For a unit investment at date 0, the bank offers a demand deposit which pays either r_1 at date 1 or r_2 at date 2. This effectively offers a gross rate of return r_2/r_1 between dates 1 and 2 which is equal to the exogenous outside option (such as government bonds) for depositors between these dates. Essentially, the bank offers one period deposits which equal the interest rate on the outside option. We will assume that depositors are sufficiently risk averse that they would like the banking system to supply one period deposits that are riskless. Hence, when we consider interventions they will be designed to deliver as this as the only possible equilibrium.

The residual claim after deposits are paid is limited liability equity retained by the banker. All equity payments are made at date 2.[e]

The bank can invest in two assets with constant returns to scale. One is a liquid asset (which we will interchangeably refer to as the safe asset) that returns $R_1>0$ per unit invested in the previous period. The other is an illiquid asset for which a unit investment at date 0 returns at date 2 an amount that exceeds the return from rolling over liquid assets ($R_2>R_1{}^*R_1$). The illiquid asset (which we will interchangeably refer to a loan)

[e] We could introduce another incentive problem for the banker to motive a minimum value of equity at all dates and states, but for now the bank will operate efficiently as long as equity remains positive in equilibrium.

can be liquidated for θR_2 date 1, where $\theta R_2 < R_1$ and $\theta \geq 0$. These restrictions imply that when the bank knows it must make a payment at date 1, it is always more efficient to do that by investing in the safe asset rather than planning to liquidate the loan.

We also assume that banking is profitable even if the bank invests exclusively in the liquid asset, so that $r_1 \leq R_1$ and $r_2 \leq R_1^2$. This is a sufficient condition to guarantee that requiring excess liquidity will not make the bank insolvent (though it still will reduce the efficiency of investment). In addition, we assume that bank profits from investing in illiquid assets when depositors hold their deposits for two periods (borrowing short-term repeatedly to fund long-term illiquid investment) is greater than from investing in liquid assets when depositors hold their deposits for only one period (or $\frac{r_2}{R_2} < \frac{r_1}{R_1}$). This implies that a bank is most profitable when in can finance loans returning R_2 with deposits for two periods at cost r_2 (as compared with financing liquid assets for one period). This second assumption is used only to obtain some results on optimal liquidity holdings.

There are many possible reasons to presume that the illiquid asset can be liquidated for only θR_2. For instance, in DD liquidation can be thought of as a nontradable production technology. Alternatively it could reflect the bank's lending skills, implying that it would be worth less to a buyer than to the bank because (compared to the bank) the buyer would be able to collect less from a borrower, as in Diamond and Rajan (2001). Nothing in our analysis hinges on why this discount exists, though we do insist that it is operative for everyone in the economy including a potential lender of last resort (LOLR). Also, our assumption that θ is a constant implies that we are not modeling a situation where the sale price depends only on the amount of remaining liquidity held by potential buyers (as in Bhattacharya and Gale, 1987; Allen and Gale, 1997; and Diamond, 1997).

For fundamental reasons, a fraction t_s of depositors want to withdraw at date 1 and $1 - t_s$ want to withdraw at date 2 in state s. The realizations of t_s are bounded below by $\underline{t} \geq 0$ and above by $\bar{t} \leq 1$. The banker will know the realization of t_s when the asset composition choice is made. This assumption is meant to capture the fact that banks have superior information about their customers. Indeed, some early theories of banking supposed that the advantage of tying lending and deposit making was that by watching a customer's checking account activities a bank could gauge that customer's creditworthiness (Black, 1975).

Mester et al. (2007) provide direct evidence supporting the assumption that banks can learn about customer credit needs by monitoring transactions accounts. Drawing on a unique data set from a Canadian bank, they demonstrate the bank is able to infer changes in the value of borrowers' collateral that is posted against commercial loans by tracking flows into and out of the borrowers' transaction accounts. At this bank, they document that the number of prior borrowings in excess of collateral is an important predictor of credit downgrades and loan write-downs. Most importantly, the bank uses this information in making credit decisions. Loan reviews become longer and more frequent for borrowers with deteriorating collateral.[f] In what follows, we make the simplifying assumption t_s is always known exactly by the bank, but the analysis also goes through so long as the bank is simply better informed than the depositors and the regulator.

To understand agents' incentives, note that if the ex-post state is s and there is not a run, a fraction $f_1 = t_s$ will withdraw r_1 each, requiring $r_1 t_s$ in date 1 resources, and this will leave a fraction $1 - t_s$ depositors at date 2 who are collectively owed $r_2(1 - t_s)$ (in date 2 resources). If we let α_s be the fraction of the bank's portfolio that is invested in the liquid asset and $(1 - \alpha_s)$ be the portion invested in the illiquid one, then the bank's profits, and hence its value of equity in general will be

$$\text{Value of equity} = \left\{ \begin{array}{ll} (1-\alpha_s)R_2 + (\alpha_s R_1 - f_1 r_1)R_1 - (1-f_1)r_2 & \text{if } f_1 r_1 \leq \alpha_s R_1 \\ \text{Max}\left\{0, \left(1 - \alpha_s - \dfrac{(f_1 r_1 - \alpha_s R_1)}{\theta R_2}\right) R_2 - (1-f_1)r_2\right\} & \text{if } f_1 r > \alpha_s R \end{array} \right\} \tag{1}$$

Because we are assuming that the bank knows t_s, its own self-interest will lead it to make sure to always have enough invested in the liquid asset to cover these withdrawals. So absent a run, the profits are very intuitive and easy to understand. The first term in Eq. (1) when $f_1 r_1 \leq \alpha_s R_1$ represents the returns from the illiquid investment, the second reflects the spread on the safe asset relative to deposits (recognizing that any leftover funds are rolled over), and the third term reflects the funding costs of the remaining two period deposits. When $f_1 r_1 > \alpha_s R_1$, the bank needs to pay out more than its liquid assets are worth at date 1. To honor its promises, the bank must liquidate illiquid assets worth θR_2 each, implying that each unit of withdrawn in excess of $\alpha_s R_1$ removes $(1/\theta R_2)$ loans from the bank's balance sheet. These loans would each be worth R_2 at date 2. For a bank in this situation that can honor all early and late withdrawals the residual profits go to the banker (otherwise the bank is insolvent). Given our assumptions about interest rates and liquidation discounts, if actual withdraws, f_1, were known, the bank would choose to hold enough liquid assets to avoid needing to liquidate any loans. We know that at all times, even absent a run in state s, $f_1 \geq t_s$. As a result, the bank will always have an incentive to choose $\alpha_s \geq \dfrac{t_s r_1}{R_1} \equiv \alpha_s^{\text{AIC}}$. As a result, we refer to α_s^{AIC} as the *automatically incentive compatible* liquidity holding of the bank.

It is interesting to consider what happens when a run is possible. We suppose that a fixed number Δ of the patient depositors are highly likely to see a sunspot. All depositors (and the bank) know Δ and upon seeing the sunspot they must decide whether they believe that the others who see it will decide withdraw their funds early. As mentioned

[f] Norden and Weber (2010) also find that credit line usage, credit limit violations, and cash inflows into checking accounts are unusual in the periods preceding defaults by small businesses and individuals in Germany.

earlier, the sunspot is intended to stand in for general fears about the solvency of the bank, so the inference problem relates to their conjecture about whether others investors might panic. In that case, they have to decide whether to join the run.[g] So in general $f_1 > t_s$ is possible.

If the bank will be insolvent with a fraction of withdrawals of any amount less than $t_s + \Delta$, then we assume each depositor who sees then sunspot will withdraw and $f_1 = t_s + \Delta$. This will give zero to all who do not withdraw, and the goal of bank or its regulator is to prevent this outcome from ever being a Nash equilibrium. We will refer to a bank as unstable if its asset holdings admit the possibility of a run. Alternatively, we refer to a bank as stable if its asset holding eliminate the possibility of a run.

In addition, we will assume that if the bank is exactly solvent at $f_1 = t_s + \Delta$, no depositor who does not need to withdraw (and only sees the sunspot) will withdraw. This condition establishes exactly how much liquidity is needed to deter a run (as opposed to providing a floor which must be exceeded). We define the *minimum stable amount of liquidity holdings*, α_s^{Stable} as the minimum fraction of liquid assets in state s which eliminate the possibility of a run. This implies that a bank with $\alpha_s \geq \alpha_s^{\text{Stable}}$ will be run-free.

3.1 Complete Information

We presume that depositors desire run-free bank deposits. As a first benchmark, suppose that depositors know all of the choices and information which banks know, and thus observe α_s, Δ, and t_s. In this case, the need to attract deposits will force the bank to make itself run-free. If, given depositor knowledge of α_s, Δ, and t_s, the bank would remain solvent in a run, then it never is individually rational to react to the sunspot, and there will be no runs. Proposition 1 shows that it is possible that the bank will not need to distort its holding of liquidity to implement run-free banking.

Proposition 1

If the bank chooses $\alpha_s^{\text{AIC}} = \dfrac{t_s r_1}{R_1}$, and if

$$t_s + \Delta_s < \frac{t_s r_1 + \left(1 - \dfrac{t_s r_1}{R_1}\right)\theta R_2 - r_2\theta}{r_1 - r_2\theta} \left(\text{equivalently } \theta \geq \frac{\Delta r_1 R_1}{R_2(R_1 - r_1 t_s) - r_2 R_1(1 - t_s - \Delta)}\right),$$

investors will not run and the bank is stable with $\alpha_s^{\text{AIC}} = \dfrac{t_s r_1}{R_1}$.

[g] Uhlig (2010) shows that partial bank runs in a DD style model can arise if there other types of dispersion in agents' beliefs. For instance, if depositors are highly uncertainty averse and differ in their estimates of θ that heterogeneity can lead to a partial bank run in his setup.

Proof

If $f_1 r > \alpha R_1$, the bank's equity is positive when $\left(1-\alpha_s - \frac{(f_1 r_1 - \alpha_s R_1)}{\theta R_2}\right) R_2 - (1-f_1) r_2 \geq 0.$

So, when the automatically incentive compatible level of initial liquidity α^{AIC} is chosen $\left(\alpha_s^{\mathrm{AIC}} = \frac{t_s r_1}{R_1}\right)$, the value of equity is decreasing in f_1 and equal zero when $f_1^* = \frac{\frac{t_s r_1}{R_1} R_1 + \left(1 - \frac{t_s r_1}{R_1}\right) \theta R_2 - r_2 \theta}{r_1 - r_2 \theta}$. Therefore, if $t_s + \Delta$ is less than f_1^*, then the depositors always know the bank will be solvent and there is no Nash equilibrium with a run. □

The proposition simply states the condition when the bank is sufficiently profitable and liquid, so that by holding only enough of the liquid asset to service fundamental withdrawals, the bank will nonetheless be solvent in the event of a run. Under these conditions, $\alpha_s^{\mathrm{AIC}} \geq \alpha_s^{\mathrm{Stable}}$.

When the conditions for Proposition 1 fail, because loans are quite illiquid or the bank is not very profitable, then to deter runs, a bank must hold more liquidity than is needed to meet normal withdrawals. One useful case to contemplate is when loans are totally illiquid ($\theta = 0$). In this case, the bank must always hold enough liquidity to fully finance the run because there is no other way to get access to liquidity or $\alpha_s^{\mathrm{Stable}} = (t_s + \Delta)\frac{r_1}{R_1} > \alpha_s^{\mathrm{AIC}} = \frac{t_s r_1}{R_1}$. Therefore, the bank must always hold more liquidity than is needed for normal withdrawals in order to deter a run. More generally, whenever

$$t_s + \Delta > \frac{t_s r_1 + \left(1 - \frac{t_s r_1}{R_1}\right) \theta R_2 - r_2 \theta}{r_1 - r_2 \theta} \quad \text{or } \theta < \frac{\Delta r_1 R_1}{R_2 (R_1 - r_1 t_s) - r_2 R_1 (1 - t_s - \Delta)}$$

then the bank must increase α_s to $\alpha_s^{\mathrm{stable}}$ to definitely deter the run, where $\alpha_s^{\mathrm{stable}}$ is such that $t_s + \Delta = \frac{\alpha_s^{\mathrm{stable}} R_1 + \left(1 - \alpha_s^{\mathrm{stable}}\right) \theta R_2 - r_2 \theta}{r_1 - r_2 \theta}$. This yields

$$\alpha_s^{\mathrm{stable}} = \frac{(t_s + \Delta) r_1 + \theta((1 - t_s - \Delta) r_2 - R_2)}{R_1 - \theta R_2}.$$

So when it is sufficiently illiquid, merely preparing to service fundamental withdrawals will not always be enough to deter a run.

This threshold tells us how much liquidity is needed when there is full information such that all variables including t_s are known and all parties understand the bank's incentives. Under the conditions of Proposition 1, the bank will choose $\alpha_s = \frac{t_s r_1}{R_1}$ and no unused liquidity is held from dates 1 to 2. Because depositors might choose to run and the incentive for this must be removed, this will not be enough liquidity when the conditions for Proposition 1 do not hold. To always deter a possible run, the bank will have to hold $\alpha_s = \alpha_s^{\text{Stable}} > \alpha_s^{\text{AIC}}$. This will require that some unused liquidity, $\left(\alpha_s^{\text{Stable}} - \alpha_s^{\text{AIC}}\right) R_1 \equiv U(t_s) > 0$, to be held from date 1 to 2, after the normal withdraws are met at date 1. If the bank is free to use all of this unused liquidity if a run should occur, then depositors can see that the liquidity is present and will never choose to run. Once the run is deterred, the liquidity will be in excess of what is needed. This is the simplest example of the benefits of holding unused liquidity or leaving extra taxicabs at the train station.

With full information available to all parties, market forces will produce run-free banking. Alternatively, suppose the depositors do not observe t_s or α_s, but the bank and a regulator do. Then the following arrangement is possible, but only by regulation.

Proposition 2

With full information available to the bank or regulators, a bank (or a regulator) seeking to deter runs will choose $\alpha_s^* = \max\left\{\alpha_s^{\text{AIC}}, \alpha_s^{\text{Stable}}\right\}$.

Proof

The bank is automatically stable when $\frac{r_1 t_s}{R_1} \geq \alpha_s^{\text{Stable}}$ so the regulator would always want to maximize lending and allow the bank to follow its self-interest and select that level $\left(\frac{r_1 t_s}{R_1}\right)$ of liquidity. Otherwise, the minimum amount of liquidity that is needed is α_s^{Stable}. □

More generally, for arbitrary anticipated withdrawals of t_s, α_s^{AIC} and α_s^{Stable} will differ and if liquidity, θ, is not too high or too low, and their relationship will be similar to what is shown in Fig. 2. For very low levels of anticipated withdrawals, where the condition in

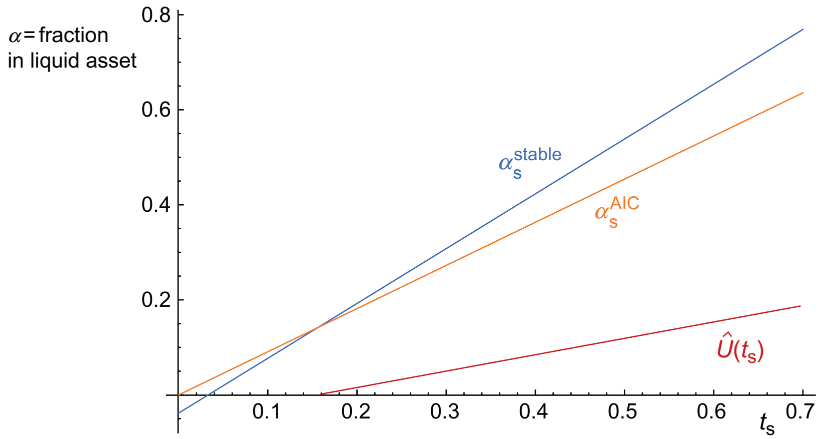

Fig. 2 Comparison of automatically incentive compatible and stable liquidity choices and the implied amount of unused liquidity held from date 1 to 2. *Note*: parameter values are $\Delta = 0.3$, $\theta = 0.5$, $R_1 = 1.1$, $R_2 = 1.33$, $r_1 = r_2 = 1$.

Proposition 1 holds, the bank is sufficiently solvent that chooses to hold more ex-ante liquidity than is need to be stable, so that runs are impossible. At some point, however, this ceases to be true and the amount needed to just be solvent in a run is higher than the bank would hold out of pure self-interest. So in this case run deterrence would require a higher level of initial liquidity. This observation will be helpful in understanding some of the regulatory trade-offs that we subsequently explore.

Note that because some liquidity must be unused, it will appear that there is an unneeded amount of liquidity. With full information, this amount will serve to deter runs and will be chosen at date 0 with all knowing the amount of normal withdrawals at date 1 t_s. If more than a fraction t_s were to withdraw at date 1, the unused liquidity could be used because all would know that a run was occurring. The bank, or regulator acting for depositors, could use liquidity holdings to deter runs in the efficient way which maximizes lending. Because depositors always desire run-free deposits, with full information, banks would be forced to hold the extra unused liquidity because otherwise no deposits would be attracted.

To summarize, with complete information, a bank will be forced to hold enough liquidity to deter runs, and its desire to maximize profits will assure that it holds no more than this amount. The next section explains why the complete information benchmark may not be very informative. Once the possibility of incomplete information is considered, we can see that arriving at run-free banking can be challenging.

3.2 Incomplete Information: Is It a Problem?

While the full-information benchmark is helpful, we think it is too extreme to be realistic. Banks disclosures may be very difficult to interpret. We describe a few compelling reasons to doubt that simply disclosing some information about liquidity holdings will make depositors (or regulators) well informed about all of these quantities. This suggests that disclosure of such information may not, by itself, force a bank to make the decisions, which they would make under complete information.

There is one important situation where incomplete information is not necessarily a problem. Even if there is no disclosure of asset holdings, depositors, who know Δ and observe a such t_s the conditions of Proposition 1 are satisfied, will know that the bank's choice will eliminate run risk in state s, because $\alpha_s^{\text{AIC}} = \dfrac{t_s r_1}{R_1} \geq \alpha_s^{\text{Stable}}$ (the bank is automatically stable in this case). If this was satisfied for all states, s, a bank would always choose a level of liquid asset holdings which always results in stability even if no one could verify those holdings and if no depositor knew the state s. Whenever this condition is not universally satisfied, the bank's incentives to hold liquidity will depend on the information available to depositors (or regulators) and on the incentives provided to the bank.

We believe that in most cases a bank's liquidity choice is not always automatically stable. This suggests that some forms of disclosure or regulation will influence its choice of liquidity. We describe two types of reasons that simple disclosure of liquidity is difficult to interpret. First, if disclosure (or a regulatory requirement) regarding liquidity only applies on some dates (such as the end of an accounting period), the bank can distort the disclosure. Second, even if a liquidity disclosure (or requirement) is on all dates, it is plausible that the bank knows much more about its customers liquidity needs than anyone else, which makes it very difficult to determine if a given level of liquidity is sufficient to make the bank stable and run-free.

3.2.1 Problems with the Periodic Disclosure of Liquidity

One important problem facing depositors is the difficulty in interpreting the kind of accounting data that must be parsed in order to decide whether to join a run. Disclosures that are made on liquidity positions typically occur with a delay and are periodic (such as at the end of a quarter or a fiscal year). The inference problem for depositors can be compounded by the temptation for banks to engage in window dressing of their accounting information.

One eye-opening example of the problem, analyzed in Munyan (2015), is the tendency of (mostly) European banks to disguise borrowing around quarter-end dates. As Munyan (2015) explains, many non-US banks are required to report their accounting information that forms the basis various regulatory ratios only on the last day of the quarter. In the United States, banks also have to show average daily ratios for critical balance sheet variables which caps the gains from manipulating end-of-quarter data. The non-US banks apparently sell some safe assets just before the end of the quarter and then buy them back shortly afterwards. This transaction allows them to report lower leverage across the quarter-end date.

The ingenious aspect of Munyan's analysis is using detailed data on the tri-party repo market to infer this behavior. He explains how the banks' would normally be borrowing in this market to fund these assets. Because they step back only briefly, their window dressing shows up in reduced repo volumes. Fig. 3 (reproduced from fig. 1 of Munyan) shows the raw data on repo volumes with the quarter-end dates indicated with dashed vertical lines. The pattern is so strong that it is clearly evident from inspection. Munyan's econometric estimates suggest that the non-US banks trim their end of quarter borrowing by about $170 billion, with the vast majority of the decline coming from European banks.

This problem of the potential window dressing of periodic disclosures is relevant to measuring bank liquidity, due to the complicated nature of the kind of liquidity information that needs to be inferred. Cetina and Gleason (2015) provide a series of examples about how the LCR is vulnerable to this type of manipulation. Some of the problems come because of the ability to use repurchase agreements (and reverse repurchase

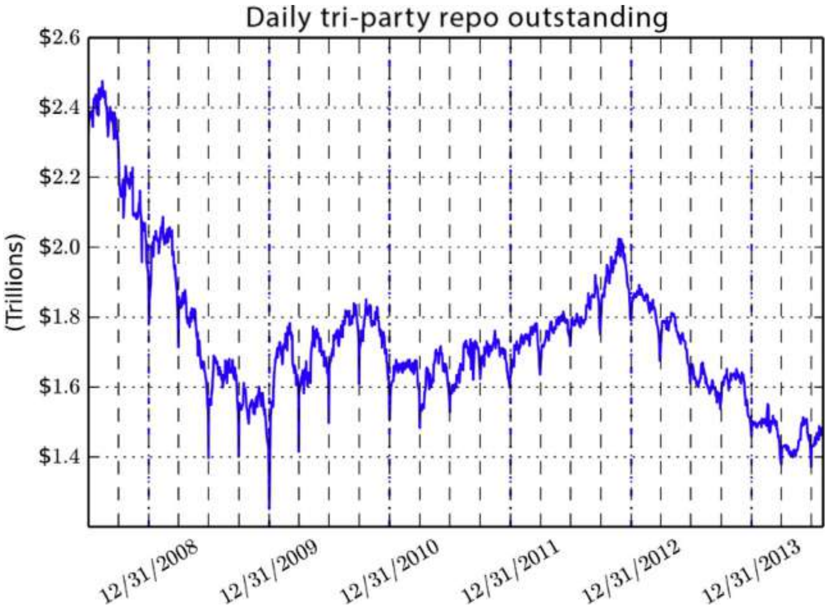

Fig. 3 Tri-party repo volumes outstanding from Munyan (2015).

agreements) to move the timing of cash flows. But the rules also distinguish between the assumed levels of liquidity of different asset class and some types of transactions can alter both the numerator and denominator of a ratio in different ways. Moreover, the computations in different jurisdictions vary which further complicates comparisons.

In summary, this possibility for window dressing implies that liquidity disclosures and regulations should hold on all dates rather than being applied periodically. In our model, this will mean that it may be difficult to credibly disclose α_s, the initial holding of liquidity, because this could be invested in illiquid loans after the disclosure. Requiring liquidity to be held on all dates (after date 1 in our model) will of course limit its use to meet withdraws of deposits. This again brings back the problem of not allowing the last taxicab to leave the station. In addition, disclosure or regulation of complicated liquidity holdings may require careful auditing (for disclosure) or supervision (for regulation).

