log \pi_t = \beta \log (\pi^* \gamma / \beta) - \log \pi^*.$$

Because in the actual data $\beta \log R_t - \log \pi_t$ is time varying, the likelihood function is equal to zero and not usable for inference. The literature has adopted two types of approaches to address the singularity, which we refer to as the "measurement error" approach and the "more structural shocks" approach.

Under the measurement error approach (78) is augmented by a measurement error process u_t, which in general may be serially correlated. The term "measurement error" is a bit of a misnomer. It tries to blame the discrepancy between the model and the data on the accuracy of the latter rather than the quality of the former. In a typical DSGE model application, the blame should probably be shared by both. A key feature of the "measurement error" approach is that the agents in the model do not account for the presence of u_t when making their decisions. The "measurement error" approach has been particularly popular in the real business cycle literature—it was used, for instance, in Altug (1989). The real business cycle literature tried to explain business cycle fluctuations based on a small number of structural shocks, in particular, technology shocks.

The "more structural shocks" approach augments the DSGE model with additional structural shocks until the number of shocks is equal to or exceeds the desired number of observables stacked in the vector y_t. For instance, if we add the three remaining shock processes ϕ_t, λ_t, $\epsilon_{R,t}$ back into the prototypical DSGE model, then a stochastic singularity is no longer an obstacle for the evaluation of the likelihood function. Of course, at a deeper level, the stochastic singularity problem never vanishes, as we could also increase the dimension of the vector y_t. Because the policy functions in the solution of the DSGE model express the control variables as functions of the state variables, the set of potential observables y_t in any DSGE model exceeds the number of shocks (which are exogenous state variables from the perspective of the underlying agents' optimization problems). Most of the literature that estimates loglinearized DSGE models uses empirical specifications in which the number of exogenous shocks is at least as large as the number of observables. Examples are Schorfheide (2000), Rabanal and Rubio-Ramírez (2005), and Smets and Wouters (2007).

The converse of the "more structural shocks" approach would be a "fewer observables" approach, ie, one restricts the number of observables used in the construction of the likelihood function to the number of exogenous shocks included in the model. This raises the question of which observables to include in the likelihood function, which is discussed in Guerrón-Quintana (2010) and Canova et al. (2014). Qu (2015) proposes to use a composite likelihood to estimate singular DSGE models. A composite likelihood function is obtained by partitioning the vector of observables y_t into subsets, eg, $y_t' = [y_{1,t}', y_{2,t}', y_{3,t}']$ for which the likelihood function is nonsingular, eg, "composite likelihood" and then use the product of marginals $p(Y_{1,1:T}|\theta)p(Y_{2,1:T}|\theta)$ $p(Y_{3,1:T}|\theta)$ as the estimation objective function.

11.1.4 Dealing with Lack of Identification

In many applications it is quite difficult to maximize the likelihood function. This difficulty is in part caused by the presence of local extrema and/or weak curvature in some directions of the parameter space and may be a manifestation of identification problems. One potential remedy that has been widely used in practice is to fix a subset of the parameters at plausible values, where "plausible" means consistent with some empirical observations that are not part of the estimation sample Y. Conditional on the fixed parameters, the likelihood function for the remaining parameters may have a more elliptical shape and therefore may be easier to maximize. Of course, such an approach ignores the uncertainty with respect to those parameters that are being fixed. Moreover, if they are fixed at the "wrong" parameter values, inference about the remaining parameters will be distorted.

Building on the broader literature on identification-robust econometric inference, the recent literature has developed inference methods that remain valid even if some parameters of the DSGE model are only weakly or not at all identified. Guerrón-Quintana et al. (2013) propose a method that relies on likelihood-based estimates of the system matrices of the state-space representation $\hat{\Psi}_0$, $\hat{\Psi}_1$, $\hat{\Phi}_1$ and $\hat{\Phi}_\epsilon$. In view of the identification problems associated with the Ψ and Φ matrices discussed in Section 9.1, their approach requires a reparameterization of the state-space matrices in terms of an identifiable reduced-form parameter vector $\phi = f(\theta)$ that, according to the DSGE model, is a function of θ. In the context of our stylized DSGE model, such a reparameterization could be obtained based on the information in Table 4.

Let M_1^ϕ denote the state-space representation of the DSGE model in terms of ϕ and let $\hat{\phi}$ be the ML estimator of ϕ. The hypothesis $H_0 : \theta = \theta_0$ can be translated into the hypothesis $\phi = f(\theta_0)$ and the corresponding likelihood ratio statistic takes the form

$$LR(Y|\theta_0) = 2\left[\log p(Y|\hat{\phi}, M_1^\phi) - \log p(Y|f(\theta_0), M_1^\phi)\right] \Longrightarrow \chi^2_{\dim(\phi)}. \qquad (174)$$

The degrees of freedom of the χ^2 limit distribution depend on the dimension of ϕ (instead of θ), which means that it is important to reduce the dimension of ϕ as much as possible by using a minimal state-variable representation of the DSGE model solution and to remove elements from the Ψ and Φ matrices that are zero for all values of θ. The likelihood ratio statistic can be inverted to generate a $1-\alpha$ joint confidence set for the vector θ:

$$CS^{\theta}(Y)=\{\theta \mid LR(Y|\theta)\leq \chi^2_{crit}\}, \tag{175}$$

where χ^2_{crit} is the $1-\alpha$ quantile of the $\chi^2_{\dim(\phi)}$ distribution. Subvector inference can be implemented by projecting the joint confidence set on the desired subspace. The inversion of test statistics is computationally tedious because the test statistic has to be evaluated for a wide range of θ values. However, it does not require the maximization of the likelihood function. Guerrón-Quintana et al. (2013) show how the computation of the confidence interval can be implemented based on the output from a Bayesian estimation of the DSGE model.

Andrews and Mikusheva (2015) propose an identification-robust Lagrange multiplier test. The test statistic is based on the score process and its quadratic variation

$$s_{T,t}(\theta)=\nabla_{\theta}\ell(\theta|Y_{1:t})-\nabla_{\theta}\ell(\theta|Y_{1:t-1}),\ \ J_T(\theta)=\sum_{t=1}^{T}s_{T,t}(\theta)s'_{T,t}(\theta)$$

and is defined as

$$LM(\theta|Y)=\nabla'_{\theta}\ell_T(\theta_0|Y)[J_T(\theta_0)]^{-1}\nabla_{\theta}\ell_T(\theta_0|Y)\Longrightarrow\chi^2_{\dim(\theta_0)}. \tag{176}$$

Note that the degrees of freedom of the χ^2 limit distribution now depend on the dimension of the parameter vector θ instead of the vector of identifiable reduced-form coefficients. A confidence set for θ can be obtained by replacing the LR statistic in (175) with the LM statistic. Andrews and Mikusheva (2015) also consider subvector inference based on a profile likelihood function that concentrates out a subvector of well-identified DSGE model parameters. A frequency domain version of the LM test based on the Whittle likelihood function is provided by Qu (2014). Both Andrews and Mikusheva (2015) and Qu (2014) provide detailed Monte Carlo studies to assess the performance of the proposed identification-robust tests.

11.2 (Simulated) Minimum Distance Estimation

Minimum distance (MD) estimation is based on the idea of minimizing the discrepancy between sample moments of the data, which we denoted by $\hat{m}_T(Y)$, and model-implied moments, which we denoted by $\mathbb{E}[\hat{m}_T(Y)|\theta,M_1]$. The MD estimator $\hat{\theta}_{md}$ was defined in (135) and (136). Examples of the sample statistics $\hat{m}_T(Y)$ are the sample autocovariances $\hat{\Gamma}_{yy}(h)$, a smoothed periodogram $\bar{f}_{yy}(\omega)$ as in Diebold et al. (1998), or estimates of the parameters of an approximating model, eg, the VAR(p) in (113) as in Smith (1993). If $\hat{m}_T(Y)$ consists of parameter estimates of a reference model, then the moment-based estimation is also called indirect inference; see Gourieroux et al. (1993). In some cases it is possible to calculate the model-implied moments analytically. For instance, suppose that $\hat{m}_T(Y) = \frac{1}{T}\sum y_t y'_{t-1}$, then we can derive

$$\mathbb{E}[\hat{m}_T(Y)|\theta, M_1] = \frac{1}{T}\sum \mathbb{E}[y_t y'_{t-1}|\theta, M_1] = \mathbb{E}[y_2 y'_1|\theta, M_1] \tag{177}$$

from the state-space representation of a linearized DSGE model. Explict formulae for moments of pruned models solved with perturbation methods are provided by Andreasen et al. (2013) (recall Section 4.4). Alternatively, suppose that $\hat{m}_T(Y)$ corresponds to the OLS estimates of a VAR(1). In this case, even for a linear DSGE model, it is not feasible to compute

$$\mathbb{E}[\hat{m}_T(Y)] = \mathbb{E}\left[\left(\frac{1}{T}\sum_{t=1}^{T} y_{t-1}y'_{t-1}\right)^{-1} \frac{1}{T}\sum_{t=1}^{T} y_{t-1}y'_t \middle| \theta, M_1\right]. \tag{178}$$

The model-implied expectation of the OLS estimator has to be approximated, for instance, by a population regression:

$$\hat{\mathbb{E}}[\hat{m}_T(Y)] = \left(\mathbb{E}[y_{t-1}y'_{t-1}|\theta, M_1]\right)^{-1}\mathbb{E}[y_{t-1}y'_t|\theta, M_1], \tag{179}$$

or the model-implied moment function has to be replaced by a simulation approximation, which will be discussed in more detail below.

11.2.1 Textbook Analysis

We proceed by sketching the asymptotic approximation of the frequentist sampling distribution of the MD estimator. Define the discrepancy

$$G_T(\theta|Y) = \hat{m}_T(Y) - \hat{\mathbb{E}}[\hat{m}_T(Y)|\theta, M_1], \tag{180}$$

such that the criterion function of the MD estimator in (135) can be written as

$$Q_T(\theta|Y) = \|G_T(\theta|Y)\|_{W_T}. \tag{181}$$

Suppose that there is a unique θ_0 with the property that[as]

$$\hat{m}_T(Y) - \mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1] \xrightarrow{a.s.} 0 \tag{182}$$

and that the sample criterion function $Q_T(\theta|Y)$ converges uniformly almost surely to a limit criterion function $Q(\theta)$, then the MD estimator is consistent in the sense that $\hat{\theta}_{md} \xrightarrow{a.s.} \theta_0$.

The analysis of the MD estimator closely mirrors the analysis of the ML estimator, because both types of estimators are defined as the extremum of an objective function.

[as] In some DSGE models a subset of the series included in y_t is nonstationary. Thus, moments are only well defined after a stationarity-inducing transformation has been applied. This problem is analyzed in Gorodnichenko and Ng (2010).

The sampling distribution of $\hat{\theta}_{md}$ can be derived from a second-order approximation of the criterion function $Q_T(\theta|Y)$ around θ_0:

$$\begin{aligned} TQ_T(\theta|Y) &= \sqrt{T}\nabla_\theta Q_T(\theta_0|Y)\sqrt{T}(\theta-\theta_0)' \\ &\quad + \frac{1}{2}\sqrt{T}(\theta-\theta_0)'\left[\frac{1}{T}\nabla_\theta^2 Q_T(\theta_0|Y)\right]\sqrt{T}(\theta-\theta_0) + \text{small}. \end{aligned} \tag{183}$$

If the minimum of $Q_T(\theta|Y)$ is obtained in the interior, then

$$\sqrt{T}(\hat{\theta}_{md}-\theta_0) = \left[-\frac{1}{T}\nabla_\theta^2 Q_T(\theta_0|Y)\right]^{-1}\sqrt{T}\nabla_\theta Q_T(\theta_0|Y) + \text{small}. \tag{184}$$

Using (180), the "score" process can be expressed as

$$\sqrt{T}\nabla_\theta Q_T(\theta_0|Y) = (\nabla_\theta G_T(\theta_0|Y))W_T\sqrt{T}G_T(\theta_0|Y) \tag{185}$$

and its distribution depends on the distribution of

$$\begin{aligned} \sqrt{T}G_T(\theta_0|Y) &= \sqrt{T}(\hat{m}_T(Y) - \mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]) \\ &\quad + \sqrt{T}\left(\hat{\mathbb{E}}[\hat{m}_T(Y)|\theta_0, M_1] - \mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]\right) \\ &= I + II, \end{aligned} \tag{186}$$

say. Term I captures the variability of the deviations of the sample moment $\hat{m}_T(Y)$ from its expected value $\mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]$ and term II captures the error due to approximating $\mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]$ by $\hat{\mathbb{E}}[\hat{m}_T(Y)|\theta_0, M_1]$. Under suitable regularity conditions

$$\sqrt{T}G_T(\theta_0|Y) \Longrightarrow N(0, \boldsymbol{\Omega}), \tag{187}$$

and

$$\sqrt{T}(\hat{\theta}_{md}-\theta_0) \Longrightarrow N\left(0, (DWD')^{-1}DW\boldsymbol{\Omega}WD'(DWD')^{-1}\right), \tag{188}$$

where W is the limit of the sequence of weight matrices W_T and the matrix D is defined as the probability limit of $\nabla_\theta G_T(\theta_0|Y)$. To construct tests and confidence sets based on the limit distribution, the matrices D and $\boldsymbol{\Omega}$ have to be replaced by consistent estimates. We will discuss the structure of $\boldsymbol{\Omega}$ in more detail below.

If the number of moment conditions exceeds the number of parameters, then the model specification can be tested based on the overidentifying moment conditions. If $W_T = [\hat{\boldsymbol{\Omega}}_T]^{-1}$, where $\hat{\boldsymbol{\Omega}}_T$ is a consistent estimator of $\boldsymbol{\Omega}$, then

$$TQ_T(\hat{\theta}_{md}|Y) \Longrightarrow \chi^2_{df}, \tag{189}$$

where the degrees of freedom df equal the number of overidentifying moment conditions. The sample objective function can also be used to construct hypothesis tests for θ. Suppose that the null hypothesis is $\theta = \theta_0$. A quasi-likelihood ratio test is based on $T(Q_T(\theta_0|Y) - Q_T(\hat{\theta}_{md}|Y)$; a quasi-Lagrange-multiplier test is based on a properly standardized quadratic form of $\sqrt{T}\nabla_\theta Q_T(\theta_0|Y)$; and a Wald test is based on a properly standardized quadratic form of $\sqrt{T}(\hat{\theta}_{md}-\theta_0)$. Any of these test statistics can be inverted to construct a confidence set. Moreover, if the parameters suffer from identification problems, then the approach of Andrews and Mikusheva (2015) can be used to conduct identification-robust inference based on the quasi-Lagrange-multiplier test.

11.2.2 Approximating Model-Implied Moments

In many instances the model-implied moments $\mathbb{E}[m_T(Y)|\theta,M_1]$ are approximated by an estimate $\hat{\mathbb{E}}[m_T(Y)|\theta,M_1]$. This approximation affects the distribution of $\hat{\theta}_{md}$ through term *II* in (186). Consider the earlier example in (178) and (179) in which $\hat{m}_T(Y)$ corresponds to the OLS estimates of a VAR(1). Because the OLS estimator has a bias that vanishes at rate $1/T$, we can deduce that term *II* converges to zero and does not affect the asymptotic covariance matrix $\mathbf{\Omega}$.

The more interesting case is the one in which $\hat{\mathbb{E}}[m_T(Y)|\theta,M_1]$ is based on the simulation of the DSGE model. The asymptotic theory for simulation-based extremum estimators has been developed in Pakes and Pollard (1989). Lee and Ingram (1991) and Smith Jr. (1993) are the first papers that use simulated method of moments to estimate DSGE models. For concreteness, suppose that $m_T(Y)$ corresponds to the first-order (uncentered) sample autocovariances. We previously showed that, provided the y_t's are stationary, $\mathbb{E}[m_T(Y)|\theta,M_1]$ is given by the DSGE model population autocovariance matrix $\mathbb{E}[y_2y_1'|\theta,M_1]$, which can be approximated by simulating a sample of length λT of artificial observations Y^* from the DSGE model M_1 conditional on θ. Based on these simulated observations one can compute the sample autocovariances $\hat{m}_{\lambda T}(Y^*(\theta,M_1))$. In this case term *II* is given by

$$II=\frac{1}{\sqrt{\lambda}}\sqrt{\lambda T}\left(\frac{1}{\lambda T}\sum_{t=1}^{\lambda T}y_t^*y_{t-1}^*-\mathbb{E}[y_2y_1'|\theta_0,M_1]\right) \tag{190}$$

and satisfies a CLT. Because the simulated data are independent of the actual data, terms *I* and *II* in (186) are independent and we can write

$$\mathbf{\Omega}=\mathbb{V}_\infty[I]+\mathbb{V}_\infty[II], \tag{191}$$

where

$$\mathbb{V}_\infty[II]=\frac{1}{\lambda}\left(\lim_{T\to\infty}T\mathbb{V}[\hat{m}_T(Y^*(\theta_0,M_1))]\right) \tag{192}$$

and can be derived from the DSGE model. The larger λ, the more accurate the simulation approximation and the contribution of $\mathbb{V}_\infty[II]$ to the overall covariance matrix $\mathbf{\Omega}$.

We generated the simulation approximation by simulating one long sample of observations from the DSGE model. Alternatively, we could have simulated λ samples Y^i, $i=1,\lambda$ of size T. It turns out that for the approximation, say, of $\mathbb{E}[y_2y_1'|\theta,M_1]$, it does not matter because $\hat{m}_T(Y^*(\theta,M_1))$ is an unbiased estimator of $\mathbb{E}[y_2y_1'|\theta,M_1]$. However, if

$\hat{m}_T(Y)$ is defined as the OLS estimator of a VAR(1), then the small-sample bias of the OLS estimator generates an $O(T^{-1})$ wedge between

$$\left(\sum_{t=1}^{\lambda T} y_{t-1}^{*} y_{t-1}^{*\prime}\right)^{-1} \sum_{t=1}^{\lambda T} y_{t-1}^{*} y_{t-1}^{*\prime} \quad \text{and} \quad \mathbb{E}\left[\left(\sum_{t=1}^{T} y_{t-1} y_{t-1}^{\prime}\right)^{-1} \sum_{t=1}^{T} y_{t-1} y_{t-1}^{\prime} \middle| \theta, M_1\right].$$

For large values of λ, this wedge can be reduced by using

$$\hat{E}[m_T(Y)|\theta, M_1] = \frac{1}{\lambda} \sum_{i=1}^{\lambda} \left(\sum_{t=1}^{T} y_{t-1}^{i} y_{t-1}^{i\prime}\right)^{-1} \sum_{t=1}^{T} y_{t-1}^{i} y_{t-1}^{i\prime}$$

instead. Averaging OLS estimators from model-generated data reproduces the $O(T^{-1})$ bias of the OLS estimator captured by $\mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]$ and can lead to a final sample bias reduction in term II, which improves the small sample performance of $\hat{\theta}_{md}$.[at]

When implementing the simulation approximation of the moments, it is important to fix the random seed when generating the sample Y^* such that for each parameter value of θ the same sequence of random variables is used in computing $Y^*(\theta, M_1)$. This ensures that the sample objective function $Q_T(\theta|Y)$ remains sufficiently smooth with respect to θ to render the second-order approximation of the objective function valid.

11.2.3 Misspecification

Under the assumption that the DSGE model is correctly specified, the MD estimator has a well-defined almost-sure limit θ_0 and the asymptotic variance $\mathbb{V}_\infty[I]$ of term I in (186) is given by the model-implied variance

$$\mathbb{V}_\infty[I] = \left(\lim_{T\to\infty} T\mathbb{V}[\hat{m}_T(Y^*(\theta_0, M_1))]\right), \tag{193}$$

which up to the factor of $1/\lambda$ is identical to the contribution $\mathbb{V}_\infty[II]$ of the simulation approximation of the moments to the overall asymptotic variance $\boldsymbol{\Omega}$; see (192). Under the assumption of correct specification, it is optimal to choose the weight matrix W based on the accuracy with which the elements of the moment vector $\hat{m}_T(Y)$ measure the population analog $\mathbb{E}[\hat{m}_T(Y)|\theta_0, M_1]$. If the number of moment conditions exceeds the number of parameters, it is optimal (in the sense of minimizing the sampling variance of $\hat{\theta}_{md}$) to place more weight on matching moments that are accurately measured in the data, by setting $W = \boldsymbol{\Omega}^{-1}$. In finite sample, one can construct W_T from a consistent estimator of $\boldsymbol{\Omega}^{-1}$.

[at] See Gourieroux et al. (2010) for a formal analysis in the context of a dynamic panel data model.

If the DSGE model is regarded as misspecified, then the sampling distribution of the MD estimator has to be derived under the distribution of a reference model $p(Y|M_0)$. In this case we can define

$$\theta_0(Q) = \lim_{T\to\infty} \operatorname{argmin}_\theta \|\mathbb{E}[\hat{m}_T(Y)|M_0] - \mathbb{E}[\hat{m}|\theta, M_1]\|_W \tag{194}$$

and, under suitable regularity, the estimator $\hat{\theta}_{md}$ will converge to the pseudo-optimal value θ_0. Note that θ_0 is a function of the moments $\hat{m}_T(Y)$ that are being matched and the weight matrix W (indicated by the Q argument). Both $\hat{m}$ and W are chosen by the researcher based on the particular application. The vector $\hat{m}$ should correspond to a set of moments that are deemed to be informative about the desired parameterization of the DSGE model and reflect the ultimate purpose of the estimated DSGE model. The weight matrix W should reflect beliefs about the informativeness of certain sample moments with respect to the desired parameterization of the DSGE model.

To provide an example, consider the case of a DSGE model with stochastic singularity that attributes all business cycle fluctuations to technology shocks. To the extent that the observed data are not consistent with this singularity, the model is misspecified. A moment-based estimation of the model will ultimately lead to inflated estimates of the standard deviation of the technology shock innovation, because this shock alone has to generate the observed variability in, say, output growth, the labor share, and other variables. The extent to which the estimated shock variance is upwardly biased depends on exactly which moments the estimator is trying to match. If one of the priorities of the estimation exercise is to match the unconditional variance of output growth, then the weight matrix W should assign a large weight to this moment, even if it is imprecisely measured by its sample analog in the data.

The asymptotic variance $\mathbb{V}_\infty[I]$ of term I in (186) is now determined by the variance of the sample moments implied by the reference model M_0:

$$\mathbb{V}_\infty[I] = \left(\lim_{T\to\infty} T\mathbb{V}[\hat{m}_T(Y)|M_0]\right). \tag{195}$$

Suppose that $\hat{m}_T(Y) = \frac{1}{T}\sum_{t=1}^T y_t y_{t-1}'$, which under suitable regularity conditions converges to the population autocovariance matrix $\mathbb{E}[y_1 y_0'|M_0]$ under the reference model M_0. If the reference model is a linear process, then the asymptotic theory developed in Phillips and Solo (1992) can be used to determine the limit covariance matrix $\mathbb{V}_\infty[I]$. An estimate of $\mathbb{V}_\infty[I]$ can be obtained with a heteroskedasticity and autocorrelation consistent (HAC) covariance matrix estimator that accounts for the serial correlation in the matrix-valued sequence $\{y_t y_{t-1}'\}_{t=1}^T$. An extension of indirect inference in which $\hat{m}_T(Y)$ comprises estimates of an approximating model to the case of misspecified DSGE models is provided in Dridi et al. (2007).