3.2.2 Liquidity Disclosures Are Difficult to Interpret

A second challenge facing depositors and regulators in interpreting disclosed information is placing it in appropriate context. Suppose all parties are truthfully told the level of liquid asset holdings in the banking system at a given date (or even on every date). Judging whether these are adequate to service impending withdrawals requires knowledge of how far along a potential run might be on that date and how many normal withdrawals are anticipated. If a bank has a small amount of liquidity after its normal withdraws (of $t_s r_1$ in state s), this is very different than if normal withdrawals have not yet occurred. It is possible that very little additional liquidity would be needed if most potential withdrawals have already occurred. How could banks credibly communicate such information? The next section provides a model of this, based on the bank's private information about the normal level of withdrawals, t_s.

3.2.3 A Bank Has Private Information About Needed Liquidity

Before turning to the details of the model, it is helpful to provide some intuition about how private information possessed by the bank interacts with the incentives of depositors to run. Similar problems arise at both date 0 and date 1 in the model, but we will describe them in turn. One reason for separating out the discussion is because in our framework the most natural analogs to the Basel-style regulation can be thought of in terms what they imply as of different dates.

If there is no way to communicate what the bank knows, and it is not automatically stable, then disclosing a level of liquidity at date 0, α_s, which would make the bank stable only in some states of nature, t_s, will not be adequate completely eliminate runs. In these cases, depositors will have two reasons to be worried. First, in the states of nature where it would not be stable, a run would cause the bank to fail and thus would be self-fulfilling, leading to losses by depositors who did not run.

Second, because depositors do not know t_s, a depositor (whom we assume to be very risk averse) who sees a sunspot and worries about a run will always withdraw rather than face losses if the unknown state turns out to be one that makes the bank fail. As a result, a level of liquidity disclosure, which is not sufficient to makes a bank run-free for all levels of t_s, will lead to runs whenever they are feared, even for the levels of t_s where this does not cause bank failure. In the next section, we will explain why an NSFR approach to liquidity regulation (which can be mapped into restrictions on date 0 liquidity choices) can be susceptible to such concerns.

Suppose that a positive level of liquidity held at date 1, after withdrawals from a fraction f_1 of deposits, is regulated and required. It can also be very difficult to interpret this level when the normal level of withdrawals, t_s, is unknown. Any liquidity which must be held from date 1 to date 2 is not available to service withdrawals at date 1. From Proposition 2, we would like to require a level of unused liquidity $U(t_s)$ that coincides with the amount specified under full information. This amount would deter runs in state s by being available to be completely used to meet the withdrawals in a run from a fraction $t_s + \Delta$ of depositors.

When depositors must guess about the level of normal withdrawals, merely observing the actual outflows in period 1 is not necessarily enough to assure them about the safety of their deposits. To see the problem consider two levels of normal withdrawals, High and Low such that $t_{s=\text{High}} = t_{s=\text{Low}} + \Delta$. A positive level of liquidity which must be held if $f_1 = t_{s=\text{high}}$ cannot be released to meet with the same number of withdrawals during a

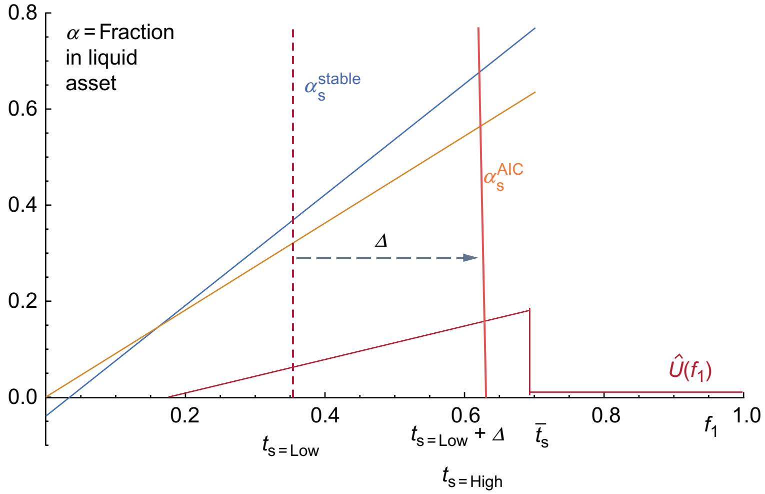

Fig. 4 Inability to distinguish between runs and large fundamental withdrawals.

run with $f_1 = t_{s=\text{low}} + \Delta$. This is shown in Fig. 4. Therefore, the full-information level of liquidity required at date 1 cannot be implemented without a way to learn the bank's information about the normal level of withdrawals, t_s. We will show how this is related to the implementation of the LCR approach to regulating liquidity in the next section.

For the balance of this chapter, we assume that liquidity on date 0 and date 1 can be measured (for example by a regulator) but that the bank has private information about the normal levels of withdrawals, t_s. This information friction alone is sufficient to study many interesting issues in the regulation of liquidity needed to make banks run-free. If the regulator cannot learn this information, it will constrain the efficiency of regulation.

4. BASEL-STYLE REGULATORY OPTIONS

Based on these observations about the efficacy of disclosure, for the remainder of our analysis we assume that liquidity on date 0 and date 1 can be measured (for example by a regulator), but we want understand the limitations that arise if the bank has private information about the normal levels of withdrawals, t_s. This information friction alone is sufficient to study many interesting issues in the regulation of liquidity needed to make banks run-free. To see how things unfold, we will begin again with a case where the regulator can also observe the state and then contrast that with what happens if the regulator cannot learn this information. Throughout we continue to assume that depositors are sufficiently risk averse so that run-free banking is social optimum which we seek to implement.

We consider two potential approaches that a regulator could pursue. These are inspired by the kinds of regulations that are proposed as part of Basel III. We suppose that she can credibly certify that the bank has some level of the liquid asset present (as a percentage of deposits). One option is to report on this ratio at the time when the liquid assets are acquired at time zero. This would amount to regulating α, and this is similar in spirit the NSFR. The NSFR requires "banks to maintain a stable funding profile in relation to the composition of their assets and off-balance sheet activities" (Basel Committee on Bank Supervision 2014). Loosely speaking, the NSFR can be thought of as forcing banks to match long-term assets with long-term funding. Our interpretation of this requirement is that the bank is free to violate the requirement temporarily in the future, so it is not always a binding restriction. As a result, it is very much like a requirement that the bank chooses a level of liquid holdings at date 0, α_s. From Proposition 2, we know that with complete information a regulation that is bank and state specific can be effective in delivering run-free banking, the question we ask now is what happens in other situations.

Alternatively, a regulator could insist that the bank will always have a certain amount of liquid assets relative to deposits at all times, including after any withdrawals. This kind of regulation is more like the LCR. The LCR requires "that banks have an adequate stock of unencumbered high-quality liquid assets that can be converted easily and immediately in private markets into cash to meet their liquidity needs for a 30 calendar day liquidity stress scenario" (Basel Committee on Bank Supervision, 2013a).

4.1 An LCR Regulation

Ultimately we are interested in understanding how the LCR works when the regulator cannot learn the bank's information about t_s. As a first step, we consider an LCR regulation where the state is known by the regulator and where the regulation says the bank must always (on both dates) hold a fraction ρ_s of deposits in liquid assets in state s. At date, 1 the bank has promised depositors $r_1(1-f_1)$. The important consequence of this is that regulation would even apply after first period withdrawals (f_1), when the bank would have to have a minimum level of safe assets equal to $\rho_s r_1(1-f_1)$.

If the bank is subject to this requirement, and it conjectures that f_1 depositors will withdraw in state s, then its optimal initial level of safe assets (α_s) will satisfy $\alpha_s R_1 = f_1 r_1 + \rho_s r_1(1-f_1)$. This choice follows trivially because it is never efficient to make loans with intention of liquidating them, and this is the minimum amount of liquid assets that will satisfy the regulation. Accordingly, the bank knows that the depositors will know this (and also understand that the bank is trying to maximize its profits). The residual value of the bank's equity will be:

$$E_2(f_1;\rho)=\begin{cases}(\alpha_s R_1-f_1r_1)R_1+(1-\alpha_s)R_2-(1-f_1)r_2 & \text{if } f_1<\dfrac{\alpha_s R_1-r_1\rho_s}{r_1(1-\rho_s)},\\ \left((1-\alpha_s)-\dfrac{f_1r_1-\alpha_s R_1+\rho_s(1-f_1)}{\theta R_2}\right)R_2 & \text{if } f_1\geq\dfrac{\alpha_s R_1-r_1\rho_s}{r_1(1-\rho_s)} \text{ and}\\ +(\rho_s R_1-r_2)(1-f_1) & \text{if } f_1\leq\dfrac{\alpha_s R_1+(1-\alpha_s)\theta R_2-\rho_s r_1(1-\theta R_1)-r_2\theta}{r_1-\rho_s r_1(1-\theta R_1)-r_2\theta},\\ 0 & \text{if } f_1>\dfrac{\alpha_s R_1+(1-\alpha_s)\theta R_2-\rho_s r_1(1-\theta R_1)-r_2\theta}{r_1-\rho_s r_1(1-\theta R_1)-r_2\theta}.\end{cases}$$

Each branch of the expression is intuitive. The top branch shows the profits that accrue when withdrawals are small enough that the bank can pay all depositors without liquidating any loans and still satisfy the LCR; this will be the case whenever $f_1r_1<\alpha_s R_1+\rho_s r_1(1-f_1)$, which when rearranged is the threshold condition that is listed. In this case, the bank has two sources of revenue, one coming from rolling over the residual safe assets after paying early depositors and the other coming from the return on the loans. The date 2 depositors must be paid and the banker keeps everything that is left.

The second branch represents a case where the bank must liquidate some loans to service the early withdrawals. In this case, the bank liquidates just enough loans so that after the deposits are paid, it exactly satisfies the LCR. The same two sources of revenues and deposit cost are present, but the formula adjusts for the liquidations. Recall that each loan that is liquidated yields θR_2 at date 1. Hence rather than having the revenue from the full set of loans $(1-\alpha_s)$ that were initially granted, the bank only receives returns on the portion that remains after some loans that were liquidated in order to pay the depositors and comply with the LCR. Because the LCR is binding from date 1 until date 2, the bank has exactly $\rho_s r_1(1-f_1)$ of the safe asset that is rolled over and that money can also be used to pay the remaining patient depositors. Notice that if the loans are totally illiquid and $\theta=0$, then there is no possibility of this second branch (where free liquidity in excess of the coverage ratio is fully used but the bank remains solvent).

The third branch obtains when the level of withdrawals is sufficiently large that the bank becomes insolvent. Insolvency occurs when $f_1>\dfrac{\alpha_s R_1+(1-\alpha_s)\theta R_2-\rho_s r_1(1-\theta R_1)-r_2\theta}{r_1-\rho_s r_1(1-\theta R_1)-r_2\theta}$ because at that point the depositors can see that the liquidations do not generate enough to fully cover the promised repayments.

The bank knows that depositors consider all these possibilities in trying to infer what the bank will do. If the coverage ratio can be set such that the bank chooses to hold sufficient liquidity to remain solvent during a run, then runs will be deterred. Proposition 3 examines the outcomes if the bank faces a state-contingent LCR in state s, $\rho_s\in[0,1]$.

Proposition 3

There is an LCR in state s, $\rho_s \in [0, 1]$ which will deter runs. When ρ_s is not zero or one it satisfies:

$$t_s + \Delta = \frac{\frac{t_s r_1 + \rho_s r_1(1-t_s)}{R_1} R_1 + \left(1 - \frac{t_s r_1 + \rho_s r_1(1-t_s)}{R_1}\right)\theta R_2 - \rho_s r_1(1-\theta R_1) - r_2\theta}{r_1 - \rho_s r_1(1-\theta R_1) - r_2\theta},$$

implying that

$$\rho_s = \frac{\theta R_1((1-t_s-\Delta)r_2 - R_2) + r_1(\Delta R_1 + t_s\theta R_2)}{r_1(\Delta R_1 + (1-t_s-\Delta)\theta R_1^2 - (1-t_s)\theta R_2)}.$$

A regulator who knows t_s can choose ρ_s so as to deter runs.

Proof

If the bank is run-free in state s and $f_1 = t_s$, then it will pick α_s to satisfy:

$$\alpha_s R_1 = t_s r_1 + \rho_s r_1(1-t_s)$$

Because the bank will be solvent for all $f_1 \leq \bar{f}_1(\rho_s) = \dfrac{\alpha_s R_1 + (1-\alpha_s)\theta R_2 - \rho_s r_1(1-\theta R_1) - r_2\theta}{r_1 - \rho_s r_1(1-\theta R_1) - r_2\theta}$, the regulator can pick ρ_s such that it delivers $t_s + \Delta \leq \bar{f}_1(\rho_s)$ and $\alpha_s = \dfrac{t_s r_1 + \rho_s r_1(1-t_s)}{R_1}$. If $t_s + \Delta \leq \bar{f}(\rho_s)$ at $\rho_s = 0$, then $\rho_s = 0$ suffices. If instead $t_s + \Delta > \bar{f}(\rho_s)$ at $\rho_s = 0$, then either a $\rho_s < 1$ solves (2) as an equality or if not then we will see that $\rho_s = 1$ satisfies (2):

$$t_s + \Delta \leq \frac{\frac{t_s r_1 + \rho_s(1-t_s)}{R_1} R_1 + \left(1 - \frac{t_s r_1 + \rho_s(r_1 1-t_s)}{R_1}\right)\theta R_2 - \rho_s r_1(1-\theta R_1) - r_2\theta}{r_1 - \rho_s r_1(1-\theta R_1) - r_2\theta} \tag{2}$$

From our assumptions that $r_1 \leq R_1$ and $r_2 \leq R_1^2$, the bank is solvent with $\rho_s = 1$ and there will always be a value of ρ between 0 and 1 which satisfies (2). If the bank is not solvent given a run with $\rho_s = 0$, then either a $\rho_s \in (0, 1)$ exists where (2) holds with equality or no $\rho_s < 1$ keeps the bank solvent and then lowest ρ_s is given by $\rho_s = \min\left[1, \dfrac{\theta R_1((1-t_s-\Delta)r_2 - R_2) + r_1(\Delta R_1 + t_s\theta R_2)}{r_1(\Delta R_1 + (1-t_s-\Delta)\theta R_1^2 - (1-t_s)\theta R_2)}\right]$. □

If the regulator chooses an appropriate level of $\rho_s \leq 1$ knowing t_s, then depositors can be sure that the bank is stable and will never want to join a run, even though they cannot observe or interpret the level of liquidity at any instant. The intuition for why the regulation (which is a combination of a rule which can be enforced and credibly auditing) is sufficient to foreclose a run, even when the bank's liquidity choice is unobservable to depositors, is straightforward. The LCR forces the bank to invest in more liquid assets than it would voluntarily prefer to hold and the depositors know that the regulator is doing this to try to prevent runs. The bank's own self-interest continues to insure that it plans to always hold enough liquid assets to cover its anticipated fundamental withdrawals, and we are assuming that it can do that perfectly. Consequently, knowing that the extra liquidity cannot be avoided removes the incentive to run.

Importantly, once the run has been prevented the liquidity still will have to remain on the bank's balance sheet. So, under these assumptions it is beneficial to force the last taxi cab to always remain at the train station.

There are several special cases where there is an interesting corner solution. If $\theta = 0$, then for all values of t_s, $\rho_s = \dfrac{r_1(\Delta R_1)}{r_1 \Delta R_1} = 1$ and as a result $\alpha_s = \dfrac{t_s r_1 + r_1(1-t_s)}{R_1} = \dfrac{r_1}{R_1}$. This implies that the bank must invest in a sufficient fraction of liquid assets to finance a withdrawal of 100% of deposits. This is not surprising because in this case the loans are so illiquid as to have no value during a run.

Alternatively, if the asset is not totally illiquid, $\theta > 0$, but $r_1 = R_1 = 1$, then the bank earns no spread between its deposits and its liquid asset holdings and there exists a possible value of t_s such that a complete run is possible, $t_s + \Delta = 1$, then for that value of t_s

$$\rho_s = \frac{\theta R_1((1-t_s-\Delta)r_2 - R_2) + r_1(\Delta R_1 + t_s \theta R_2)}{r_1(\Delta R_1 + (1-t_s-\Delta)\theta R_1^2 - (1-t_s)\theta R_2)} = \frac{\Delta - (1-t_s)\theta R_2}{\Delta - (1-t_s)\theta R_2} = 1.$$

In this case, if the bank experiences a complete run and holds just enough liquid assets to meet withdrawals in a complete run ($\alpha_s = \dfrac{r_1}{R_1} = 1$, ie, 100% liquid assets), it is just solvent (net worth is just zero), and any reduction in holdings of liquidity would make it insolvent given a run by all depositors.

To better understand how the model works, consider the following example (which is not calibrated in any particular way). Suppose the value of t_s is $t_s = ½$, and $\theta = ½$, $R_1 = 1.1$, $R_2 = 1.5$, $r_1 = r_2 = 1$, then it is possible to solve for the ρ_s needed to deter the run as a function of Δ. Fig. 5 shows this correspondence.

For these parameters, there are two interesting regions. First, up until the point when Δ reaches about 0.32, the optimal value of ρ_s is zero. In this region runs that are small enough so that the condition in Proposition 1 holds and the bank selfishly will always hold enough liquid assets so as to deter a run.

At certain point, however, the condition in Proposition 1 no longer applies and profits are no longer sufficient to prevent the run. For potential runs that are this size (or larger), ρ_s must be positive and it increases as the size of the potential run does, up until the point where a full run is a possibility.

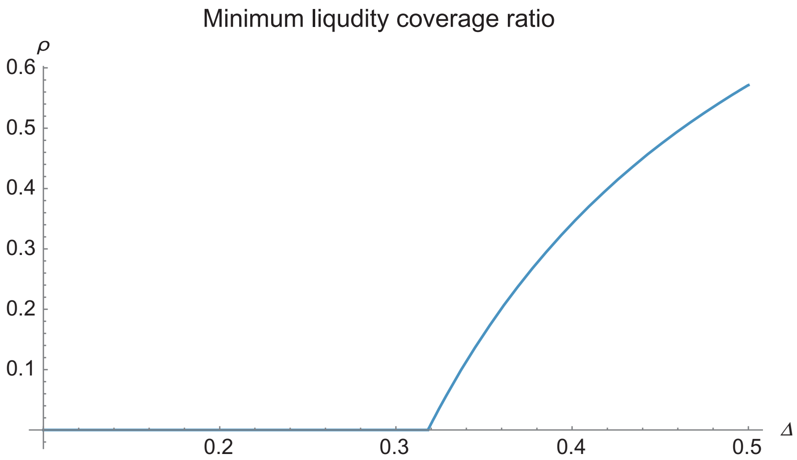

Fig. 5 Liquidity coverage ratio as a function of the potential run risk.

While a highly contingent LCR type regulation is a useful benchmark, we believe a more accurate description of this type of regulation is one where ρ is identical in all states. The constancy could arise because of limited information available to regulators and/or the desire for simplicity. Proposition 4 characterizes the optimal LCR when t_s is private information to the bank and required ratio is constant, ρ.

Proposition 4

If the regulator must specify an LCR with a constant ρ knowing only the distribution of outcomes, then a value which leads the bank to be stable for all t_s must be specified. The worst case for solvency given a run is the bank with anticipated withdrawals of $\bar{t}$ (the highest possible value of t_s). An LCR ratio which makes the bank with $\bar{t}$ anticipated withdrawals just solvent in a complete run will make all types of banks safe.

Proof

A bank of type t_s, subject to an LCR of ρ will choose $\alpha_s R_1 = t_s r_1 + \rho r_1(1 - t_s)$ and given a run, the value of its equity when withdrawals exceed t_s and $f_1 = t_s + \Delta$ is

$$E(\rho, t = t_s, f_1 = t_s + \Delta)$$
$$= \left(1 - \left(\frac{t_s r_1 + r_1 \rho(1 - t_s)}{R_1} \right) - \frac{t_s r_1 - \dfrac{t_s r_1 + \rho r_1(1 - t_s)}{R_1} R_1 + \rho r_1(1 - t_s - \Delta)}{\theta R_2} \right) R_2$$
$$+ (\rho r_1 R_1 - r_2)(1 - t_s - \Delta)$$

Define $\hat{\rho}$ to be the lowest ρ for a type $\hat{t}_s$, such that the value of equity given a run for that type will be exactly zero (so it will just be solvent). To determine the solvency of types

$t_s < \hat{t}_s$ subject to this sort of regulation, note each will choose $\alpha_s = \dfrac{t_s r_1 + \hat{\rho} r_1 (1 - t_s)}{R_1}$. Differentiating $E(\hat{\rho}, t = t_s, f_1 = t_s + \Delta)$ with respect to t_s yields:

$$\frac{\partial E(\hat{\rho}, t = t_s, f_1 = t_s + \Delta)}{\partial t_s} = r_2 + \frac{(r_1 \hat{\rho} - r_1) R_2}{R_1} - \hat{\rho} r_1 R_1.$$

From the assumption that it is more profitable to finance illiquid assets with deposits absent a withdrawal than to finance liquid asset with one period deposits, $\dfrac{r_1}{R_1} > \dfrac{r_2}{R_2}$, we know $r_2 < \dfrac{R_2 r_1}{R_1}$, which implies that:

$$r_2 + \frac{(\hat{\rho} r_1 - r_1) R_2}{R_1} - \hat{\rho} r_1 R_1 < \frac{R_2 r_1}{R_1} + \frac{(\hat{\rho} r_1 - r_1) R_2}{R_1} - \hat{\rho} r_1 R_1 = \hat{\rho} r_1 \left(\frac{R_2}{R_1} - R_1 \right) < 0.$$

The final inequality follows from the profitability of the illiquid asset (ie, $R_2 > R_1^2$). This implies that for all $t_s \leq \hat{t}$, banks are stable and no one would join an anticipated run. An LCR ratio $\rho^* = \hat{\rho}$ which makes the bank with anticipated withdrawals of $t_s = \bar{t}$ just solvent in a run of $\bar{t}_s + \Delta$ will therefore make all types of banks stable. No lower value of ρ will suffice. □

Finally, recall that we already have seen a couple of special cases where stability requires that the LCR must be set at $\rho = 1$: when either the assets are totally illiquid, $\theta = 0$, or when there is no spread earned from investing in liquidity, $r_1 = R_1 = 1$, and the worst case is a complete run, $\bar{t}_s + \Delta = 1$.

4.2 NSFR Regulation

In our interpretation of an NSFR, a bank is subject to a long-term limit on how many illiquid assets it can fund, but this is not imposed as a real time constraint at all times in the future. As a result, when a bank is subject only to an NSFR, it gets to release all of its liquidity in the event of a run. That is the initial level of liquidity is regulated but not future liquidity after withdrawals have occurred. If the regulator knows all the information as in Proposition 2, then the best NSFR is the full-information amount, $\alpha_s^* = \max\{\alpha^{\text{AIC}}, \alpha_s^{\text{stable}}\}$. This will always be better than the LCR which does not release all liquidity after a run, except in the case of a complete run where $t_s = 1 - \Delta$.

More realistically, suppose depositors or regulators can perfectly observe α_s, but do not know how many people need to withdraw for fundamental reasons (t_s) and only know its probability distribution (where we again denote the maximum value by $\bar{t}$). The bank can continue to see t_s, and all parties know Δ.

While these assumptions allow for regulations akin to the NSFR, the regulation still must be very crude. The only certain way to assure the depositors that adequate ex-ante liquidity is being held is to insist that the bank invests in enough safe assets to cover the worst case withdrawals, $\bar{t}+\Delta$. Otherwise there will be an equilibrium where there is a run under the belief that other depositors conjecture that $t_s=\bar{t}$.[h] Only covering this worst case will definitely remove the incentive to run, but whenever fewer fundamental withdrawals are required, the bank is left with many liquid assets that must be rolled over.

4.3 Comparing the LCR and NSFR

Having characterized the two types of regulation, we can now compare them. First, we contrast an NSFR which is sufficient to make stable a bank with $t_s=\bar{t}$ to an LCR which will make that same type of bank stable. Either will make stable banks of all values of t_s (and no lower values will achieve this). To illustrate the possible disadvantages of a constant NSFR, we show what happens when the worst case is $\bar{t}+\Delta=1$, and where the best possible LCR is implemented

Proposition 5

An LCR regulation can potentially support more lending than an NSFR regulation when depositors and regulators cannot condition on t_s.

Proof

The simplest way to see that this might occur is to suppose that in the worst case the run is complete, $\bar{t}+\Delta=1$. In this case, we know that $\alpha=\alpha^*=\dfrac{r_1-\theta R_2}{R_1-\theta R_2}$ is the optimal NSFR, because this is the full-information level of liquidity given by α_s^{Stable} when $t_s=1-\Delta$. But in this case, the regulator can choose $\rho=\rho^*$, where $\rho^*=\dfrac{\theta R_1((1-t_s-\Delta)r_2-R_2)+r_1(\Delta R_1+t_s\theta R_2)}{r_1(\Delta R_1+(1-t_s-\Delta)\theta R_1^2-(1-t_s)\theta R_2)}=\dfrac{\theta R_1(-R_2)+r_1(\Delta R_1+(1-\Delta)\theta R_2)}{r_1(\Delta R_1+(\Delta)\theta R_2)}$ and implement the same outcome with the same amount of liquidity when $t_s=\bar{t}=1-\Delta$ such that $\alpha^*=\dfrac{\bar{t}r_1+\rho^* r_1(1-\bar{t})}{R_1}$. Because a run on a bank with $\bar{t}+\Delta=1$ will be complete, all its liquidity can be released in a run (the LCR becomes $\rho^*(1-\bar{t}-\Delta)=0$). From Proposition 4, this LCR will make stable the other types of banks with lower $t_s<\bar{t}$, and they will be able to invest a smaller amount in liquid assets $\alpha_s=\dfrac{t_s r_1+\rho^* r_1(1-t_s)}{R_1}$. Because they are stable, there will not be runs and they will never need to liquidate illiquid assets. Each bank will choose $\alpha_s=\dfrac{t_s r_1+\rho^*(1-t_s)}{R_1}<\alpha^*$ while a bank subject to the NSFR would still have to hold α^*. □

The complete run case is some sense the most favorable environment for the LCR-style regulation because in the event of a full run, the requirement to maintain extra

[h] Because depositors are very risk averse and there is a positive probability of receiving zero if there is a run, then a signal (observed by a fraction Δ of depositors) which indicates a positive probability of a run will always lead to a run if the other depositors who see the signal believe that it will.

liquidity after the first date is irrelevant. In this case, the last taxicab is allowed to depart (because $\rho^*(1-t_s-\Delta)=0$). If the worst possible case involves only a partial run, there would then be a trade-off because the incentive effects of the LCR require that some liquid assets remain on the balance sheet and the NSFR ratio does not. Further, if there is no private information (uncertainty about t_s), then the NSFR achieves the full-information outcome, with $\alpha_s=\alpha_s^{\text{Stable}}$ (and for a partial run, the LCR cannot).

These polar cases provide some general guidance about the relative efficacy of the two types of regulations. The LCR will work well when monitoring the bank's liquidity is difficult because the regulation forces the bank to carry more safe assets than it would prefer to. Depositors understand this and in some cases this will be enough to quell any concerns about the bank having insufficient funds to withstand a run.

The main cost of the LCR is that deterring the run requires the bank to continue to have some funds invested in liquid assets, even if a run has occurred. Ex-post this liquidity is inefficient and everyone would be better off if more loans had been made instead. But, the incentive effects vanish if the depositors are not convinced that the liquidity will always be present. The only situation when this is not true in the case of a full run.

Conversely, the NSFR is an attractive run deterrent when the regulator is well informed about the fundamental deposit outflows, so that initial liquidity requirement can be varied. In this case, the bank can be forced to hold just enough to survive a run, but never have to hold more than is needed. Importantly, during a run a bank subject to an NSFR can always use all of its liquid assets to serve depositors. So this kind of regulation does not require the bank to liquidate any more loans than is necessary, and hence in the best-case it avoids the inefficiency associated with the LCR.

Once the regulator does not have good knowledge about the fundamental needs of the depositors, using the NSFR becomes less efficient. In this case, depositors cannot generally be confident that the bank will have a portfolio that guarantee solvency in all cases. The best the regulator can, therefore, accomplish is to protect against a worst case set of withdrawals. This can remove the incentive to run, but doing so will mean that all but the worst case the bank over-invests in safe assets. The LCR potentially is less distorting in this case.

This intuition suggests that the relative advantages of the two approaches to regulation will hinge on two considerations. One is the variability of potential fundamental withdrawal requirements. When t_s fluctuates considerably, then regulation that relies on a fixed value of α will only deter runs if the liquidity requirement is set high enough to cover the worst case outcome. When the worst case does not materialize, this will result in the banking holding surplus liquidity. Because the LCR regulation exploits the bank's knowledge about impending withdrawals and relies on its incentives to plan for these withdrawals, variability of t_s is not as severe a problem for this kind of regulation.

The other consideration is the size of the runs that are possible. The Achilles' heel of the LCR is that even after a run has taken place, the bank must continue to hold liquid assets. The NSFR avoids this (ex-post) inefficiency because all the liquid assets that the bank has can be used in the event of a run. So if runs are never complete, the inefficiency associated with the LCR will be at a disadvantage.

It strikes us that the information requirements that would favor the NSFR are relatively onerous. One of the most difficult challenges in a real-time crisis is gauging the extent of a run. In that case, even if it possible to verify and certify that some liquid assets are present at any given point in time, it make be difficult to forecast whether they will be adequate to meet potential subsequent withdrawals. Hence, releasing all liquidity on hand can be risky.

One can see a further disadvantage of the NSFR by introducing the possibility that the bank can secretly alter its liquidity holdings after meeting the NSFR, and this can happen at date 0. This is similar to window dressing when liquidity must be reported only at the end of a calendar year. In this case, liquidity must be disclosed at every date and there must be a future commitment to hold liquidity. The LCR is just such a commitment. It does not do as well as the full-information commitment, but it does succeed in forcing the bank to remain free of runs (while an NSFR single disclosure will not).

5. EXTENSIONS

Having characterized the properties of Basel-style regulations in this model, we now discuss the implications of extending the model in two directions. First, there is no reason to restrict regulations to only look like the NSFR and the LCR, so it makes sense to expand the range of regulatory tools considered. Diamond and Kashyap (2016) provide a complete analysis of how to optimally regulate liquidity in this kind of a model, and we begin with a review of those results.

Second, we discuss several of the issues that arise if the bank faces capital regulation. Allowing savers to have a choice between investing in deposits and equity greatly complicates the model. Part of the complication comes because our model abstracts from asset risk, and many of the benefits of capital regulation arise from creating a buffer against loan losses so that any discussion of capital without asset risk is necessarily incomplete. Nonetheless, there are a couple of interesting possible comparisons between capital and liquidity regulation that can be made even without developing a full-blown model.

5.1 Optimal Regulation of Liquidity

Stepping away from the Basel approach, how should liquidity optimally be regulated in this kind of environment? To find the most efficient set of choices which can be implemented, we describe the results from undertaking a mechanism design analysis.[i] This will achieve the best outcome by providing incentives for the bank to reveal to a regulator the

[i] The analysis here is a special case of the more general treatment in Diamond and Kashyap (2016).

information needed to implement run-free banking most efficiently. Proposition 2 already describes the full-information choices, and it turns out that these can be implemented with the optimal regulation.

To understand what happens where t_s is known only to the bank, we describe a mechanism to which accounts for this information asymmetry and still induces the bank to make efficient choices. The challenge in this situation is that a bank with private information about t_s could have an incentive to misreport t_s. The condition for efficient investment from the bank's point of view without a run remains $\alpha_s = \frac{r_1 t_s}{R_1}$. When the conditions of Proposition 1 regarding the range of possible withdrawals are satisfied, this level of liquidity automatically leads to a stable, run-free bank. This is what both the bank and its depositors desire and runs will be avoided without any regulation or even any disclosure.

When the bank is not automatically stable, to make it incentive compatible to honestly report t_s, the bank must be provided an incentive for reporting high levels of anticipated withdrawals that offsets any increased profits that could arise from underreporting. The potential gains from underreporting come from making more loans and hence having less unused liquidity which is held after normal withdrawals occur. Diamond and Kashyap (2016) prove that under our assumptions there is a way to implement the full-information choice of $\alpha_s{}^*$ (from Proposition 2) and, which is similar to, but not exactly the same as an LCR requirement.

This is possible whenever the regulator has sufficient tools to penalize the banker when actual withdrawals deviate from those that the banker reports are anticipated. These tools share the feature that they eliminate the profits that accrue from underreporting. There are various tools that can achieve this outcome. For instance, one approach is to place limits on compensation whenever reports turn out to be inaccurate (to reduce spoils from underreporting). Another strategy is to deploy fines that would be tied to the use of the supposedly required liquidity given the report. If such tools exist, then the regulator can require the bank to hold $\alpha_s{}^*$ and can punish any cases where the unused liquidity after the withdrawals departs from what would be needed when the bank is run-free (ie, when actual withdrawals, f_1, deviate from what the bank reports as anticipated withdrawals, t_s), but also allow the bank to use the extra liquidity if a run were to occur.

In other words, it is possible to implement the full-information outcomes because if the bank can be induced to be run-free, the actual withdrawals, f_1, will be exactly equal to the (state-contingent) fraction of normal withdrawals, t_s. In essence, an honestly reported value of t_s allows the regulator to determine whether the realized withdrawal f_1 is or is not due to a run and release liquidity only in a run. The critical decision by the regulator is to carefully choose how much mandated excess liquidity must be held in all circumstances to create the right incentives for the banker to truthfully report anticipated fundamental withdrawals. Diamond and Kashyap (2016) characterize these choices under various assumptions about the nature of run risk.

The formal mechanism design problem in Diamond and Kashyap (2016) solves for the optimal mechanism by looking for the one where the bank is given incentives to honestly report its private information to the regulator and the regulator uses the honestly reported information to choose a run-free level of liquidity to make the bank stable. Once the bank is run-free, any misreporting of t_s by the bank will be measured by a level of withdrawals, f_1, which differ from t_s. Assessing a sufficiently large penalty (such as driving the banker's compensation to zero without imposing losses on depositors) for such a misreport will provide incentives for accurate reporting without the need to distort liquidity holding away from the full-information level.

As in the analysis in this chapter, the full-information level of liquidity results in excess liquidity held from date 1 to date 2, but with the optimal mechanism all of this liquidity can always be used if a run should occur. While the excess liquidity is available for use, because it deters runs, it is in fact never needed. Returning to our metaphor, the last taxicab is allowed to leave the station, but in equilibrium there are enough cabs such that some always remain at the station.

5.2 Integrating Liquidity Regulation with LOLR Policy

If the regulator can also serve as an LOLR, then the efficient mechanism, that we just described earlier, can be implemented by requiring a level of liquidity holdings which depends on the quantity of deposits. This is essentially a generalized LCR. In this case, no actual report of anticipated withdrawals, t_s, is required. This is implemented by requiring the amount of unused liquidity at date 1 (to be held until date 2) equal to the full-information level from Proposition 2, α_s^{Stable}, which is given by $U(f_1 = t_s) = \text{Max}\left[0, \alpha_s^{\text{Stable}} - \alpha_s^{\text{AIC}}\right] R_1$, and allowing the bank to use this liquidity in a run, but with a penalty which drives banker compensation to zero in that case.

The goal from this policy is to induce the bank to always use its private information to choose to hold just enough liquidity to make sure that after normal withdrawals, $t_{s,}$ it will meet the requirement, $U(f_1 = t_s)$. This is the equal to the investment in liquidity from the full-information level presented in Proposition 2.

To accomplish this outcome, liquidity requirements and LOLR policy should be integrated in the following way. Banks are forced to hold the specified amount of liquidity but are allowed to borrow against it for use during a run. If there is a sufficient penalty to the bank for violating its liquidity requirement, the bank will hold the specified amount of liquidity and will never use borrowing to meet normal withdrawals. As a result, the run will be deterred and the extra liquidity need not be borrowed against.

Remarkably, there is historical precedent for this sort of policy: the original United States Federal Reserve Act prohibited dividend payments for banks which were in violation of the reserve (liquidity) requirement. In that period, most banks were closely held, implying that a dividend was a significant part of management compensation. This policy is not necessarily akin to charging a high interest rate for such borrowing, because a penalty rate could be so severe that it might make the bank fail due to a run (making the bank unstable and defeating the purpose of holding extra liquidity).

Note that this type of LOLR lends against liquid assets, allowing them to be used during a crisis while providing incentives to get the bank to hold the higher level of liquidity needed to make it stable. This lending does not have moral hazard of inducing the bank to hold excessive amounts of illiquid assets (as described in Bagehot (1873), Goodfriend and King (1988), and Diamond and Rajan (2012)). It may appear pointless to lend against liquid assets, but the ability to penalize the bank for such the borrowing induces the bank to make the proper ex-ante liquidity choice. Once the liquidity is in place, its existence can deter bank runs. Finally, notice that if the LOLR acquired (or lent against) illiquid assets and could then only recover their illiquid value, θR_2, if the bank were to fail, then lending an amount in excess of this value could distort bank incentives and lead to losses by the LOLR. Lending against liquid assets has no such problem.

To summarize, the optimal mechanism induces a bank to hold excess liquidity but allows access to it during a run. The robust conclusion from this analysis is that the optimal regulation requires less unused liquidity than the simple Basel-style regulations because the excess liquidity can be released if a run should occur. If there are additional constraints on what the regulator can do, which limit the ability to release this liquidity, then a regulation like the LCR could be nearly optimal. If all liquidity cannot be released in a run, then the best regulations will have the property that as anticipated withdrawals rise, the amount of required surplus liquidity falls.

5.3 Interactions Between Capital and Liquidity Regulations

Finally, it is worth noting several observations about interactions between capital and liquidity regulation. In our baseline model, there is no credit risk associated with loans, so the usual arguments for capital requirements do not hold. Generically, however, the incentive to run is still related to depositors' assessments about the solvency of the bank so the presence of equity could still matter.

The role that capital would play in deterring a run is subtle. On the one hand, if the bank issued capital (nondemandable liabilities) and invested the proceeds in loans, this can leave the bank more solvent when a fixed number of deposits are withdrawn, moving the bank to a situation where it is solvent during a (potential) run of fixed size. This is due to the liquidation value of the additional loans made. On the other hand, added equity would be irrelevant if a (potential) run of given size given is still going to make the bank insolvent. In our framework, this is easiest to see if the liquidation value of the loans (θ) is zero. In that case, the future value of the assets that would otherwise be the basis of the equity value would be of no value in a run. So the liquidity requirements needed to deliver stability would be unchanged, and capital requirements would be completely ineffective.

Once assets become risky, the analysis becomes much more complicated. In this kind of environment, depositors will make withdrawals based both on their fundamental liquidity needs and based on beliefs about the future value a bank's assets. In addition, if the bank can fail simply because loans turn out to default, the bank's choice between loans and liquid assets can also be distorted if there is limited liability; banks in this kind of an environment can in some situations have an incentive to shift risk on depositors.

A full analysis of this kind of model is beyond the scope of our survey, especially because there are so many additional assumptions that are needed to maintain tractability. However, Kashyap et al. (2015) have solved one particular version of this kind of model, and their analysis does deliver one apparently general result about the interactions between capital and liquidity requirements in deterring runs that is worth mentioning.

They show that there is a fundamental asymmetry in the way that liquidity and capital regulations work in preventing runs. Capital requirements essentially work on the liability-side of a bank's balance sheet without directly constraining the bank's asset choices. Hence, when a bank is forced to have higher equity, it can on the margin reduce its reliance on deposit financing. The need for fewer deposits means that the bank can marginally reduce liquid asset holdings too. This frees up the bank to make marginally more loans. While this marginal adjustment is not enough to raise the overall risk of a run, it does suggest that the bank's assets will become less liquid.[j]

Conversely, liquidity regulation, either in the form of an LCR or NSFR, work very differently. The LCR, as we have seen, directly forces the bank to substitute from illiquid assets toward liquid assets. So the run deterrence automatically is accompanied by having less liquidity risk. The NSFR forces the bank to finance illiquid assets with long-term liabilities. Therefore, if the bank wants to take on additional illiquid assets, it cannot fund them with runnable deposits. Instead, short-term deposits will shrink along with liquid assets.

Kashyap et al. (2015) describe many other ways in which capital regulations and liquidity regulations can complement or substitute for each other. The asymmetry in how they marginally influence asset illiquidity is robust.

6. CONCLUSION

Our analysis provides some novel insights that can inform subsequent discussions of how to design liquidity regulation. Our starting point is the recognition that for a forward looking intermediary, anticipated withdrawals, and access to other funding influences the desired ex-ante, profit-maximizing choice of how much liquidity to hold. Absent

[j] This is not arising because of a Modigliani–Miller type fallacy whereby depositors fail to recognize that the bank's deposits are safer. Instead, this happens because the liquid assets are held only to deter runs, and when capital requirements make them less likely the bank cut back on liquid assets.

any regulation, the bank will voluntarily opt to hold more liquidity when higher exogenous deposit reductions are anticipated. Hence, it is helpful to understand whether, and when, this incentive alone will lead to banking stability even when it is not directly a goal of the bank.

In this kind of model that we have explored, stability is not guaranteed when bank assets are sufficiently illiquid and profitability is below a certain level because depositors may have doubts about whether the bank will make choices which lead it to able to withstand a panic. The lack of confidence that creates this problem can arise for various reasons. Banks are opaque and even for sophisticated counterparties assessing their balance sheet can be challenging. Information about the balance sheet is rarely available contemporaneously, so some forecasting (about the bank's condition and the decisions of other depositors) is inevitable. This will cause problems when the bank's incentives are not automatically aligned with enhancing stability.

Imperfect information also creates a problem for the bank. Cutting back on lending and holding additional liquidity is not fully rewarded when depositors cannot determine if the given amount of liquidity is sufficient to make the bank stable, so the bank's private incentive to become super-safe is limited (unless it can show depositors that it is sufficiently stable to cover all possible circumstances). Regulation that mandates some additional liquidity can potentially circumvent this problem.

Analogs to both of the two regulations contemplated as part of the Basel process, the NSFR and LCR, are among the various types of regulations that we explore. These can arise as approximations of a general type of regulation that is optimally designed to resolve the information friction. All of the ones we consider are designed to eliminate runs.

The generic form of the optimal regulation specifies that the bank must hold a level of liquid assets that is tied to anticipated withdrawals, but which often will exceed the level that it would choose on its own. If the regulator is well-informed about these withdrawals (and the risk of a run), then there are many equivalent ways to guarantee that the bank makes adequate liquidity choices. In particular, stability can be achieved either by having the bank hold the correct amount of liquid assets up-front as with an NSFR, or by imposing restrictions that require liquidity be available even after withdrawals are underway (as with an LCR). Using combinations of these kinds of policies will work too.

To achieve the efficient outcome (which in our model is the same as that which would prevail with full-information available to all), the regulator must be able to induce the bank to disclose everything it knows about the deposit risk that it faces (or have access to that information from some other way). With the ability to impose taxes on bank compensation, the regulator could elicit this from the bank. This need not even involve any direct communication of information to regulators by the bank. A liquidity regulation combined with an LOLR policy which penalizes liquidity regulation violations by limiting compensation, but allows the bank to borrow can implement this optimal arrangement.

One generic property of all of the optimally designed regulations when banks are not automatically stable is that they involve requiring the bank to hold some liquidity that goes unused. So even in the best possible case, the last taxi cab often remains at the station. Fundamentally, this occurs because the unused liquidity is needed to deter the run.

There are two separate forces that lead to this result. First, a prudent provision that forecloses a run necessarily requires that the bank has enough liquidity to be able to service depositors if they did run. This might be possible through liquidating loans. But liquidations are highly inefficient so this typically this will not be sufficient and the bank needs to have some liquid assets which could be deployed if needed. By mandating the "dry powder," the regulator preserves solvency in a run and thus removes the depositors' incentive to run.

The second consideration is that a regulator cannot count on being able to distinguish a run from a situation where fundamental withdrawal needs are simply high. The goal in preventing runs is to do so without mandating more dry powder than is needed. Unfortunately, even when exceptionally high levels of withdrawals are anticipated, some dry powder is needed.

These observations suggest are a number of other directions that would be interesting to explore. In Diamond and Kashyap (2016), we generalize the environment to allow for different types of run dynamics and investigate the implications for regulation. Let us close with three much broader issues that merit further consideration.

First, our analysis suggests a novel type of interaction between LOLR policy and liquidity regulation. Most discussions of the LOLR start with the Bagehot dictum of lending freely against good collateral but at a penalty rate. However, the reason which many loans are illiquid is because they are difficult to quickly value and their value may depend on actions or relationships of the bank. A system where all assets were illiquid and all liquidity (even for normal withdrawals) is provided by the LOLR could be highly problematic. If a private bank is to provide much of its own liquidity, our analysis shows that there is a role for integrating liquidity regulation with an LOLR which lends against required liquid holdings of a bank. This allows banks to access to liquidity without distorting their incentives to minimize the risk of a run.

Carlson et al. (2015) make one attempt to investigate the degree to which liquidity requirements and LOLR policies complement each other. More work in this vein that could probe other interactions between these tools seems promising.

Second, it would also be interesting in future research to examine other mechanisms to provide incentives for banks to hold sufficient liquidity to make them stable and run-free. We focus on liquid asset quantity requirements, but there may be interesting price-based mechanisms. One example is adjusting the interest rates paid on central bank reserves. This is especially relevant in times (like today) when the aggregate quantity of central bank reserves is large in many countries. On a related note, the large central bank balance sheets and the low interest rates in the many counties today make it difficult to use historical data to calibrate the incentive effect of liquidity requirements or the effects of changes in the interest on reserves on endogenous liquidity holdings.

Finally, there are interesting issues involving the need for and effect of liquidity regulation on interbank competition for funding and liquidity sharing between banks. When banks can raise liquidity from the customers of other banks (or from others outside the banking system) then some interactions that we have ignored come into play. As noted by Bhattacharya and Gale (1987) and Farhi et al. (2009), in these circumstances, liquidity regulation can be needed to prevent banks from free riding on others' liquidity. This becomes even more difficult if some of the participants in the market are unregulated "shadow banks." It would be interesting to examine how this interacts with our notion of providing incentives for banks to choose an efficient level of liquidity based on their private information about their own future needs for liquidity.

Abstract

We develop the theory of price-level determination in a range of models using both ad hoc policy rules and jointly optimal monetary and fiscal policies and discuss empirical issues that arise when trying to identify monetary–fiscal regime. The chapter concludes with directions in which theoretical and empirical developments may go.

Keywords

Monetary policy, Fiscal policy, Price level determination, Optimal policy, Tax smoothing, Government debt

1. INTRODUCTION

There is a long tradition in macroeconomics of modeling inflation in stable economies by focusing on monetary policy and abstracting from fiscal policy.[a] As the global financial crisis and its aftermath rocked the world economy, the tenability of that modeling approach has been strained.