11.2.4 Illustration

Detailed studies of the small-sample properties of MD estimators for DSGE models can be found in Ruge-Murcia (2007) and Ruge-Murcia (2012). To illustrate the behavior of the MD estimator we repeatedly generate data from the stylized DSGE model, treating the values listed in Table 5 as "true" parameters. We fix all parameters except for the Calvo parameter ζ_p at their "true" values and use two versions of the MD procedure to estimate ζ_p. The vector of moment conditions $\hat{m}_T(Y)$ is defined as follows. Let $y_t = [\log(X_t/X_{t-1}), \pi_t]'$ and consider a VAR(2) in output growth and inflation:

$$y_t = \Phi_1 y_{t-1} + \Phi_2 y_{t-2} + \Phi_0 + u_t. \tag{196}$$

Let $\hat{m}_T(Y) = \hat{\Phi}$ be the OLS estimate of $[\Phi_1, \Phi_2, \Phi_0]'$.

The results in the left panel of Fig. 28 are obtained by a simulation approximation of the model-implied expected value of $\hat{m}_T(Y)$. We simulate $N = 100$ trajectories of length $T + T_0$ and discarding the first T_0 observations. Let $Y_{1:T}^{(i)}(\theta)$ be the i-th simulated trajectory and define

$$\mathbb{E}[\hat{m}_T(Y)|\theta, M_1] \approx \frac{1}{N}\sum_{i=1}^{N} \hat{m}_T(Y^{(i)}(\theta)), \tag{197}$$

which can be used to evaluate the objective function (181). For the illustration we use the optimal weight matrix $W_T = \hat{\Sigma}^{-1} \otimes X'X$, where X is the matrix of regressors for the VAR(2) and $\hat{\Sigma}$ an estimate of the covariance matrix of the VAR innovations. Because we are estimating a single parameter, we compute the estimator $\hat{\theta}_{md}$ by grid search. It

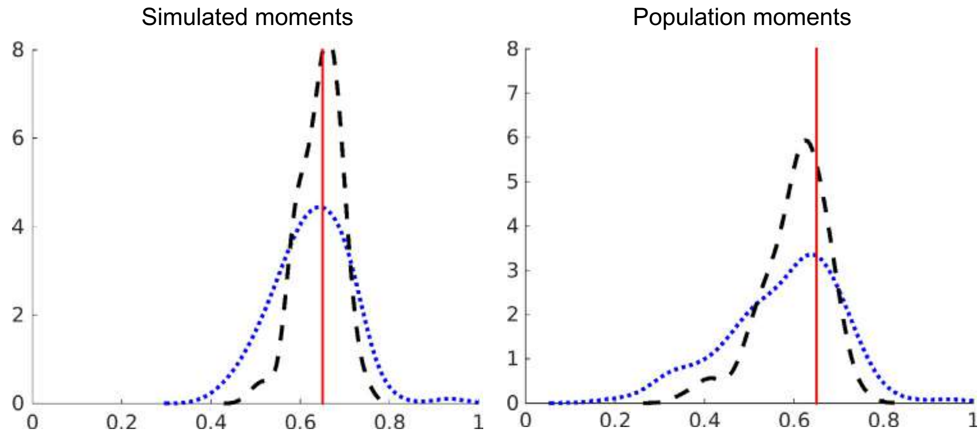

Fig. 28 Sampling distribution of $\hat{\zeta}_{p,md}$. *Notes*: We simulate samples of size $T = 80$ (*dotted*) and $T = 200$ (*dashed*) and compute two versions of an MD estimator for the Calvo parameter ζ_p. All other parameters are fixed at their "true" value. The plots depict densities of the sampling distribution of $\hat{\zeta}_{p,md}$. The vertical line indicates the "true" value of ζ_p.

is important to use the same sequence of random numbers for each value of $\theta \in \mathcal{T}$ to compute the simulation approximation $\mathbb{E}[\hat{m}_T(Y)|\theta, M_1]$. The results in the right panel of Fig. 28 are based on the VAR(2) approximation of the DSGE model based on a population regression. Let $x_t' = [y_{t-1}', y_{t-2}', 1]$ and let

$$\mathbb{E}[\hat{m}_T(Y)|\theta, M_1] \approx \left(\mathbb{E}[x_t x_t'|\theta, M_1]\right)^{-1} \mathbb{E}[x_t y_t'|\theta, M_1]. \tag{198}$$

Fig. 28 depicts density estimates of the sampling distribution of $\hat{\zeta}_{p,md}$. The vertical line indicates the "true" parameter value of ζ_p. As the sample size increases from $T = 80$ to $T = 200$, the sampling distribution concentrates around the "true" value and starts to look more like a normal distribution, as the asymptotic theory presented in this section suggests. The distribution of the estimator based on the simulated objective function is more symmetric around the "true" value and also less variable. However, even based on a sample size of 200 observations, there is considerable uncertainty about the Calvo parameter and hence the slope of the New Keynesian Phillips curve. A comparison with Fig. 27 indicates that the MD estimator considered in this illustration is less efficient than the ML estimator.

11.2.5 Laplace Type Estimators

In DSGE model applications the estimation objective function $Q_T(\theta|Y)$ is often difficult to optimize. Chernozhukov and Hong (2003) proposed computing a mean of a quasi-posterior density instead of computing an extremum estimator. The resulting estimator is called a Laplace-type (LT) estimator and defined as follows (provided the integral in the denominator is well defined):

$$\hat{\theta}_{LT} = \frac{\exp\left\{-\frac{1}{2} Q_T(\theta|Y)\right\}}{\int \exp\left\{-\frac{1}{2} Q_T(\theta|Y)\right\} d\theta}. \tag{199}$$

This estimator can be evaluated using the Metropolis–Hastings algorithm discussed in Section 12.2 or the sequential Monte Carlo algorithm presented in Section 12.3 below. The posterior computations may be more accurate than the computation of an extremum. Moreover, suppose that the objective function is multimodal. In repeated sampling, the extremum of the objective function may shift from one mode to the other, making the estimator appear to be unstable. On the other hand, owing to the averaging, the LT estimator may be more stable. Chernozhukov and Hong (2003) establish the consistency and asymptotic normality of LT estimators, which is not surprising because the sample objective function concentrates around its extremum as $T \longrightarrow \infty$ and the discrepancy between the extremum and the quasi-posterior mean vanishes. DSGE model applications of LT estimators are provided in Kormilitsina and Nekipelov (2012, 2016).

LT estimators can be constructed not only from MD estimators but also from IRF matching estimators and GMM estimators discussed below.

11.3 Impulse Response Function Matching

As discussed previously, sometimes DSGE models are misspecified because researchers have deliberately omitted structural shocks that contribute to business cycle fluctuations. An example of such a model is the one developed by Christiano et al. (2005). The authors focus their analysis on the propagation of a single shock, namely, a monetary policy shock. If it is clear that if the DSGE model does not contain enough structural shocks to explain the variability in the observed data, then it is sensible to try to purge the effects of the unspecified shocks from the data, before matching the DSGE model to the observations. This can be done by "filtering" the data through the lens of a VAR that identifies the impulse responses to those shocks that are included in the DSGE model. The model parameters can then be estimated by minimizing the discrepancy between model-implied and empirical impulse response functions. A mismatch between the two sets of impulse responses provides valuable information about the misspecification of the propagation mechanism and can be used to develop better-fitting DSGE models. Influential papers that estimate DSGE models by matching impulse response functions include Rotemberg and Woodford (1997), Christiano et al. (2005), and Altig et al. (2011). The casual description suggests that impulse response function matching estimators are a special case of the previously discussed MD estimators (the DSGE model M_1 is misspecified and a structural VAR serves as reference model M_0 under which the sampling distribution of the estimator is derived). Unfortunately, several complications arise, which we will discuss in the remainder of this section. Throughout, we assume that the DSGE model has been linearized. An extension to the case of nonlinear DSGE models is discussed in Ruge-Murcia (2014).

11.3.1 Invertibility and Finite-Order VAR Approximations

The empirical impulse responses are based on a finite-order VAR, such as the one in (113). However, even linearized DSGE models typically cannot be written as a finite-order VAR. Instead, they take the form of a state-space model, which typically has a VARMA representation. In general we can distinguish the following three cases: (i) the solution of the DSGE model can be expressed as a VAR(p). For the stylized DSGE model, this is the case if y_t is composed of four observables: output growth, the labor share, inflation, and interest rates. (ii) The moving average polynomial of the VARMA representation of the DSGE model is invertible. In this case the DSGE model can be expressed as an infinite-order VAR driven by the structural shock innovations ϵ_t. (iii) The moving average polynomial of the VARMA representation of the DSGE model is not invertible. In this case the innovation of the VAR(∞) approximation do not correspond to the structural innovations ϵ_t. Only in case (i) can one expect a direct match between the empirical IRFs and the DSGE model IRFs. Cases (ii) and (iii) complicate econometric inference. The extent to which impulse-response-function-based estimation and model evaluation may be misleading has been fiercely debated in Christiano et al. (2007) and Chari et al. (2008).

Fernández-Villaverde et al. (2007) provide formal criteria to determine whether a DSGE model falls under case (i), (ii), or (iii). Rather than presenting a general analysis of this problem, we focus on a simple example. Consider the following two MA processes that represent the DSGE models in this example:

$$\begin{array}{lcl} M_1 & : & y_t = \epsilon_t + \theta\epsilon_{t-1} = (1+\theta L)\epsilon_t \\ M_2 & : & y_t = \theta\epsilon_t + \epsilon_{t-1} = (\theta + L)\epsilon_t, \end{array} \tag{200}$$

where $0 < \theta < 1$, L denotes the lag operator, and $\epsilon_t \sim iidN(0,1)$. Models M_1 and M_2 are observationally equivalent, because they are associated with the same autocovariance sequence. The root of the MA polynomial of model M_1 is outside of the unit circle, which implies that the MA polynomial is invertible and one can express y_t as an AR(∞) process:

$$AR(\infty) \text{ for } M_1: \; y_t = -\sum_{j=1}^{\infty}(-\theta)^j y_{t-j} + \epsilon_t. \tag{201}$$

It is straightforward to verify that the AR(∞) approximation reproduces the impulse response function of M_1:

$$\frac{\partial y_t}{\partial \epsilon_t} = 1, \quad \frac{\partial y_{t+1}}{\partial \epsilon_t} = \theta, \quad \frac{\partial y_{t+h}}{\partial \epsilon_t} = 0 \text{ for } h > 1.$$

Thus, the estimation of an autoregressive model with many lags can reproduce the monotone impulse response function of model M_1.

The root of the MA polynomial of M_2 lies inside the unit circle. While M_2 could also be expressed as an AR(∞), it would be a representation in terms of a serially uncorrelated one-step-ahead forecast error u_t that is a function of the infinite history of the ϵ_t's: $u_t = (1+\theta L)^{-1}(\theta + L)$. As a consequence, the AR(∞) is unable to reproduce the hump-shaped IRF of model M_2. More generally, if the DSGE model is associated with a noninvertible moving average polynomial, its impulse responses cannot be approximated by a VAR(∞) and a direct comparison of VAR and DSGE IRFs may be misleading.

11.3.2 Practical Considerations

The objective function for the IRF matching estimator takes the same form as the criterion function of the method of moments estimator in (180) and (181), where $\hat{m}_T(Y)$ is the VAR IRF. For $\hat{\mathbb{E}}[\hat{m}_T(Y)|\theta, M_1]$ researchers typically just use the DSGE model impulse response, say, $IRF(\cdot|\theta,M_1)$. In view of the problems caused by noninvertible moving-average polynomials and finite-order VAR approximations of infinite-order VAR representations, a more prudent approach would be to replace

$IRF(\cdot|\theta,M_1)$ by average impulse response functions that are obtained by repeatedly simulating data from the DSGE model (given θ) and estimating a structural VAR, as in the indirect inference approach described in Section 11.2. Such a modification would address the concerns about IRF matching estimators raised by Chari et al. (2008).

The sampling distribution of the IRF matching estimator depends on the sampling distribution of the empirical VAR impulse responses $\hat{m}_T(Y)$ under the VAR M_0. An approximation of the distribution of $\hat{m}_T(Y)$ could be obtained by first-order asymptotics and the delta method as in Lütkepohl (1990) and Mittnik and Zadrozny (1993) for stationary VARs; or as in Phillips (1998), Rossi and Pesavento (2006), and Pesavento and Rossi (2007) for VARs with persistent components. Alternatively, one could use the bootstrap approximation proposed by Kilian (1998, 1999). If the number of impulse responses stacked in the vector $\hat{m}_T(Y)$ exceeds the number of reduced-form VAR coefficient estimates, then the sampling distribution of the IRFs becomes asymptotically singular. Guerrón-Quintana et al. (2014) use nonstandard asymptotics to derive the distribution of IRFs for the case in which there are more responses than reduced-form parameters.

Because for high-dimensional vectors $\hat{m}_T(Y)$ the joint covariance matrix may be close to singular, researchers typically choose a diagonal weight matrix W_T, where the diagonal elements correspond to the inverse of the sampling variance for the estimated response of variable i to shock j at horizon h. As discussed in Section 11.2, to the extent that the DSGE model is misspecified, the choice of weight matrix affects the probability limit of the IRF matching estimator and should reflect the researcher's loss function.

In fact, impulse response function matching is appealing only if the researcher is concerned about model misspecification. This misspecification might take two forms: First, the propagation mechanism of the DSGE model is potentially misspecified and the goal is to find pseudo-optimal parameter values that minimize the discrepancy between empirical and model-implied impulse responses. Second, the propagation mechanisms for the shocks of interest are believed to be correctly specified, but the model lacks sufficiently many stochastic shocks to capture the observed variation in the data. In the second case, it is in principle possible to recover the subset of "true" DSGE model parameters θ_0 that affect the propagation of the structural shock for which the IRF is computed. The consistent estimation would require that the DSGE model allow for a VAR(∞) representation in terms of the structural shock innovations ϵ_t; that the number of lags included in the empirical VAR increase with sample size T; and that the VAR identification scheme correctly identify the shock of interest if the data are generated from a version of the DSGE model that is augmented by additional structural shocks.

11.3.3 Illustration

To illustrate the properties of the IRF matching estimator, we simulate data from the stylized DSGE model using the parameter values given in Table 5. We assume that the econometrician considers an incomplete version of the DSGE model that only includes the monetary policy shock and omits the remaining shocks. Moreover, we assume that the econometrician only has to estimate the degree of price stickiness captured by the Calvo parameter ζ_p. All other parameters are fixed at their "true" values during the estimation.

The empirical impulse response functions stacked in the vector $\hat{m}_T(Y)$ are obtained by estimating a VAR(p) for interest rates, output growth, and inflation:

$$y_t = [R_t - \pi_t/\beta, \log(X_t/X_{t-1}), \pi_t]'. \tag{202}$$

The first equation of this VAR represents the monetary policy rule of the DSGE model. The interest rate is expressed in deviations from the central bank's systematic reaction to inflation. Thus, conditional on β, the monetary policy shock is identified as the orthogonalized one-step-ahead forecast error in the first equation of the VAR. Upon impact, the response of y_t to the monetary policy shock is given by the first column of the lower-triangular Cholesky factor of the covariance matrix Σ of the reduced-form innovations u_t.

Because y_t excludes the labor share, the state-space representation of the DSGE model cannot be expressed as a finite-order VAR. However, we can construct a VAR approximation of the DSGE model as follows. Let $x_t = [y'_{t-1},\ldots,y'_{t-p},1']'$ and define the functions[au]

$$\begin{aligned} \Phi*(\theta) &= \left(\mathbb{E}[x_t x'_t|\theta, M_1]\right)^{-1}\left(\mathbb{E}[x_t y'_t|\theta, M_1]\right), \\ \Sigma^*(\theta) &= \mathbb{E}[y_t y'_t|\theta, M_1] - \mathbb{E}[y_t x'_t|\theta, M_1]\left(\mathbb{E}[x_t x'_t|\theta, M_1]\right)^{-1}\mathbb{E}[x_t y'_t|\theta, M_1]. \end{aligned} \tag{203}$$

Note that $\Phi*(\theta)$ and $\Sigma*(\theta)$ are functions of the population autocovariances of the DSGE model. For a linearized DSGE model, these autocovariances can be expressed analytically as a function of the coefficient matrices of the model's state-space representation.

The above definition of $\Phi*(\theta)$ and $\Sigma^*(\theta)$ requires that $\mathbb{E}[x_t x'_t|\theta, M_1]$ is nonsingular. This condition is satisfied as long as $n_y \leq n_\epsilon$. However, the appeal of IRF matching estimators is that they can be used in settings in which only a few important shocks are incorporated into the model and $n_y > n_\epsilon$. In this case, $\Phi*(\theta)$ and $\Sigma^*(\theta)$ have to be modified, for instance, by computing the moment matrices based on $\tilde{y}_t = y_t + u_t$, where u_t is a "measurement error," or by replacing $\left(\mathbb{E}[x_t x'_t|\theta, M_1]\right)^{-1}$ with $\left(\mathbb{E}[x_t x'_t|\theta, M_1] + \lambda I\right)^{-1}$, where λ is a scalar and I is the identity matrix. In the subsequent illustration, we keep all the structural shocks in the DSGE model active, ie, $n_y \leq n_\epsilon$, such that the restriction functions can indeed be computed based on (203).

[au] For the evaluation of the moment matrices $\mathbb{E}[\cdot|\theta, M_1]$ see Section 8.2.1.

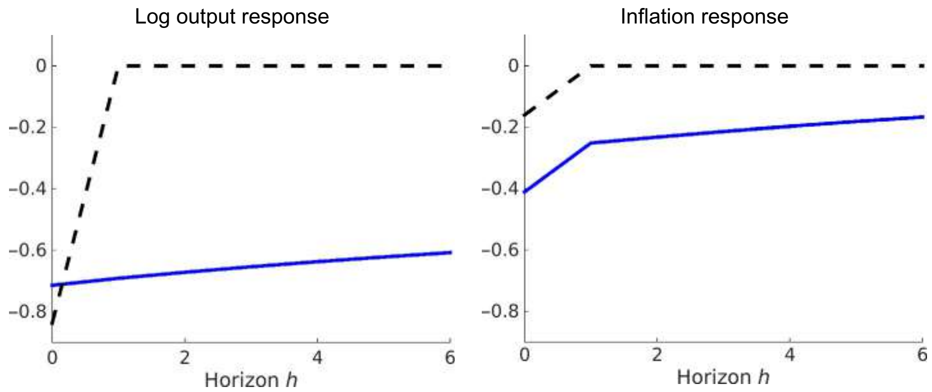

Fig. 29 DSGE model and VAR impulse responses to a monetary policy shock. *Notes*: The figure depicts impulse responses to a monetary policy shock computed from the state-space representation of the DSGE model (*dashed*) and the VAR(1) approximation of the DSGE model (*solid*).

Fig. 29 compares the impulse responses from the state-space representation and the VAR approximation of the DSGE model. It turns out that there is a substantial discrepancy. Because the monetary policy shock is *iid* and the stylized DSGE model does not have an endogenous propagation mechanism, both output and inflation revert back to the steady state after one period. The VAR response, on the other hand, is more persistent and the relative movement of output and inflation is distorted. Augmenting a VAR(1) with additional lags has no noticeable effect on the impulse response.

The IRF matching estimator minimizes the discrepancy between the empirical and the DSGE model-implied impulse responses by varying ζ_p. Fig. 30 illustrates the effect of ζ_p on the response of output and inflation. The larger ζ_p, the stronger the nominal rigidity, and the larger the effect of a monetary policy shock on output. Fig. 31 shows the sampling distribution of the IRF matching estimator for the sample sizes $T = 80$ and $T = 200$. We match IRFs over 10 horizons and use an identity weight matrix. If $\hat{\mathbb{E}}[\hat{m}_T(Y)|\theta, M_1]$ is defined as the IRF implied by the state-space representation, then the resulting estimator of ζ_p has a fairly strong downward bias. This is not surprising in view of the mismatch depicted in Figs. 29 and 30. If the state-space IRF is replaced by the IRF obtained from the VAR approximation of the DSGE model, then the sampling distribution is roughly centered at the "true" parameter value, though it is considerably more dispersed, also compared to the MD estimator in Fig. 28. This is consistent with the fact that the IRF matching estimator does not utilize variation in output and inflation generated by the other shocks.

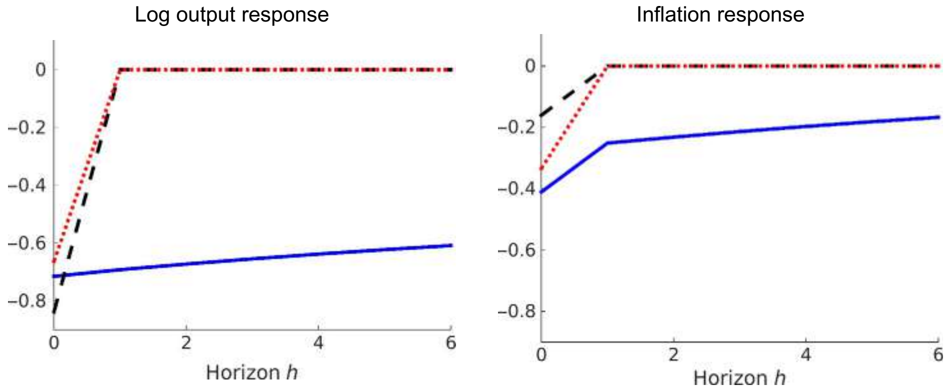

Fig. 30 Sensitivity of IRF to ζ_p. *Notes*: The *solid lines* indicate IRFs computed from the VAR approximation of the DSGE model. The other two lines depict DSGE model-implied IRFs based on $\zeta_p = 0.65$ (*dashed*) and $\zeta_p = 0.5$ (*dotted*).