This chapter introduces readers to the interactions between monetary and fiscal policies and their role in determining macroeconomic outcomes, particularly the aggregate price level. By incrementally widening the scope of those interactions and considering both simple ad hoc rules and optimal policy, we aim to make accessible the intricacies that policy interactions entail. We hope the material will entice young macroeconomists to engage a set of issues that we regard as both not fully resolved and fundamental to macroeconomic policy analysis.

1.1 Some Observations

Let us start with a few observations of economic developments since 2008:

1. Many countries reacted to the financial crisis and recession that began in 2008 with joint policy actions that sharply reduced monetary policy interest rates and implemented large fiscal stimulus packages.
2. Central banks reacted to the financial crisis by purchasing large quantities of private assets and government bonds in actions that bear a striking resemblance to fiscal policy (Brunnermeier and Sannikov, 2013; Leeper and Nason, 2014).
3. Sovereign debt crises in the Euro zone culminated in the European Central Bank's 2012 policy of "outright monetary transactions," a promise to purchase sovereign debt in secondary markets in unlimited quantities for countries that satisfied conditionality restrictions.
4. Rapid adoption of fiscal austerity measures beginning in 2010 and 2011 created challenges for central banks that were already operating at or near the lower limits for nominal interest rates.
5. Exploding central bank balance sheets also grew riskier, increasing concerns about whether the requisite fiscal backing or support for monetary policy is guaranteed (Del Negro and Sims, 2015).
6. In 2013, Japan's newly elected prime minister Shinzō Abe adopted "Abenomics," a mix of fiscal stimulus, monetary easing, and structural reforms designed to reinflate a Japanese economy that has languished since the early 1990s.

[a] Focusing on stable economies rules out hyperinflations, which are widely believed to have fiscal origins.

Table 1 Net general government debt as percentage of GDP

	2008	2015
Euro area	54.0	74.0
Japan	95.3	140.0
United Kingdom	47.5	85.0
United States	50.4	80.9

Projections for 2015.
Source: International Monetary Fund, 2014. Fiscal Monitor-Back To Work: How Fiscal Policy Can Help. IMF, Washington, DC.

7. Table 1 reports that government debt expansions during the recession were significant: net debt as a share of GDP rose between 37% and 79% across four advanced-economy country groups. As central banks begin to raise interest rates toward more normal levels, these debt expansions will carry with them dramatically higher debt service to create fresh fiscal pressures. The Congressional Budget Office (2014) projects that U.S. federal government net interest payments will rise dramatically as a share of GDP from 2014 to 2024. Evidently, there are substantial fiscal consequences from central bank exits from very low policy interest rates.
8. With an increasing number of central banks now paying interest on reserves at rates close to those on short-term government bonds, one important distinction between high-powered money and nominal government bonds has disappeared, removing a principal distinction between monetary and fiscal policy (Cochrane, 2014).
9. Sovereign debt troubles in the Euro area and political polarization in many countries remind us that every country faces a fiscal limit, which is the point at which the adjustments in primary surpluses needed to stabilize debt are not assured. Uncertainty about future fiscal adjustments can untether fiscal expectations, making it difficult or impossible for monetary policy to achieve its objectives (Davig et al., 2010, 2011).
10. Exacerbating the fiscal fallout from the crisis, aging populations worldwide create long-run fiscal stress whose resolution in most countries is uncertain. This kind of uncertainty operates at low frequencies and may conflict with the long-run objectives of monetary policy (Carvalho and Ferrero, 2014).

It is hard to think about these developments without bringing monetary and fiscal policy *jointly* into the analysis. Several of these examples also run counter to critical maintained assumptions in monetarist/Wicksellian perspectives, including:

- fiscal policies will adjust government revenues and expenditures as needed to finance and stabilize government debt; this ensures that fiscal actions are "self-correcting" and need not concern monetary policymakers;
- sufficiently creative monetary policies—which include interest rate settings, quantitative easing, credit easing, government debt management, forward guidance—can always achieve desired inflation and macroeconomic objectives;
- impacts of monetary policy on fiscal choices are small enough to be of negligible importance to monetary policy decisions, freeing central banks to focus on a narrow set of goals.

As even this handful of examples makes clear, it is unlikely to be fruitful to interpret recent macroeconomic policy issues by studying monetary or fiscal policy in isolation. This chapter takes that premise as given to explore how macro policies interact to determine aggregate prices and quantities.

1.2 Our Remit

We were invited to write a chapter on the "fiscal theory of the price level," an assignment that we gladly accepted, but chose to broaden to the theory of price-level determination. A broader perspective, like the observations earlier, brings monetary and fiscal policy jointly into the picture to produce a more general understanding of the inflation process than either the monetarist/Wicksellian or the fiscal theory alone provide. We show that only in very special circumstances can the two perspectives be treated as distinct theories. Despite this broader perspective, both to fulfill our remit and to draw attention to aspects of monetary and fiscal policy interaction that are often overlooked, the chapter will often (but not solely) focus on the mechanisms that the fiscal theory emphasizes.

1.3 What Is the Fiscal Theory?

We consider a class of dynamically efficient models with monetary policy, a maturity structure for nominal government debt, taxes—distorting or lump-sum—government expenditures—purchases or transfers—and a government budget identity. In models of this kind, four key features of equilibrium may emerge:

1. There is a prominent role for nominal government debt revaluations that stabilize debt through surprise changes in inflation and bond prices.
2. It is possible for monetary–fiscal policy mixes to permit nominal government debt expansions or increases in the monetary policy interest rate instrument to increase nominal private wealth, nominal aggregate demand, and the price level.
3. Expectations of fiscal policy are equally important to those of monetary policy in determining prices and, sometimes, quantities, as in Brunner and Meltzer (1972), Tobin (1980), and Wallace (1981).[b]
4. Debt management policies matter for equilibrium dynamics, contributing an additional instrument to the standard macroeconomic policy toolkit, as Tobin (1963) argued.

Analyses of the implications of these features in this class of models constitute what we call the "fiscal theory of the price level."[c]

[b] Brunner and Meltzer anticipate the fiscal theory by showing that a government debt expansion unaccompanied by higher base money is inflationary when the fiscal deficit is held constant. But they dismiss this result on the grounds that "Price-level changes of this kind have not been important [foonote 13]."

[c] Early contributors to the theory include Begg and Haque (1984), Auernheimer and Contreras (1990), Leeper (1991), Sims (1994), Woodford (1995), and Cochrane (1999).

The fiscal theory is a complement to, rather than a substitute for, conventional views of price-level determination. It emerges by filling in the fiscal sides of models and broadening the rules that monetary and fiscal authorities can obey. By doing so, the fiscal theory extracts what assumptions about fiscal behavior are required to deliver conventional views. More importantly, being explicit about both monetary and fiscal behavior reveals that a far richer set of equilibria can arise from the previously suppressed, but undeniable, fact that monetary and fiscal policies are intrinsically intertwined.

The chapter aims to be constructive and instructive, so it does not refight the battles that surround the fiscal theory. Accusations against the fiscal theory include: it confuses equilibrium conditions with budget constraints; it violates Walras' law; it treats private agents and the government differently; it is merely an equilibrium selection device; it is little more than a retread of Sargent and Wallace's (1981) unpleasant monetarist arithmetic.[d] Each of these arguments has been discussed at length in Sims (1999a), Cochrane (2005), and Leeper and Walker (2013). Rehashing those debates detracts from the chapter's aims.

Cochrane (2011b, 2014) and Sims (1999b, 2013), two leading proponents of the fiscal theory, explore a wide range of issues through the lens of the fiscal theory to reach conclusions that contrast sharply with conventional perspective. This chapter also reexamines some practical issues in the light of the fiscal theory.

Most of the chapter focuses on the nature of equilibrium, including price-level determination, in models with nontrivial specifications of monetary and fiscal policy behavior. In this sense, the chapter, like the fiscal theory itself, echoes Wallace's (1981) insight that the effects of central bank open-market operations hinge on the precise sense in which fiscal policy is held constant. Under some assumptions on fiscal behavior, open-market operations are neutral, but different fiscal behavior permits monetary policy actions to have different impacts. Wallace did not explore the nature of price-level determination in the presence of nominal government bonds, which the fiscal theory emphasizes, but his results nonetheless foreshadow the newer literature. We also examine interactions in the opposite direction: how monetary policy behavior can influence the impacts of fiscal actions.

1.3.1 Real vs Nominal Government Debt

Central to the fiscal theory is the distinction between real and nominal government debt. This distinction matters little in conventional views that maintain that future revenues and expenditures always adjust to stabilize government debt. But the presence—in fact, the prevalence, of nominal government debt in many countries—lies at the core of the fiscal theory.[e]

[d] These accusations appear in Kocherlakota and Phelan (1999), McCallum (2001), Bassetto (2002), Buiter (2002), and Ljungqvist and Sargent (2004).

[e] See Cochrane (2011b) and Sims (2013).

Real debt can take the form of inflation-indexed bonds or bonds denominated in units whose supply the country does not control. Real debt is a claim to real goods, which the government must acquire through taxation. This imposes a budget constraint that the government's choices must satisfy. If the government does not have the taxing capacity to acquire the goods necessary to finance outstanding debt, it has no option other than outright default. Under the gold standard with fixed parities, countries effectively issued real debt because the real value of government bonds was determined by factors outside their control—worldwide supply and demand for gold.

Nominal debt is much like government-issued money: it is merely a claim to fresh currency in the future. The government may choose to raise taxes to acquire the requisite currency or it may opt to print up new currency, if currency creation is within its purview. Because the value of nominal debt depends on the price level and bond prices, the government really does not face a budget constraint when all its debt is nominal. Some readers may object to the idea that a government does not face a budget constraint, but the logic here is exactly the logic that underlies fiat currency. By conventional quantity theory reasoning, the central bank is free to double or half the money supply without fear of violating a budget constraint because the price level will double or half to maintain the real value of money. The direct analog to this reasoning is that the government is free to issue any quantity of nominal bonds, whose real value adjusts with the price level, without reference to a budget constraint. Of course, as with a money rain, by doing so the government is giving up control of the price level.

Member nations of the European Monetary Union issue debt denominated in euros, their home currency, but because monetary policy is under the control of the ECB rather than individual nations, the debt is effectively real from the perspective of member nations. The United States issues indexed debt, but it comprises only 10% of the debt outstanding. Even in the United Kingdom, which is known for having a thick market in indexed bonds, the percentage is only about 20. Five percent or less of total debt issued is indexed in the Euro Area, Japan, Australia, and Sweden.

1.3.2 Themes of the Chapter

Several themes run through this paper. First, it is always the *joint* behavior of monetary and fiscal policies that determine inflation and stabilize debt. While this point might seem obvious—echoing, as it does, a viewpoint that dates back at least to Friedman (1948)—it is easily missed in the classes of models and descriptions of policy typically employed in modern macroeconomic policy analyses. In those models, inflation appears to be determined entirely by monetary policy behavior—specifically, by the responsiveness of monetary policy to inflation—while debt dynamics seem to be driven only by fiscal behavior—the strength of primary surplus responses to debt. Of course, *in equilibrium* the two policies must interact in particular ways to deliver a determinate equilibrium with bounded debt, but this point is often swept under the carpet in order to focus the analysis solely on monetary policy.[f]

In dynamic models, macroeconomic policies have two fundamental tasks to achieve: determine the price level and stabilize debt. Two distinct monetary–fiscal policy mixes can accomplish those tasks. A second theme is that it is useful for some purposes to categorize those policy mixes in terms of "active" or "passive" policy behavior.[g] An active authority pursues its objectives unconstrained by the state of government debt and is free to set its control variables as it sees fit. But then the other authority must behave passively to stabilize debt, constrained by the active authority's actions and private-sector behavior. A determinate bounded equilibrium requires the mix of one active and one passive policy; that mix achieves the two macroeconomic objectives of delivering unique inflation and stable debt processes.[h] The combination of active monetary and passive fiscal policies delivers the usual monetarist/new Keynesian setup in which monetary policy can target inflation and fiscal policy exhibits Ricardian equivalence. We call this policy mix regime M, but it also goes by the label "monetary dominance." An alternative combination of passive monetary and active fiscal policies gives fiscal policy important effects on inflation, while monetary policy ensures that debt is stable. The latter policy regime has been given the unfortunate label "the fiscal theory of the price level." The fiscal theory mix is called regime F or "fiscal dominance."

Third, regime F policies produce equilibria in which the maturity structure of government debt affects equilibrium dynamics, as Cochrane (2001) and Sims (2011) emphasize. In contrast, without frictions that make short and long debt imperfect substitutes and in the special case of flexible prices and lump-sum taxes, maturity structure is irrelevant in regime M. Under the fiscal theory, long debt permits both current and future inflation (bond prices) to adjust to shocks that perturb the market value of debt, which serves to make inflation and, if prices are sticky, real activity less volatile than they would be if all debt were one period.

Fourth, only in the special cases of flexible prices and lump-sum fiscal shocks/surplus adjustments can simple active monetary policy rules hit their inflation target in regime M. More generally, with sticky prices and distortionary taxation, we observe revaluation effects and pervasive interactions between monetary and fiscal policy across both the M and F regimes.

Fifth, the "active/passive" rubrics also lose their usefulness once one considers optimal policies. Jointly optimal monetary and fiscal policies generally combine elements of

[f] See, for example, Woodford (2003) and Galí (2008).

[g] Leeper (1991) develops this categorization to study bounded equilibria.

[h] There are unbounded equilibria also. Sims (2013) and Cochrane (2011a) emphasize the possibility of solutions with unbounded inflation; McCallum (1984) and Canzoneri et al. (2001b) display solutions with unbounded debt that hinge on the presence of nondistorting taxes.

both regimes M and F: when long-maturity government debt is outstanding, it is always optimal to stabilize debt partly through distorting taxes and partly through surprise changes in inflation and bond prices (Cochrane, 2001; Leeper and Zhou, 2013; Sims, 2013). How important inflation is as a debt stabilizer—or in Sims' (2013) terminology, a "fiscal cushion"—depends on model specifics: the maturity structure of debt, the costliness of inflation variability, the level of outstanding government debt, whether optimal policy is with commitment or discretion, proximity of the economy to its fiscal limit, and so forth.

The fact that key features of the fiscal theory emerge as jointly optimal monetary and fiscal policy elevates the theory from a theoretical oddity to an integral part of macroeconomic policies that deliver desirable outcomes.

1.4 Overview of the Chapter

As we progress through the chapter we gradually widen the extent of monetary and fiscal policy interactions. We start with a simple flexible-price endowment economy subject to shocks to lump-sum transfers. This environment limits the extent of monetary and fiscal interactions to the revaluation effects emphasized by the fiscal theory and supports the strong dichotomy between the M and F regimes. Even in this simple environment, though, there are important spillovers between monetary and fiscal policy under either regime when we allow for either government spending or monetary policy shocks.

We then turn to consider the same rules in a production economy subject to nominal rigidities, but where we retain the assumption that taxes are lump sum. This adds a new channel for monetary and fiscal interactions because monetary policy can affect real interest rates when prices are sticky which, in turn, influence debt dynamics through real debt service costs. We then generalize this further by adding distortionary taxation to a new Keynesian economy. Then tax policy affects inflation through its impact on marginal costs, government spending feeds into aggregate demand, and monetary policy affects real interest rates to influence the size of the tax base. In this richer specification, equilibrium outcomes are always the result of interactions between monetary and fiscal policy and a key issue is the balance between monetary and fiscal policy in the control of inflation and stabilization of debt. We show that the conventional policy assignment of delegating monetary policy to achieve an inflation target and fiscal policy to stabilize debt is not always optimal.

Most expositions of the fiscal theory posit simple ad hoc rules for monetary and fiscal behavior and characterize the nature of equilibria under alternative settings of those rules. This chapter follows that path in the next two sections to derive clean analytical results that explain how the fiscal theory operates and how it differs from alternative policy mixes. Then the paper turns to study jointly optimal monetary and fiscal policies as an alternative vehicle for describing the economic mechanisms that underlie the fiscal theory. Optimal policies make clear that the distinguishing features of the fiscal theory are generally part of a policy mix that produces desirable economic outcome. But the incentive to use surprise inflation to stabilize debt, especially when debt levels are high, can also create significant time-consistency issues when policymakers cannot credibly commit. When private agents know that policymakers may be tempted to induce inflation surprises to reduce the debt burden, economic agents raise their inflation expectations as debt levels rise until that temptation has been offset. This produces a sizeable debt stabilization bias that drives policymakers to reduce debt levels rapidly, at large cost in terms of social welfare, to avoid the high equilibrium rates of inflation associated with the temptation to inflate that debt away. We explore the sharp contrast between time-consistent and time-inconsistent optimal policy in this context in detail.

After those purely theoretical explorations, the paper turns to consider the empirical relevance of those mechanisms. We describe some subtle issues that arise in efforts to identify monetary–fiscal regime and review existing evidence both for and against fiscal interpretations of time series. The chapter then discusses three practical applications of the theory: fiscal prerequisites for successful inflation targeting, consequences of alternative fiscal reactions to a return to more normal levels of interest rates, and why the central bank needs understand the prevailing monetary–fiscal regime in order to conduct monetary policy. To wrap up, we describe outstanding issues in both theoretical and empirical analyses of monetary and fiscal policy interactions to point out directions for future research.

2. ENDOWMENT ECONOMIES WITH AD HOC POLICY RULES

This section aims to present the distinguishing features of the fiscal theory listed in Section 1.3 in the simplest possible model. A representative consumer lives forever and receives a constant endowment of goods, y, each period. The economy is cashless and financial markets are complete.

2.1 A Simple Model

The consumer optimally chooses consumption, c_t, may buy or sell nominal assets, D_t, at price $Q_{t,t+1}$, receives lump-sum transfers from the government, z_t, and pays lump-sum taxes, τ_t.[i] The representative household maximizes

$$E_0\left\{\sum_{t=0}^{\infty}\beta^t U(c_t)\right\}$$

with $0<\beta<1$, subject to the sequence of flow budget constraints

[i] D_t consists of privately issued, B_t^p, and government issued, B_t, assets. Government bonds cost $\$1/R_t$ per unit and are perfectly safe pure discount bonds.

$$P_t c_t + P_t \tau_t + E_t[Q_{t,t+1} D_t] = P_t y + P_t z_t + D_{t-1} \tag{1}$$

given D_{-1}. $Q_{t,t+1}$ is the nominal price at t of an asset that pays \$1 in period $t+1$ and P_t is the general price level in units of mature government bonds required to purchase one unit of goods. Government bonds sold at t, which are included in D_t, pay gross nominal interest R_t in period $t+1$. Letting $m_{t,t+1}$ denote the real contingent claims price, a no-arbitrage condition implies that

$$Q_{t,t+1} = m_{t,t+1} \frac{P_t}{P_{t+1}} \tag{2}$$

The short-term nominal interest rate, R_t, which is also the central bank's policy instrument, is linked to the nominal bond price: $1/R_t = E_t[Q_{t,t+1}]$.

Setting government purchases of goods to zero,[j] the primary surplus is simply $s_t \equiv \tau_t - z_t$. The household's intertemporal budget identity comes from iterating on (1) and imposing the no-arbitrage condition, (2), and the transversality condition

$$\lim_{T\to\infty} E_t\left[m_{t,T} \frac{D_{T-1}}{P_T}\right] = 0 \tag{3}$$

to yield

$$E_t \sum_{j=0}^{\infty} m_{t,t+j} c_{t+j} = \frac{D_{t-1}}{P_t} + E_t \sum_{j=0}^{\infty} m_{t,t+j}(y - s_{t+j}) \tag{4}$$

where $m_{t,t+j} \equiv \prod_{k=0}^{j} m_{t+k,t+k+1}$ is the real discount factor, with $m_{t,t} = 1$.

After imposing equilibrium in the goods market, $c_t = y$, the real discount factor is constant, $m_{t,t+1} = \beta$, and the nominal interest rate obeys a Fisher relation

$$\frac{1}{R_t} = \beta E_t \frac{P_t}{P_{t+1}} = \beta E_t \frac{1}{\pi_{t+1}} \tag{5}$$

where $\pi_t \equiv P_t/P_{t-1}$ is the gross inflation rate. In equilibrium there will be no borrowing or lending among private agents, so the household's bond portfolio consists entirely of government bonds. Imposing both bond and goods market clearing and the constant real discount factor the household's intertemporal constraint produces the ubiquitous equilibrium condition

$$\frac{B_{t-1}}{P_t} = E_t \sum_{j=0}^{\infty} \beta^j s_{t+j} \tag{6}$$

Cochrane (2001) refers to (6) as an "equilibrium valuation equation" because it links the market value of debt outstanding at the beginning of period t, B_{t-1}/P_t, to the expected

[j] We shall relax this assumption below.

present value of the cash flows that back debt, primary surpluses. Notice that we derived this valuation equation entirely from private optimizing behavior and market clearing, without reference to government behavior or to the government's budget identity. The valuation equation imposes no restrictions on the government's choices of future surpluses, in the same way that the Fisher relation does not limit the central bank's choices of the nominal interest rate.

For each date t, equations (5) and (6) constitute two equilibrium conditions in four unknowns: $R_t, P_t, E_t(1/P_{t+1}), E_t\sum_{j=0}^{\infty}\beta^j s_{t+j}$. Private-sector behavior alone cannot uniquely determine the equilibrium. We turn now to a class of monetary and fiscal policy rules that may deliver determinate equilibria.

2.1.1 Policy Rules

The central bank obeys a simple interest rate rule, come to be called a Taylor (1993) rule, that makes deviations of the nominal interest rate from steady state proportional to deviations of inflation from steady state

$$\frac{1}{R_t} = \frac{1}{R^*} + \alpha_\pi\left(\frac{1}{\pi_t} - \frac{1}{\pi^*}\right) + \varepsilon_t^M \tag{7}$$

where ε_t^M is an exogenous shock to monetary policy. The government sets deviations of the primary surplus from steady state proportional to steady-state deviations of debt

$$s_t = s^* + \gamma\left(\frac{1}{R_{t-1}}\frac{B_{t-1}}{P_{t-1}} - \frac{b^*}{R^*}\right) + \varepsilon_t^F \tag{8}$$

where ε_t^F is an exogenous fiscal shock to the primary surplus. The inverse of the nominal interest rate is the price of nominal debt, so $\frac{1}{R_{t-1}}\frac{B_{t-1}}{P_{t-1}}$ is the real market value of debt issued at $t-1$. Policy choices must be consistent with the government's flow budget identity

$$\frac{1}{R_t}\frac{B_t}{P_t} + s_t = \frac{B_{t-1}}{P_t}$$

where the steady state of the model is

$$\frac{B}{P} = b^*, \quad s^* = (\beta^{-1} - 1)\frac{b^*}{R^*}, \quad R^* = \frac{\pi^*}{\beta}, \quad m^* = \beta$$

It is convenient to express things in terms of the inverse of inflation (ie, deflation) and real debt, so let $\nu_t \equiv \pi_t^{-1}$ and $b_t \equiv B_t/P_t$. Combining the monetary policy rule with the Fisher equation yields the difference equation in deflation

$$E_t(\nu_{t+1} - \nu^*) = \frac{\alpha_\pi}{\beta}(\nu_t - \nu^*) + \frac{1}{\beta}\varepsilon_t^M \tag{9}$$

Combining the fiscal rule and the government's flow budget identity, taking expectations, and employing the Fisher relation yield real debt dynamics

$$E_t\left(\frac{b_{t+1}}{R_{t+1}}-\frac{b^*}{R^*}\right)=(\beta^{-1}-\gamma)\left(\frac{b_t}{R_t}-\frac{b^*}{R^*}\right)-E_t\varepsilon^F_{t+1} \tag{10}$$

Equations (9) and (10) constitute a system of expectational difference equations in inflation and real debt, which is driven by the exogenous policy disturbances ε^M and ε^F. Given the consumer's discount factor, β, this system appears as though inflation dynamics depend only on the monetary policy choice of α_π, while debt dynamics hinge only on the fiscal policy choice of γ: it is not obvious that monetary and fiscal behavior *jointly* determine inflation and real debt. This apparent separation of the system is deceptive. Because the government issues *nominal* bonds, B_t, the price level appears in both equations and $1/P_t$ is the value of bonds maturing at t.