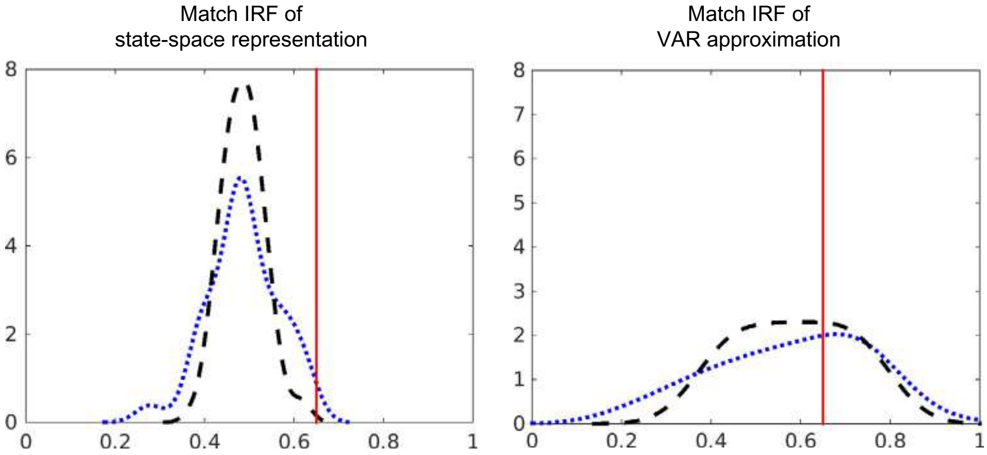

Fig. 31 Sampling distribution of $\hat{\zeta}_{p,irf}$. *Notes*: We simulate samples of size $T = 80$ and $T = 200$ and compute IRF matching estimators for the Calvo parameter ζ_p based on two choices of $\hat{\mathbb{E}}[\hat{m}_T(Y)|\theta,M_1]$. For the *left panel* we use the IRFs from the state-space representation of the DSGE model; for the *right panel* we use the IRF from the VAR approximation of the DSGE model. All other parameters are fixed at their "true" value. The plot depicts densities of the sampling distribution of $\hat{\zeta}_p$ for $T = 80$ (*dotted*) and $T = 200$ (*dashed*). The vertical line indicates the "true" value of ζ_p.

11.4 GMM Estimation

We showed in Section 8.2.4 that one can derive moment conditions of the form

$$\mathbb{E}[g(y_{t-p:t}|\theta, M_1)] = 0 \tag{204}$$

for $\theta = \theta_0$ from the DSGE model equilibrium. For instance, based on (106) and (107) we could define

$$g(y_{t-p:t}|\theta, M_1) = \begin{bmatrix} (-\log(X_t/X_{t-1}) + \log R_{t-1} - \log \pi_t - \log(1/\beta))Z_{t-1} \\ (\log R_t - \log(\gamma/\beta) - \psi \log \pi_t - (1-\psi)\log \pi^*)Z_{t-1} \end{bmatrix}. \tag{205}$$

The identifiability of θ requires that the moments be different from zero whenever $\theta \neq \theta_0$. A GMM estimator is obtained by replacing population expectations by sample averages. Let

$$G_T(\theta|Y) = \frac{1}{T}\sum_{t=1}^{T} g(y_{t-p:t}|\theta, M_1). \tag{206}$$

The GMM objective function is given by

$$Q_T(\theta|Y) = G_T(\theta|Y)' W_T G_T(\theta|Y) \tag{207}$$

and looks identical to the objective function studied in Section 11.2. In turn, the analysis of the sampling distribution of $\hat{\theta}_{md}$ carries over to the GMM estimator.

The theoretical foundations of GMM estimation were developed by Hansen (1982), who derived the first-order asymptotics for the estimator assuming that the data are stationary and ergodic. Christiano and Eichenbaum (1992) and Burnside et al. (1993) use GMM to estimate the parameters of real business cycle DSGE models. These papers use sufficiently many moment conditions to be able to estimate all the parameters of their respective DSGE models. GMM estimation can also be applied to a subset of the equilibrium conditions, eg, the consumption Euler equation or the New Keynesian Phillips curve to estimate the parameters related to these equilibrium conditions.

Unlike all the other estimators considered in this paper, the GMM estimators do not require the researchers to solve the DSGE model. To the extent that solving the model is computationally costly, this can considerably speed up the estimation process. Moreover, one can select moment conditions that do not require assumptions about the law of motion of exogenous driving processes, which robustifies the GMM estimator against misspecification of the exogenous propagation mechanism. However, it is difficult to exploit moment conditions in which some of the latent variables appear explicitly. For instance, consider the Phillips curve relationship of the stylized DSGE model, which suggests setting

$$g(y_{t-p:t}|\theta, M_1) = \left(\hat{\pi}_{t-1} - \beta\hat{\pi}_t - \kappa_p(\widehat{lsh}_{t-1})\right)Z_{t-1}. \tag{208}$$

Note that λ_{t-1} is omitted from the definition of $g(y_{t-p:t}|\theta,M_1)$ because it is unobserved. However, as soon as Z_t is correlated with the latent variable λ_t the expected value of $g(y_{t-p:t}|\theta,M_1)$ is nonzero even for $\theta = \theta_0$:

$$\mathbb{E}[g(y_{t-p:t}|\theta_0, M_1)] = -\kappa_0\mathbb{E}[\lambda_{t-1}Z_{t-1}] \neq 0. \tag{209}$$

To the extent that λ_t is serially correlated, using higher-order lags of y_t as instruments does not solve the problem.[av] Recent work by Gallant et al. (2013) and Shin (2014) considers extensions of GMM estimation to moment conditions with latent variables.

The recent literature on GMM estimation of DSGE models has focused on identification-robust inference in view of the weak identification of Phillips curve and monetary policy rule parameters. Generic identification problems in the context of monetary policy rule estimation are highlighted in Cochrane (2011) and methods to conduct identification-robust inference are developed in Mavroeidis (2010). Identification-robust inference for Phillips curve parameters is discussed in Mavroeidis (2005), Kleibergen and Mavroeidis (2009), and Mavroeidis et al. (2014). Dufour et al. (2013) consider identification-robust moment-based estimation of all of the equilibrium relationships of a DSGE model.

12. BAYESIAN ESTIMATION TECHNIQUES

Bayesian inference is widely used in empirical work with DSGE models. The first papers to estimate small-scale DSGE models using Bayesian methods were DeJong et al. (2000), Schorfheide (2000), Otrok (2001), Fernández-Villaverde and Rubio-Ramírez (2004), and Rabanal and Rubio-Ramírez (2005). Subsequent papers estimated open-economy DSGE models, eg, Lubik and Schorfheide (2006), and larger DSGE models tailored to the analysis of monetary policy, eg, Smets and Wouters (2003) and Smets and Wouters (2007). Because Bayesian analysis treats shock, parameter, and model uncertainty symmetrically by specifying a joint distribution that is updated in view of the observations Y, it provides a conceptually appealing framework for decision making under uncertainty. Levin et al. (2006) consider monetary policy analysis under uncertainty based on an estimated DSGE model and the handbook chapter by Del Negro and Schorfheide (2013) focuses on forecasting with DSGE models.

Conceptually, Bayesian inference is straightforward. A prior distribution is updated in view of the sample information contained in the likelihood function. This leads to a posterior distribution that summarizes the state of knowledge about the unknown parameter vector θ. The main practical difficulty is the calculation of posterior moments and quantiles of transformations $h(\cdot)$ of the parameter vector θ. The remainder of this section is organized as follows. We provide a brief discussion of the elicitation of prior distributions in Section 12.1. Sections 12.2 and 12.3 discuss two important algorithms to generate parameter draws from posterior distributions: Markov chain Monte Carlo (MCMC) and sequential Monte Carlo (SMC). Bayesian model diagnostics are reviewed in

[av] Under the assumption that λ_t follows an AR(1) process, one could quasi-difference the Phillips curve, which would replace the term $\lambda_{t-1}Z_{t-1}$ with $\epsilon_{\lambda,t-1}Z_{t-1}$. If Z_{t-1} is composed of lagged observables dated $t-2$ and earlier, then the validity of the moment condition is restored.

Section 12.4. Finally, we discuss the recently emerging literature on limited-information Bayesian inference in Section 12.5. Sections 12.1 and 12.3 are based on Herbst and Schorfheide (2015), who provide a much more detailed exposition. Section 12.4 draws from Del Negro and Schorfheide (2011).

12.1 Prior Distributions

There is some disagreement in the Bayesian literature about the role of prior information in econometric inference. Some authors advocate "flat" prior distributions that do not distort the shape of the likelihood function, which raises two issues: first, most prior distributions are not invariant under parameter transformations. Suppose a scalar parameter $\theta \sim U[-M,M]$. If the model is reparameterized in terms of $1/\theta$, the implied prior is no longer flat. Second, if the prior density is taken to be constant on the real line, say, $p(\theta) = c$, then the prior is no longer proper, meaning the total prior probability mass is infinite. In turn, it is no longer guaranteed that the posterior distribution is proper.

In many applications prior distributions are used to conduct inference in situations in which the number of unknown parameters is large relative to the number of sample observations. An example is a high-dimensional VAR. If the number of variables in the VAR is n and the number of lags is p, then each equation has at least np unknown parameters. For instance, a 4-variable VAR with $p = 4$ lags has 16 parameters. If this model is estimated based on quarterly post-Great Moderation and pre-Great Recession data, the data-to-parameter ratio is approximately 6, which leads to very noisy parameter estimates. A prior distribution essentially augments the estimation sample Y by artificial observations Y^* such that the model is estimated based on the combined sample (Y,Y^*).

Prior distributions can also be used to "regularize" the likelihood function by giving the posterior density a more elliptical shape. Finally, a prior distribution can be used to add substantive information about model parameters not contained in the estimation sample θ to the inference problem. Bayesian estimation of DSGE models uses prior distributions mostly to add information contained in data sets other than Y and to smooth out the likelihood function, down-weighing regions of the parameter space in which implications of the structural model contradict nonsample information and the model becomes implausible. An example would be a DSGE model with a likelihood that has a local maximum at which the discount factor is, say, $\beta = 0.5$. Such a value of β would strongly contradict observations of real interest rates. A prior distribution that implies that real interest rates are between 0% and 10% with high probability would squash the undesirable local maximum of the likelihood function.

To the extent that the prior distribution is "informative" and affects the shape of the posterior distribution, it is important that the specification of the prior distribution be carefully documented. Del Negro and Schorfheide (2008) developed a procedure to construct prior distributions based on information contained in presamples or in time series that are not directly used for the estimation of the DSGE model. To facilitate the elicitation of a prior distribution it is useful to distinguish three groups of parameters: steady-state-related parameters, exogenous shock parameters, and endogenous propagation parameters.

In the context of the stylized DSGE model, the steady-state-related parameters are given by β (real interest rate), π^* (inflation), γ (output growth rate), and λ (labor share). A prior for these parameters could be informed by presample averages of these series. The endogenous propagation parameters are ζ_p (Calvo probability of not being able to reoptimize price) and ν (determines the labor supply elasticity). Micro-level information about the frequency of price changes and labor supply elasticities can be used to specify a prior distribution for these two parameters. Finally, the exogenous shock parameters are the autocorrelation parameters ρ and the shock standard deviations σ.

Because the exogenous shocks are latent, it is difficult to specify a prior distribution for these parameters directly. However, it is possible to map beliefs about the persistence and volatility of observables such as output growth, inflation, and interest rates into beliefs about the exogenous shock parameters. This can be done using the formal procedure described in Del Negro and Schorfheide (2008) or, informally, by generating draws of θ from the prior distribution, simulating artificial observations from the DSGE model, and computing the implied sample moments of the observables. If the prior predictive distribution of these sample moments appears implausible, say, in view of sample statistics computed from a presample of actual observations, then one can adjust the prior distribution of the exogenous shock parameters and repeat the simulation until a plausible prior is obtained. Table 7 contains an example of a prior distribution for our stylized DSGE model. The joint distribution for θ is typically generated as a product of marginal distributions for the elements (or some transformations thereof) of the vector θ.[aw] In most applications this product of marginals is truncated to ensure that the model has a unique equilibrium.

12.2 Metropolis–Hastings Algorithm

Direct sampling from the posterior distribution of θ is unfortunately not possible. One widely used algorithm to generate draws from $p(\theta|Y)$ is the Metropolis–Hastings (MH) algorithm, which belongs to the class of MCMC algorithms. MCMC algorithms produce a sequence of serially correlated parameter draws θ^i, $i = 1,\ldots,N$ with the property that the random variables θ^i converge in distribution to the target posterior distribution, which we abbreviate as

[aw] In high-dimensional parameter spaces it might be desirable to replace some of the θ elements by transformations, eg, steady states, that are more plausibly assumed to be independent. This transformation essentially generates nonzero correlations for the original DSGE model parameters. Alternatively, the method discussed in Del Negro and Schorfheide (2008) also generates correlations between parameters.

Table 7 Prior distribution

Name	**Domain**	**Prior**		
		Density	***Para (1)***	***Para (2)***
Steady-state-related parameters $\theta_{(ss)}$				
$100(1/\beta-1)$	$\mathbb{R}^+$	Gamma	0.50	0.50
$100\log\pi^*$	$\mathbb{R}^+$	Gamma	1.00	0.50
$100\log\gamma$	$\mathbb{R}$	Normal	0.75	0.50
λ	$\mathbb{R}^+$	Gamma	0.20	0.20
Endogenous propagation parameters $\theta_{(endo)}$				
ζ_p	[0,1]	Beta	0.70	0.15
$1/(1+\nu)$	$\mathbb{R}^+$	Gamma	1.50	0.75
Exogenous shock parameters $\theta_{(exo)}$				
ρ_ϕ	[0,1)	Uniform	0.00	1.00
ρ_λ	[0,1)	Uniform	0.00	1.00
ρ_z	[0,1)	Uniform	0.00	1.00
$100\sigma_\phi$	$\mathbb{R}^+$	InvGamma	2.00	4.00
$100\sigma_\lambda$	$\mathbb{R}^+$	InvGamma	0.50	4.00
$100\sigma_z$	$\mathbb{R}^+$	InvGamma	2.00	4.00
$100\sigma_r$	$\mathbb{R}^+$	InvGamma	0.50	4.00

Notes: Marginal prior distributions for each DSGE model parameter. Para (1) and Para (2) list the means and the standard deviations for Beta, Gamma, and Normal distributions; the upper and lower bound of the support for the Uniform distribution; s and ν for the Inverse Gamma distribution, where $p_{\mathcal{IG}}(\sigma|\nu,s)\propto\sigma^{-\nu-1}e^{-\nu s^2/2\sigma^2}$. The joint prior distribution of θ is truncated at the boundary of the determinacy region.

$$\pi(\theta)=p(\theta|Y)=\frac{p(Y|\theta)p(\theta)}{p(Y)}, \tag{210}$$

as $N\rightarrow\infty$. More important, under suitable regularity conditions sample averages of draws converge to posterior expectations:

$$\frac{1}{N-N_0}\sum_{i=N_0+1}^{N}h(\theta^i)\xrightarrow{a.s.}\mathbb{E}_\pi[h(\theta)]. \tag{211}$$

Underlying this convergence result is the fact that the algorithm generates a Markov transition kernel $K(\theta^i|\theta^{i-1})$, characterizing the distribution of θ^i conditional on θ^{i-1}, with the invariance property

$$\int K(\theta^i|\theta^{i-1})\pi(\theta^{i-1})d\theta^{i-1}=\pi(\theta^i). \tag{212}$$

Thus, if θ^{i-1} is a draw from the posterior distribution, then so is θ^i. Of course, this invariance property is not sufficient to guarantee the convergence of the θ^i draws. Chib and

Greenberg (1995) provide an excellent introduction to MH algorithms and detailed textbook treatments can be found, for instance, in Robert and Casella (2004) and Geweke (2005).

12.2.1 The Basic MH Algorithm

The key ingredient of the MH algorithm is a proposal distribution $q(\vartheta|\theta^{i-1})$, which potentially depends on the draw θ^{i-1} in iteration $i-1$ of the algorithm. With probability $\alpha(\vartheta|\theta^{i-1})$ the proposed draw is accepted and $\theta^i = \vartheta$. If the proposed draw is not accepted, then the chain does not move and $\theta^i = \theta^{i-1}$. The acceptance probability is chosen to ensure that the distribution of the draws converges to the target posterior distribution. The algorithm takes the following form:

Algorithm 7 (Generic MH Algorithm). For $i = 1$ to N:

1. Draw ϑ from a density $q(\vartheta|\theta^{i-1})$.

2. Set $\theta^i = \vartheta$ with probability

$$\alpha(\vartheta|\theta^{i-1}) = \min\left\{1, \frac{p(Y|\vartheta)p(\vartheta)/q(\vartheta|\theta^{i-1})}{p(Y|\theta^{i-1})p(\theta^{i-1}))/q(\theta^{i-1}|\vartheta)}\right\}$$

and $\theta^i = \theta^{i-1}$ otherwise.

Because $p(\theta|Y) \propto p(Y|\theta)p(\theta)$ we can replace the posterior densities in the calculation of the acceptance probabilities $\alpha(\vartheta|\theta^{i-1})$ with the product of the likelihood and prior, which does not require the evaluation of the marginal data density $p(Y)$.

12.2.2 Random-Walk Metropolis–Hastings Algorithm

The most widely used MH algorithm for DSGE model applications is the *random walk MH* (RWMH) algorithm. The basic version of this algorithm uses a normal distribution centered at the previous θ^i draw as the proposal density:

$$\vartheta|\theta^i \sim N\left(\theta^i, c^2\hat{\Sigma}\right). \tag{213}$$

Given the symmetric nature of the proposal distribution, the acceptance probability becomes

$$\alpha = \min\left\{\frac{p(\vartheta|Y)}{p(\theta^{i-1}|Y)}, 1\right\}.$$

A draw, ϑ, is accepted with probability one if the posterior at ϑ has a higher value than the posterior at θ^{i-1}. The probability of acceptance decreases as the posterior at the candidate value decreases relative to the current posterior.

To implement the RWMH, the user needs to specify c, and $\hat{\Sigma}$. The proposal variance controls the relative variances and correlations in the proposal distribution. The sampler can work very poorly if q is strongly at odds with the target distribution. A good choice for $\hat{\Sigma}$ seeks to incorporate information from the posterior, to potentially capture the *a posteriori* correlations among parameters. Obtaining this information can be difficult. A popular approach, used in Schorfheide (2000), is to set $\hat{\Sigma}$ to be the negative of the inverse Hessian at the mode of the log posterior, $\hat{\theta}$, obtained by running a numerical optimization routine before running the MCMC algorithm. Using this as an estimate for the covariance of the posterior is attractive, because it can be viewed as a large sample approximation to the posterior covariance matrix.

Unfortunately, in many applications, the maximization of the posterior density is tedious and the numerical approximation of the Hessian may be inaccurate. These problems may arise if the posterior distribution is very nonelliptical and possibly multimodal, or if the likelihood function is replaced by a nondifferentiable particle filter approximation. In both cases, a (partially) adaptive approach may work well: First, generate a set of posterior draws based on a reasonable initial choice for $\hat{\Sigma}$, eg, the prior covariance matrix. Second, compute the sample covariance matrix from the first sequence of posterior draws and use it as $\hat{\Sigma}$ in a second run of the RWMH algorithm. In principle, the covariance matrix $\hat{\Sigma}$ can be adjusted more than once. However, $\hat{\Sigma}$ must be fixed eventually to guarantee the convergence of the posterior simulator. Samplers that constantly (or automatically) adjust $\hat{\Sigma}$ are known as adaptive samplers and require substantially more elaborate theoretical justifications.

12.2.3 Numerical Illustration

We generate a single sample of size $T = 80$ from the stylized DSGE model using the parameterization in Table 5. The DSGE model likelihood function is combined with the prior distribution in Table 7 to form a posterior distribution. Draws from this posterior distribution are generated using the RWMH described in the previous section. The chain is initialized with a draw from the prior distribution. The covariance matrix $\hat{\Sigma}$ is based on the negative inverse Hessian at the mode. The scaling constant c is set equal to 0.075, which leads to an acceptance rate for proposed draws of 0.55.

The top panels of Fig. 32 depict the sequences of posterior draws of the Calvo parameter ζ_p^i and preference shock standard deviation σ_ϕ^i. It is apparent from the figure that the draws are serially correlated. The draws for the standard deviation are strongly contaminated by the initialization of the chain, but they eventually settle to a range of 0.8–1.1. The bottom panel depicts recursive means of the form

$$\bar{h}_{N|N_0} = \frac{1}{N - N_0} \sum_{i=N_0+1}^{N} h(\theta^i). \tag{214}$$

To remove the effect of the initialization of the Markov chain, it is common to drop the first N_0 draws from the computation of the posterior mean approximation. In the figure we set $N_0 = 7500$ and $N = 37{,}500$. Both recursive means eventually settle to a limit point.

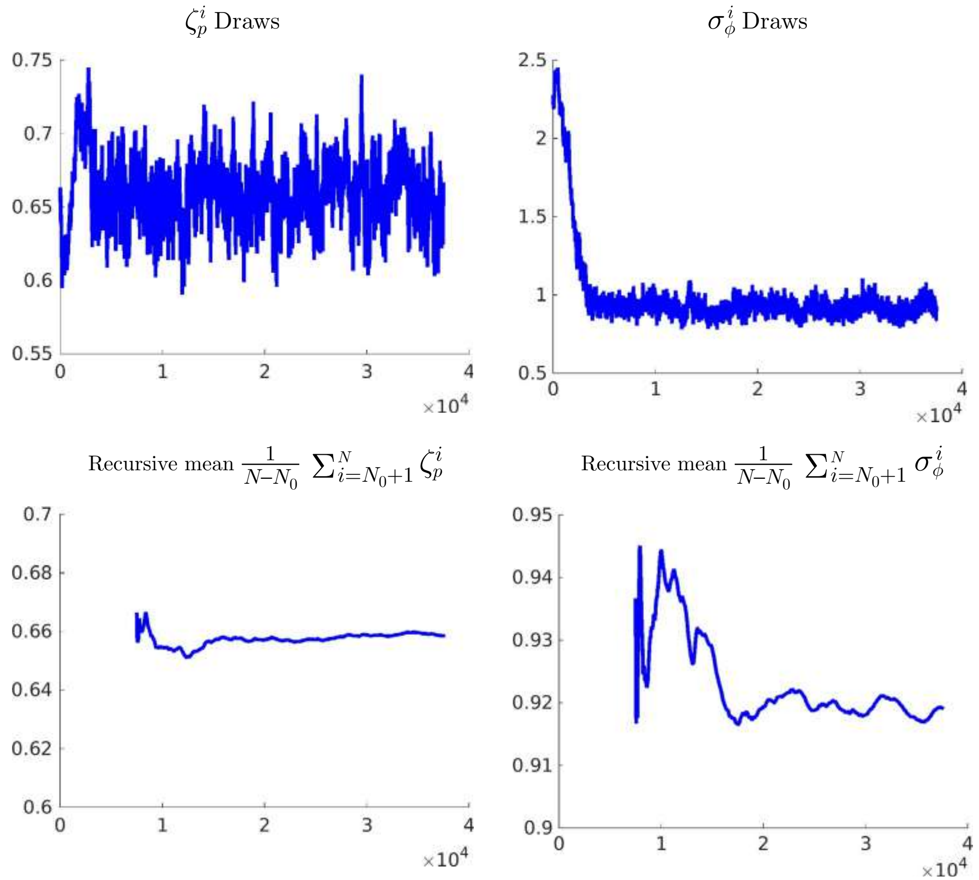

Fig. 32 Parameter draws from MH algorithm. *Notes*: The posterior is based on a simulated sample of observations of size $T = 80$. The *top panel* shows the sequence of parameter draws and the *bottom panel* shows recursive means.

The output of the algorithm is stochastic, which implies that running the algorithm repeatedly will generate different numerical results. Under suitable regularity conditions the recursive means satisfy a CLT. The easiest way to obtain a measure of numerical accuracy is to run the RWMH algorithm, say, fifty times using random starting points, and compute the sample variance of $\bar{h}_{N|N_0}$ across chains. Alternatively, one could compute a heteroskedasticity and autocorrelation consistent (HAC) standard error estimate for $\bar{h}_{N|N_0}$ based on the output of a single chain.

Fig. 33 depicts univariate prior and posterior densities, which are obtained by applying a standard kernel density estimator to draws from the prior and posterior distribution. In addition, one can also compute posterior credible sets based on the output of the

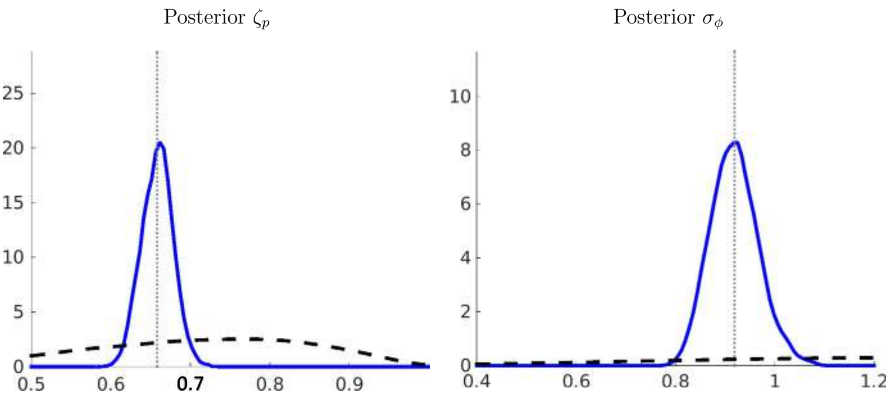

Fig. 33 Prior and posterior densities. *Notes*: The *dashed lines* represent the prior densities, whereas the *solid lines* correspond to the posterior densities of ζ_p and σ_ϕ. The posterior is based on a simulated sample of observations of size $T = 80$. We generate $N = 37{,}500$ draws from the posterior and drop the first $N_0 = 7{,}500$ draws.

posterior sampler. For a univariate parameter, the shortest credible set is given by the highest-posterior-density (HPD) set defined as

$$CS_{HPD}(Y) = \{\theta \, | p(\theta|Y) \geq \kappa_\alpha\}, \tag{215}$$

where κ_α is chosen to ensure that the credible set has the desired posterior coverage probability.

12.2.4 Blocking

Despite a careful choice of the proposal distribution $q(\cdot|\theta^{i-1})$, it is natural that the efficiency of the MH algorithm decreases as the dimension of the parameter vector θ increases. The success of the proposed random walk move decreases as the dimension d of the parameter space increases. One way to alleviate this problem is to break the parameter vector into blocks. Suppose the dimension of the parameter vector θ is d. A partition of the parameter space, B, is a collection of N_{blocks} sets of indices. These sets are mutually exclusive and collectively exhaustive. Call the subvectors that correspond to the index sets θ_b, $b = 1,\ldots,N_{blocks}$. In the context of a sequence of parameter draws, let θ_b^i refer to the b-th block of i-th draw of θ and let $\theta_{<b}^i$ refer to the i-th draw of all of the blocks before b and similarly for $\theta_{>b}^i$. Algorithm 8 describes a generic Block MH algorithm.

Algorithm 8 (Block MH Algorithm). Draw $\theta^0 \in \Theta$ and then for $i = 1$ to N:

1. Create a partition B^i of the parameter vector into N_{blocks} blocks $\theta_1,\ldots,\theta_{N_{blocks}}$ via some rule (perhaps probabilistic), unrelated to the current state of the Markov chain.
2. For $b = 1,\ldots,N_{blocks}$:

(a) Draw $\vartheta_b \sim q(\cdot|[\theta^i_{<b},\, \theta^{i-1}_b,\, \theta^{i-1}_{\geq b}])$.

(b) With probability,

$$\alpha = \max\left\{\frac{p([\theta^i_{<b},\vartheta_b,\theta^{i-1}_{>b}]|Y)q(\theta^{i-1}_b,|\theta^i_{<b},\vartheta_b,\theta^{i-1}_{>b})}{p(\theta^i_{<b},\theta^{i-1}_b,\theta^{i-1}_{>b}|Y)q(\vartheta_b|\theta^i_{<b},\theta^{i-1}_b,\theta^{i-1}_{>b})},1\right\},$$

set $\theta^i_b = \vartheta_b$, otherwise set $\theta^i_b = \theta^{i-1}_b$.

In order to make the Block MH algorithm operational, the researcher has to decide how to allocate parameters to blocks in each iteration and how to choose the proposal distribution $q(\cdot|[\theta^i_{<b},\theta^{i-1}_b,\theta^{i-1}_{>b}])$ for parameters of block b.

A good rule of thumb, however, is that we want the parameters *within* a block, say, θ^b, to be as correlated as possible, while we want the parameters between blocks, say, θ_b and θ_{-b}, to be as independent as possible, according to Robert and Casella (2004). Unfortunately, picking the "optimal" blocks to minimize dependence across blocks requires *a priori* knowledge about the posterior and is therefore often infeasible. Chib and Ramamurthy (2010) propose grouping parameters randomly. Essentially, the user specifies how many blocks to partition the parameter vector into and every iteration a new set of blocks is constructed. Key to the algorithm is that the block configuration be independent of the Markov chain. This is crucial for ensuring the convergence of the chain.

In order to tailor the block-specific proposal distributions, Chib and Ramamurthy (2010) advocate using an optimization routine—specifically, simulated annealing—to find the mode of the conditional posterior distribution. As in the RWMH-V algorithm, the variance of the proposal distribution is based on the inverse Hessian of the conditional log posterior density evaluated at the mode. Unfortunately, the tailoring requires many likelihood evaluations that slow down the algorithm and a simpler procedure, such as using marginal or conditional covariance matrices from an initial approximation of the joint posterior covariance matrix, might be computationally more efficient.

12.2.5 Marginal Likelihood Approximations

The computations thus far do not rely on the marginal likelihood $p(Y)$, which appears in the denominator of Bayes Theorem. Marginal likelihoods play an important role in assessing the relative fit of models because they are used to turn prior model probabilities into posterior probabilities. The most widely used marginal likelihood approximation in the DSGE model literature is the modified harmonic mean estimator proposed by Geweke (1999). This estimator is based on the identity

$$\int \frac{f(\theta)}{p(Y)} d\theta = \int \frac{f(\theta)}{p(Y|\theta)p(\theta)} p(\theta|Y)d\theta, \tag{216}$$

where $f(\theta)$ has the property that $\int f(\theta)d\theta = 1$. The identity is obtained by rewriting Bayes Theorem, multiplying both sides with $f(\theta)$ and integrating over θ. Realizing that the left-hand side simplifies to $1/p(Y)$ and that the right-hand side can be approximated by a Monte Carlo average we obtain

$$\hat{p}_{HM}(Y) = \left[\frac{1}{N}\sum_{i=1}^{N}\frac{f(\theta^i)}{p(Y|\theta^i)p(\theta^i)}\right]^{-1}, \tag{217}$$

where the θ_i's are drawn from the posterior $p(\theta|Y)$. The function $f(\theta)$ should be chosen to keep the variance of $f(\theta^i)/p(Y|\theta^i)p(\theta^i)$ small. Geweke (1999) recommends using for $f(\theta)$ a truncated normal approximation of the posterior distribution for θ that is computed from the output of the posterior sampler. Alternative methods to approximate the marginal likelihood are discussed in Chib and Jeliazkov (2001), Sims et al. (2008), and Ardia et al. (2012). An and Schorfheide (2007) and Herbst and Schorfheide (2015) provide accuracy comparisons of alternative methods.

12.2.6 Extensions

The basic estimation approach for linearized DSGE models has been extended in several dimensions. Typically, the parameter space is restricted to a subspace in which a linearized model has a unique nonexplosive rational expectations solution (determinacy). Lubik and Schorfheide (2004) relax this restriction and also consider the region of the parameter space in which the solution is indeterminate. By computing the posterior probability of parameter values associated with indeterminacy, they are able to conduct a posterior odds assessment of determinacy vs indeterminacy. Justiniano and Primiceri (2008) consider a linearized DSGE model with structural shocks that exhibit stochastic volatility and develop an MCMC algorithm for posterior inference. A further extension is provided by Curdia et al. (2014), who also allow for shocks that, conditional on the volatility process, have a fat-tailed student-t distribution to capture extreme events such as the Great Recession. Schorfheide (2005a) and Bianchi (2013) consider the estimation of linearized DSGE models with regime switching in the coefficients of the state-space representation.

Müller (2012) provides an elegant procedure to assess the robustness of posterior inference to shifts in the mean of the prior distribution. One of the attractive features of his procedure is that the robustness checks can be carried out without having to reestimate the DSGE model under alternative prior distributions. Koop et al. (2013) propose some diagnostics that allow users to determine the extent to which the likelihood function is informative about the DSGE model parameters. In a nutshell, the authors recommend examining whether the variance of marginal posterior distributions shrinks at the rate T^{-1} (in a stationary model) if the number of observations is increased in a simulation experiment.

12.2.7 Particle MCMC

We now turn to the estimation of fully nonlinear DSGE models. As discussed in Section 10, for nonlinear DSGE models the likelihood function has to be approximated by a nonlinear filter. Embedding a particle filter approximation into an MCMC sampler leads to a so-called particle MCMC algorithm. We refer to the combination of a particle-filter approximated likelihood and the MH algorithm as a PFMH algorithm. This idea was first proposed for the estimation of nonlinear DSGE models by Fernández-Villaverde and Rubio-Ramírez (2007). The theory underlying the PFMH algorithm is developed in Andrieu et al. (2010). Flury and Shephard (2011) discuss non-DSGE applications of particle MCMC methods in econometrics. The modification of Algorithm 7 is surprisingly simple: one only has to replace the exact likelihood function $p(Y|\theta)$ with the particle filter approximation $\hat{p}(Y|\theta)$.

Algorithm 9 (PFMH Algorithm). For $i = 1$ to N:

1. Draw ϑ from a density $q(\vartheta|\theta^{i-1})$.

2. Set $\theta^i = \vartheta$ with probability

$$\alpha(\vartheta|\theta^{i-1}) = \min\left\{1, \frac{\hat{p}(Y|\vartheta)p(\vartheta)/q(\vartheta|\theta^{i-1})}{\hat{p}(Y|\theta^{i-1})p(\theta^{i-1})/q(\theta^{i-1}|\vartheta)}\right\}$$

and $\theta^i = \theta^{i-1}$ otherwise. The likelihood approximation $\hat{p}(Y|\vartheta)$ is computed using Algorithm 6.

The surprising implication of the theory developed in Andrieu et al. (2010) is that the distribution of draws generated by Algorithm 9 from the PFMH algorithm that replaces $p(Y|\theta)$ with $\hat{p}(Y|\theta)$ in fact does converge to the exact posterior. The replacement of the exact likelihood function by the particle-filter approximation generally increases the persistence of the Markov chain and makes Monte Carlo approximations less accurate; see Herbst and Schorfheide (2015) for numerical illustrations. Formally, the key requirement is that the particle-filter approximation provide an unbiased estimate of the likelihood function. In practice it has to be ensured that the variance of the numerical approximation is small relative to the expected magnitude of the differential between $p(Y|\theta^{i-1})$ and $p(Y|\vartheta)$ in an ideal version of the algorithm in which the likelihood could be evaluated exactly. Thus, before embedding the particle-filter approximation into a likelihood function, it is important to assess its accuracy for low- and high-likelihood parameter values.

12.3 SMC Methods

Sequential Monte Carlo (SMC) techniques to generate draws from posterior distributions of a static parameter θ are emerging as an attractive alternative to MCMC methods. SMC algorithms can be easily parallelized and, properly tuned, may produce more accurate approximations of posterior distributions than MCMC algorithms. Chopin (2002) showed how to adapt the particle filtering techniques discussed in Section 10.3 to conduct posterior inference for a static parameter vector. Textbook treatments of SMC algorithms can be found, for instance, in Liu (2001) and Cappé et al. (2005).

The first paper that applied SMC techniques to posterior inference in a small-scale DSGE models was Creal (2007). Herbst and Schorfheide (2014) develop the algorithm further, provide some convergence results for an adaptive version of the algorithm building on the theoretical analysis of Chopin (2004), and show that a properly tailored SMC algorithm delivers more reliable posterior inference for large-scale DSGE models with a multimodal posterior than the widely used RWMH-V algorithm. Creal (2012) provides a recent survey of SMC applications in econometrics. Durham and Geweke (2014) show how to parallelize a flexible and self-tuning SMC algorithm for the estimation of time series models on graphical processing units (GPU). The remainder of this section draws heavily from the more detailed exposition in Herbst and Schorfheide (2014, 2015).

SMC combines features of classic importance sampling and modern MCMC techniques. The starting point is the creation of a sequence of intermediate or bridge distributions $\{\pi_n(\theta)\}_{n=0}^{N_\phi}$ that converge to the target posterior distribution, ie, $\pi_{N_\phi}(\theta)=\pi(\theta)$. At any stage the posterior distribution $\pi_n(\theta)$ is represented by a swarm of particles $\{\theta_n^i, W_n^i\}_{i=1}^N$ in the sense that the Monte Carlo average

$$\bar{h}_{n,N}=\frac{1}{N}\sum_{i=1}^{N}W_n^i h(\theta_n^i)\overset{a.s.}{\longrightarrow}\mathbb{E}_{\pi_n}[h(\theta_n)]. \tag{218}$$

The bridge distributions can be generated either by taking power transformations of the entire likelihood function, that is, $[p(Y|\theta)]^{\phi_n}$, where $\phi_n\uparrow 1$, or by adding observations to the likelihood function, that is, $p(Y_{1:t_n}|\theta)$, where $t_n\uparrow T$. We refer to the first approach as likelihood tempering and the second approach as data tempering. Formally, the sequences of bridge distributions are defined as (likelihood tempering)

$$\pi_n(\theta)=\frac{[p(Y|\theta)]^{\phi_n}p(\theta)}{\int[p(Y|\theta)]^{\phi_n}p(\theta)d\theta}\quad n=0,\ldots,N_\phi,\quad \phi_n\uparrow 1, \tag{219}$$

and (data tempering, writing $t_n=\lfloor\phi_n T\rfloor$)

$$\pi_n^{(D)}(\theta)=\frac{p(Y_{1:\lfloor\phi_n T\rfloor})p(\theta)}{\int p(Y_{1:\lfloor\phi_n T\rfloor})p(\theta)d\theta}\quad n=0,\ldots,N_\phi,\quad \phi_n\uparrow 1, \tag{220}$$

respectively. While data tempering is attractive in sequential applications, eg, real-time forecasting, likelihood tempering generally leads to more stable posterior simulators for two reasons: First, in the initial phase it is possible to add information that corresponds to a fraction of an observation. Second, if the latter part of the sample contains influential observations that drastically shift the posterior mass, data tempering may have difficulties adapting to the new information.

12.3.1 The SMC Algorithm

The algorithm can be initialized with draws from the prior density $p(\theta)$, provided the prior density is proper. For the prior in Table 7 it is possible to directly sample independent draws

θ_0^i from the marginal distributions of the DSGE model parameters. One can add an accept-reject step that eliminates parameter draws for which the linearized model does not have a unique stable rational expectations solution. The initial weights W_0^i can be set equal to one. We adopt the convention that the weights are normalized to sum to N.

The SMC algorithm proceeds iteratively from $n = 0$ to $n = N_\phi$. Starting from stage $n-1$ particles $\{\theta_{n-1}^i, W_{n-1}^i\}_{i=1}^N$ each stage n of the algorithm consists of three steps: *correction*, that is, reweighting the stage $n-1$ particles to reflect the density in iteration n; *selection*, that is, eliminating a highly uneven distribution of particle weights (degeneracy) by resampling the particles; and *mutation*, that is, propagating the particles forward using a Markov transition kernel to adapt the particle values to the stage n bridge density.

Algorithm 10 (Generic SMC Algorithm with Likelihood Tempering).

1. **Initialization.** ($\phi_0 = 0$). Draw the initial particles from the prior: $\theta_0^i \overset{iidp}{\sim} p(\theta)$ and $W_0^i = 1$, $i = 1,\ldots,N$.
2. **Recursion.** For $n = 1,\ldots,N_\phi$,
   (a) **Correction.** Reweight the particles from stage $n-1$ by defining the incremental weights
$$\tilde{w}_n^i = [p(Y|\theta_{n-1}^i)]^{\phi_n - \phi_{n-1}} \tag{221}$$
   and the normalized weights
$$\tilde{W}_n^i = \frac{\tilde{w}_n^i W_{n-1}^i}{\frac{1}{N}\sum_{i=1}^N \tilde{w}_n^i W_{n-1}^i,} \qquad i = 1,\ldots,N. \tag{222}$$
   (b) **Selection (Optional).** Resample the particles via multinomial resampling. Let $\{\hat{\theta}\}_{i=1}^N$ denote N *iid* draws from a multinomial distribution characterized by support points and weights $\{\theta_{n-1}^i, \tilde{W}_n^i\}_{i=1}^N$ and set $W_n^i = 1$.
   (c) **Mutation.** Propagate the particles $\{\hat{\theta}_i, W_n^i\}$ via N_{MH} steps of an MH algorithm with transition density $\theta_n^i \sim K_n(\theta_n|\hat{\theta}_n^i; \zeta_n)$ and stationary distribution $\pi_n(\theta)$. An approximation of $\mathbb{E}_{\pi_n}[h(\theta)]$ is given by
$$\bar{h}_{n,N} = \frac{1}{N}\sum_{i=1}^N h(\theta_n^i) W_n^i. \tag{223}$$
3. For $n = N_\phi$ ($\phi_{N_\phi} = 1$) the final importance sampling approximation of $\mathbb{E}_\pi[h(\theta)]$ is given by:
$$\bar{h}_{N_\phi,N} = \sum_{i=1}^N h(\theta_{N_\phi}^i) W_{N_\phi}^i. \tag{224}$$

The correction step is a classic importance sampling step, in which the particle weights are updated to reflect the stage n distribution $\pi_n(\theta)$. Because this step does not change the particle value, it is typically not necessary to reevaluate the likelihood function.

The selection step is optional. On the one hand, resampling adds noise to the Monte Carlo approximation, which is undesirable. On the other hand, it equalizes the particle weights, which increases the accuracy of subsequent importance sampling approximations. The decision of whether or not to resample is typically based on a threshold rule for the variance of the particle weights. As for the particle filter in Section 10.3, we can define an effective particle sample size as:

$$\widehat{ESS}_n = N \Big/ \left(\frac{1}{N} \sum_{i=1}^{N} (\tilde{W}_n^i)^2 \right) \tag{225}$$

and resample whenever $\widehat{ESS}_n$ is less that $N/2$ or $N/4$. In the description of Algorithm 10 we consider multinomial resampling. Other, more efficient resampling schemes are discussed, for instance, in the books by Liu (2001) or Cappé et al. (2005) (and references cited therein).

The mutation step changes the particle values. In the absence of the mutation step, the particle values would be restricted to the set of values drawn in the initial stage from the prior distribution. This would clearly be inefficient, because the prior distribution is a poor proposal distribution for the posterior in an importance sampling algorithm. As the algorithm cycles through the N_ϕ phases, the particle values successively adapt to the shape of the posterior distribution. The key feature of the transition kernel $K_n(\theta_n|\hat{\theta}_n;\zeta_n)$ is the invariance property:

$$\pi_n(\theta_n) = \int K_n(\theta_n|\hat{\theta}_n;\zeta_n)\pi_n(\hat{\theta}_n)d\hat{\theta}_n. \tag{226}$$

Thus, if $\hat{\theta}_n^i$ is a draw from π_n, then so is θ_n^i. The mutation step can be implemented by using one or more steps of the RWMH algorithm described in Section 12.2.2. The probability of mutating the particles can be increased by blocking or by iterating the RWMH algorithm over multiple steps. The vector ζ_n summarizes the tuning parameters, eg, c and $\hat{\Sigma}$ of the RWMH algorithm.

The SMC algorithm produces as a by-product an approximation of the marginal likelihood. It can be shown that

$$\hat{p}_{SMC}(Y) = \prod_{n=1}^{N_\phi} \left(\frac{1}{N} \sum_{i=1}^{N} \tilde{w}_n^i W_{n-1}^i \right)$$

converges almost surely to $p(Y)$ as the number of particles $N \to \infty$.

12.3.2 Tuning the SMC Algorithm

The implementation of the SMC algorithm requires the choice of several tuning constants. The most important choice is the number of particles N. As shown in Chopin (2004), Monte Carlo averages computed from the output of the SMC algorithm satisfy a CLT as the number of particles increases to infinity. This means that the variance of the Monte Carlo approximation decreases at the rate $1/N$. The user has to determine the number of bridge distributions N_ϕ and the tempering schedule ϕ_n. Based on experiments with a small-scale DSGE model, Herbst and Schorfheide (2015) recommend a convex tempering schedule of the form $\phi_n = (n/N_\phi)^\lambda$ with $\lambda \approx 2$. Durham and Geweke (2014) recently developed a self-tuning algorithm that chooses the sequence ϕ_n adaptively as the algorithm cycles through the stages.

The mutation step requires the user to determine the number of MH steps N_{MH} and the number of parameter blocks. The increased probability of mutation raises the accuracy but unfortunately, the number of likelihood evaluations increases as well, which slows down the algorithm. The scaling constant c and the covariance matrix $\hat{\Sigma}$ can be easily chosen adaptively. Based on the MH rejection frequency, c can be adjusted to achieve a target rejection rate of approximately 25–40%. For $\hat{\Sigma}_n$ one can use an approximation of the posterior covariance matrix computed at the end of the stage n correction step.

To monitor the accuracy of the SMC approximations Durham and Geweke (2014) suggest creating H groups of N particles and setting up the algorithm so that there is no communication across groups. This leads to H Monte Carlo approximations of posterior moments of interest. The across-group standard deviation of within-group Monte Carlo averages provides a measure of numerical accuracy. Parallelization of the SMC algorithm is relatively straightforward because the mutation step and the computation of the incremental weights in the correction step can be carried out in parallel on multiple processors, each of which is assigned a group of particles. In principle, the exact likelihood function can be replaced by a particle-filter approximation, which leads to an SMC^2 algorithm, developed by Chopin et al. (2012) and discussed in more detail in the context of DSGE models in Herbst and Schorfheide (2015).