2.1.2 Solving the Model

We focus on bounded solutions.[k] Stability of inflation depends on α_π/β and stability of debt depends on $\beta^{-1}-\gamma$.[l]

2.1.2.1 Regime M

If $\alpha_\pi/\beta > 1$, then the bounded solution for inflation is

$$\nu_t=\nu^*-\frac{1}{\alpha_\pi}\sum_{j=0}^{\infty}\left(\frac{\beta}{\alpha_\pi}\right)^j E_t\varepsilon^M_{t+j} \tag{11}$$

which delivers a solution for $\{P_{t-1}/P_t\}$ for $t\geq 0$ and the equilibrium nominal interest rate is

$$\frac{1}{R_t}=\frac{1}{R^*}-\sum_{j=1}^{\infty}\left(\frac{\beta}{\alpha_\pi}\right)^j E_t\varepsilon^M_{t+j}$$

In this simple model, both actual and expected inflation depend on the monetary policy parameter and shock, but they appear not to depend in any way on fiscal behavior.

[k] Unbounded solutions for inflation also exist, as Benhabib et al. (2001) show. Sims (1999b), Cochrane (2011a), and Del Negro and Sims (2015) thoroughly explore those equilibria to argue that a determinate price level requires appropriate fiscal backing. As Del Negro and Sims (2015, p. 3) define it: "Fiscal backing requires that explosive inflationary or deflationary behavior of the price level is seen as impossible because the fiscal authority will respond to very high inflation with higher primary surpluses and to near-zero interest rates with lower, or negative, primary surpluses." Solutions with unbounded debt inevitably rely on nondistorting taxes, which permit revenues to grow forever at the same rate as interest receipts on government bond holdings. Although such paths for revenues are equilibria in the present model, because they are infeasible in economies where taxes distort, we find them to be uninteresting.

[l] We consider the implications of temporarily being in active–active or passive–passive regimes in Section 7.3.

This appearance is deceptive because (11) does not constitute a complete solution to the model; we also need to ensure that there is a bounded solution for real debt. If fiscal policy chooses $\gamma > \beta^{-1} - 1$, then when real debt rises, future surpluses rise by more than the net real interest rate with the change in debt in order to cover both debt service and a little of the principal. In this case, the debt dynamics in (10) imply that for arbitrary deviations of real debt from steady state, $\lim_{T \to \infty} E_t b_{T+1} = b^*$, so debt eventually returns to steady state.

Digging into exactly what fiscal policy does to stabilize debt reveals the underlying policy interactions. Suppose that at time t news arrives of a higher path for $\{\varepsilon^M_{t+j}\}$. This news reduces ν_t, raising the price level P_t. With fiscal rule (8), in the first instance the monetary news leaves s_t unaffected, but household holdings of outstanding bonds, B_{t-1}/P_t, decline. From the government budget identity, this implies that the market value of debt issued at t also falls, even if there is no change in the price of bonds, $1/R_t$

$$\frac{B_t}{P_t R_t} = -s_t + \frac{B_{t-1}}{P_t}$$

In the absence of future fiscal adjustments—such as those in which $\gamma > \beta^{-1} - 1$—household wealth would decline, reducing aggregate demand and counteracting the inflationary effect of the monetary expansion. But when fiscal policy reduces surpluses with debt by more than the real interest rate, surpluses are expected to fall by an amount equal in present value to the initial drop in the value of household bond holdings. This eliminates the negative wealth effect to render monetary policy expansionary.

When the news of higher $\{\varepsilon^M_{t+j}\}$ extends to affect the equilibrium beyond the current period, the nominal interest rate rises, reducing the price of new bonds at t. Lower bond prices implicitly raise interest yields on these bonds that mature in period $t+1$ to create a second channel by which monetary policy affects household wealth. As with the first channel, though, these wealth effects evaporate with the expected adjustments in surpluses.

These fiscal adjustments connect to Wallace's (1981) point that the impacts of open-market operations hinge on the sense in which fiscal policy is "held constant." In regime M, the "constancy" of fiscal policy is quite specific: it eliminates any monetary effects on balance sheets. By neutralizing the fiscal consequences of monetary policy actions, this regime leaves the impression that, in Friedman's (1970) famous aphorism, "inflation is always and everywhere a monetary phenomenon." Of course, it is the *joint* behavior of monetary and fiscal policies that delivers this impression.

Regime M also delivers the fiscal counterpart to Friedman's monetarist adage: Ricardian equivalence.[m] A fiscal shock at t that reduces the surplus by one unit is financed

[m] Tobin (1980, p. 53) made this point: "Thus the Ricardian equivalence theorem is fundamental, perhaps indispensable, to monetarism."

initially by an expansion in nominal debt of P_t units. With inflation pinned down by expression (11), real debt also increases by P_t units. Higher real debt, through the fiscal rule, triggers higher future surpluses whose present value equals the original debt expansion. Even in this completely standard Ricardian experiment, it is the joint policy behavior—monetary policy's aggressive response to inflation and fiscal policy's passive adjustment of surpluses—that produces the irrelevance result.

2.1.2.2 Regime F

Consider the case in which fiscal policy is active, with exogenous surpluses, so $\gamma = 0$ to make the fiscal rule is $s_t = s^* + \varepsilon_t^F$. The solution for real debt is[n]

$$\frac{b_t}{R_t} = \frac{b^*}{R^*} + \sum_{j=1}^{\infty} \beta^j E_t \varepsilon_{t+j}^F \tag{12}$$

which implies that the value of debt at t depends on the expected present value of surpluses from $t + 1$ onward.

We can solve for inflation by combining this solution for b_t with the government's flow budget identity, noting that $B_{t-1}/P_t = \nu_t b_{t-1}$

$$\nu_t = \frac{(1-\beta)^{-1} s^* + \sum_{j=0}^{\infty} \beta^j E_t \varepsilon_{t+j}^F}{b_{t-1}} \tag{13}$$

where at t, b_{t-1} is predetermined, which produces the solution for the price level

$$P_t = \frac{B_{t-1}}{(1-\beta)^{-1} s^* + \sum_{j=0}^{\infty} \beta^j E_t \varepsilon_{t+j}^F} \tag{14}$$

News of lower surpluses raises the price level and reduces the value of outstanding debt. In contrast to regime M equilibria, in regime F *nominal* government debt is an important state variable.[o] Higher nominal debt or higher debt service raises the price level next period. These results reflect the impacts of higher nominal household wealth. Lower future surpluses—stemming from either lower taxes or higher transfers—or higher initial nominal assets raise households' demand for goods when there is no prospect that future taxes will rise to offset the higher wealth. Unlike regime M, now equilibrium inflation, as given by (13), depends explicitly on current and expected fiscal choices—through the steady-state surplus, s^*, and fiscal disturbances, $\sum_{j=0}^{\infty} \beta^j E_t \varepsilon_{t+j}^F$.

[n] To derive (12), define $\tilde{b}_t \equiv B_t / P_t R_t$ to write the flow government budget identity as $\tilde{b}_t + s_t = R_{t-1} \nu_t \tilde{b}_{t-1}$. Take expectations at $t - 1$, apply the Euler equation $\beta^{-1} = E_{t-1} R_{t-1} \nu_t$, iterate forward, and impose transversality to obtain (12).

[o] Debt is also a state variable in regime M because it contains information about future surpluses. But in M, changes in the *real* value of debt induce changes in expectations of future *real* government claims on private resources.

Expression (12) gives the real market value of debt. But in the absence of any stabilizing response of surpluses to real debt ($\gamma = 0$), debt's deviations from steady state are expected to grow over time at the real rate of interest, $1/\beta$, according to (10). Such growth in debt would violate the household's transversality condition, which is inconsistent with equilibrium. To reconcile these seemingly contradictory implications of the equilibrium, we need to understand the role that monetary policy plays in regime F.

Monetary policy ensures that actual debt, as opposed to expected debt, is stable by preventing interest payments on the debt from exploding and permitting surprise inflation to revalue government debt. In regime F, higher interest payments raise nominal wealth, increasing nominal aggregate demand, and future inflation, as both (13) and (14) indicate. To understand monetary policy behavior, substitute the solution for ν_t from (13) into the monetary policy rule, (7). To simplify the expression, assume that the policy shocks are *i.i.d.* so that

$$\frac{1}{R_t} - \frac{1}{R^*} = \frac{\alpha_\pi}{\beta}\left[\frac{\beta(1-\beta)^{-1}s^* + \beta\varepsilon_t^F}{b_{t-1}} - \frac{1}{R^*}\right] + \varepsilon_t^M \tag{15}$$

In response to a fiscal expansion—$\varepsilon_t^F < 0$—the central bank reduces $1/R_t$ by $\alpha_\pi \varepsilon_t^F$ to lean against the fiscally induced inflation. A serially uncorrelated fiscal disturbance leaves the market value of debt at its steady state, $b_{t+j}/R_{t+j} = b^*/R^*$ for $j \geq 0$. This greatly simplifies the time $t + 1$ version of (15) to yield

$$\frac{1}{R_{t+1}} - \frac{1}{R^*} = \frac{\alpha_\pi}{\beta}\left(\frac{1}{R_t} - \frac{1}{R^*}\right) \tag{16}$$

If monetary policy were to respond aggressively to inflation by setting $\alpha_\pi/\beta > 1$, $1/R$ would diverge to positive or negative infinity, both situations that violate lower bound conditions on the net, $R - 1$, nominal interest rate. Economically, these exploding paths stem from strong wealth effects that arise from ever-growing interest receipts to holders of government bonds. When $\alpha_\pi/\beta > 1$ the central bank raises the nominal interest rate by a factor that exceeds the real interest rate, which increases private agents' nominal wealth and inflation in the next period; this process repeats in subsequent periods. Active monetary policy essentially converts stable fiscally induced inflation into explosive paths.

Existence of equilibrium requires that the monetary reaction to inflation not be too strong—specifically, that $\alpha_\pi/\beta < 1$, what is called "passive monetary policy." A pegged nominal interest rate, $\alpha_\pi = 0$, is the easiest case to understand. By holding the nominal rate fixed at R^*, monetary policy prevents the fiscal expansion from affecting future inflation by fixing interest payments on the debt. A one-time reduction in s_t that is financed by new nominal bond sales raises P_t enough to keep B_t/P_t unchanged. But the higher price level also reduces the real value of existing nominal debt, B_{t-1}/P_t, and in doing so reduces the implicit real interest payments. In terms of the flow budget identity

$$\frac{b^*}{R^*} + s_t = \frac{B_{t-1}}{P_t}$$

where real debt remains at steady state because $\gamma = 0$ implies that expected surpluses are unchanged. The larger is the stock of outstanding debt, the less the price level must rise to keep the budget in balance.

More interesting results emerge when there is some monetary policy response to inflation—$0 < \alpha_\pi < \beta$.[p] When monetary policy tries to combat fiscal inflation by raising the nominal interest rate, inflation is both amplified and propagated. Pegging R_t forces all inflation from a fiscal shock to occur at the time of the shock. Raising R_t permits the inflation to persist and the more strongly monetary policy reacts to inflation, the longer the inflation lasts.

Difference equations (15) and (16) make the monetary policy impacts clear. When $\alpha_\pi = 0$, a shock to ε_t^F has no effect on the nominal interest rate. But the larger is α_π, though still less than β, the stronger are the effects of ε_t^F on future nominal interest rates and, through the Fisher relation, future inflation.

Even though the transitory fiscal expansion has no effect on real debt, higher nominal rates bring forth new nominal bond issuances that are proportional to the increases in the price level. Higher nominal debt coupled with higher interest on the debt increases interest payments that raise household nominal wealth in the future. Because future taxes do not rise to offset that wealth increase, aggregate demand and the price level rise in the future.

Expression (15) reveals that an exogenous monetary contraction—lower ε_t^M that raises R_t—triggers exactly the same macroeconomic effects as an exogenous fiscal expansion. Higher interest rates raise debt service and nominal wealth, which increases inflation in the future. In this simple model with a fixed real interest rate, only this perverse implication for monetary policy obtains. We shall discuss the effects of monetary policy contractions in a production economy with longer maturity debt in Section 2.2.[q]

2.2 The Role of Maturity Structure

Tobin (1963) discusses debt management in the context of the "monetary effect of the debt," contrasting this to the "direct fiscal effect" that is determined by the initial increase in the bond-financed deficit. The monetary effect stems from the maturity structure of the debt, which Tobin reasons outlasts the direct effect because it endures over the maturity horizon of the debt. Changes in the maturity composition of debt operate through

[p] Impulse responses to this case are considered in Section 2.3.

[q] The result that a monetary contraction raises future inflation is reminiscent of Sargent and Wallace's (1981) unpleasant monetarist arithmetic, but the mechanism is completely different. In Sargent and Wallace, tighter money today implies looser money in the future and the higher future inflation can feed back to reduce money demand today. Their result does not stem from wealth effects of monetary policy.

impacts on the size and composition of private wealth. Such changes can affect the macro economy, even if they do not entail changing the overall size of the debt. This section obtains closely related impacts from maturity structure in regime F.

The section introduces a full maturity structure of government debt in general form to derive the bond valuation equation and develop some intuition about the role that maturity plays in the endowment economy in regime F. It then uses a simple special case to make transparent the mechanisms at work in regime F.[r]

2.2.1 A General Maturity Structure

Let $B_t(t+j)$ denote the nominal quantity of zero-coupon bonds outstanding in period t that matures in period $t+j$ and let the dollar-price of those bonds be $Q_t(t+j)$. The government's flow budget identity at t is

$$B_{t-1}(t) - \sum_{j=1}^{\infty} Q_t(t+j)[B_t(t+j) - B_{t-1}(t+j)] = P_t s_t$$

In a constant-endowment economy, the bond-pricing equations are

$$Q_t(t+k) = \beta^k E_t \frac{P_t}{P_{t+k}} \tag{17}$$

for $k = 1, 2, \ldots$. These pricing equations imply the no-arbitrage condition that links the price of a k-period bond to the expected sequence of k 1-period bonds

$$Q_t(t+k) = E_t[Q_t(t+1)Q_{t+1}(t+2)\ldots Q_{t+k-1}(t+k)]$$

To derive the bond valuation equation with a general maturity structure, define

$$B_{t-1} \equiv B_{t-1}(t) + \sum_{j=1}^{\infty} Q_t(t+j)B_{t-1}(t+j)$$

as the portfolio of bonds outstanding at the end of period $t-1$ and rewrite the government budget identity as

$$\frac{B_{t-1}}{P_t} = Q_t(t+1)\frac{B_t}{P_t} + s_t$$

Iterating on this bond portfolio version of the constraint, taking expectations and imposing the bond-pricing relations and the consumer's transversality condition yields the valuation equation

$$\frac{B_{t-1}}{P_t} = \sum_{j=0}^{\infty} \beta^j E_t s_{t+j}$$

[r] These derivations draw on Cochrane (2001, 2014).

or, in terms of the underlying bonds

$$\frac{B_{t-1}(t)}{P_t} + \sum_{j=1}^{\infty} \beta^j E_t \frac{B_{t-1}(t+j)}{P_{t+j}} = \sum_{j=0}^{\infty} \beta^j E_t s_{t+j} \tag{18}$$

Use (18) to repeatedly substitute out future price levels to make explicit how maturity structure enters the valuation equation

$$\begin{aligned} \frac{B_{t-1}(t)}{P_t} = E_t \Bigg\{ & s_t + \beta \underbrace{\left[1 - \frac{B_{t-1}(t+1)}{B_t(t+1)}\right]}_{\text{weight on } t+1} s_{t+1} \\ & + \beta^2 \underbrace{\left\{1 - \left[\frac{B_{t-1}(t+2)}{B_{t+1}(t+2)} \frac{B_{t-1}(t+1)}{B_t(t+1)} \left(1 - \frac{B_t(t+2)}{B_{t+1}(t+2)}\right)\right]\right\}}_{\text{weight on } t+2} s_{t+2} + \ldots \Bigg\} \end{aligned} \tag{19}$$

We write this valuation equation more compactly by defining

$$\Lambda_t(t+k) \equiv \frac{B_t(t+k) - B_{t-1}(t+k)}{B_{t+k-1}(t+k)}$$

as newly issued debt that matures in period $t + k$ as a share of total outstanding debt in period $t + k - 1$ that matures at $t + k$. We can now define the maturity weight on the surplus at $t + k$, $L_{t,t+k}$, as depending recursively on these ratios

$$\begin{aligned} L_{t,t} &= 1 \\ L_{t,t+1} &= \Lambda_t(t+1) \\ L_{t,t+2} &= \Lambda_{t+1}(t+2) L_{t,t+1} + \Lambda_t(t+2) \\ L_{t,t+3} &= \Lambda_{t+2}(t+3) L_{t,t+2} + \Lambda_{t+1}(t+3) L_{t,t+1} + \Lambda_t(t+3) \\ &\vdots \\ L_{t,t+k} &= \sum_{j=0}^{k-1} \Lambda_{t+j}(t+k) L_{t,t+j} \end{aligned}$$

The compact form of valuation equation (19) is now

$$\frac{B_{t-1}(t)}{P_t} = \sum_{j=0}^{\infty} \beta^j E_t [L_{t,t+j} s_{t+j}] \tag{20}$$

Given a sequence of surpluses, $\{s_t\}$, discount factors and maturity determine the expected present value of surpluses. Shortening maturity (eg, reducing $\frac{B_{t-1}(t+1)}{B_t(t+1)}$) raises the weights on s_{t+1}, s_{t+2}, s_{t+3}, raising that present value—the backing of debt—and the value of debt. Shortening maturity of bonds due at $t+k$ raises weights on all $s_{t+j}, j \geq k$. In this sense, shortening maturity can offset a decline in surpluses.

Surprise changes in future maturity structure appear as innovations in the weights, $L_{t,t+j}$, in valuation equation (20). If primary surpluses are given, an unanticipated shortening of maturity of bonds held by the public would, by raising the value of outstanding debt, reduce the current price level. Viewed through the lens of the fiscal theory, the Federal Reserve's "operation twist" in 2011 would have a contractionary effect on the economy initially.[s] As the example to which we now turn illustrates, the lower price level at t would ultimately be offset by a higher future price level.

2.2.1.1 An Illustrative Example

To cleanly illustrate the role that changes in maturity structure play in determining the timing of inflation, we examine an example from Cochrane (2014). We use the same constant-endowment economy, but it operates only in periods $t=0, 1, 2$, and then ends; we set the real interest rate to zero, so the discount factor is $\beta=1$. The government issues one- and two-period nominal bonds at the beginning of time, $t=0$, denoted by $B_0(1)$ and $B_0(2)$, and uses surpluses in periods 1 and 2, s_1 and s_2, to retire the debt. At date $t=1$ the government may choose to issue new one-period debt, $B_1(2)$, so the change in debt at $t=1$ is $B_1(2)-B_0(2)$. The three potentially different quantities of bonds sell at nominal prices $Q_0(1), Q_0(2), Q_1(2)$ that obey (17) with $\beta=1$.[t]

Given initial choices of debt, $B_0(1)$ and $B_0(2)$, the government's budget identities in periods 1 and 2 are

$$B_0(1) = P_1 s_1 + Q_1(2)[B_1(2) - B_0(2)] \tag{21}$$

$$B_1(2) \; = P_2 s_2 \tag{22}$$

When primary surpluses are given at $\{s_1, s_2\}$, expression (22) immediately yields the price level in period 2 as

$$\frac{B_1(2)}{P_2} = s_2$$

because $B_1(2)$ is predetermined in period 2.

[s] The premise of the Fed's actions was that if short and long bonds are imperfect substitutes, then increasing demand for long bonds would reduce long-term interest rates. Lower long rates, it was hoped, would stimulate business investment and the housing market.

[t] We normalize the initial price level to be $P_0 = 1$.

Now impose the asset-pricing relations on the bond prices in the period 1 government budget identity, (21), to obtain the bond valuation equation

$$\frac{B_0(1)}{P_1} = s_1 + \left[\frac{B_1(2) - B_0(2)}{B_1(2)}\right] E_1 s_2$$

P_1 depends on the choice of newly issued bonds in period 1.

Solving for expected inflation and bond prices yields

$$E_0\left(\frac{1}{P_2}\right) = Q_0(2) = E_0\left(\frac{s_2}{B_1(2)}\right) = E_0\left[\frac{1}{B_0(2) + (B_1(2) - B_0(2))}\right] s_2$$

$$E_0\left(\frac{1}{P_1}\right) = Q_0(1) = \frac{E_0[s_1]}{B_0(1)} + \frac{1}{B_0(1)} E_0\left[\frac{B_1(2) - B_0(2)}{B_1(2)}\right] s_2$$

So the term structure of interest rates also depends on choices about maturity structure.

We can derive explicit solutions for the actual or realized price level at $t = 1$ in terms of innovations

$$B_0(1)(E_1 - E_0)\left(\frac{1}{P_1}\right) = (E_1 - E_0)s_1 + (E_1 - E_0)\left(\frac{B_1(2) - B_0(2)}{B_1(2)}\right) s_2$$

Surprise increases in the price level in period 1 depend negatively on innovations in time-1 and time-2 surpluses and on unexpected lengthening of the maturity of bonds due in period 2.

These derivations show that the government can achieve any path of the nominal term structure—and in this example, expected inflation—that it wishes by adjusting maturity structure. By unexpectedly selling less time-2 debt, the government reduces the claims to time-2 surpluses, which reduces the revenues that can be used to pay off period-1 bonds. This raises inflation in period 1. That increase in inflation comes from reducing $B_1(2)$, which lowers the price level in period 2, as seen from

$$(E_1 - E_0)\left(\frac{B_1(2)}{P_2}\right) = (E_1 - E_0)s_2$$

If s_2 is given, selling less $B_1(2)$ requires P_2 to fall.

2.2.2 A Useful Special Case

Suppose that the maturity structure declines at a constant rate $0 \leq \rho \leq 1$ each period so that the pattern of bonds issued at $t - 1$ obeys

$$B_{t-1}(t+j) = \rho^j B_{t-1}^m$$

where B_{t-1}^m is the portfolio of these specialized bonds in $t - 1$. When $\rho = 0$ all bonds are one period, whereas when $\rho = 1$ all bonds are consols. The average maturity of the portfolio is $1/(1 - \beta\rho)$.

With this specialization, the government's flow constraint is

$$B_{t-1}^m\left[1-\sum_{j=1}^{\infty}Q_t(t+j)\rho^j\right]=P_ts_t+B_t^m\sum_{j=1}^{\infty}Q_t(t+j)\rho^{j-1}$$

If we define the price of the bond portfolio as

$$P_t^m\equiv\sum_{j=1}^{\infty}Q_t(t+j)\rho^{j-1}$$

then the government's budget identity becomes

$$B_{t-1}^m(1+\rho P_t^m)=P_ts_t+P_t^mB_t^m \tag{23}$$

Bond portfolio prices obey the recursion

$$P_t^m=Q_t(t+1)[1+\rho E_tP_{t+1}^m]=R_t^{-1}[1+\rho E_tP_{t+1}^m] \tag{24}$$

This shows that a constant geometric decay rate in the maturity structure of zero-coupon bonds is equivalent to the interpretation of bonds that pay geometrically decaying coupon payments, as in Woodford (2001) and Eusepi and Preston (2013).