12.3.3 Numerical Illustration

We now illustrate the SMC model in the context of the stylized DSGE models. The setup is similar to the one in Section 12.2.3. We generate $T = 80$ observations using the parameters listed in Table 5 and use the prior distribution given in Table 7. The algorithm is configured as follows. We use $N = 2048$ particles and $N_\phi = 500$ tempering stages. We set $\lambda = 3$, meaning that we add very little information in the initial stages to ensure that the prior draws adapt to the shape of the posterior. We use one step of a single-block RWMH algorithm in the mutation step and choose c and $\hat{\Sigma}_n$ adaptively as described in Herbst and Schorfheide (2014). The target acceptance rate for the mutation step is 0.25. Based on the output of the SMC algorithm, we plot marginal bridge densities $\pi_n(\cdot)$ for the price stickiness parameter ζ_p and the shock standard deviation σ_ϕ in Fig. 34. The initial set of particles is drawn from the prior distribution. As ϕ_n increases to one, the distribution concentrates. The final stage approximates the posterior distribution.

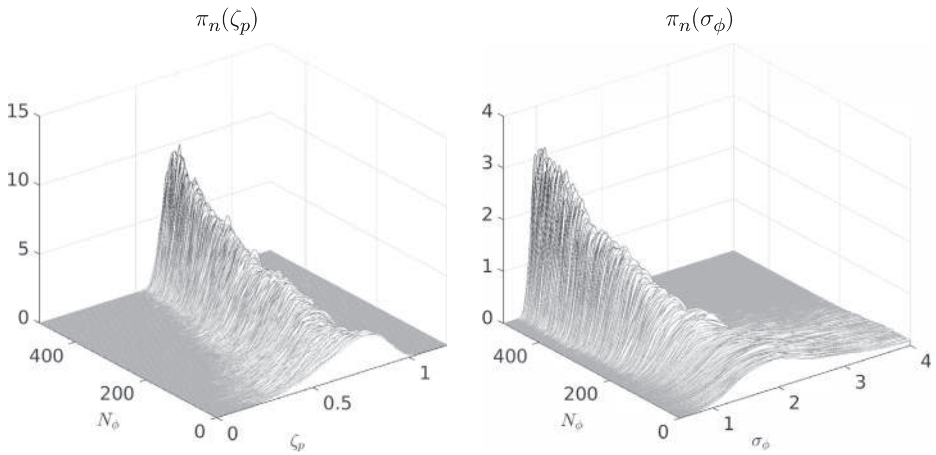

Fig. 34 SMC bridge densities. *Notes*: The posterior is based on a simulated sample of observations of size $T = 80$. The two panels show the sequence of posterior (bridge) densities $\pi_n(\cdot)$.

12.4 Model Diagnostics

DSGE models provide stylized representations of the macroeconomy. To examine whether a specific model is able to capture salient features of the data Y from an *a priori* perspective, prior predictive checks provide an attractive diagnostic. Prior (and posterior) predictive checks are discussed in general terms in the textbooks by Lancaster (2004) and Geweke (2005). The first application of a prior predictive check in the context of DSGE models is Canova (1994).

Let $Y_{1:T}^*$ be an artificial sample of length T. The predictive distribution for $Y_{1:T}^*$ based on the time t information set $\mathcal{F}_t$ is

$$p(Y_{1:T}^*|\mathcal{F}_t) = \int p(Y_{1:T}^*|\theta)p(\theta|\mathcal{F}_t)d\theta. \tag{227}$$

We used a slightly more general notation (to accommodate posterior predictive checks below) with the convention that $\mathcal{F}_0$ corresponds to prior information. The idea of a predictive check is to examine how far the actual realization $Y_{1:T}$ falls into the tail of the predictive distribution. If $Y_{1:T}$ corresponds to an unlikely tail event, then the model is regarded as poorly specified and should be adjusted before it is estimated.

In practice, the high-dimensional vector $Y_{1:T}$ is replaced by a lower-dimensional statistic $\mathcal{S}(Y_{1:T})$, eg, elements of the sample autocovariance matrix $vech(\hat{\Gamma}_{yy}(h))$, for which it is easier to calculate or visualize tail probabilities. While it is not possible to directly evaluate the predictive density of sample statistics, it is straightforward to generate draws. In the case of a prior predictive check, let $\{\theta^i\}_{i=1}^N$ be a sequence of parameter draws from the prior. For each draw, simulate the DSGE model, which leads to the trajectory

$Y^{*i}_{1:T}$. For each of the simulated trajectories, compute the sample statistic $\mathcal{S}(\cdot)$, which leads to a draw from the predictive density.

For a posterior predictive check one equates $\mathcal{F}_t$ with the sample $Y_{1:T}$. The posterior predictive check examines whether the estimated DSGE model captures the salient features of the sample. A DSGE model application can be found in Chang et al. (2007), who examine whether versions of an estimated stochastic growth model are able to capture the variance and the serial correlation of hours worked.

12.5 Limited Information Bayesian Inference

Bayesian inference requires a likelihood function $p(Y|\theta)$. However, as discussed in Section 11, many of the classical approaches to DSGE model estimation, eg, (generalized) methods of moments and impulse response function matching, do not utilize the likelihood function of the DSGE model, in part because there is some concern about misspecification. These methods are referred to as limited-information (instead of full information) techniques. This subsection provides a brief survey of Bayesian approaches to limited-information inference.

12.5.1 Single-Equation Estimation

Lubik and Schorfheide (2005) estimate monetary policy rules for small open economy models by augmenting the policy rule equation with a vector-autoregressive law of motion for the endogenous regressors, eg, the output gap and inflation in the case of our stylized model. This leads to a VAR for output, inflation, and interest rates, with cross-coefficient restrictions that are functions of the monetary policy rule parameters. The restricted VAR can be estimated with standard MCMC techniques. Compared to the estimation of a fully specified DSGE model, the limited-information approach robustifies the estimation of the policy rule equation against misspecification of the private sector's behavior. Kleibergen and Mavroeidis (2014) apply a similar technique to the estimation of a New Keynesian Phillips curve. Their work focuses on the specification of prior distributions that regularize the likelihood function in settings in which the sample only weakly identifies the parameters of interest, eg, the slope of the New Keynesian Phillips curve.

12.5.2 Inverting a Sampling Distribution

Suppose one knows the sampling distribution $p(\hat{\theta}|\theta)$ of an estimator $\hat{\theta}$. Then, instead of updating beliefs conditional on the observed sample Y, one could update the beliefs about θ based on the realization of $\hat{\theta}$:

$$p(\theta|\hat{\theta}) = \frac{p(\hat{\theta}|\theta)p(\theta)}{\int p(\hat{\theta}|\theta)p(\theta)}. \tag{228}$$

This idea dates back at least to Pratt et al. (1965) and is useful in situations in which a variety of different distributions for the sample Y lead to the same distribution of the estimator $\hat{\theta}$. The drawback of this approach is that a closed-form representation of the density $p(\hat{\theta}|\theta)$ is typically not available.

In practice one could use a simulation-based approximation of $p(\hat{\theta}|\theta)$, which is an idea set forth by Boos and Monahan (1986). Alternatively, one could replace the finite-sample distribution with a limit distribution, eg,

$$\sqrt{T}(\hat{\theta}_T - \theta_T)|\theta_T \Longrightarrow N(0, V(\theta)), \tag{229}$$

where the sequence of "true" parameters θ_T converges to θ. This approach is considered by Kwan (1999). In principle $\hat{\theta}_T$ could be any of the frequentist estimators studied in Section 11 for which we derived an asymptotic distribution, including the MD estimator, the IRF matching estimator, or the GMM estimator. However, in order for the resulting limited-information posterior to be meaningful, it is important that the convergence to the asymptotic distribution be uniform in θ, which requires (229) to hold for each sequence $\theta_T \longrightarrow \theta$. A uniform convergence to a normal distribution is typically not attainable as θ_T approaches the boundary of the region of the parameter space in which the time series $Y_{1:T}$ is stationary.

Rather than making statements about the approximation of the limited-information posterior distribution $p(\theta|\hat{\theta})$, Müller (2013) adopts a decision-theoretic framework and shows that decisions based on the quasi-posterior that is obtained by inverting the limit distribution of $\hat{\theta}_T|\theta$ are asymptotically optimal (in the sense that they minimize expected loss) under fairly general conditions. Suppose that the likelihood function of a DSGE model is misspecified. In this case the textbook analysis of the ML estimator in Section 11.1 has to be adjusted as follows. The information matrix equality that ensures that $\| -\nabla^2_\theta \ell_T(\theta|Y) - \mathcal{I}(\theta_0) \|$ converges to zero is no longer satisfied. If we let $D = \text{plim}_{T\rightarrow\infty} - \nabla^2_\theta \ell_T(\theta|Y)$, then the asymptotic variance of the ML estimator takes the sandwich form $D\mathcal{I}(\theta_0)D'$. Under the limited-information approach coverage sets for individual DSGE model parameters would be computed based on the diagonal elements of $D\mathcal{I}(\theta_0)D'$, whereas under a full-information Bayesian approach with misspecified likelihood function, the coverage sets would (asymptotically) be based on $\mathcal{I}^{-1}(\theta_0)$. Thus, the limited-information approach robustifies the coverage sets against model misspecification.

Instead of inverting a sampling distribution of an estimator, one could also invert the sampling distribution of some auxiliary sample statistic $\hat{\varphi}(Y)$. Not surprisingly, the main obstacle is the characterization of the distribution $\hat{\varphi}|\theta$. A collection of methods referred to as approximate Bayesian computations (ABC) use a simulation approximation of $p(\hat{\varphi}|\theta)$ and they could be viewed as a Bayesian version of indirect inference. These algorithms target

$$p^{\delta}_{ABC}(\theta, \hat{\varphi}^*|\hat{\varphi}) \propto p(\hat{\varphi}^*|\theta)p(\theta)\mathbb{I}\{\| \hat{\varphi}^* - \hat{\varphi} \| \leq \delta\}, \tag{230}$$

where $\hat{\varphi}$ refers to the auxiliary statistic computed from the observed data, $\hat{\varphi}^*$ is the auxiliary statistic computed from data simulated from the model conditional on a parameter θ, and δ is the level of tolerance for discrepancies between model-simulated and observed statistics. To date, there are few applications of ABC in econometrics. Forneron and Ng (2015) discuss the relationship between ABC and the simulated MD estimators introduced in Section 11.2 and Scalone (2015) explores a DSGE model application.

12.5.3 Limited-Information Likelihood Functions

Kim (2002) constructs a limited-information likelihood function from the objective function of an extremum estimator. For illustrative purposes we consider the GMM estimator discussed in Section 11.4, but the same idea can also be applied to the MD estimator and the IRF matching estimator. Suppose the data are generated under the probability measure $\mathbb{P}$ and at $\theta = \theta_0$ the following GMM moment condition is satisfied: $\mathbb{E}_{\mathbb{P}}[g(y_{t-p:t}|\theta_0)] = 0$. The sample objective function $Q_T(\theta|Y)$ for the resulting GMM estimator based on a weight matrix W was given in (207). Assuming uniform integrability of the sample objective function

$$\lim_{T\to\infty} \mathbb{E}_{\mathbb{P}}[Q_T(\theta_0|Y)] = r \tag{231}$$

where r is the number of overidentifying moment conditions (meaning the difference between the number of moments stacked in the vector $g(\cdot)$ and the number of elements of the parameter vector θ).

Let $\mathcal{P}(\theta)$ denote the collection of probability distributions that satisfy the moment conditions in the following sense:

$$\mathcal{P}(\theta) = \left\{ P \mid \lim_{T\to\infty} \mathbb{E}_P[TQ_T(\theta|Y)] = r \right\}. \tag{232}$$

$\mathcal{P}(\theta)$ cannot be used directly for likelihood-based inference because it comprises a collection of probability distributions indexed by θ. To obtain a unique distribution for each θ, Kim (2002) projects the "true" distribution $\mathbb{P}$ onto the set $\mathcal{P}(\theta)$ using the Kullback–Leibler discrepancy as the metric:

$$P^*(Y|\theta) = \text{argmin}_{P\in\mathcal{P}(\theta)} \int \log(dP/d\mathbb{P})dP. \tag{233}$$

The solution takes the convenient form

$$p^*(Y|\theta) \propto \exp\left\{ -\frac{1}{2} Q_T(\theta|Y) \right\}, \tag{234}$$

where $p^*(Y|\theta) = dP/d\mathbb{P}$ is the Radon–Nikodym derivative of P with respect to $\mathbb{P}$.

Kim's (2002) results suggest that the frequentist objective functions of Sections 11.2–11.4 can be combined with a prior density and used for (limited information) Bayesian inference. The posterior mean

$$\hat{\theta} = \frac{\int \theta \exp\left\{-\frac{1}{2}Q_T(\theta|Y)\right\}p(\theta)d\theta}{\int \exp\left\{-\frac{1}{2}Q_T(\theta|Y)\right\}p(\theta)d\theta} \tag{235}$$

resembles the LT estimator discussed in Section 11.2. The main difference is that the LT estimator was interpreted from a frequentist perspective, whereas the quasi-posterior based on $p^*(Y|\theta)$ and statistics such as the posterior mean are meant to be interpreted from a Bayesian perspective. This idea has been recently exploited by Christiano et al. (2010) to propose a Bayesian IRF matching estimator. An application to an asset pricing model is presented in Gallant (2015) and an extension to models with latent variables is provided in Gallant et al. (2013). Inoue and Shintani (2014) show that the limited information marginal likelihood

$$p^*(Y|M) = \int p^*(Y|\theta, M)p(\theta)d\theta$$

can be used as a model selection criterion that asymptotically is able to select a correct model specification.

12.5.4 Nonparametric Likelihood Functions

There is also a literature on nonparametric likelihood functions that are restricted to satisfy model-implied moment conditions. Lazar (2003) and Schennach (2005) use empirical likelihood functions, which, roughly speaking assign probability p_t to observation y_t such that the likelihood function is written as $\prod_{t=1}^{T} p_t$, at least if the data are *iid*. One then imposes the side constraint $\sum_{t=1}^{T} p_t g(y_{t-p:t}|\theta) = 0$ and concentrates out p_t probabilities to obtain a profile objective function that only depends on θ. This method is designed for *iid* data and possible models in which $g(y_{t-p:t}|\theta)$ is a martingale difference sequence. Kitamura and Otsu (2011) propose to using a Dirichlet process to generate a prior for the distribution of $Y_{1:T}$ and then project this distribution on the set of distributions that satisfies the moment restrictions. Shin (2014) uses a Dirichlet process mixture and provides a time series extension.

13. CONCLUSION

Over the past two decades the development and application of solution and estimation methods for DSGE models have experienced tremendous growth. Part of this growth has been spurred by central banks, which have included DSGE models in their suites of models used for forecasting and policy analysis. The rapid rise of computing power has enabled researchers to study more and more elaborate model specifications. As we have been writing this chapter, new methods have been developed and novel applications have been explored. While it is impossible to provide an exhaustive treatment of such a dynamic field, we hope that this chapter provides a thorough training for those who are interested in working in this area, offers a good overview of the state of the art as of 2015, and inspires innovative research that expands the frontier of knowledge.

Abstract

In this chapter we study dynamic incentive models in which risk sharing is endogenously limited by the presence of informational or enforcement frictions. We comprehensively overview one of the most important tools for the analysis such problems—the theory of recursive contracts. Recursive formulations allow us to reduce often complex models to a sequence of essentially static problems that are easier to analyze both analytically and computationally. We first provide a self-contained treatment of the basic theory: the Revelation Principle, formulating and simplifying the incentive constraints, using promised utilities as state variables, and analyzing models with persistent shocks using the first-order approach. We then discuss more advanced topics: duality theory and Lagrange multiplier techniques, models with lack of commitment, and martingale methods in continuous time. Finally, we show how a variety of applications in public economics, corporate finance, development and international economics featuring incomplete risk sharing can be analyzed using the tools of the theory of recursive contracts.

1. INTRODUCTION

Dynamic incentive problems are ubiquitous in macroeconomics. The design of social insurance programs by governments, long-run relationships between banks and entrepreneurs, informal insurance contracts against idiosyncratic shocks provided in village economies, sovereign borrowing and lending between countries can all be understood using the theory of dynamic incentives. These models have been widely used in macroeconomics, public economics, international macroeconomics, finance, development, and political economy, both for explaining existing patterns in the data and for normative policy analysis. The unifying feature of these models is that, at their essence, they study endogenously incomplete markets, ie, environments in which risk sharing is constrained by (informational or enforcement) frictions, and where insurance arrangements arise endogenously.

One of the most important tools used for studying dynamic incentive problems is the theory of recursive contracts. Recursive formulations allow one to reduce often complex models to a sequence of essentially static problems that are easier to analyze both analytically and computationally. This substantially simplifies the analysis and the characterization of the optimal insurance arrangements in rich and realistic environments. The goal of this chapter is to provide an overview of the theory of recursive contracts and give a number of examples of application. The analysis in the theoretical part is self-contained; whenever a textbook approach is not directly applicable (eg, when the assumptions needed to apply the recursive techniques in Stokey et al., 1989 are not met), we provide the necessary mathematical background. We also discuss the strengths and weaknesses of several alternative approaches to solving dynamic incentive problems that emerged in the literature. In the last part of the chapter we show how the methods of recursive contracts can be used in a variety of applications.

Our paper is organized as follows. Section 2 considers a prototypical dynamic incentive problem—insurance against privately observable idiosyncratic taste shocks under perfect commitment by the principal. The goal of this section is to provide an example of a self-contained, rigorous, and relatively general treatment of a dynamic incentive problem. We also use this economy in subsequent sections to illustrate other approaches to the analysis of dynamic incentive problems. In Section 2 we highlight the three main steps in the analysis: first, applying the Revelation Principle to set up a mechanism design problem with incentive constraints; second, simplifying this problem by focusing on one-shot incentive constraints; and third, writing this problem recursively using "promised utilities" as state variables. We then show how this recursive formulation can be used to characterize the properties of the optimal insurance arrangements in our economy. We derive general features of the optimal insurance contract and characterize the long-run behavior of the economy in Section 2.4. We show how to overcome the technical difficulties that arise when the idiosyncratic shocks are persistent in Section 2.5. Next we discuss in a simple version of the framework how the optimal insurance arrangement is affected when the agent can unobservably save in Section 2.6. We conclude by showing how the same techniques can be applied to other dynamic incentive problems, such as moral hazard in Section 2.7.

Section 3 considers more advanced topics. We focus on three of them: using Lagrange multiplier tools in recursive formulations, studying dynamic insurance problems in economies in which the principal has imperfect commitment, and applying martingale techniques to study recursive contracts in continuous time. Section 3.1 discusses the Lagrangian techniques. Using Lagrangians together with the recursive methods of Section 2 greatly expands the class of problems that can be characterized. We first provide an overview of the theory of constrained optimization using Lagrange multipliers, with a particular focus on showing how to use them in the infinite dimensional settings that frequently arise in macroeconomic applications. We then show how to apply these theoretical techniques to incentive problems to obtain several alternative recursive formulations having some advantages relative to those discussed in Section 2. A number of results in this section are new to the dynamic contracts literature. In Section 3.2 we show how to analyze dynamic insurance problems in settings where the principal cannot commit to the contracts. The arguments used to prove simple versions of the Revelation Principle under commitment fail in such an environment; we discuss several ways to generalize it and write a recursive formulation of the mechanism design problem. Our characterization of such problems relies heavily on our analysis of Section 3.1. Finally, in Section 3.3, we show how to analyze a dynamic contracting problem in continuous time using martingale methods and the dynamic programming principle. To keep the analysis self-contained, we start by stating the stochastic calculus results that we use. Continuous-time methods often simplify the characterization of optimal contracts, allowing for analytical comparative statics and easier numerical analysis of the solution.

Section 4 gives a number of applications of the recursive techniques discussed in Sections 2 and 3 to various environments. We show that these diverse applications share three key features: (i) insurance is endogenously limited by the presence of a friction; (ii) the problem is dynamic; and (iii) the recursive contract techniques that we develop in the theoretical sections allow us to derive deep characterizations of these problems. We explain how theoretical constructs such as the incentive constraints and promised utilities can be mapped into concrete economic concepts, and how the predictions of dynamic incentive models can be tested empirically and used for policy analysis. In Section 4.1, we apply the techniques and results of Section 2 to public finance where the endogenous market incompleteness and the limited social insurance arise due to the unobservability of the shocks that agents receive. We derive several central results characterizing the optimal social insurance mechanisms and show how to implement the optimal allocations with a tax and transfer system that arises endogenously, without restricting the system exogenously to a specific functional form. In Section 4.2 we show how recursive techniques can be applied to corporate finance problems to study the effects of informational frictions on firm dynamics and the optimal capital structure. Section 4.3 presents applications of these techniques to study insurance in village economies in developing countries where contracts are limited by enforcement and informational frictions. Section 4.4 discusses applications to international borrowing and lending.

2. A SIMPLE MODEL OF DYNAMIC INSURANCE

In this section we study a prototypical model of dynamic insurance against privately observed idiosyncratic shocks. Our goal is to explain the key steps in the analysis and the main insights in the simplest setting. The mathematical techniques that we use as well as the economic insights that we obtain extend to many richer and more realistic environments. We discuss examples of such environments in the following sections.

2.1 Environment

We consider a discrete-time economy that lasts T periods, where T may be finite or infinite. The economy is populated by a continuum of ex ante identical agents whose preferences over period-t consumption $c_t \geq 0$ are given by $\theta_t U(c_t)$, where $\theta_t \in \Theta \subset \mathbb{R}_+$ is an idiosyncratic "taste shock" that the individual receives in period t, and U is a utility function.

Assumption 1 The utility function $U : \mathbb{R}_+ \to \mathbb{R}$ is an increasing, strictly concave, differentiable function that satisfies the Inada conditions $\lim_{c \to 0} U'(c) = \infty$ and $\lim_{c \to \infty} U'(c) = 0$.

All agents have the same discount factor $\beta \in (0,1)$. In each period the economy receives e units of endowment which can be freely transferred between periods at rate β.

The idiosyncratic taste shocks are stochastic. We use the notations $\theta^t = (\theta_1, \ldots, \theta_t) \in \Theta^t$ to denote a history of realizations of shocks up to period t and $\pi_t(\theta^t)$ to denote the probability of realization of history θ^t. We assume that the law of large numbers holds so that $\pi_t(\theta^t)$ is also the measure of individuals who experienced history θ^t.[a] An individual privately learns his taste shock θ_t at the beginning of period t. Thus, at the beginning of period t an agent knows his history θ^t of current and past shocks, but not his future shocks. This implies that his choices in period t, and more generally all the period-t random variables x_t that we encounter, can only be a function of this history.