Let R_{t+1}^m denote the gross nominal return on the bond portfolio between t and $t+1$. Then $R_{t+1}^m=(1+\rho P_{t+1}^m)/P_t^m$ and the no-arbitrage condition implies that

$$\frac{1}{R_t}=\beta E_t\nu_{t+1}=E_t\left(\frac{1}{R_{t+1}^m}\right) \tag{25}$$

Combining (24) and (25) and iterating forward connects bond prices to expected paths of the short-term nominal interest rate and inflation

$$P_t^m=\sum_{j=0}^{\infty}\rho^jE_t\left(\prod_{i=0}^{j}R_{t+i}^{-1}\right)=\beta\sum_{j=0}^{\infty}(\beta\rho)^jE_t\left(\prod_{i=0}^{j}\nu_{t+i+1}\right) \tag{26}$$

2.3 Maturity Structure in Regime F

Ricardian equivalence in regime M makes the maturity structure of debt irrelevant for inflation, so in this section we focus solely on regime F. When surpluses are exogenous ($\gamma=0$), the debt valuation equation becomes[u]

[u] To derive (27), convert the nominal budget identity in (23) into a difference equation in the real value of debt, P^mB^m/P, impose pricing equations (24) and (25), using the fact that $\beta^{-1}=E_{t-1}[\nu_t(1+\rho P_t^m)/P_{t-1}^m]$, iterate forward, and impose the household's transversality condition for debt.

$$\frac{(1+\rho P_t^m)B_{t-1}^m}{P_t} = (1-\beta)^{-1} s^* + \sum_{j=0}^{\infty} \beta^j E_t \varepsilon_{t+j}^F \tag{27}$$

In contrast to the situation with only one-period debt ($\rho = 0$) when fiscal news appeared entirely in jumps in the price level, now there is an additional channel through which debt can be revalued: bond prices that reflect expected inflation over the entire duration of debt. News of lower future surpluses reduces the value of debt through both a higher P_t and a lower P_t^m. By (26), the lower bond price portends higher inflation and higher one-period nominal interest rates. The ultimate mix between current and future inflation is determined by the monetary policy rule. Long-term debt opens a new channel for monetary and fiscal policy to interact.

No-arbitrage condition (26) reveals a key aspect of regime F equilibria with long debt. With the simplified maturity structure, ρ determines the average maturity of the zero-coupon bond portfolio. A given future inflation rate has a larger impact on the price of bonds, the larger is ρ or the longer is the average maturity of debt. The maturity parameter serves as an additional discount factor, along with β, so more distant inflation rates have a smaller impact on bond prices than do rates in the near future. Of course, the date t expected present value of inflation influences only the price of bonds that are outstanding at the beginning of t, namely, B_{t-1}^m.

To understand monetary policy's influence on the timing of inflation, note that when monetary policy is passive, $\alpha_\pi/\beta < 1$, (9) implies that k-step-ahead expected inflation is

$$E_t \nu_{t+k} = \left(\frac{\alpha_\pi}{\beta}\right)^k (\nu_t - \nu^*) + \nu^*$$

which may be substituted into the pricing equation that links P_t^m to the term structure of inflation rates, (26), to yield[v]

$$\rho P_t^m = \sum_{j=1}^{\infty} (\beta\rho)^j \left\{ \prod_{i=0}^{j-1} \left[\left(\frac{\alpha_\pi}{\beta}\right)^{i+1} (\nu_t - \nu^*) + \nu^* \right] \right\}$$

Monetary policy's reaction to inflation—through α_π—interacts with the average maturity of debt—ρ—to determine how current inflation—ν_t, which is given by (13) in regime F—affects the price of bonds. More aggressive monetary policy and longer maturity debt both serve to amplify the impact of current inflation on bond prices, suggesting that higher α_π and higher ρ permit fiscal disturbances to have a smaller impact on current inflation at the cost of a larger impact on future inflation.

[v] Here we shut down the exogenous monetary policy shock, $\varepsilon_t^M \equiv 0$.

Consider two polar cases of passive monetary policy. When $\alpha_\pi = 0$, so the central bank pegs the nominal interest rate and bond prices at $\rho P_t^m = \beta\rho\nu^*/(1-\beta\rho\nu^*)$, the valuation expression becomes

$$\left(\frac{1}{1-\beta\rho\nu^*}\right)\nu_t b_{t-1}^m = (1-\beta)^{-1}s^* + \sum_{j=0}^{\infty}\beta^j E_t\varepsilon_{t+j}^F$$

where we define $b_{t-1}^m \equiv B_{t-1}^m/P_{t-1}$. In this case, expected inflation returns to target immediately, $E_t\nu_{t+j} = \nu^*$ for $j \geq 1$.

The second case is when monetary policy reacts as strongly as possible to inflation, while still remaining passive: $\alpha_\pi = \beta$.[w] Then $\rho P_t^m = \beta\rho\nu_t/(1-\beta\rho\nu_t)$ and the valuation equation is[x]

$$\left(\frac{\nu_t}{1-\beta\rho\nu_t}\right)b_{t-1}^m = (1-\beta)^{-1}s^* + \sum_{j=0}^{\infty}\beta^j E_t\varepsilon_{t+j}^F$$

Now inflation follows a martingale with $E_t\nu_{t+j} = \nu_t$ for $j \geq 1$.

The two polar cases are starkly different. By pegging the nominal interest rate, monetary policy anchors expected inflation on the steady-state (target) inflation rate and bond prices are constant. The full impact of a lower present value of surpluses must be absorbed by higher current inflation—lower ν_t—alone. But when monetary policy raises the nominal rate with current inflation by a proportion equal to the discount factor, higher current inflation is expected to persist indefinitely. Bond prices fall by the expected present value of that higher inflation rate, discounted at the rate $\beta\rho$. With the required change in inflation spread evenly over the term to maturity of outstanding debt, when fiscal news arrives, inflation needs to rise by far less than it does when bond prices are pegged. Of course, the "total"—present value—inflation effect of the fiscal shock is identical in the two cases. Although aggressive monetary policy cannot diminish the total inflationary impact, it can influence the timing of when inflation occurs.

We can consider both these polar cases and the intermediate case where $0 < \alpha_\pi < \beta$, by solving the model numerically in the presence of transfer shocks.[y] These are calibrated following Bi et al. (2013). We assume that the steady-state ratio of transfers to GDP is 0.18, government spending is 21% of GDP and taxes amount to 41% of GDP implying an (annualized) steady-state debt–GDP ratio of 50%. Transfers fluctuate according to an autoregressive process with persistence parameter of $\rho_z = 0.9$, and variance of $(0.005z^*)$.

[w] If monetary policy were to turn active, while fiscal policy remained active, then we would have an unstable equilibrium. The implications of temporarily being in such a regime are considered in Section 7.3.

[x] This result requires that $\beta\rho\nu_t < 1$ for all realizations of ν_t, so there cannot be "too much" deflation.

[y] The solution procedure follows Leith and Liu (2014), which relies on Chebyshev collocation methods and Gauss–Hermite quadrature to evaluate the expectations terms.

In this simple model with an active fiscal policy that does not respond to debt levels, the equilibrium outcome depends on the maturity of the debt stock and the responsiveness of monetary policy to inflation.

Fig. 1 plots the response to an increase in transfers. Each column represents a different value of the response of monetary policy to inflation. Monetary policy pegs the nominal rate in the first column, so the paths of all variables are the same across maturities: the entire adjustment occurs through surprise inflation in the initial period. In the second column $\alpha_\pi = 0.5$. Now differences emerge across maturities. With one-period debt the magnitude of the initial jump in inflation is the same as under a pegged interest rate because this is the price-level jump that is required to reduce the real value of debt to be consistent with lower surpluses. But the monetary policy reaction keeps inflation high for a prolonged period even though it is only the initial jump in inflation that serves to reduce the debt burden. As average maturity increases, the initial jump in inflation becomes smaller. A sustained rise in interest rates depresses bond prices, which allow the bond valuation equation to be satisfied at lower initial inflation rates. It is the surprise change in the *path* of inflation that occurs over the life of the maturing debt stock that reduces the real value of debt. With a positive value of α_π, any jump in inflation is sustained, which unexpectedly reduces the real returns that bondholders receive before that debt is rolled over. As we increase the responsiveness of the interest rate to inflation further to $\alpha_\pi = 0.9$, the surprise inflation needed to deflate the real value of debt remains unchanged for single-period debt, but is dramatically reduced for longer period debt. When $\alpha_\pi = 0.99$, as demonstrated analytically earlier, and $\rho > 0$, the rate of inflation follows a near-random walk, jumping to the level needed to satisfy the valuation equation.

The timing of the transfer shock—whether it is *i.i.d.* or persistent, realized immediately or in the future—does not matter beyond the change in the expected discounted value of surpluses that it produces. That present value must be financed with a path of inflation that combines current inflation surprises, and through bond prices, future inflation surprises, to ensure solvency. An anticipated increase in transfers produces surprise inflation today that reduces the current value of the outstanding debt stock, but whose value increase after the increase in transfers is realized.

This result foreshadows an important aspect of optimal policy, which Sections 4 and 5 explore: monetary policy can smooth the distortionary effects of fiscally induced inflation. The above analysis uses an endowment economy subjected to transfer shocks. That environment has the feature that under regime M, monetary policy can perfectly control inflation, while under regime F, prices are determined by the needs of fiscal solvency—the dichotomy across regimes that was emphasized in the original fiscal theory. The more general case breaks the dichotomy to produce interactions between monetary and fiscal policy in both policy regimes. This situation can arise even in the endowment economy when we consider government spending shocks rather than shocks to lump-sum transfers.

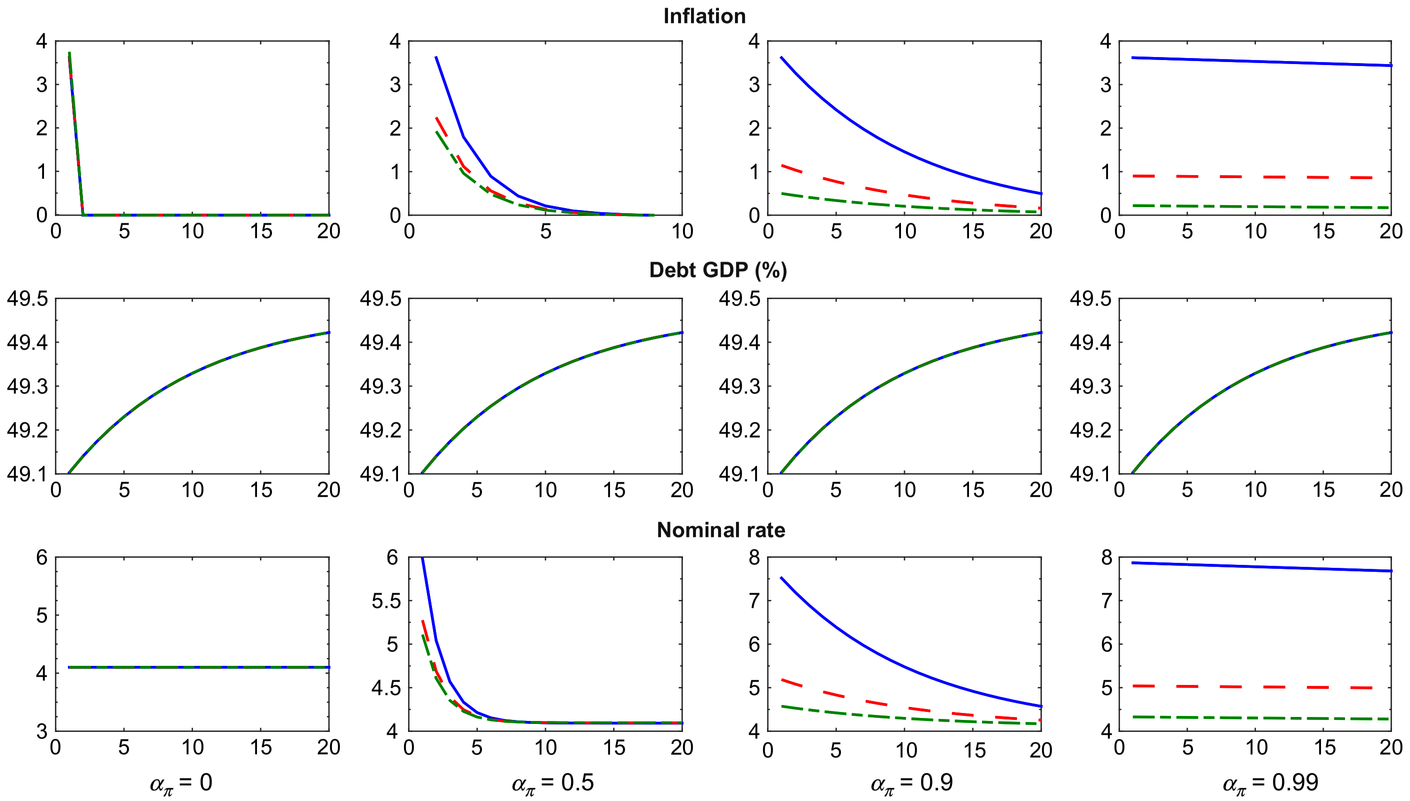

Fig. 1 Responses to an increase in transfers under alternative monetary policy rules and alternative maturity structures. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), and 5-year debt (*dot-dashed lines*).

2.3.1 Increase in Government Spending

Government spending has implications for both monetary and fiscal policy. The direct impact on the government's finances is obvious. But given the resource constraint, $y = c_t + g_t$, variations in public consumption will have a one-for-one impact on private consumption which affects the stochastic discount factor. Through this channel government purchases carry additional effects on inflation and debt dynamics. Again we distinguish between the M and F regimes, although monetary and fiscal policy will interact under both.

2.3.1.1 Policy Under Regime M

When monetary policy is active and fiscal policy is passive, the analysis of the case of transfer shocks largely carries through, although with some additional monetary and fiscal interactions. Substituting the Fisher relation into the monetary policy rule yields the deflation dynamics[z]

$$v_t - v^* = \frac{\beta}{\alpha_\pi} E_t \left[\frac{u'(c_{t+1})}{u'(c_t)} v_{t+1} - v^* \right]$$

which can be solved forward as

$$v_t = \frac{\alpha_\pi - \beta}{\alpha_\pi} E_t \sum_{i=0}^{\infty} \left(\frac{\beta}{\alpha_\pi} \right)^i \frac{u'(c_{t+i})}{u'(c_t)} v^*$$

Inflation deviates from target in proportion to the deviations of the real interest rate path from steady state. Higher government spending raises the real interest rate and inflation.

Debt dynamics emerge from three distinct impacts of government spending: the direct effect on the fiscal surplus, the surprise inflation that arises in conjunction with the monetary policy rule, and movements in real interest rates. Monetary policy can insulate inflation from government spending shocks by reacting to real interest rates, as well as inflation, with the rule

$$\frac{1}{R_t} = \frac{1}{R^*} E_t \frac{u'(c_{t+1})}{u'(c_t)} + \alpha_\pi (\nu_t - \nu^*) \tag{28}$$

By this rule, the policymaker accommodates changes in the natural rate of interest caused by fluctuations in public consumption without deviating from the inflation target. To see this, combine this rule with the Fisher equation to get

[z] When the real interest rate can vary, the Fisher relation is

$$\frac{1}{R_t} = \beta E_t \frac{u'(c_{t+1})}{u'(c_t)} \nu_{t+1}$$

$$v_t - v^* = \frac{\beta}{\alpha_\pi} E_t \frac{u'(c_{t+1})}{u'(c_t)} (v_{t+1} - v^*)$$

Policy rule (28) implies that inflation/deflation is always equal to target, $v_t = v^*$. If the monetary policy rule does not respond to fiscal variables, inflation will be influenced by government spending shocks. Inflation can be insulated from fiscal shocks by allowing monetary policy to directly respond to the effects of fiscal policy on the natural rate of interest.

2.3.1.2 Policy Under Regime F

In regime F government spending shocks require jumps in inflation to satisfy the bond valuation equation[aa]

$$\begin{aligned}(1+\rho P_t^m)\frac{B_{t-1}^m}{P_t} &= E_t \sum_{i=0}^{\infty} \beta^i \frac{u'(c_{t+i})}{u'(c_t)} s_{t+i} \\ &= E_t \sum_{i=0}^{\infty} \beta^i \frac{u'(c_{t+i})}{u'(c_t)} s^* - E_t \sum_{i=0}^{\infty} \beta^i \frac{u'(c_{t+i})}{u'(c_t)} \varepsilon_{t+i}^G\end{aligned}$$

An increase in government spending increases the marginal utility of consumption, which increases real interest rates and requires a larger initial jump in inflation and drop in bond prices. Bond prices themselves are directly affected by the change in private consumption that arises when the government absorbs a larger share of resources, as the bond-pricing equation shows

$$P_t^m = \beta E_t (1 + \rho P_{t+1}^m) v_{t+1} \frac{u'(c_{t+1})}{u'(c_t)}$$

Bond prices fall initially and then gradually increase as the period of raised public consumption passes.

Adopting a specific form of utility, $u(c_t) = c_t^{1-\sigma}/(1-\sigma)$, with $\sigma = 2$, we can solve the model in the face of autocorrelated government spending shocks with $\rho_g = 0.9$, and variance of $0.005g^*$. As before, the stochastic model is solved nonlinearly using Chebyshev collocation methods (see Leith and Liu, 2014). Fig. 2 reflects the response to government spending shocks which are broadly consistent with the impacts of transfer shocks that appear in Fig. 1. The main difference is that the growth in consumption as government spending returns to steady state is equivalent to an increase in the real interest rate. But the main message that single-period debt requires an initial jump in inflation to stabilize debt and that this jump is unaffected by the description of the monetary policy parameter α_π remains. Once debt maturity extends beyond a single period, prolonging the initial

[aa] Shutting down shocks to lump-sum taxes and transfers, the surplus is defined as $s_t = \tau^* - z^* - g_t$, where $g_t = g^* \varepsilon_t^G$, and $\ln \varepsilon_t^g = \rho_g \ln \varepsilon_{t-1}^g + \xi_t$.

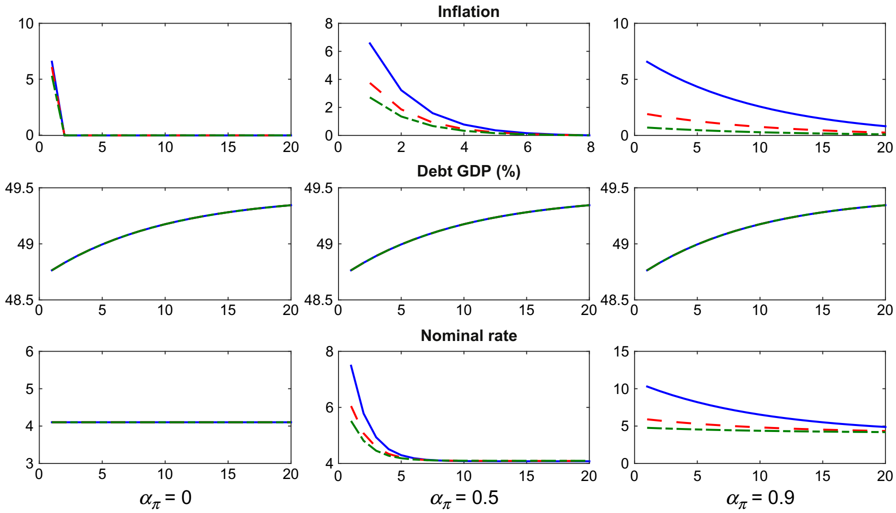

Fig. 2 Responses to an increase in government purchases under alternative monetary policy rules and alternative maturity structures. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), and 5-year debt (*dot-dashed lines*).

jump in inflation can serve to reduce the magnitude of that initial jump. A sustained rise in inflation can also serve to satisfy the government's intertemporal budget identity through reducing bond prices. Essentially the inflation surprise is spread throughout the life to maturity of the outstanding debt stock.

3. PRODUCTION ECONOMIES WITH AD HOC POLICY RULES

The endowment economy is useful for understanding the mechanisms that underlie the fiscal theory. But the exogeneity of the real interest rate and the constancy of output limit a complete understanding of the theory and, in some cases, distort that understanding. We now turn to a conventional model in which inflation and output are determined jointly. In extending the analysis to the new Keynesian model we are widening the potential channels through which monetary and fiscal policy interact. To do so incrementally, we assume that taxes remain lump sum so that the effects of monetary policy on output do not affect the tax base to which a distortionary tax is applied. This means that the extra channel we are adding by introducing nominal inertia to a production economy is that monetary policy has influence over ex-ante real interest rates as well as nominal interest rates. This in turn means that the policymaker can ensure the bond valuation equation holds following fiscal shocks through a reduction in ex-ante real interest rates and not just ex-post real interest rates through inflation surprises.[ab] When we consider optimal policy in the new Keynesian model we shall allow taxes to distort behavior.

3.1 A Conventional New Keynesian Model

Endogenous output together with sticky prices allow both monetary policy and, in the case of regime F, fiscal policy to have real effects on the economy. We use a textbook version of a new Keynesian model of the kind that Woodford (2003) and Galí (2008) present. Because existing literature, including those two textbooks, thoroughly examines the nature of regime M equilibria, our exposition focuses exclusively on regime F.[ac]

The model's key features include: a representative consumer and firm; monopolistic competition in final goods; Calvo (1983) sticky prices in which a fraction $1-\phi$ of goods suppliers sets a new price each period; a cashless economy with one-period nominal bonds, B_t, that sell at price $1/R_t$, where R_t is also the monetary policy instrument; for now, government purchases are zero, so the aggregate resource constraint is $c_t = y_t$; an exogenous primary government surplus, s_t, with lump-sum taxes; and shocks only to monetary and fiscal policies.[ad] We solve a version of the model that is log-linearized around the deterministic steady state with zero inflation.

Let $\hat{x}_t \equiv \ln(x_t) - \ln(x^*)$ denote log deviations of a variable x_t from its steady-state value. Private-sector behavior reduces to a consumption-Euler equation

$$\hat{y}_t = E_t\hat{y}_{t+1} - \sigma(\hat{R}_t - E_t\hat{\pi}_{t+1}) \tag{29}$$

and a Phillips curve

$$\hat{\pi}_t = \beta E_t\hat{\pi}_{t+1} + \kappa\hat{y}_t \tag{30}$$

where $\sigma \equiv -\dfrac{u'(y^*)}{u''(y^*)y^*}$ is the intertemporal elasticity of substitution, $\omega \equiv \dfrac{w'(y^*)}{w''(y^*)y^*}$ is the elasticity of supply of goods, $\kappa \equiv \dfrac{(1-\phi)(1-\phi\beta)}{\phi}\dfrac{\omega+\sigma}{\sigma(\omega+\theta)}$ is the slope of the Phillips curve, and θ is the elasticity of substitution among differentiated goods. The parameters obey $0 < \beta < 1, \sigma > 0, \kappa > 0$.