Some parts of our analysis use results from probability theory and require us to be more formal about the probability spaces that we use. A standard way to formalize these stochastic processes is as follows.[b] Let Θ^T be the space of all histories θ^T and let π_T be a probability measure over the Borel subsets $\mathcal{B}(\Theta^T)$ of Θ^T. Thus, $(\Theta^T, \mathcal{B}(\Theta^T), \pi_T)$ forms a probability space. Any period-t random variable is required to be measurable with respect to $\mathcal{B}(\Theta^t)$, that is, for any Borel subset M of $\mathbb{R}$, $x_t^{-1}(M) = B \times \Theta^{T-t}$, where B is a Borel subset of Θ^t. This formalizes the intuition that the realization of shocks in future periods is not known as of period t.

Until Section 2.5.2 we make the following assumptions about the idiosyncratic taste shocks:

Assumption 2 The set $\Theta \subset \mathbb{R}_+$ of taste shocks is discrete and finite with cardinality $|\Theta|$. Agents' shocks evolve according to a first-order Markov process, that is, the probability of drawing type θ_t in period t depends only on the period-$(t-1)$ type:

$$\pi_t\left(\theta_t \middle| \theta^{t-1}\right) = \pi(\theta_t | \theta_{t-1}), \forall \theta^{t-1} \in \Theta^{t-1}, \theta_t \in \Theta,$$

where θ_{t-1} is the last component of θ^{t-1}.

We use the notation $\pi_t(\theta^t | \theta^s)$ for $t > s$ to denote the probability of realization of history θ^t up to period t conditional on the realization of history θ^s up to period s, with

[a] The assumption that the law of large numbers holds can be justified formally (see Uhlig, 1996; Sun, 2006).

[b] See Stokey et al. (1989, Chapter 7) for a review of the measure-theoretic apparatus.

a convention that $\pi_t(\theta^t|\theta^s)=0$ if the first s elements of θ^t are not θ^s (history θ^t in period t cannot occur if θ^s was not realized up to period s). We use θ_s^t to denote $(\theta_s,\ldots,\theta_t)$. Finally we index the elements of Θ by the subscript (j) for $j\in\{1,\ldots,|\Theta|\}$, and assume that $\theta_{(1)}<\theta_{(2)}<\ldots<\theta_{(|\Theta|)}$.

We consider the problem of a social planner that chooses consumption allocations[c] $c_t:\Theta^t\to\mathbb{R}_+$ to maximize agents' ex ante expected utility and has the ability to commit to such allocations in period 0. At this stage we are agnostic about who or what this planner is. One can think of it as a government that provides insurance to agents, or as some decentralized market arrangement. We study the optimal insurance contract that such a planner can provide given a feasibility constraint and informational constraints. We use the shortcut $\mathbf{c}$ to denote the consumption plan $\{c_t(\theta^t)\}_{t\geq 1,\theta^t\in\Theta^t}$.

The ex ante, "period-0" expected utility of all agents is denoted by $U_0(\mathbf{c})$ and is given by

$$U_0(\mathbf{c})\equiv\mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}\theta_t U(c_t)\right]=\sum_{t=1}^{T}\sum_{\theta^t\in\Theta^t}\beta^{t-1}\pi_t(\theta^t)\,\theta_t U\left(c_t(\theta^t)\right). \tag{1}$$

Here $\mathbb{E}_0$ represents the (unconditional) expectation at time 0, before the first-period type θ_1 is known. Under our assumption that resources can be freely transferred between periods, the resource constraint is

$$\mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}c_t\right]\leq\frac{1-\beta^T}{1-\beta}e. \tag{2}$$

Note that to write the left hand side of this feasibility constraint we again implicitly invoked the law of large numbers.

When the realizations of the taste shocks are observable by the planner, this problem can easily be solved explicitly. Let $\zeta>0$ be the Lagrange multiplier on the feasibility constraint. The optimal allocation $\mathbf{c}^{\text{fb}}$ in the case where shocks are observable (the "first best" allocation) is a solution to

$$\theta_t U'\left(c_t^{\text{fb}}(\theta^t)\right)=\zeta,\ \forall t\geq 1,\ \forall\theta^t\in\Theta^t. \tag{3}$$

It is immediate to see that this equation implies that $c_t^{\text{fb}}(\theta^t)$ is independent of period t or the past history of shocks θ^{t-1}, and only depends on the current realization of the shock θ_t. That is, the informationally unconstrained optimal insurance in this economy gives to agents with a higher realization of the shock θ in any period (hence with a higher current marginal utility) more consumption than to agents with a lower realization of a taste shock.

[c] Formally, c_t is a random variable over the probability space $\left(\Theta^T,\mathcal{B}\left(\Theta^T\right),\pi_T\right)$ that is measurable with respect to $\mathcal{B}(\Theta^t)$.

2.2 The Revelation Principle and Incentive Compatibility

We are interested in understanding the properties of the best insurance arrangements that a planner can provide in the economy with private information. This insurance can be provided by many different mechanisms: the agents may be required to live in autarky and consume their endowment, or may be allowed to trade assets, or may be provided with more sophisticated arrangements by the planner. A priori it is not obvious how to set up the problem of finding the best mechanism to provide the highest utility to agents. This problem simplifies once we apply the results of the mechanism design literature, in particular the Revelation Principle. Textbook treatments of the Revelation Principle are widely available (see, eg, Chapter 23 in Mas-Colell et al., 1995). Here we outline the main arguments behind the Revelation Principle in our context. This overview is useful both to keep the analysis self-contained and to emphasize subtleties that emerge in using the Revelation Principle once additional frictions, such as lack of commitment by the planner, are introduced.

Hurwicz (1960, 1972) provided a general framework to study various arrangements of allocation provision in environments with private information. He showed that such arrangements can be represented as abstract communication mechanisms. Consider an arbitrary message space M that consists of a collection of messages m. Each agent observes his shock θ_t and sends a (possibly random) message $m_t \in M$ to the principal. The agent's reporting strategy in period t is a map $\tilde{\sigma}_t : \Theta^t \to \Delta(M)$. The planner in turn chooses a (possibly stochastic) allocation rule $\tilde{c}_t : M^t \to \Delta(\mathbb{R}_+)$, where $\Delta(\mathbb{R}_+)$ denotes the space of probability measures on $\mathbb{R}_+$. The strategies $\tilde{\boldsymbol{\sigma}} = \left\{\tilde{\sigma}_t(\theta^t)\right\}_{t\geq 1, \theta^t \in \Theta^t}$ and $\tilde{\boldsymbol{c}} = \left\{\tilde{c}_t(m^t)\right\}_{t\geq 1, m^t \in M^t}$ induce a measure over the consumption paths $\{c_t\}_{t\geq 1} \in \mathbb{R}_+^T$, which we denote by $\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}$. The expected utility of each agent is then equal to $\mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}\left[\sum_{t=1}^{T} \beta^{t-1} U(c_t)\right]$, where the superscript in $\mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}$ means that the expectation is computed using the probability distribution $\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}$ over the paths $\{c_t\}_{t\geq 1}$. The strategy $\tilde{\boldsymbol{\sigma}}$ is *incentive compatible* for the agent if[d,e]

$$\mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}\left[\sum_{t=1}^{T} \beta^{t-1} \theta_t U(c_t)\right] - \mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}'}\left[\sum_{t=1}^{T} \beta^{t-1} \theta_t U(c_t)\right] \geq 0, \forall \tilde{\boldsymbol{\sigma}}'. \tag{4}$$

A mechanism $\tilde{\Gamma} = \left(M, \tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}\right)$ is incentive compatible if it satisfies (4), and *feasible* if it satisfies

[d] When T is allowed to be infinite, these sums may not be well defined for all $\boldsymbol{\sigma}$, and we require (4) to hold as $\limsup_{T\to\infty}$.

[e] Note that the constraints (4) also include all the constraints that ensure that $\tilde{\boldsymbol{\sigma}}$ is optimal after any history t, θ^t, ie, $\mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}\left[\sum_{s=t}^{T} \beta^{s-t} \theta_s U(c_s) | \theta^t\right] - \mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}'}\left[\sum_{s=t}^{T} \beta^{s-t} \theta_s U(c_s) | \theta^t\right] \geq 0, \forall \tilde{\boldsymbol{\sigma}}'$.

$$\mathbb{E}^{\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}}\left[\sum_{t=1}^{T}\beta^{t-1}c_t\right]\leq\frac{1-\beta^T}{1-\beta}e. \tag{5}$$

The key insight behind the Revelation Principle is that any outcome $\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}$ of an incentive-compatible and feasible mechanism can be achieved as the outcome of a *direct-truthtelling* mechanism, in which agents report their types directly to the principal. Define a direct mechanism as a reporting strategy $\sigma_t:\Theta^t\to\Theta$. Define a truthtelling strategy $\boldsymbol{\sigma}^{truth}$ as $\sigma_t^{truth}\left(\theta^{t-1},\theta\right)=\theta$ for all θ^{t-1}, θ. The key observation is that there exists $\boldsymbol{c}=\{c_t\}_{t\geq1}$, with $c_t:\Theta^t\to\Delta(\mathbb{R}_+)$ for each t, such that the (induced) measure $\boldsymbol{c}\circ\boldsymbol{\sigma}^{truth}$ replicates the measure $\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}$.[f]

Theorem 1 (Revelation Principle) *The outcome of any incentive-compatible and feasible mechanism* $\tilde{\Gamma}=\left(M,\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}\right)$ *is also the outcome of an incentive-compatible and feasible direct truthful mechanism* $\Gamma=\left(\Theta,\boldsymbol{c}\circ\boldsymbol{\sigma}^{truth}\right)$.

Proof By construction, we have

$$\mathbb{E}^{\boldsymbol{c}\circ\boldsymbol{\sigma}^{truth}}\left[\sum_{t=1}^{T}\beta^{t-1}c_t\right]=\mathbb{E}^{\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}}\left[\sum_{t=1}^{T}\beta^{t-1}c_t\right],$$

so that the truthtelling strategy satisfies (5). Any alternative strategy $\boldsymbol{\sigma}'$ induces a measure $\boldsymbol{c}\circ\boldsymbol{\sigma}'$ which replicates the measure $\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}'$ for some strategy $\tilde{\boldsymbol{\sigma}}'$ in the original mechanism. Therefore

$$\mathbb{E}^{\boldsymbol{c}\circ\boldsymbol{\sigma}^{truth}}\left[\sum_{t=1}^{T}\beta^{t-1}\theta_tU(c_t)\right]-\mathbb{E}^{\boldsymbol{c}\circ\boldsymbol{\sigma}'}\left[\sum_{t=1}^{T}\beta^{t-1}\theta_tU(c_t)\right]\geq0,\forall\boldsymbol{\sigma}'. \tag{6}$$

This concludes the proof. □

We can simplify our analysis further by showing that there is no loss of generality in focusing on *deterministic* direct mechanisms, where each history of reports yields a deterministic consumption allocation (rather than a measure) $\boldsymbol{c}_t^{\det}:\Theta^t\to\mathbb{R}_+$. We show:

[f] The proof of this observation is straightforward. For simplicity, assume that $\tilde{\boldsymbol{\sigma}}$ and $\tilde{\boldsymbol{c}}$ involve randomization over a finite number of elements after each history and let $\tilde{\sigma}^t(m^t|\theta^t)$ be the probability that agent θ^t sends a history of messages m^t, and $\tilde{c}_t(x|m^t)$ be the probability that the principal delivers consumption x to an agent with a reported history m^t. Then c_t is simply defined by $c_t(x|\theta^t)\equiv\sum_{m^t}\tilde{c}_t(x|m^t)\tilde{\sigma}^t(m^t|\theta^t)$. Given this definition of $\boldsymbol{c}$ the payoff of any strategy $\tilde{\boldsymbol{\sigma}}$ in the original mechanism $\left(M,\tilde{\boldsymbol{c}}\circ\tilde{\boldsymbol{\sigma}}\right)$ can be replicated by a strategy $\boldsymbol{\sigma}$ in the truthtelling mechanism.

Proposition 1 *For any incentive-compatible and feasible direct mechanism* $\Gamma = \left(\Theta, \boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}\right)$ *there exists an incentive-compatible, feasible, deterministic direct mechanism* $\left(\Theta, \boldsymbol{c}^{det} \circ \boldsymbol{\sigma}^{truth}\right)$ *that achieves the same ex ante utility.*

Proof Consider any incentive-compatible and feasible, but possibly stochastic, direct mechanism $\Gamma = \left(\Theta, \boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}\right)$. Define a deterministic consumption allocation $\boldsymbol{c}_t^{\det} : \Theta^t \to \mathbb{R}_+$ implicitly by

$$U\left(\boldsymbol{c}_t^{\det}(\theta^t)\right) = \mathbb{E}^{\boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}}\left[U(c_t)|\theta^t\right], \quad \forall t \geq 1, \theta^t \in \Theta^t, \tag{7}$$

where the right hand side is the expected consumption given at time t under the mechanism Γ to the agent who reports the history θ^t. Since U is concave by Assumption 1, Jensen's inequality implies that

$$\mathbb{E}^{\boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}}\left[c_t|\theta^t\right] \geq \boldsymbol{c}_t^{\det}(\theta^t), \forall \theta^t,$$

hence the mechanism $\left(\Theta, \boldsymbol{c}^{\det} \circ \boldsymbol{\sigma}^{truth}\right)$ is feasible. By construction, we have that for all t, θ^t, $\mathbb{E}^{\boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}}\left[U(c_t)|\theta^t\right] = \mathbb{E}^{\boldsymbol{c}^{\det} \circ \boldsymbol{\sigma}^{truth}}\left[U(c_t)|\theta^t\right]$, since the conditional expectation in (7) implies that for any report the agent receives the same expected utility under $\boldsymbol{c}$ and under $\boldsymbol{c}^{\det}$. Hence the mechanism is incentive compatible. This concludes the proof. □

With a slight abuse of notation we will use $\mathbf{c} = \{c_t(\theta^t)\}_{t \geq 1, \theta^t \in \Theta^t}$ instead of $\boldsymbol{c}_t^{\det}$. The incentive constraint in the deterministic direct mechanism can be written simply as

$$\sum_{t=1}^{T} \sum_{\theta^t \in \Theta^t} \beta^{t-1} \pi_t(\theta^t) \theta_t \left[U(c_t(\theta^t)) - U(c_t(\sigma'^t(\theta^t)))\right] \geq 0, \quad \forall \boldsymbol{\sigma}'. \tag{8}$$

The proof of the Revelation Principle requires very few assumptions except the ability of the social planner to commit to the long-term contract in period 0. Theorem 1 and Proposition 1 are very powerful results that provide a simple way to find informationally constrained optimal allocations. In particular, such allocations are a solution to the problem

$$\begin{gathered} V(e) \equiv \sup_{\mathbf{c}} \sum_{t=1}^{T} \sum_{\theta^t \in \Theta^t} \beta^{t-1} \pi_t(\theta^t) \theta_t U(c_t(\theta^t)) \\ \text{subject to } (2),\ (8). \end{gathered} \tag{9}$$

If the supremum of this problem is attained by some vector $\mathbf{c}^*$, any insurance arrangement in which agents consume $\mathbf{c}^*$ in equilibrium is efficient.

In Sections 2.3–2.5 we focus on describing general methods to solve the maximization problem defined in (9). We give examples of specific insurance arrangements when discussing various applications in Section 4.

2.3 Recursive Formulation with i.i.d. Shocks

The analysis of the solution to problem (9) is significantly simplified if shocks are independently and identically distributed (i.i.d.). In more general Markov settings, many of the same arguments continue to hold but they are more cumbersome, and analytical results are more difficult to obtain. For this reason we first focus on i.i.d. shocks and discuss general Markov shocks in Section 2.5.

Assumption 3 Types $\{\theta_t\}_{t\geq 1}$ are independent and identically distributed, that is, $\pi_t\left(\theta_t|\theta^{t-1}\right)=\pi(\theta_t)$. Without loss of generality we assume that $\mathbb{E}[\theta]=\sum_{\theta\in\Theta}\pi(\theta)\theta=1$.

2.3.1 Main Ideas in a Finite-Period Economy

In an economy with a finite number of periods, the maximization problem (9) is defined over a closed and bounded set, because the feasibility constraint imposes that for all t,θ^t, we have $0\leq c_t(\theta^t)\leq \beta\dfrac{1-\beta^T}{1-\beta}(\beta\min_{\theta\in\Theta}\pi(\theta))^{-T}e$. In finite dimensions closed and bounded sets are compact and therefore by Weierstrass' theorem the maximum of problem (9) is achieved, so that we can replace the "sup" with a "max." Moreover, it is easy to see that at the optimum the feasibility constraint must hold with equality.

We want to simplify the set of the incentive constraints in problem (9). Eq. (8) should hold for all possible reporting strategies $\boldsymbol{\sigma}'$. The set of such strategies is large; it consists of all strategies in which an agent misreports his type in some (possibly all) states only in period 1, all strategies in which he misreports his types in some states in periods 1 and 2, and so on. Most of these constraints are redundant. We say that $\boldsymbol{\sigma}''$ is a one-shot deviation strategy if $\sigma''_t\left(\theta^{t-1},\theta_t\right)\neq\theta_t$ for only one θ^t. It turns out that if (8) is satisfied for one-shot deviations, it is satisfied for all deviations in a finite period economy. Formally, we can write a *one-shot* incentive constraint (see Green, 1987) as: for all $\theta^{t-1},\theta,\hat{\theta}$,

$$\begin{aligned}
&\theta U\left(c_t\left(\theta^{t-1},\theta\right)\right)+\beta\sum_{s=1}^{T-t}\sum_{\theta^{t+s}\in\Theta^{t+s}}\beta^{s-1}\pi_{t+s}\left(\theta^{t+s}|\theta^{t-1},\theta\right)\theta_{t+s}U\left(c_{t+s}\left(\theta^{t-1},\theta,\theta_{t+1}^{t+s}\right)\right)\\
\geq\ &\theta U\left(c_t\left(\theta^{t-1},\hat{\theta}\right)\right)+\beta\sum_{s=1}^{T-t}\sum_{\theta^{t+s}\in\Theta^{t+s}}\beta^{s-1}\pi_{t+s}\left(\theta^{t+s}|\theta^{t-1},\theta\right)\theta_{t+s}U\left(c_{t+s}\left(\theta^{t-1},\hat{\theta},\theta_{t+1}^{t+s}\right)\right).
\end{aligned}\tag{10}$$

Proposition 2 *Suppose that T is finite and Assumption 3 is satisfied. An allocation* **c** *satisfies (8) if and only if it satisfies (10).*

Proof That (8) implies (10) is clear, since (10) considers a strict subset of the possible deviations. To show the converse, consider any reporting strategy $\boldsymbol{\sigma}'$. Suppose that the last period in which the agent misreports his type is period t. By (10), for any θ_t the agent gets higher utility from reporting his type truthfully in that period than from deviating. Therefore, the strategy $\boldsymbol{\sigma}''$ which coincides with $\boldsymbol{\sigma}'$ in the first $t-1$ periods and reveals types truthfully from period t onward gives higher utility to the agent than $\boldsymbol{\sigma}'$. Backward induction then implies that truthtelling gives higher utility than $\boldsymbol{\sigma}'$, establishing the result. □

Proposition 2 simplifies the maximization problem (9) by replacing the constraint set (8) with a smaller number of constraints (10). This simplified problem is still too complicated to be solved directly. We next show how to rewrite this problem recursively to reduce it to a sequence of essentially static problems which can be easily analyzed analytically and computationally.

We take several intermediate steps to rewrite constraints (2) and (10). First, observe that the constraint set defined by Eqs. (2) and (10) is not convex. Although much of the analysis can be done for a nonconvex maximization problem, we can obtain convexity by a simple change of variables: instead of choosing consumption $c_t(\theta^t)$ we can choose utils $u_t(\theta^t) \equiv U(c_t(\theta^t))$. The resource cost of providing u units of utils is $C(u) = U^{-1}(u)$, where the cost function C, defined on the range of U, is increasing, differentiable, and strictly convex by Assumption 1. Let $\underline{u}$ and $\bar{u}$ be the (possibly infinite) greatest lower bound and smallest upper bound of U. Observe that $\lim_{u \to \underline{u}} C(u) = 0$ and $\lim_{u \to \bar{u}} C(u) = \infty$. We use $\mathbb{U}$ to denote the domain of C, which is $(\underline{u}, \bar{u})$ if the utility function is unbounded below and $[\underline{u}, \bar{u})$ if it is bounded below. Given this change of variables, the incentive constraint (10) becomes linear in $\mathbf{u} = \{u_t(\theta^t)\}_{t,\theta^t}$, while the resource constraint becomes

$$\mathbb{E}_0\left[\sum_{t=1}^{T} \beta^{t-1} C(u_t)\right] \leq \frac{1-\beta^T}{1-\beta} e,$$

which defines a convex set of feasible $\mathbf{u}$.

The second simplification is to define a *continuation (or promised) utility* variable

$$v_t(\theta^t) \equiv \sum_{s=1}^{T-t} \sum_{\theta^{t+s} \in \Theta^{t+s}} \beta^{s-1} \pi_{t+s}(\theta^{t+s}|\theta^t) \theta_{t+s} u_{t+s}\left(\theta^t, \theta_{t+1}^{t+s}\right). \tag{11}$$

Using repeated substitution we get

$$v_t(\theta^t) = \sum_{\theta \in \Theta} \pi(\theta)[\theta u_{t+1}(\theta^t, \theta) + \beta v_{t+1}(\theta^t, \theta)], \forall \theta^t, \tag{12}$$

where we use the convention $v_T = 0$. Given this definition we can rewrite the incentive constraints (10) as

$$\theta u_t(\theta^{t-1},\theta) + \beta v_t(\theta^{t-1},\theta) \geq \theta u_t(\theta^{t-1},\hat{\theta}) + \beta v_t(\theta^{t-1},\hat{\theta}), \forall \theta^{t-1},\theta,\hat{\theta}. \tag{13}$$

We are now ready to simplify our analysis by observing that while the original maximization problem does not have an obvious recursive structure, its *dual* does. Our arguments imply that the maximization problem (9) can be rewritten as the maximization of the planner's objective over $(\mathbf{u},\mathbf{v}) = \left(\{u_t(\theta^t)\}_{t,\theta^t}, \{v_t(\theta^t)\}_{t,\theta^t}\right)$ subject to the constraints (2), (12), and (13). Let $(\mathbf{u}^*,\mathbf{v}^*)$ be the solution to that problem and v_0 be the value of the maximum. Then, by standard duality arguments, $(\mathbf{u}^*,\mathbf{v}^*)$ also minimizes the cost of providing $(\mathbf{u},\mathbf{v})$ subject to the incentive-compatibility constraints and the "promise-keeping constraint"

$$\mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}\theta_t u_t(\theta^t)\right] = v_0. \tag{14}$$

Using the definition of $v_1(\theta^1)$, this constraint can be rewritten as

$$v_0 = \sum_{\theta\in\Theta}\pi(\theta)[\theta u_1(\theta) + \beta v_1(\theta)]. \tag{15}$$

Define the set $\Gamma(v_0)$ as

$$\Gamma(v_0) = \left\{(\mathbf{u},\mathbf{v}) : (12), (13), (15) \text{ hold}\right\}. \tag{16}$$

We thus obtain that $(\mathbf{u}^*,\mathbf{v}^*)$ is the solution to

$$K_0(v_0) \equiv \max_{(\mathbf{u},\mathbf{v})\in\Gamma(v_0)} \mathbb{E}_0\left[-\sum_{t=1}^{T}\beta^{t-1}C(u_t)\right]. \tag{17}$$

The key simplification allowed by this formulation is that it can be easily solved using recursive techniques. Let $K_{T-1}(\cdot) \equiv -C(\cdot)$, which has domain $\mathbb{V}_{T-1} = \mathbb{U}$. Define the functions K_t for $0 \leq t \leq T-2$ and their domains $\mathbb{V}_t$ recursively by

$$K_t(v) \max_{\{(u(\theta),w(\theta))\}_{\theta\in\Theta}} \sum_{\theta\in\Theta}\pi(\theta)[-C(u(\theta)) + \beta K_{t+1}(w(\theta))] \tag{18}$$

subject to the promise-keeping constraint:

$$v = \sum_{\theta\in\Theta}\pi(\theta)[\theta u(\theta) + \beta w(\theta)], \tag{19}$$

and the incentive-compatibility constraint:

$$\theta u(\theta) + \beta w(\theta) \geq \theta u(\hat{\theta}) + \beta w(\hat{\theta}), \forall \theta,\hat{\theta}, \tag{20}$$

and

$$u(\theta)\in\mathbb{U},\quad w(\theta)\in\mathbb{V}_{t+1}.$$

Eq. (18) defines the domain of K_t, denoted by $\mathbb{V}_t$. It is easy to verify that it is either $\left[\frac{1-\beta^{T-t}}{1-\beta}\underline{u},\frac{1-\beta^{T-t}}{1-\beta}\bar{u}\right)$ or $\left(\frac{1-\beta^{T-t}}{1-\beta}\underline{u},\frac{1-\beta^{T-t}}{1-\beta}\bar{u}\right)$, depending on whether the utility function is bounded below or not. It is easy to see that the function K_0 defined in (17) satisfies (18) for $t = 0$. Standard arguments establish that K_t is a continuous, strictly decreasing, strictly concave, and differentiable function. For any value $v\in\mathbb{V}_{t-1}$ for $t\geq 1$, let $\vec{u}_{v,t}=\{u_{v,t}(\theta)\}_{\theta\in\Theta}$ and $\vec{w}_{v,t}=\{w_{v,t}(\theta)\}_{\theta\in\Theta}$ denote the solution (ie, the argmax) of the Bellman equation (18). We call $\left(\vec{u}_{v,t},\vec{w}_{v,t}\right)$ the *policy functions* of the Bellman equation. Given our assumption that C is strictly convex, these policy functions are unique for each v,t.

We can now describe how to find the solution to (17). The main simplification comes from the fact that if we know the optimal value $v_t^*(\theta^t)$ after any history θ^t, we can find the optimal allocations in the nodes following θ^t without having to know the optimal allocations in any other node. We start with $t = 1$. Since $K_0(v)$ is (minus) the amount of resources required to achieve the expected utility v, the initial value v_0 must satisfy $K_0(v_0)=-\frac{1-\beta^T}{1-\beta}e$. The constrained-optimal utility allocation in period 1 for an agent with shock θ_1 is then given by $u_1^*(\theta_1)=u_{v_0,1}(\theta_1)$, and his expected utility starting from period 2 is $v_1^*(\theta_1)=w_{v_0,1}(\theta_1)$. The optimal utility allocation in period two for a history of shocks (θ_1,θ_2) is then given by $u_2^*(\theta_1,\theta_2)=u_{w_{v_0,1}(\theta_1),2}(\theta_2)$, and similarly $v_2^*(\theta_1,\theta_2)=w_{w_{v_0,1}(\theta_1),2}(\theta_2)$. This way we can use forward induction to find the solution to (9), $(\mathbf{u}^*,\mathbf{v}^*)$. We say that the solution $(\mathbf{u}^*,\mathbf{v}^*)$ is *generated by the policy functions* of the Bellman equation (18) given v_0.

2.3.2 Extension to an Infinite Period Economy

In the previous section we showed a simple way to characterize the solution to a dynamic contracting problem recursively when the number of periods is finite. For many applications it is more convenient to work with infinite periods for at least two reasons. The first is that many problems do not have a natural terminal period so that the assumption of infinite periods is more convenient. The second reason is that the assumption of infinite periods allows us to obtain sharp insights about the economic forces behind the optimal provision of incentives that are more difficult to see in finite-period economies.

The key step in the analysis of Section 2.3.1 consisted of setting up the dual problem (17) and its recursive representation (18). In the finite-horizon setting, we were able to obtain the formulation (17) by proving the one-shot deviation principle (Proposition 2). Here, we start by *assuming* that the one-shot deviation principle holds, and solve a relaxed problem where the incentive constraints (8) are replaced with (10). We then show later in Proposition 4 that under some conditions, the solution to the relaxed problem is also a solution to the original problem. The infinite period analogue of the (relaxed) sequential dual problem is

$$K(v_0) \equiv \sup_{\mathbf{u}} \mathbb{E}_0 \left[-\sum_{t=1}^{\infty} \beta^{t-1} C(u_t) \right] \tag{21}$$
$$\text{subject to (11), (13), (14).}$$

We now show that the value function K defined in (21) can be written recursively, and that the solution to this recursive formulation can, under some conditions, recover the maximum to our primal problem (9). Let $\bar{v} = \frac{1}{1-\beta}\bar{u}$, $\underline{v} = \frac{1}{1-\beta}\underline{u}$, and let $\mathbb{V} = [\underline{v}, \bar{v})$ if the utility is bounded below and $\mathbb{V} = (\underline{v}, \bar{v})$ otherwise.[g] We denote by $B(v)$ the set of pairs $(\vec{u}, \vec{w}) = \left(\{u(\theta)\}_{\theta\in\Theta}, \{w(\theta)\}_{\theta\in\Theta}\right)$ that satisfy the constraints of the recursive problem, ie,

$$B(v) \equiv \left\{ (\vec{u}, \vec{w}) \in \mathbb{U}^{|\Theta|} \times \mathbb{V}^{|\Theta|} : (19), (20) \text{ hold} \right\}. \tag{22}$$

We first prove an infinite period analogue of the Bellman equation (18). Some of the arguments are based on those in Farhi and Werning (2007).

Proposition 3 *Suppose that the utility function satisfies Assumption 1, shocks satisfy Assumptions 2 and 3, and $T = \infty$. Then K satisfies the Bellman equation*

$$K(v) = \max_{(\vec{u}, \vec{w}) \in B(v)} \sum_{\theta\in\Theta} \pi(\theta) [-C(u(\theta)) + \beta K(w(\theta))]. \tag{23}$$

Proof We first show that the maximum in problem (23) is well defined. That is, for any $v \in \mathbb{V}$, there exist $(\vec{u}_v, \vec{w}_v)$ that maximize the right hand side of (23) within the set $B(v)$ defined in (22). To do so we restrict the optimization over $(\vec{u}, \vec{w})$ to a compact set.

[g] In our benchmark taste shock model it is easy to find the domain of K that we denote by $\mathbb{V}$. Any constant consumption sequence is incentive compatible. Since the consumption set is bounded below by 0, the greatest lower bound for the set $\mathbb{V}$ must be $\underline{v} = \sum_{\theta\in\Theta} \pi(\theta)\theta[U(0) + \beta\underline{v}] = \frac{1}{1-\beta}\underline{u}$, where we used the normalization $\mathbb{E}\theta = 1$. If $U(0)$ is finite, so is $\underline{v}$. Similarly, since the consumption set is unbounded above, $\bar{v} = \frac{1}{1-\beta}\bar{u}$ is the least upper bound of $\mathbb{V}$. Since (13) and (14) define a convex set, any $v_0 \in (\underline{v}, \bar{v})$ can be attained by incentive-compatible allocations, which establishes that $\mathbb{V} = [\underline{v}, \bar{v})$ if the utility is bounded below and $\mathbb{V} = (\underline{v}, \bar{v})$ otherwise. It is not always possible to characterize the domain of the value function in such a simple way. The general way to characterize the set $\mathbb{V}$ is described in Proposition 8.

Since the right hand side of (23) is a continuous function of $\left(\vec{u}, \vec{w}\right)$, this implies that it reaches its maximum.

The allocation $\left(\vec{u}\,', \vec{w}\,'\right)$ defined by $u'(\theta) = (1-\beta)v$ and $w'(\theta) = v$ for all $\theta \in \Theta$ satisfies the constraints (19) and (20) and yields value $-C((1-\beta)v) + \beta K(v) \equiv \underline{K}_v$. Therefore the r.h.s. of the Bellman equation is larger than $\underline{K}_v$. Now suppose that for some θ, $w(\theta)$ is such that $\beta\pi(\theta)K(w(\theta)) < \underline{K}_v$. Then we have

$$\sum_{\theta\in\Theta} \pi(\theta)[-C(u(\theta)) + \beta K(w(\theta))] < \underline{K}_v,$$

a contradiction. Thus we can restrict the search to $\left\{w(\theta) \text{ s.t. } \beta\pi(\theta)K(w(\theta)) \geq \underline{K}_v\right\}$ and, similarly, to $\left\{u(\theta) \text{ s.t. } -\pi(\theta)C(u(\theta)) \geq \underline{K}_v\right\}$. Moreover, we have $\lim_{u\to\bar{u}} - C(u) = -\infty$ and $\lim_{v\to\bar{v}} K(v) = -\infty$. To show the latter, consider the function $\bar{K}(v)$ which maximizes the objective function (21) subject to delivering lifetime utility $v_0 = v$, without the incentive constraints. Obviously $\bar{K}(v) \geq K(v)$. We easily obtain that the solution to this relaxed problem is $\bar{K}(v) = -\dfrac{1}{1-\beta}\mathbb{E}\left[C\left(C'^{-1}(\gamma_v\theta)\right)\right]$ where $\gamma_v > 0$ is the multiplier on the promise-keeping constraint. We have $\mathbb{E}\left[\theta C'^{-1}(\gamma_v\theta)\right] = (1-\beta)v$, so $\lim_{v\to\bar{v}}\gamma_v = \infty$ and hence $\lim_{v\to\bar{v}}\bar{K}(v) = -\infty$. This implies that $\lim_{v\to\bar{v}} K(v) = -\infty$, and therefore the previous arguments lead to upper bounds $\bar{\bar{u}}_\theta, \bar{\bar{v}}_\theta$ for $u(\theta)$ and $w(\theta)$, respectively. Moreover, $\mathbb{E}[\theta u(\theta) + \beta w(\theta)]$ goes to $-\infty$ if $u(\theta)$ or $w(\theta)$ go to $-\infty$ because of the upper bounds $\bar{\bar{u}}_\theta$, $\bar{\bar{w}}_\theta$. This contradicts the promise-keeping constraint and thus gives us lower bounds $\underline{\underline{u}}_\theta$, $\underline{\underline{w}}_\theta$ for all θ. Therefore, we can restrict the search for $\{u(\theta), w(\theta)\}_{\theta\in\Theta}$ to the compact set $\prod_{\theta\in\Theta}\left[\underline{\underline{u}}_\theta, \bar{\bar{u}}_\theta\right] \times \left[\underline{\underline{w}}_\theta, \bar{\bar{w}}_\theta\right]$. This concludes the proof that the maximum in the right hand side of (23) is attained.

Next, we show that K, the solution to (21), satisfies the Bellman equation (23). We start by showing that the left hand side is weakly smaller than the right hand side. Suppose that for some v, we have

$$K(v) > \max_{\left(\vec{u}, \vec{w}\right)\in B(v)} \sum_{\theta\in\Theta} \pi(\theta)[-C(u(\theta)) + \beta K(w(\theta))].$$

Thus there exists $\varepsilon > 0$ such that

$$K(v) \geq \mathbb{E}[-C(u(\theta)) + \beta K(w(\theta))] + \varepsilon, \quad \forall\left(\vec{u}\,, \vec{w}\right) \in B(v).$$

Now consider any allocation $\mathbf{u} = \{u_t(\theta^t)\}_{t\geq 1, \theta^t\in\Theta^t}$ that satisfies incentive compatibility (10) and delivers lifetime utility v. We can write $\mathbf{u} = \left(\{u_1(\theta_1)\}_{\theta_1\in\Theta}, \{\mathbf{u}_2(\theta_1)\}_{\theta_1\in\Theta}\right)$, where for all θ_1, $\mathbf{u}_2(\theta_1) = \left\{u_t\left(\theta_1, \theta_2^t\right)\right\}_{t\geq 2, \theta_2^t\in\Theta^{t-1}}$. Let $w_2(\theta_1)$ denote the lifetime utility achieved by $\mathbf{u}_2(\theta_1)$.[h] The pair $\left(\vec{u}_1, \vec{w}_2\right) = \left(\{u_1(\theta_1)\}_{\theta_1\in\Theta}, \{w_2(\theta_1)\}_{\theta_1\in\Theta}\right)$ satisfies (19) and (20), ie, $\left(\vec{u}_1, \vec{w}_2\right) \in B(v)$. Thus, the previous inequality implies that

$$\begin{aligned} K(v) &\geq \mathbb{E}[-C(u_1(\theta_1)) + \beta K(w_2(\theta_1))] + \varepsilon \\ &\geq \mathbb{E}\left[-C(u_1(\theta_1)) + \beta \mathbb{E}_1\left[-\sum_{t=2}^{\infty} \beta^{t-2} C\left(u_t\left(\theta_1, \theta_2^t\right)\right)\right]\right] + \varepsilon \\ &= \mathbb{E}_0\left[-\sum_{t=1}^{\infty} \beta^{t-1} C(u_t(\theta^t))\right] + \varepsilon, \end{aligned}$$

where the second inequality follows from the definition (21) of $K(w_2(\theta_1))$, since the allocation $\mathbf{u}_2(\theta_1)$ satisfies (10) and yields $w_2(\theta_1)$. Since this reasoning holds for any allocation $\mathbf{u}$ that satisfies (10) and delivers v, we get a contradiction.

Next we show the reverse inequality. Note that by definition of the supremum in (21), for all v and $\varepsilon > 0$ there exists an allocation $\tilde{\mathbf{u}}^{v,\varepsilon} = \left\{\tilde{u}_t^{v,\varepsilon}(\theta^t)\right\}$ that satisfies (10) and delivers v with cost

$$\mathbb{E}_0\left[-\sum_{t=1}^{\infty} \beta^{t-1} C\left(\tilde{u}_t^{v,\varepsilon}(\theta^t)\right)\right] > K(v) - \varepsilon.$$

Let

$$\left(\vec{u}_v, \vec{w}_v\right) \in \arg \max_{\left(\vec{u}, \vec{w}\right) \in B(v)} \mathbb{E}[-C(u(\theta)) + \beta K(w(\theta))].$$

Consider the incentive-compatible allocation $\mathbf{u}$ defined by $u_1\left(\theta^1\right) = u_v(\theta_1)$ for all $\theta_1 \in \Theta$ and $u_t\left(\theta_1, \theta_2^t\right) = \tilde{u}_t^{w_v(\theta_1),\varepsilon}(\theta^t)$ for all $t \geq 2$, $\theta^t \in \Theta^t$. We have

[h] Note that the continuation utilities, and in particular $w_2(\theta)$ for all θ, are well defined. Indeed, if not, then for some $s \geq 0$, $U_s^+ \equiv \lim_{T\to\infty} \mathbb{E}_s\left[\sum_{t=1}^{T} \beta^{t-1}\{\theta_t u_t(\theta^t) \vee 0\}\right] = \infty$. Since the cost function is convex, we have $C(u) \geq -B + A\{(\max_\Theta \theta) u \vee 0\}$ for some $A, B > 0$, and hence $\lim_{T\to\infty} \mathbb{E}_s\left[\sum_{t=1}^{T} \beta^{t-1} C(u_t(\theta^t))\right] \geq -\frac{B}{1-\beta} + AU_s^+ = \infty$. This implies

$$\lim_{T\to\infty} \mathbb{E}_0\left[\sum_{t=1}^{T} \beta^{t-1} C(u_t(\theta^t))\right] = \sum_{\theta^s \in \Theta^s} \pi_s(\theta^s) \lim_{T\to\infty} \mathbb{E}_s\left[\sum_{t=1}^{T} \beta^{t-1} C(u_t(\theta^t))\right] = \infty,$$

which contradicts the feasibility constraint (2).

$$
\begin{aligned}
K(v) &\geq \mathbb{E}_0\left[-\sum_{t=1}^{\infty}\beta^{t-1}C(u_t(\theta^t))\right]\\
&= \mathbb{E}_0\left[-C(u_v(\theta_1)) + \beta\mathbb{E}_1\left[-\sum_{t=2}^{\infty}\beta^{t-2}C\left(\tilde{u}_t^{w_v(\theta_1),\varepsilon}(\theta^t)\right)\right]\right]\\
&\geq \mathbb{E}_0[-C(u_v(\theta_1)) + \beta K(w_v(\theta_1))] - \beta\varepsilon\\
&= \max_{\left(\vec{u},\vec{w}\right)\in B(v)} \mathbb{E}[-C(u(\theta)) + \beta K(w(\theta))] - \beta\varepsilon.
\end{aligned}
$$

Since $\varepsilon > 0$ was arbitrary, we can let $\varepsilon \to 0$ in this inequality. We have thus shown that the value function (21) of the dual planner's problem satisfies the Bellman equation (23). □

The function K inherits the same properties as the function K_t in the finite period version of this economy.

Lemma 1 *Suppose that the utility function satisfies Assumption 1, shocks satisfy Assumptions 2 and 3, and $T = \infty$. Then K is continuous on $\mathbb{V}$, strictly concave, strictly decreasing, and differentiable, with $\lim_{v\to\underline{v}}K(v) = \lim_{v\to\underline{v}}K'(v) = 0$ and $\lim_{v\to\bar{v}}K(v) = \lim_{v\to\bar{v}}K'(v) = -\infty$.*

Proof The objective function in (21) is concave and the constraint set is convex; therefore, K is weakly concave. To show the strict concavity of K, pick any $v^a, v^b \in \mathbb{V}$ such that $v^a \neq v^b$, and let $\left(\vec{u}_{v^a}, \vec{w}_{v^a}\right)$ and $\left(\vec{u}_{v^b}, \vec{w}_{v^b}\right)$ be the corresponding policy functions that maximize the right hand side of (23). The incentive constraint (20) implies that $\vec{u}_{v^a} \neq \vec{u}_{v^b}$. Let, for $\alpha \in [0,1]$, $v^\alpha \equiv \alpha v^a + (1-\alpha)v^b$, and $\left(\vec{u}_{v^\alpha}, \vec{w}_{v^\alpha}\right)$ be the corresponding policy function. Since (19) and (20) are linear in $u(\theta)$ and $w(\theta)$, we obtain that

$$\left(\alpha\vec{u}_{v^a} + (1-\alpha)\vec{u}_{v^b}, \alpha\vec{w}_{v^a} + (1-\alpha)\vec{w}_{v^b}\right) \in B(v^\alpha).$$

Thus K satisfies

$$
\begin{aligned}
K(v^\alpha) &= \sum_{\theta\in\Theta}\pi(\theta)[-C(u_{v^\alpha}(\theta)) + \beta K(w_{v^\alpha}(\theta))]\\
&\geq \sum_{\theta\in\Theta}\pi(\theta)[-C(\alpha u_{v^a}(\theta) + (1-\alpha)u_{v^b}(\theta)) + \beta K(\alpha w_{v^a}(\theta) + (1-\alpha)w_{v^b}(\theta))].
\end{aligned}
$$

so that by the strict concavity of $-C$ and the weak concavity of K we get

$$K(v^{\alpha}) > \alpha \sum_{\theta \in \Theta} \pi(\theta)[-C(u_{v^a}(\theta)) + \beta K(w_{v^a}(\theta))]$$
$$+ (1-\alpha) \sum_{\theta \in \Theta} \pi(\theta)[-C(u_{v^b}(\theta)) + \beta K(w_{v^b}(\theta))] = \alpha K(v^a) + (1-\alpha) K\left(v^b\right),$$

Therefore K is strictly concave.

The concavity of K implies that it is continuous in the interior of $\mathbb{V}$ (Exercise 4.23 in Rudin, 1976). To show the continuity of K on $\mathbb{V}$ it remains to show that $\lim_{v \to \underline{v}} K(v) = K(\underline{v})$ when the utility is bounded below. Since the only feasible solution that delivers $\underline{v}$ has $u_t(\theta^t) = \underline{u}$ for all t, θ^t, we have in this case $K(\underline{v}) = -\frac{1}{1-\beta} C(\underline{u}) = 0$. Therefore showing the continuity at $\underline{v}$ is equivalent to showing that $\lim_{v \to \underline{v}} K(v) = 0$. Let $\underline{K}(v) = -\frac{1}{1-\beta} C((1-\beta)v)$ be the cost of delivering $u_t(\theta^t) = (1-\beta)v$ independently of θ^t. Since this allocation is incentive compatible, we have $0 \geq K(v) \geq \underline{K}(v)$ for all v. $\underline{K}$ is continuous on $\mathbb{V}$ with $\lim_{v \to \underline{v}} \underline{K}(v) = 0$; therefore, $\lim_{v \to \underline{v}} K(v) = 0$.

We already showed that $\lim_{v \to \bar{v}} K(v) = -\infty$ in the proof of Proposition 3.

To show the strict monotonicity, for any $v_0^a < v_0^b$ pick $v \in \left(\underline{v}, v_0^a\right)$ and $\alpha_v \in [0, 1)$ such that $v_0^a = \alpha_v v + (1-\alpha_v) v_0^b$. Since K is strictly concave, we have $K\left(v_0^a\right) > \alpha_v K(v) + (1-\alpha_v) K\left(v_0^b\right)$. Letting $v \to \underline{v}$ in this inequality, we obtain $K\left(v_0^a\right) \geq \left(1-\alpha_{\underline{v}}\right) K\left(v_0^b\right) \geq K\left(v_0^b\right)$, and hence K is weakly decreasing. But then using $K(v) \geq K\left(v_0^b\right)$ in the previous inequality leads to $K\left(v_0^a\right) > \alpha_v K\left(v_0^b\right) + (1-\alpha_v) K\left(v_0^b\right) = K\left(v_0^b\right)$, so that K is strictly decreasing.