[ab] By introducing this channel we could, in fact, turn off the revaluation effects stressed by the fiscal theory by assuming debt was solely real but still consider equilibria where monetary policy was passive and fiscal active. In this sense, as we widen the range of monetary and fiscal interactions, unconventional policy assignments do not necessarily require the revaluation mechanisms inherent in the fiscal theory to support determinate equilibria.

[ac] We draw from Woodford (1998a), but Kim (2003), Cochrane (2014), and Sims (2011) study closely related models.

[ad] Because these shocks have no effects on the natural rate of output, there is no distinction between deviations in output from steady state and the output gap.

3.1.1 Policy Rules

Monetary policy follows a conventional interest rate rule

$$\hat{R}_t = \alpha_\pi \hat{\pi}_t + \alpha_y \hat{y}_t + \varepsilon_t^M \tag{31}$$

and fiscal policy sets the surplus process, $\{\hat{s}_t\}$, exogenously, where $\hat{s}_t \equiv (s_t - s^*)/s^*$. By setting the surplus exogenously, we are implicitly assuming that taxes are lump sum so that any variations in real activity do not impact on the size of the tax base.

Policy choices must satisfy the flow budget identity, $\frac{1}{R_t}\frac{B_t}{P_t} + s_t = \frac{B_{t-1}}{P_t}$, which is linearized as

$$\hat{b}_t - \hat{R}_t + \left(\beta^{-1} - 1\right)\hat{s}_t = \beta^{-1}\left(\hat{b}_{t-1} - \hat{\pi}_t\right) \tag{32}$$

where b_t is real debt at the end of period t and π_t is the inflation rate between $t-1$ and t. Although this linearized budget identity does not appear to contain the steady-state debt-to-GDP ratio, the calibration of the surplus shock does implicitly capture the underlying steady-state level of debt.

3.1.2 Solving the Model in Regime F

The four-equation system—(29)–(32)—together with exogenous $\{\hat{s}_t\}$ yields solutions for $\{\hat{y}_t, \hat{\pi}_t, \hat{R}_t, \hat{b}_t\}$. Woodford (1998a) shows that a unique equilibrium requires that monetary policy react relatively weakly to inflation and output: α_π and α_y must satisfy

$$-1 - \frac{1+\beta}{\kappa}\alpha_y - \frac{2(1+\beta)}{\kappa\sigma} < \alpha_\pi < 1 - \frac{1-\beta}{\kappa}\alpha_y$$

For practical reasons, we restrict α_π's lower bound to 0. In this case, when monetary policy does not respond to output, this reduces to the condition that passive monetary policy requires $0 \le \alpha_\pi < 1$. In the analytical results that follow, we use this simplified policy rule; numerical results will bring the output response of monetary policy back in.

Substituting the simplified version of the monetary policy rule ($\alpha_y = 0$) into the government budget identity and iterating forward immediately yield several robust features of regime F equilibria

$$E_t\sum_{j=0}^{\infty}\beta^j\hat{\pi}_{t+j} = \left(\frac{1}{1-\alpha_\pi\beta}\right)\left[\hat{b}_{t-1} - (1-\beta)E_t\sum_{j=0}^{\infty}\beta^j\hat{s}_{t+j} + \beta E_t\sum_{j=0}^{\infty}\beta^j\varepsilon_{t+j}^M\right] \tag{33}$$

Although expression (33) is not an equilibrium solution to the model (since we still need to solve the path for inflation), it highlights several features that the solution displays. First, higher initial debt, a lower expected path of surpluses, or a higher expected path of the monetary shock all raise the present value of inflation. Second, a stronger response of monetary policy to inflation, but still consistent with existence of a bounded equilibrium, *amplifies* those inflationary effects. Dependence of inflation on the debt stock and surpluses is ubiquitous in regime F. Perversely, a higher path of the monetary shock or a higher value for α_π constitute a tightening of policy, yet they raise inflation.

In the flexible-price case, $\kappa = \infty$, so $\hat{y}_t \equiv 0$, and a solution for equilibrium inflation is immediate. This case collapses back to the endowment economy in Section 2.1.2.2 with a constant real rate and the simple Fisher relation $\hat{R}_t = E_t\hat{\pi}_{t+1}$. Combine the monetary policy rule with $\alpha_y = 0$ with the Fisher relation to solve for expected inflation

$$E_t\hat{\pi}_{t+j} = \alpha_\pi^j \hat{\pi}_t + \alpha_\pi^{j-1}\varepsilon_t^M + \alpha_\pi^{j-2}E_t\varepsilon_{t+1}^M + \cdots + \alpha_\pi E_t\varepsilon_{t+j-2}^M + E_t\varepsilon_{t+j-1}^M$$

and use this expression to replace expected inflation rates in (33). Equilibrium inflation is

$$\hat{\pi}_t = \hat{b}_{t-1} + \beta(1-\alpha_\pi\beta)E_t\sum_{j=0}^{\infty}\beta^j\varepsilon_{t+j}^M - (1-\beta)E_t\sum_{j=0}^{\infty}\beta^j\hat{s}_{t+j}$$

Actual inflation rises with initial debt, a higher path of the monetary policy shock, or a lower path for surpluses. The effects of surpluses on inflation are independent of the monetary policy choice of α_π, although we saw above that those fiscal effects on expected inflation are amplified by more aggressive monetary policy.

Solving the sticky-price new Keynesian model is more complicated. When $0 < \kappa < \infty$, both output and the real interest rate are endogenous. Defining the real interest rate as $\hat{r}_{t+j} \equiv \hat{R}_{t+j-1} - \hat{\pi}_{t+j}$, write the bond valuation equation as

$$\hat{\pi}_t - E_t\sum_{j=1}^{\infty}\beta^j\hat{r}_{t+j} = \hat{b}_{t-1} - (1-\beta)E_t\sum_{j=0}^{\infty}\beta^j\hat{s}_{t+j}$$

News about lower future surpluses shows up as a mix of higher current inflation and a lower path for the real interest rate. Lower real rates, in turn, transmit into higher output. Fiscal expansions have the old-Keynesian effects—higher real activity and inflation—and monetary policy behavior determines the split between them.

Combining the Euler equation, the Phillips curve and the monetary policy rule produce a second-order difference equation in inflation

$$E_t\hat{\pi}_{t+2} - \frac{1+\beta+\sigma\kappa}{\beta}E_t\hat{\pi}_{t+1} + \frac{1+\alpha_\pi\sigma\kappa}{\beta}\hat{\pi}_t = -\frac{\sigma\kappa}{\beta}\varepsilon_t^M$$

One can show that, given the restrictions on the underlying model parameters, this difference equation has two real roots, one inside $|\lambda_1| < 1$ and one outside $|\lambda_2 > 1|$ the unit circle, which yields the solution for expected inflation[ae]

[ae] Letting $\gamma_1 \equiv (1 + \beta + \sigma\kappa)/\beta$ and $\gamma_0 \equiv (1 + \alpha_\pi\sigma\kappa)/\beta$, the roots are $\lambda_1 = (1/2)(\gamma_1 - \sqrt{\gamma_1^2 - 4\gamma_0})$ and $\lambda_2 = (1/2)(\gamma_1 + \sqrt{\gamma_1^2 - 4\gamma_0})$. These derivations owe much to Tan (2015) who employs the techniques that Tan and Walker (2014) develop.

$$E_t\hat{\pi}_{t+1} = \lambda_1\hat{\pi}_t + (\beta\lambda_2)^{-1}\sigma\kappa E_t\sum_{j=0}^{\infty}\lambda_2^j\varepsilon_{t+j}^M \tag{34}$$

We can now solve for the j-step-ahead expectation of inflation by defining the operator $\mathcal{B}^{-j}x_t \equiv E_t x_{t+j}$ and iterating on (34)

$$\mathcal{B}^{-j}\hat{\pi}_t = \lambda_1^j\hat{\pi}_t + \frac{\sigma\kappa}{\lambda_2\beta}\frac{1}{1-\lambda_2^{-1}\mathcal{B}^{-1}}\left(\lambda_1^{j-1} + \lambda_1^{j-2}\mathcal{B}^{-1} + \cdots + \mathcal{B}^{-j+1}\right)\varepsilon_t^M$$

This yields the solution for expected discounted inflation that appears in (33)

$$E_t\sum_{j=0}^{\infty}\beta^j\hat{\pi}_{t+j} = \frac{1}{1-\lambda_1\beta}\hat{\pi}_t + \frac{\sigma\kappa}{\lambda_2(1-\lambda_1\beta)}\frac{1}{(1-\lambda_2^{-1}\mathcal{B}^{-1})(1-\beta\mathcal{B}^{-1})}\varepsilon_t^M$$

Using this expression for discounted inflation in (33) delivers a solution for equilibrium inflation

$$\begin{aligned}\hat{\pi}_t = {} & \left(\frac{1-\lambda_1\beta}{1-\alpha_\pi\beta}\right)\left[\hat{b}_{t-1} - \left(\frac{1-\beta}{1-\beta\mathcal{B}^{-1}}\right)\hat{s}_t\right] \\ & + \left[\frac{1-\lambda_1\beta}{1-\alpha_\pi\beta} - \frac{\sigma\kappa}{\lambda_2}\frac{1}{(1-\lambda_2^{-1}\mathcal{B}^{-1})}\right]\frac{1}{1-\beta\mathcal{B}^{-1}}\varepsilon_t^M\end{aligned} \tag{35}$$

It is straightforward to show how the monetary policy parameter affects inflation

$$\frac{\partial\lambda_1}{\partial\alpha_\pi} > 0, \quad \frac{\partial\lambda_2}{\partial\alpha_\pi} < 0, \quad \frac{\partial[\lambda_2(1-\lambda_1\beta)]}{\partial\alpha_\pi} < 0 \quad \frac{\partial\left(\frac{1-\lambda_1\beta}{1-\alpha_\pi\beta}\right)}{\partial\alpha_\pi} > 0$$

More aggressive monetary policy—larger α_π—affects the equilibrium in the following ways

- amplifies the impacts on inflation from outstanding debt and exogenous disturbances to monetary policy and surpluses
- makes the effects of these shocks on inflation more persistent.

Evidently, if fiscal policies set surpluses exogenously, monetary policy is impotent to offset fiscal effects on inflation. And adopting a more hawkish monetary policy stance has the perverse effect of amplifying and propagating the effects of shocks on inflation.

In this basic new Keynesian model, fiscal disturbances are transmitted to output through the path of the ex-ante real interest rate, as the consumption-Euler equation, (29), makes clear. Define the one-period real interest rate as $\hat{r}_t \equiv \hat{R}_t - E_t\hat{\pi}_{t+1}$. To simplify expressions, temporarily shut down the monetary policy shock, $\varepsilon_t^M \equiv 0$. Date the solution for inflation from (35) at t + 1, take expectations, and substitute the monetary policy rule for the interest rate. After some tedious algebra, the equilibrium real interest rate is

$$\hat{r}_t = \frac{(\alpha_\pi - \lambda_1)(1-\lambda_1\beta)}{1-\alpha_\pi\beta}\left[\hat{b}_{t-1} - (1-\beta)\sum_{j=0}^{\infty}\hat{s}_{t+j}\right]$$

The lead coefficient, $\alpha_\pi - \lambda_1$, depends on monetary policy behavior and on all the model parameters. Because its sign can be positive or negative, lower expected surpluses may lower or raise the short-term real interest rate on impact.

Substituting the monetary policy rule into the definition of the real interest rate and suppressing the monetary policy shock yield

$$\hat{r}_t = \alpha_\pi\hat{\pi}_t - E_t\hat{\pi}_{t+1}$$

Using the Phillips curve to eliminate inflationary expectations we obtain

$$\hat{r}_t = (\alpha_\pi - \beta^{-1})\hat{\pi}_t - \beta^{-1}\kappa\hat{y}_t$$

which shows that a given level of positive inflation and output deviations from steady state will be consistent with lower real interest rates the smaller is the monetary policy response to inflation. The intuition is very similar to that in the endowment economy: a passive monetary policy that responds to inflation generates a sustained rise in inflation which does not facilitate the stabilization of single-period debt. In the new Keynesian case such a policy response mitigates the reduction in debt service costs which are an additional channel through which the passive monetary policy stabilizes debt in a sticky-price economy.

3.2 Maturity Structure in Regime F

We introduce the simplified maturity structure that Section 2.2.2 describes, in which government debt maturity decays at the constant rate ρ each period, into the new Keynesian model of Section 3.1. The no-arbitrage condition links bond prices to the one-period nominal interest rate

$$\hat{P}_t^m = -\hat{R}_t + \beta\rho E_t\hat{P}_{t+1}^m$$

which implies the term structure relation

$$\begin{aligned}\hat{P}_t^m &= -E_t\sum_{j=0}^{\infty}(\beta\rho)^j\hat{R}_{t+j}\\ &= -\frac{1}{1-\beta\rho\mathcal{B}^{-1}}\left[\alpha_\pi\hat{\pi}_t + \varepsilon_t^M\right]\end{aligned}$$

where we have substituted the simpler monetary policy rule in for the nominal interest rate.

The government's flow budget identity is

$$\beta(1-\rho)\hat{P}_t^m + \beta\hat{b}_t^m + (1-\beta)\hat{s}_t + \hat{\pi}_t = \hat{b}_{t-1}^M \tag{36}$$

where we are defining $b_t^m \equiv B_t^m / P_t$ to be the real face value of outstanding debt.[af] Because bond prices depend on the expected infinite path of inflation and the monetary policy shock, analytical solutions along the lines of Section 3.1.2, though feasible, are cumbersome. For example, the analog to the discounted inflation expression, (33), is

$$\frac{1}{1-\beta\mathcal{B}^{-1}}\left[1-\frac{\alpha_\pi\beta(1-\rho)}{1-\beta\rho\mathcal{B}^{-1}}\right]\hat{\pi}_t = \hat{b}_{t-1}^m - \left(\frac{1-\beta}{1-\beta\mathcal{B}^{-1}}\right)\hat{s}_t + \frac{\beta(1-\rho)}{(1-\beta\mathcal{B}^{-1})(1-\beta\rho\mathcal{B}^{-1})}\varepsilon_t^M$$

which collapses to (33) when $\rho = 0$ so all debt is one period. The solution for equilibrium inflation, like that when there is only one-period debt in equation (35), depends on all the parameters of the model through the eigenvalues λ_1 and λ_2, but the analytical expression for inflation is too complex to offer useful intuition.

One-period debt makes the value of debt depend only on the current nominal interest rate and, through the monetary policy rule, current inflation. A maturity structure makes that value depend on the entire expected path of nominal interest rates. This gives monetary policy an expanded role in debt stabilization, allowing expected future monetary policy to affect the value of current debt. This additional channel operates through terms in $1/(1-\beta\rho\mathcal{B}^{-1})$ that create double infinite sums in the equilibrium solution.

3.2.1 Impacts of Fiscal Shocks

Figs. 3 and 4 illustrate the impacts of a serially correlated increase in the primary fiscal deficit financed by nominal bond sales.[ag] Fig. 3 maintains that all debt is one period to focus on how different monetary policy rules alter the impacts of a fiscal expansion.

When monetary policy pegs the nominal interest rate—$\alpha_\pi = \alpha_Y = 0$—it fixes the bond price, which front loads fiscal adjustments through current inflation and the real interest rate. Inflation rises, the real rate falls and output increases. Responses inherit the serial correlation properties of the fiscal disturbance. As monetary policy becomes progressively less passive, reacting more strongly to inflation and output, it amplifies and propagates the fiscal shock (dashed lines in Fig. 3). By reacting more strongly to inflation, monetary policy ensures that the real interest rate declines by less, tempering the short-run output increases.

The figure makes clear the role that debt plays in propagating shocks in regime F. Stronger and more persistent nominal interest rate increases transmit directly into stronger and more persistent growth in the nominal market value of debt.[ah] And persistently higher nominal debt keeps household nominal wealth and, therefore, nominal demand elevated, creating strong serial correlation in inflation and output. This internal

[af] The real market value is $P_t^m B_t^m / P_t$. To derive (36), we use the steady-state relationships $P^{m*} = 1/(\beta^{-1} - \rho)$ and $s^*/b^{m*} = (1-\beta)/(1-\beta\rho)$ in log-linearizing the government budget identity.

[ag] We calibrate the model to an annual frequency, setting $\beta = 0.95, \sigma = 1, \kappa = 0.3$. The surplus is $AR(1)$, $\hat{s}_t = \rho_{FP}\hat{s}_{t-1} + \varepsilon_t^F$, with $\rho_{FP} = 0.6$.

[ah] Growth in the nominal market value of debt is $P_t^m B_t^M / P_{t-1}^m B_{t-1}^m$.

Calibration reported in Footnote ag. $\alpha_\pi = \alpha_Y = 0$ (*solid lines*), $\alpha_\pi = \alpha_Y = 0.5$ (*dashed lines*), and $\alpha_\pi = 0.9$, $\alpha_Y = 0.5$ (*dot-dashed lines*).

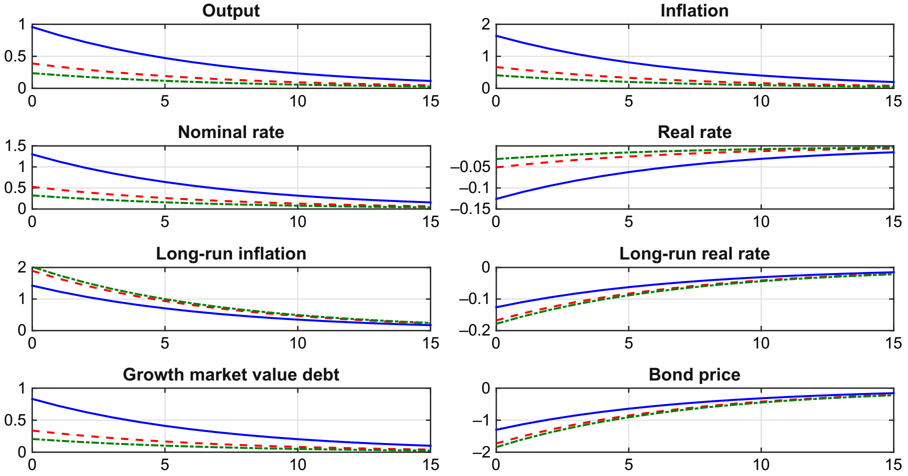

Fig. 4 Responses to a 20% increase in the initial deficit under alternative maturity structures. Calibration reported in Footnote ag with $\alpha_\pi = \alpha_Y = 0.5$. 1-year debt (*solid lines*), 5-year debt (*dashed lines*), and consol debt (*dot-dashed lines*).

propagation mechanism through government debt is absent from regime M, where higher debt carries with it the promise of higher taxes that eliminate wealth effects.

Fig. 4 holds the monetary policy rule fixed, setting $\alpha_\pi = \alpha_Y = 0.5$, to reveal how changes in maturity affect fiscal impacts. The figure contrasts one-period debt (solid lines) to an average of 5-year maturity (dashed lines) and consol debt (dot-dashed lines). Longer

Table 2 The fiscal shock initially raises the deficit by 20%

α_π	α_Y	Maturity	% due to $\hat{\pi}_t$	% due to $\hat{P}_t^m$	% due to $\hat{r}_{t+j}^m$
0	0	1 period	44	0	56

0.9	0.5	Consol	6	94	0

"% due to" are the ratios of the right-hand components of (38) to ξ_t, which is computed from the impulse response of $\hat{s}_{t+j}$, as described in the text. Calibration reported in Footnote ag.

maturities force more of the adjustment to higher deficits into lower bond prices, which push more of the impacts into low-frequency movements in long-run inflation and real interest rates.[ai]

Although short-run inflation is higher with one-period debt, in the long run inflation is lower with shorter maturity bonds. With long debt, bond prices reflect anticipated inflation rates farther into the future, in essence spreading inflationary effects over longer horizons. The cost of doing so is to raise the long-run inflation impacts of fiscal policy.

Another way to summarize the dynamic impacts of fiscal disturbances is to ask how a shock that raises primary deficits by a certain amount gets financed intertemporally, as a function of various model parameters. Underlying the calculations in Table 2 are two basic mechanisms that stabilize debt in the face of the surplus shock. First are the revaluation effects that we can summarize by examining the ex-post real return to holding government bonds in any period

$$r_t^m = \frac{(1+\rho P_t^m)}{P_{t-1}^m}\frac{1}{\pi_t}$$

or in linearized form

$$\hat{r}_t^m = \rho\beta\hat{P}_t^m - \hat{\pi}_t - \hat{P}_{t-1}^m$$

By contrasting this with the ex-ante returns the bond holders were expecting when they purchased the bonds in period $t-1$ we can identify the scale of the revaluation effects, which linearized, are

$$\hat{r}_t^m - E_{t-1}\hat{r}_t^m = -(\hat{\pi}_t - E_{t-1}\hat{\pi}_t) + \rho\beta(\hat{P}_t^m - E_{t-1}\hat{P}_t^m) \tag{37}$$

[ai] The long-term real interest rate, $\hat{r}_t^L$, comes from combining the bond-pricing equation and the Fisher relation to yield the recursion $\hat{r}_t^L = \hat{r}_t + \beta\rho E_t\hat{r}_{t+1}^L$. The long-run inflation rate, $\hat{\pi}_t^L$, which is the expected path of inflation discounted by $\beta\rho$, may be computed as $\hat{\pi}_t^L = -\hat{r}_t^L - \hat{P}_t^m$.

The first term on the right in (37) gives the losses suffered by bondholders due to surprise inflation in the initial period. The second term gives the losses suffered by holders of mature debt ($\rho > 0$) arising from jumps in bond prices caused by innovations to the expected future path of inflation. These latter revaluation effects are borne by the existing holders of government debt and arise for innovations to the path of inflation over the time to maturity of the debt stock they hold. In the sticky-price economy these effects can be complemented by reductions in the ex-ante real rates of return received by future bondholders, which reduce effective debt service costs to create an additional channel through which debt can be stabilized.[aj]

In the case of one-period debt it is only the surprise inflation in the initial period that reduces the real value of government debt. This is then combined with reductions in ex-ante real interest rates to stabilize debt. As α_π increases, there is less reliance on the latter effect and larger jumps in the initial rate of inflation are required to satisfy the bond valuation equation. When we move to longer period debt, there is an additional revaluation effect through the impact of innovations to the path of inflation on bond prices. With bond prices adjusting, we can have smaller, but more sustained, increases in inflation that reduce the real market value of debt. These continue to be combined with reductions in ex-ante real interest rates to satisfy the bond valuation equation with these debt service cost effects falling as monetary policy becomes less passive.

To see how this affects the decomposition of the adjustment required to stabilize the debt stock in the face of a surplus shock consider the evolution of the market value of government debt

$$\tilde{b}_t = r_t^m \tilde{b}_{t-1} - s_t$$

where $\tilde{b}_t \equiv \dfrac{P_t^m Bt}{P_t}$. This can be linearized as

$$\beta \hat{\tilde{b}}_t = \hat{r}_t^m + \hat{\tilde{b}}_{t-1} - (1-\beta)\hat{s}_t$$

Using the expected value of surpluses, $\xi_t \equiv (1-\beta)E_t \sum_{j=0}^{\infty} \beta^j \hat{s}_{t+j}$ which implies $(1-\beta)\hat{s}_t = \xi_t - \beta E_t \xi_{t+1}$, this becomes

$$\beta(\hat{\tilde{b}}_t - E_t \xi_{t+1}) - \hat{r}_t^m = \hat{\tilde{b}}_{t-1} - \xi_t$$

Iterating forward we obtain

[aj] An equivalent interpretation comes from thinking about the value of debt in the "forward" direction, as being determined by the expected present value of surpluses. Lower real interest rates raise real discount factors to increase the present value of a given stream of surpluses.

$$\begin{aligned} \xi_t &= \hat{\tilde{b}}_{t-1} + \hat{r}^m_t + E_t \sum_{j=1}^{\infty} \beta^j \hat{r}^m_{t+j} \\ &= \hat{\tilde{b}}_{t-1} - \hat{P}^m_{t-1} + \beta\rho\hat{P}^m_t - \hat{\pi}_t + E_t \sum_{j=1}^{\infty} \beta^j \hat{r}^m_{t+j} \end{aligned} \tag{38}$$

The required adjustment to a change in expected surpluses is made up of surprise changes in the returns to existing bond holders $\hat{r}^m_t$ as well as expected future returns on bond holdings, $E_t \sum_{j=1}^{\infty} \beta^j \hat{r}^m_{t+j}$. The former is made up of jumps in the initial rate of inflation combined with changes in bond prices to the extent that bonds have a maturity greater than one period, $\rho > 0$. The latter captures the reduction in ex-ante real interest rates which can occur in our sticky-price economy.