Next we show the differentiability of the cost function K in the case where the utility is unbounded. A slightly different perturbational argument can be used to establish the differentiability when the utility function is bounded, taking care of the situations when the optimum is at the corners (see, eg, Farhi and Werning, 2007). Fix an interior v and define, for all $x \in (-\varepsilon, \varepsilon)$ for some small $\varepsilon > 0$,

$$L_v(x) = \sum_{\theta \in \Theta} \pi(\theta)[-C(u_v(\theta) + x) + \beta K(w_v(\theta))].$$

The allocation $\left(\vec{u}_x, \vec{w}_x\right)$ with $u_x(\theta) = u_v(\theta) + x$ and $w_x(\theta) = w_v(\theta)$ for all θ is incentive compatible and delivers lifetime utility $v + x$. Therefore, for all x we have $L_v(x) \leq K(v+x)$, with equality if $x = 0$. Since $L_v(\cdot)$ is concave and differentiable on $(-\varepsilon, \varepsilon)$ (because $-C(\cdot)$ is), the Benveniste–Scheinkman theorem (Benveniste and Scheinkman, 1979, or Theorem 4.10 in Stokey et al., 1989) implies that K is differentiable at v and we have $K'(v) = L_v'(0)$. Direct calculation of $L_v'(0)$ shows that

$$K'(v) = \sum_{\theta \in \Theta} \pi(\theta)[-C'(u_v(\theta))] \leq 0. \tag{24}$$

The bounds $\underline{K}(v) \le K(v) \le \bar{K}(v)$ (see the proof of Proposition 3) and the limits $\lim_{v\to \underline{v}} \underline{K}'(v) = 0$ and $\lim_{v\to\bar{v}} \bar{K}'(v) = -\gamma_v = -\infty$ imply that $\lim_{v\to\underline{v}} K'(v) = 0$ and $\lim_{v\to\bar{v}} K'(v) = -\infty$. □

Finally, we are ultimately interested in recovering a solution to problem (9). Analogous to the finite period case, we call the solution to (23) a *policy function* and denote it by $\left(\vec{u}_v, \vec{w}_v\right)$. For any initial v_0 these functions *generate* $(\mathbf{u}, \mathbf{v})$ as in Section 2.3.1.

Proposition 4 *Suppose that the utility function satisfies Assumption 1, shocks satisfy Assumptions 2 and 3, and* $T = \infty$. *Let* v_0 *be defined by* $K(v_0) = -\frac{e}{1-\beta}$. *If the sequence* $(\mathbf{u},\ \mathbf{v})$ *generated by the policy functions to the Bellman equation (23) given* v_0 *satisfies*

$$\lim_{t\to\infty} \mathbb{E}_0[\beta^t v_t(\theta^t)] = 0 \tag{25}$$

and

$$\lim\sup_{t\to\infty} \mathbb{E}_0[\beta^t v_t(\sigma^t(\theta^t))] \ge 0, \forall \sigma \tag{26}$$

then $(\mathbf{u},\ \mathbf{v})$ *achieves the supremum of the primal maximization problem (9).*

Proof Let $(\mathbf{u}, \mathbf{v})$ denote the allocations generated by the policy functions $\left(\vec{u},\ \vec{w}\right)$ starting at v_0. First, we show that $(\mathbf{u}, \mathbf{v})$ achieves the supremum of the sequential *dual* problem (21) with the full set of incentive constraints (8) (rather than only the constraints (10) of the relaxed problem), ie, that $(\mathbf{u}, \mathbf{v})$ satisfies the constraints (8) and (14) and attains $K(v_0)$. To see that constraint (14) is satisfied, note that by repeated substitution, $(\mathbf{u}, \mathbf{v})$ satisfies

$$v_0 = \mathbb{E}_0\left[\sum_{t=1}^{T} \beta^{t-1} \theta_t u_t(\theta^t)\right] + \beta^T \mathbb{E}_0\left[v_T\left(\theta^T\right)\right].$$

If $(\mathbf{u}, \mathbf{v})$ satisfies (25), then taking limits as $T \to \infty$ (see Footnote h for the existence of the limit on the right hand side) leads to

$$v_0 = \mathbb{E}_0\left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t u_t(\theta^t)\right].$$

To see that $(\mathbf{u}, \mathbf{v})$ satisfies the incentive-compatibility constraint (8), consider any reporting strategy σ. Since the policy functions $\left(\vec{u},\ \vec{w}\right)$ that generate $(\mathbf{u}, \mathbf{v})$ satisfy (20), repeated substitution implies that $(\mathbf{u}, \mathbf{v})$ satisfies

$$v_0 \ge \mathbb{E}_0\left[\sum_{t=1}^{T} \beta^{t-1} \theta_t u(\sigma^t(\theta^t))\right] + \beta^T \mathbb{E}_0\left[v_T\left(\sigma^T\left(\theta^T\right)\right)\right].$$

If the condition (26) is satisfied, taking limits implies that

$$\limsup_{T\to\infty}\left\{v_0-\mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}\theta_t U(c_t(\sigma^t(\theta^t)))\right]\right\}\geq 0\,\forall\sigma,$$

establishing that $(\mathbf{u},\mathbf{v})$ satisfies (8).

We next show that $(\mathbf{u},\mathbf{v})$ attains $K(v_0)$. Repeatedly applying the Bellman equation (23) yields

$$K(v_0)=\mathbb{E}_0\left[-\sum_{t=1}^{T}\beta^{t-1}C(u_t(\theta^t))\right]+\beta^T\mathbb{E}_0\left[K\left(v_T\left(\theta^T\right)\right)\right].$$

Since $\limsup_{T\to\infty}\beta^T\mathbb{E}_0\left[K\left(v_T\left(\theta^T\right)\right)\right]\leq 0$ we obtain

$$K(v_0)\leq\mathbb{E}_0\left[-\sum_{t=1}^{\infty}\beta^{t-1}C(u_t(\theta^t))\right].$$

But $(\mathbf{u},\mathbf{v})$ satisfies the constraints of problem (21), thus $K(v_0)\geq\mathbb{E}_0\left[-\sum_{t=1}^{\infty}\beta^{t-1}C(u_t(\theta^t))\right]$. Therefore $(\mathbf{u},\mathbf{v})$ achieves the supremum of the dual problem (21).

Second, we show that the maximum to the dual problem (21) is also a maximum to the primal problem (9). Since $(\mathbf{u},\mathbf{v})$ delivers v_0 which satisfies $-K(v_0)=\frac{e}{1-\beta}$, $\mathbf{u}$ satisfies the feasibility constraint (2) and therefore $V(e)\geq v_0$. Suppose that this inequality is strict, so that there exists $(\mathbf{u}',\mathbf{v}')$ that delivers lifetime utility $v_0{}'>v_0$, is incentive compatible, and satisfies $\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}C\left(u_t'\right)\right]\leq\frac{e}{1-\beta}$. The continuity and strict monotonicity of K (Lemma 1) imply that $-K(v_0')>-K(v_0)=\frac{e}{1-\beta}$. Since $\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}C\left(u_t'\right)\right]\geq -K(v_0')$, this establishes a contradiction. □

If the utility function is bounded, then the limiting conditions (25) and (26) are automatically satisfied and Proposition 4 implies simultaneously that the supremum to problem (21) is attained and that it can be recovered from the policy functions of the Bellman equation (23). When the utility function is unbounded, an extra step is needed to verify that the policy functions generate a solution that satisfies the conditions (25) and (26). We show in an example in Section 2.4 how to verify ex post these conditions with unbounded utilities.

The analysis above can be simplified if we modify Assumption 1 and assume that the domain of U is compact. In this case $C(\cdot)$ is a bounded function on a compact set $[\underline{u},\bar{u}]$. The results of Propositions 3 and 4 can be proven immediately using standard contraction mapping arguments (see Chapter 9 in Stokey et al., 1989). Moreover, the results of Stokey et al. (1989) show that the function K that satisfies the functional equation

(23) is the unique fixed point of the Bellman operator defined on the space of continuous and bounded functions by

$$\mathscr{B}(k)(v) = \max_{(\vec{u},\vec{w}) \in B(v)} \sum_{\theta \in \Theta} \pi(\theta)[-C(u(\theta)) + \beta k(w(\theta))],$$

and that for all bounded and continuous k_0 the sequence $\{k_n\}_{n \geq 0}$ defined by $k_n = \mathscr{B}^n k_0$ for all n converges to K. This characterization can be used to compute the solution to the problem numerically.

2.4 Characterization of the Solution with i.i.d. Shocks

2.4.1 Optimal Incentive Provision

In this section we characterize the solution to the Bellman equation (23). At the end of this section we provide a simple example showing how to verify the limiting conditions (25) and (26) when the utility function is unbounded.

For simplicity, we assume that θ can take only two values, $\Theta = \{\theta_{(1)}, \theta_{(2)}\}$, with $\theta_{(1)} < \theta_{(2)}$. The incentive constraints (20) with two shocks reduce to

$$\theta_{(1)} u(\theta_{(1)}) + \beta w(\theta_{(1)}) \geq \theta_{(1)} u(\theta_{(2)}) + \beta w(\theta_{(2)}), \tag{27}$$

and

$$\theta_{(2)} u(\theta_{(2)}) + \beta w(\theta_{(2)}) \geq \theta_{(2)} u(\theta_{(1)}) + \beta w(\theta_{(1)}). \tag{28}$$

Proposition 5 *Suppose that the utility function satisfies Assumption 1, shocks satisfy Assumptions 2 and 3, $|\Theta| = 2$, and $T = \infty$. The constraint (27) binds, and the constraint (28) is slack for all interior v. Moreover $u_v(\theta_{(1)}) \leq u_v(\theta_{(2)})$ and $w_v(\theta_{(1)}) \geq v \geq w_v(\theta_{(2)})$, with strict inequalities for all interior v. The policy functions $u_v(\theta)$, $w_v(\theta)$ are continuous in v for all $\theta \in \Theta$. If $w_v(\theta_{(2)})$ is interior, the policy functions satisfy*

$$K'(v) = \mathbb{E}[K'(w_v)] = \mathbb{E}[-C'(u_v)], \forall v. \tag{29}$$

Proof The proof proceeds by guessing that the constraint (28) is slack and solving a relaxed problem (23) in which this constraint is dropped. We then verify ex post that (28) is satisfied. The strict concavity of the objective function in (23) and the convexity of the constraint set then implies that the solution to the relaxed problem is the unique solution to the original problem.

Let $\xi_v \geq 0$ and $\gamma_v \geq 0$ be the Lagrange multipliers on the incentive-compatibility constraint (27) and the promise-keeping constraint (19) in the relaxed problem. The first-order conditions with respect to $u(\theta_{(1)})$ and $u(\theta_{(2)})$ are

$$\pi\left(\theta_{(1)}\right)C'\left(u_v\left(\theta_{(1)}\right)\right)-\xi_v\theta_{(1)} \ \geq \gamma_v\pi\left(\theta_{(1)}\right)\theta_{(1)}, \tag{30}$$

$$\pi\left(\theta_{(2)}\right)C'\left(u_v\left(\theta_{(2)}\right)\right)+\xi_v\theta_{(1)} \ \geq \gamma_v\pi\left(\theta_{(2)}\right)\theta_{(2)}, \tag{31}$$

where these constraints hold with equality if $u_v\left(\theta_{(1)}\right)>\underline{u}$ and $u_v\left(\theta_{(2)}\right)>\underline{u}$, respectively. Similarly, the first-order conditions with respect to $w\left(\theta_{(1)}\right)$ and $w\left(\theta_{(2)}\right)$ are

$$-\pi\left(\theta_{(1)}\right)K'\left(w_v\left(\theta_{(1)}\right)\right)-\xi_v \ \geq \gamma_v\pi\left(\theta_{(1)}\right), \tag{32}$$

$$-\pi\left(\theta_{(2)}\right)K'\left(w_v\left(\theta_{(2)}\right)\right)+\xi_v \ \geq \gamma_v\pi\left(\theta_{(2)}\right), \tag{33}$$

where these constraints hold with equality if $w_v\left(\theta_{(1)}\right)>\underline{v}$ and $w_v\left(\theta_{(2)}\right)>\underline{v}$, respectively.

We first show that $u_v\left(\theta_{(1)}\right), w_v\left(\theta_{(1)}\right)$ are interior for all interior v. (We show below that $u_v\left(\theta_{(2)}\right)$ is also interior.) Suppose that $u_v\left(\theta_{(1)}\right)=\underline{u}$. Since $C'(\underline{u})=0$, (30) implies that $\xi_v = \gamma_v = 0$. If $u_v\left(\theta_{(2)}\right)>\underline{u}$, then (31) would hold with equality, implying $C'\left(u_v\left(\theta_{(2)}\right)\right)=0$, a contradiction. Thus we have $u_v\left(\theta_{(1)}\right)=u_v\left(\theta_{(2)}\right)=\underline{u}$, and the same reasoning implies that $w_v\left(\theta_{(1)}\right)=w_v\left(\theta_{(2)}\right)=\underline{v}$, which contradicts the promise-keeping constraint (19) when v is interior. Therefore we must have $u_v\left(\theta_{(1)}\right)>\underline{u}$ so that (30) holds with equality. An identical reasoning implies that $w_v\left(\theta_{(1)}\right)>\underline{v}$, so that (32) holds with equality.

We now show that $\xi_v > 0$ for all interior v. If $\xi_v = 0$, then (32) and (33) imply that $w_v\left(\theta_{(2)}\right)\geq w_v\left(\theta_{(1)}\right)$ by the concavity of K. Moreover (30) and (31) with $\theta_{(2)}>\theta_{(1)}$ imply that $u_v\left(\theta_{(2)}\right)>u_v\left(\theta_{(1)}\right)$. This violates the incentive constraint (27), and hence $\xi_v > 0$ if $v>\underline{v}$. This implies that the constraint (27) holds with equality for all $v>\underline{v}$, and it also trivially holds as an equality for $v=\underline{v}$.

We show next that the solution to the relaxed problem satisfies (28). Suppose not, ie,

$$\theta_{(2)}u_v\left(\theta_{(2)}\right)+\beta w_v\left(\theta_{(2)}\right)<\theta_{(2)}u_v\left(\theta_{(1)}\right)+\beta w_v\left(\theta_{(1)}\right).$$

Sum this equation with (27) which holds with equality, to obtain $u_v\left(\theta_{(2)}\right)<u_v\left(\theta_{(1)}\right)$, and thus $w_v\left(\theta_{(2)}\right)>w_v\left(\theta_{(1)}\right)>\underline{v}$. This implies that (33) holds with equality. But (32) and (33) with $\xi_v\geq 0$ then imply that $w_v\left(\theta_{(2)}\right)\leq w_v\left(\theta_{(1)}\right)$, a contradiction. Therefore the incentive constraint (28) is satisfied in the relaxed problem for all v. Moreover, if v is interior, the same reasoning with $\xi_v > 0$ implies that (28) is slack.

Summing the incentive constraints (27) and (28) implies $u_v\left(\theta_{(2)}\right)\geq u_v\left(\theta_{(1)}\right)$ and hence $w_v\left(\theta_{(1)}\right)\geq w_v\left(\theta_{(2)}\right)$. In particular, $u_v\left(\theta_{(2)}\right)$ is interior for all interior v, and (31) holds with equality. Now suppose $v>\underline{v}$. If $w_v\left(\theta_{(2)}\right)=\underline{v}$, then $w_v\left(\theta_{(1)}\right)>w_v\left(\theta_{(2)}\right)$. If $w_v\left(\theta_{(2)}\right)>\underline{v}$, then (33) holds with equality, and (32) with $\xi_v > 0$ yields $w_v\left(\theta_{(1)}\right)>w_v\left(\theta_{(2)}\right)$ by the strict concavity of K. We then obtain $u_v\left(\theta_{(1)}\right)<u_v\left(\theta_{(2)}\right)$ from (27). When v is interior, we saw that $u_v(\theta)$ is interior for all θ and therefore Benveniste–Scheinkman arguments (see the arguments leading to Eq. (24)), or using the envelope

theorem and summing (30) and (31), establish that $K'(v)=\mathbb{E}[-C'(u_v)]=-\gamma_v$. This equation also holds at the boundary $v=\underline{v}$ since in this case both sides of this expression are equal to zero. Therefore, Eqs. (32) and (33), assuming that $w_v(\theta_{(2)})$ is interior, imply that $-K'(w_v(\theta_{(1)}))>-K'(v)$ and $-K'(w_v(\theta_{(2)}))<-K'(v)$, respectively, so that $w_v(\theta_{(2)})<v<w_v(\theta_{(1)})$.

Next we show that the policy functions are continuous in v. The objective function in (23) is continuous and strictly concave on $\mathbb{U}^2\times\mathbb{V}^2$. Following the same steps as in the proof of Proposition 3, we restrict the optimization over $(\vec{u},\vec{w})$ to a compact set $\mathbb{X}\subset\mathbb{U}^2\times\mathbb{V}^2$. The constraint set $B(\cdot):\mathbb{V}\to\mathbb{X}$ defined in (22) is then a continuous, compact-valued, and convex-valued correspondence. Thus, by the Theorem of the Maximum (see, eg, Theorem 3.6 and Exercise 3.11a in Stokey et al., 1989), the function $(\vec{u}_v,\vec{w}_v)$ is continuous in v.

We now prove Eq. (29). We saw above that for all $v\geq\underline{v}$, $K'(v)=\mathbb{E}[-C'(u_v)]=-\gamma_v$. Moreover, when v is interior, summing the conditions (30) and (31) (which both hold with equality), and the conditions (32) and (33) (the former holds with equality, the latter does as well if $w_v(\theta_{(2)})>\underline{v}$) yields $\mathbb{E}[K'(w_v)]\leq\mathbb{E}[-C'(u_v)]$, with equality if $w_v(\theta_{(2)})$ is interior. Finally, this equation holds with equality if $v=\underline{v}$.

Note finally that from (30) and (31), we obtain that

$$-\theta_{(1)}K'(v)<C'(u_v(\theta_{(1)}))<-K'(v)<C'(u_v(\theta_{(2)}))<-\theta_{(2)}K'(v), \tag{34}$$

for all interior v. □

Proposition 5 highlights the main principle underlying the optimal provision of incentives in dynamic economies. Consider the unconstrained first-best allocation, given by

$$\frac{1}{\theta_{(1)}}C'\left(u_v^{\text{fb}}(\theta_{(1)})\right)=\frac{1}{\theta_{(2)}}C'\left(u_v^{\text{fb}}(\theta_{(2)})\right). \tag{35}$$

In this case the future continuation allocations are independent of the current realization of the shock: the social planner redistributes resources from agents with shock $\theta_{(1)}$ to agents with shock $\theta_{(2)}$. As we discussed above, this allocation is not incentive compatible when shocks are private information. To provide incentives, the social planner spreads out future promised utilities w_v, rewarding agents who report a lower shock and punishing those who report a higher shock. In exchange, a higher reported shock gives the agent a higher utility today. The bounds (34) imply

$$\frac{1}{\theta_{(2)}}C'(u_v(\theta_{(2)}))<\frac{1}{\theta_{(1)}}C'(u_v(\theta_{(1)})).$$

Therefore the spread in the current period utilities (or consumption allocations) is not as large as in the first best allocation. This reflects the fact that private information makes redistribution more costly. The resources are still being redistributed away from the $\theta_{(1)}$ type, but only up to the point where his incentive constraint binds.

Eq. (29) shows how the planner allocates the costs of providing incentives over time. Fluctuations in promised utilities are costly due to the concavity of the cost function, and it is optimal to smooth these costs over time. The best smoothing can be achieved if the forecast of future marginal costs of providing incentives based on the current information, $\mathbb{E}_t[K'(v_{t+s})]$, is equal to the current period marginal cost, $K'(v_t)$, so that $K'(v_t)$ is a random walk. This result is a manifestation of the same general principle that underlies consumption smoothing in the permanent income hypothesis (see Friedman, 1957; Hall, 1978) or tax smoothing in public finance (see Barro, 1979).

2.4.2 Long-Run Immiseration

Analogous to other environments with cost smoothing, the random walk nature of $K'(v_t)$ has powerful implications about the long-run properties of the solution.[i] To derive these implications, we first introduce the notion of *martingale* and the Martingale Convergence Theorem (see Billingsley, 2008, Section 35):

Definition 1 Let $X_t(\theta^t)$ be a random variable on the probability space $(\Omega, \mathcal{F}, \mathbb{P})$. The sequence $\{X_t, \mathcal{F}_t\}_{t=1,2,\ldots}$ is a *martingale* if:

(i) $\{\mathcal{F}_t\}_{t\geq 1}$ is an increasing sequence of σ-algebras,
(ii) X_t is measurable with respect to $\mathcal{F}_t$,
(iii) $\mathbb{E}_0[|X_t|] < \infty$, and
(iv) $\mathbb{E}_t[X_{t+1}] = X_t$ with probability 1.

A *submartingale* is defined as above except that the condition (iv) is replaced by $\mathbb{E}_t[X_{t+1}] \geq X_t$. Any martingale is a submartingale. We have the following important result (Theorem 35.5 in Billingsley, 2008):

Theorem 2 (Martingale Convergence Theorem) *Let $\{X_t\}_{t=0}^{\infty}$ be a submartingale. If $M \equiv \sup_t \mathbb{E}_0[|X_t|] < \infty$, then $X_t \to X$ with probability 1, where X is a random variable on $(\Omega, \mathcal{F}, \mathbb{P})$ satisfying $\mathbb{E}_0[|X|] \leq M$.*

To apply this result in our context, observe that the policy functions induce a law of motion for the distribution of promised utilities over time. For any probability distribution Ψ on $\mathbb{V}$, define an operator $\mathscr{T}$ as follows. For all Borel sets $A \subset \mathbb{V}$, let

$$(\mathscr{T}\Psi)(A) \equiv \int_{\mathbb{V}} \left[\sum_{\theta \in \Theta} \pi(\theta) \mathbb{I}_{\{w_v(\theta) \in A\}} \right] \Psi(dv). \tag{36}$$

$\mathscr{T}\Psi$ defines another probability distribution on $\mathbb{V}$. This operator allows us to study the dynamics of the distribution of lifetime utilities in our economy. In particular, let Ψ_0 be a

[i] See Chamberlain and Wilson (2000) for an analogous result in consumption smoothing models, and Aiyagari et al. (2002) for tax smoothing.

probability distribution on $\mathbb{V}$ that assigns probability 1 to v_0 and define $\boldsymbol{\Psi}_t$ recursively as $\boldsymbol{\Psi}_t = \mathscr{T}\boldsymbol{\Psi}_{t-1}$. In other words, initially in period 0 everyone is identical with the same lifetime utility v_0. Over time idiosyncratic shocks lead to inequality in lifetime promises captured by the distribution $\boldsymbol{\Psi}_t$ in period t. A distribution $\boldsymbol{\Psi}$ is *invariant* if it satisfies $\boldsymbol{\Psi} = \mathscr{T}\boldsymbol{\Psi}$.