Table 2 computes the objects in (38) from impulse responses to a deficit innovation. When debt is single period, bond prices do not contribute to financing the deficit. If monetary policy pegs the nominal interest rate, current inflation and future real interest rates play nearly equally important roles. As monetary policy reacts more aggressively to inflation and output, real interest rate responses are tempered, and an increasing fraction of the adjustment occurs through inflation at the time of the fiscal innovation. Longer maturity debt brings bond prices into the adjustment process, and their role grows with both the maturity of debt and the aggressiveness of monetary policy. As a consequence, current inflation moves much less. Consol bonds, together with aggressive monetary policy, push nearly all the adjustment into bond prices, with contemporaneous inflation playing only a minimal role, as the last row of the table reports.

3.2.2 Impacts of Monetary Shocks

Section 2.1.2.2 describes the effects of exogenous monetary policy disturbances in an endowment economy under regime F. Because future surpluses do not adjust to neutralize the wealth effects of monetary policy, contractionary policy—a higher path for the nominal interest rate—raises household interest receipts and wealth, raising nominal aggregate demand. A similar phenomenon can arise in the new Keynesian model, though the dynamics are more interesting.

Fig. 5 reports the impacts of an exogenous monetary policy action that raises the nominal interest rate. To highlight the behavior of monetary policy in regime F, we consider three different monetary policy rules. A rule that does not respond to inflation (solid lines) raises the short-term real interest rate and depresses output in the short run. Despite the drop in output, inflation rises immediately, even in a model where the Phillips curve implies a strong positive relationship between output and inflation contemporaneously ($\kappa = 0.3$).

This seemingly anomalous outcome underscores the centrality of wealth effects in regime F. Higher nominal interest rates raise households' interest receipts in the future,

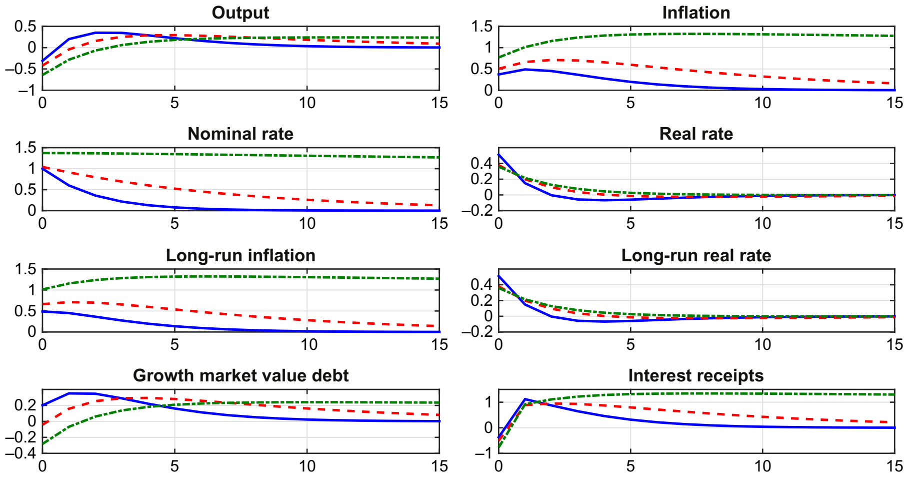

Fig. 5 Responses to a 1% monetary contraction under alternative monetary policy rules with only one-period government debt. Calibration reported in Footnote ag. The monetary policy shock follows the *AR*(1) process $\epsilon_t^M = \rho_{MP}\epsilon_{t-1}^M + \zeta_t^M$ with $\rho_{MP} = 0.6.\alpha_\pi = \alpha_Y = 0$ (*solid lines*), $\alpha_\pi = \alpha_Y = 0.5$ (*dashed lines*), and $\alpha_\pi = 0.9$, $\alpha_Y = 0.5$ (*dot-dashed lines*).

triggering an expectation of higher future demand and inflation.[ak] Through the Phillips curve, the higher expected inflation dominates the deflationary effects of lower output to raise inflation on impact. Expectations are critical to output effects as well. After an initial decline, output always eventually rises because the real interest rate declines at longer horizons.

More aggressive monetary policy behavior (dashed lines) transforms the transitory increase in the policy rate into larger and more persistent increases. Those higher nominal interest rates raise both the growth rate of the nominal market value of debt and real interest receipts. The resulting wealth effects raise and prolong the higher inflation.

That an exogenous monetary policy "contraction," which raises the nominal interest rate, also raises inflation may seem to contradict evidence from the monetary VAR literature. This pattern, dubbed the "price puzzle" by Eichenbaum (1992), is sometimes taken to indicate that monetary policy behavior is poorly identified, perhaps by misspecifying the central bank's information set, as Sims (1992) argues. Fig. 5 makes clear that there is nothing puzzling about the pattern from the perspective of the fiscal theory.

Introducing long debt makes impulse responses accord better with VAR evidence because bond prices absorb much of the monetary shock. Fig. 6 contrasts one-period (solid lines) with 5-year (dashed lines) and consol debt (dot-dashed lines). By reducing growth in the market value of debt, longer maturities attenuate the inflationary effects and make the short-run decline in output longer lasting. Inflation does eventually rise,

[ak] Real interest receipts are defined as $[(1+\rho P_t^m)/P_{t-1}^m](b_{t-1}^m/\pi_t)$.

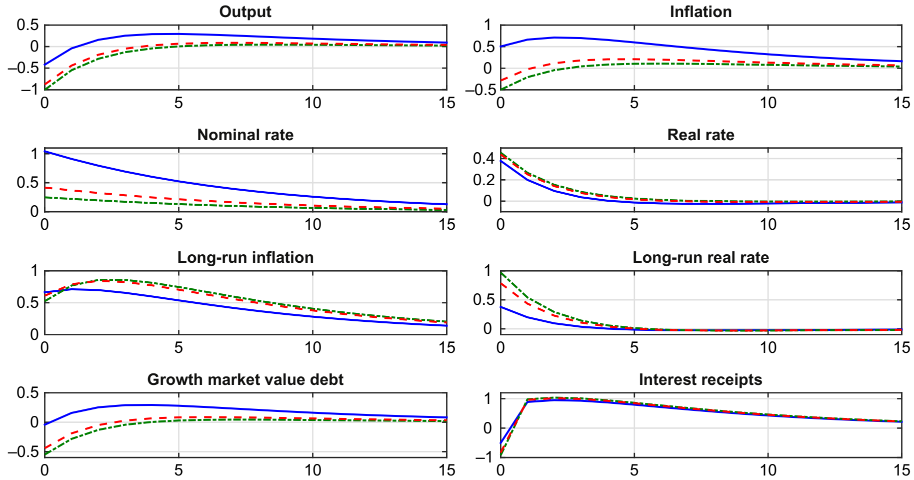

Fig. 6 Responses to a 1% monetary contraction under alternative maturity structures. Calibration reported in Footnote ag. The monetary policy shock follows the *AR*(1) process $\epsilon_t^M = \rho_{MP}\epsilon_{t-1}^M + \zeta_t^M$ with $\rho_{MP} = 0.6$ and $\alpha_\pi = \alpha_Y = 0.5$. 1-period debt (*solid lines*), 5-year debt (*dashed lines*), and consol debt (*dot-dashed lines*).

Table 3 A 1% monetary shock initially raises the short-term nominal interest rate

κ	σ	$\hat{\pi}_t$	$\hat{P}_t^m$	$\hat{r}_{t+j}^m$
0.3	1.0	−0.29	1.12	−0.83
∞	1.0	−1.54	1.54	0.0
0.1	1.0	−0.09	1.03	−0.94
0.3	5.0	−0.50	0.76	−0.26
0.3	0.5	−0.17	1.32	−1.15

"π_t" and "$\hat{P}_t^m$" are impacts of the monetary policy shock on contemporaneous inflation and bond prices; "$\hat{r}_{t+j}^m$" are the impacts on discounted real returns to bonds from expression (39). Calibration reported in Footnote ag plus $\alpha_\pi = \alpha_Y = 0.5$ and maturity set at 5 periods.

as it must if bond prices are lower. Sims (2011) calls the pattern of falling, then rising inflation following a monetary contraction "stepping on a rake."

While Fig. 6 shows how the response of short-run inflation to a monetary contraction varies with debt maturity, Table 3 reports how other model parameters affect this relationship. Following a monetary contraction, $\xi_t \equiv 0$ in expression (38), so if the monetary shock hits at time t, we have that

$$\hat{\pi}_t - \beta\rho\hat{P}_t^m - E_t\sum_{j=1}^{\infty}\beta^j\hat{r}_{t+j}^m = 0 \tag{39}$$

so the three sources of fiscal financing—higher current inflation, lower current bond prices, and lower future real bond returns—must sum to zero.

The first row of Table 3 shows that for the benchmark calibration with five-period average bond maturity, the monetary contraction initially lowers inflation along with the price of bonds, while it raises discounted real interest rates. As prices become more flexible ($\kappa \rightarrow \infty$), the impact on inflation becomes more pronounced, while that on real rates diminishes. A higher intertemporal elasticity of substitution ($\sigma \rightarrow 0$) pushes more of the adjustment into the future, reduces the effect on current inflation, and raises the impacts on bond prices and future real rates.

4. ENDOWMENT ECONOMIES WITH OPTIMAL MONETARY AND FISCAL POLICIES

In this section we turn to consider the nature of optimal policy in our simple endowment economy. In doing so we cut across various strands of the literature that addresses optimal monetary and fiscal policy issues.

4.1 Connections to the Optimal Policy Literature

We begin by considering Ramsey policies where the policymaker has an ability to make credible promises about how they will behave in the future, before turning to time-consistency issues below. We start by building on Sims' (2013) analysis. He considers a simple linearized model of tax smoothing under commitment in the face of transfer shocks and long-term debt. The policymaker can use costly inflation surprises as an alternative to distortionary taxation to ensure fiscal solvency. We extend that work in several ways. Specifically, we allow for a geometric maturity structure which nests single-period debt and consols as special cases, employ nonlinear model solution techniques, and allow for anticipated and unanticipated government spending shocks, in addition to transfer shocks. Nonlinear solutions allow us to consider the way in which the size of the debt stock, together with its maturity structure, influences the optimal combination of monetary and fiscal policy in debt stabilization. Innovations to the expected path for inflation can affect bond prices in a way which helps to satisfy the bond valuation equation even without any fiscal adjustment. These bond price movements are effective only if applied to a nonzero stock of outstanding liabilities so the optimal balance between inflation and tax financing of fiscal shocks depends on both the level of government debt and its maturity structure.

Without an ability to issue state-contingent debt or use inflation surprises to stabilize debt, Barro (1979) showed that debt and taxes should follow martingale processes to minimize the discounted value of tax distortions. While Barro did consider the impact of surprise inflation on the government's finances, these were treated as exogenous shocks rather than something that can be optimally employed to further reduce tax distortions. Lucas and Stokey (1983) is an equally influential paper that reaches quite different conclusions on the optimal response of tax rates to shocks. Lucas and Stokey consider an economy where the government can issue real state-contingent debt and show that it is optimal for a government to issue a portfolio of debt where the state-contingent returns to that debt isolate the government's finances from shocks so that there is no need for taxes to jump in the manner of Barro's tax-smoothing result. Instead, taxes are largely flat and inherit the dynamic properties of the exogenous shocks hitting the economy.

A large part of the post-Lucas and Stokey literature considers the implications of debt that is not state contingent, as well as ways of converting the payoffs from portfolios of nonstate-contingent debt into state-contingent payoffs. A key result is that when debt payoffs are not (or cannot be made) state contingent, then the optimal policy looks more like Barro's tax-smoothing result. Aiyagari et al. (2002) show this by assuming that debt is single period and noncontingent in a model otherwise identical to that of Lucas and Stokey. How might noncontingent debt instruments be made to mimic the payoffs that would be generated by state-contingent debt? Two approaches have been suggested in the literature. First, surprise inflation can render the real payoffs from risk-free nominal bonds state contingent. For example, Chari et al. (1994) use a model where surprise inflation is costless to show that the real contingencies in debt exploited by Lucas and Stokey could be created through monetary policy via surprise inflation when government debt is nominal. This underpins Sims' (2001) results in a model with costless inflation in which tax rates should be held constant to finance any fiscal shocks solely with surprise movements in inflation.

When we start to introduce a cost to surprise inflation, the optimal policy can be strikingly different. For a jointly determined optimal monetary and fiscal policy operating under commitment, Schmitt-Grohé and Uribe (2004) show that in a sticky-price stochastic production economy, even a miniscule degree of price stickiness will result, under the optimal policy, in a steady-state rate of inflation marginally less than zero, with negligible inflation volatility. In other words, although the optimal policy under flexible prices would be to follow the Friedman rule and use surprise inflation to create the desired state contingencies in the real payoffs from nominal debt, even a small amount of nominal inertia heavily tilts optimal policy toward zero inflation with little reliance on inflation surprises to insulate the government's finances from shocks. As in Benigno and Woodford (2004) and Schmitt-Grohé and Uribe (2004) return to the tax-smoothing results of Barro (1979) thanks to the effective loss of state-contingent returns to debt when prices are sticky. Sims (2013) argues that this may be due to the fact that Schmitt-Grohé and Uribe only consider single-period debt; with longer term debt the efficacy of using innovations to the expected path of inflation to affect bond prices would be enhanced. This is the first issue to which we turn: to what extent will the optimizing policymaker rely on fiscal theory-type revaluations of debt through innovations to the expected path of prices?

While the state contingencies in real bond payoffs can be generated through the impact of surprise inflation on nominal bonds, an alternative approach when bonds are real is to exploit variations in the yield curve to achieve the same contingencies for the government's whole bond portfolio. With single-period risk-free real bonds, Ramsey policy in the Lucas and Stokey model possesses a unit root as in Barro. Angeletos (2002) and Buera and Nicolini (2004) use the maturity structure of nonstate-contingent real bonds to render the overall portfolio state contingent. With two states for government spending, for example, a portfolio of positive short-term assets funded by issuing long-term debt can insulate the government's finances from government spending shocks. More generally, with a sufficiently rich maturity structure the policymaker can match the range of the stochastic shocks hitting the economy and achieve this hedging. The second broad optimal policy question we consider is: what is the role of debt management in insulating the government's finances from shocks?

Having looked at the ability of the Ramsey policymaker to both hedge against shocks and utilize monetary policy as a debt stabilization tool when complete hedging is not possible, we turn to consider the time-inconsistency problem inherent in such policies. We find that constraining policy to be time consistent radically affects the policymaker's ability to hedge against fiscal shocks and generates serious "debt stabilization bias" problems, as in Leith and Wren-Lewis (2013), that are akin to the inflationary bias problems analyzed in the context of monetary economies.

We begin by considering the role inflation surprises play in optimal policy in our simple endowment economy with a geometrically declining maturity structure. We then generalize these results to a more general maturity structure and consider the role of debt management in hedging for fiscal shocks. We then turn to a simple example where complete hedging is feasible.

4.2 The Model

We follow Sims (2013) in defining the inverse of inflation as $\nu_t = \pi_t^{-1}$, and assuming the policymaker's objective function is given by

$$-E_0 \frac{1}{2} \sum_{t=0}^{\infty} \beta^t \left[\tau_t^2 + \theta(\nu_t - 1)^2 \right]$$

which the policymaker maximizes subject to the constraints given by the resource constraint in our endowment economy,

$$y = c_t + g_t$$

the bond valuation equation (after assuming a specific form for per-period utility, $u(c_t) = \frac{c_t^{1-\sigma}}{1-\sigma}$)

$$\beta E_t \frac{(1+\rho P^m_{t+1})}{P^m_t}\nu_{t+1}\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}=1$$

the government's flow budget identity

$$b_t P^m_t=(1+\rho P^m_t)b_{t-1}\nu_t+g_t-\tau_t-z_t$$

and the associated transversality condition

$$\lim_{j\to\infty} E_t\left(\prod_{i=0}^{j}\frac{1}{R^m_{t+i+1}\nu_{t+i+1}}\right)\frac{P^m_{t+j}B^m_{t+j}}{P_{t+j}}\geq 0$$

where $R^m_{t+1}\equiv(1-\rho P^m_{t+1})/P^m_t$, and government spending and/or transfers follow exogenous stochastic processes. Our adopted objective function is clearly ad hoc in the context of our simple endowment economy. However, it can easily be motivated as capturing the trade-off between the costs of tax vs inflation financing in richer production economies. Indeed, many of the insights this analysis offers will reappear when considering optimal policy in a fully microfounded economy subject to distortionary taxation and nominal inertia in Section 5.

4.3 Ramsey Policy

We analyze the time-inconsistent Ramsey policy for our endowment economy given the policymaker's objective function by forming the following Lagrangian

$$\begin{aligned}L_t=E_0\frac{1}{2}\sum_{t=0}^{\infty}\beta^t[&-\frac{1}{2}(\tau_t^2+\theta(\nu_t-1)^2)\\&+\mu_t\left(\beta E_t\frac{(1+\rho P^m_{t+1})}{P^m_t}\nu_{t+1}\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}-1\right)\\&+\lambda_t(b_tP^m_t-(1+\rho P^m_t)b_{t-1}\nu_t-g_t-z_t+\tau_t)]\end{aligned}$$

which yields the first-order conditions

$$\begin{aligned}&\tau_t:-\tau_t+\lambda_t=0\\&\nu_t:-\theta(\nu_t-1)+\mu_{t-1}\frac{(1+\rho P^m_t)}{P^m_{t-1}}\left(\frac{c_t}{c_{t-1}}\right)^{-\sigma}-(1+\rho P^m_t)\lambda_t b_{t-1}=0\\&P^m_t:-\frac{\mu_t}{P^m_t}+\mu_{t-1}\rho\frac{\nu_t}{P^m_{t-1}}\left(\frac{c_t}{c_{t-1}}\right)^{-\sigma}+\lambda_t(b_t-\rho\nu_t b_{t-1})=0\\&b_t:\lambda_tP^m_t-\beta E_t(1+\rho P^m_{t+1})\nu_{t+1}\lambda_{t+1}=0\end{aligned}$$

Defining $\tilde{\mu}_t\equiv\dfrac{\mu_t}{P^m_t c_t^{-\sigma}}$ the system to be solved for $\{P^m_t,\tilde{\mu}_t,\nu_t,\tau_t,b_t,c_t\}$ is given by

$$-\theta(\nu_t - 1) + \widetilde{\mu}_{t-1}(1+\rho P_t^m)c_t^{-\sigma} - (1+\rho P_t^m)\tau_t b_{t-1} = 0$$

$$\tau_t b_t - \widetilde{\mu}_t c_t^{-\sigma} - \rho\nu_t(\tau_t b_{t-1} - \widetilde{\mu}_{t-1}c_t^{-\sigma}) = 0$$

$$\tau_t P_t^m - \beta E_t(1+\rho P_{t+1}^m)\nu_{t+1}\tau_{t+1} = 0$$

$$\beta E_t \frac{(1+\rho P_{t+1}^m)}{P_t^m}\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}\nu_{t+1} - 1 = 0$$

$$b_t P_t^m - (1+\rho P_t^m)b_{t-1}\nu_t - g_t + \tau_t - z_t = 0$$

$$g_t - (1-\rho_g)g^* - \rho_g g_{t-1} - \varepsilon_t^g = 0$$

$$z_t - (1-\rho_z)z^* - \rho_z z_{t-1} - \varepsilon_t^z = 0$$

$$y - c_t - g_t = 0$$

with two exogenous shocks describing the evolution of government consumption, g_t, and transfers, z_t and two endogenous state variables, $\widetilde{\mu}_{t-1}$ and b_{t-1}, where the former captures the history dependence in policymaking under commitment.

To obtain some intuition for how policy operates under commitment, it is helpful to consider three polar cases. First, where inflation is costless, so that $\theta = 0$. Second, where inflation is so costly that the economy can be considered to be real, $\theta \to \infty$. Third, we allow inflation to be costly $\theta > 0$, but assume that taxes have reached the peak of the Laffer curve so that they are no longer available to engage in tax smoothing and instead are held constant, $\tau_t = \overline{\tau}$.

4.3.1 Costless Inflation

In the former case, where inflation is costless ($\theta = 0$), the first two first-order conditions imply

$$\widetilde{\mu}_{t-1}c_t^{-\sigma} = \tau_t b_{t-1}$$

and

$$\tau_t b_t - \widetilde{\mu}_t c_t^{-\sigma} = \rho\nu_t(\tau_t b_{t-1} - \widetilde{\mu}_{t-1}c_t^{-\sigma})$$

Substituting the first into the second, lagging one period, and comparing the first condition yield

$$\tau_t = \left(\frac{c_t}{c_{t-1}}\right)^{-\sigma}\tau_{t-1}$$

In the absence of government spending shocks (the only source of variation in private consumption in our simple endowment economy) taxes are unchanged. But taxes are higher whenever government spending is higher. In the case of transfer shocks, inflation jumps to satisfy the bond valuation equation and this is a pure case of the fiscal theory. But when bonds have a maturity beyond a single period, there are an infinite number of patterns of inflation which can satisfy this, due to the impact inflation has on bond prices. While there is a unique required discounted magnitude of surprise inflation needed to satisfy the government debt valuation condition, there are a variety of paths which can achieve that magnitude. When the fiscal shock is a shock to government consumption, this affects real interest rates so that even though inflation can costlessly stabilize debt at its initial steady-state level, there is still tilting of tax rates: during periods of high real interest rates, it is desirable to suffer the short-run costs of higher taxation to avoid the longer run costs of supporting the higher steady-state level of debt that would emerge when higher interest rates raise the rate of debt accumulation. In this case it is only because of the commitment to honor the past promises not to deflate away the government's outstanding liabilities that there are positive tax rates at all.

4.3.2 Real Economy

In the second case, inflation is so costly it would never be used under the optimal policy, $\theta \rightarrow \infty$ and $\nu_t = 1$. As a result, we rely on jumps in the tax rate to satisfy government solvency and we return to a world of pure tax smoothing, where the tax rate follows the path implied by the first-order condition

$$\tau_t P_t^m = \beta E_t (1 + \rho P_{t+1}^m) \tau_{t+1}$$

Under a perfect foresight equilibrium this reduces to

$$\frac{\tau_t}{c_t^{-\sigma}} = \frac{\tau_{t+1}}{c_{t+1}^{-\sigma}}$$

This tax rate is constant in the face of transfer shocks, but will be tilted in the presence of government spending shocks—the tax rate at t is higher (lower) when public consumption is anticipated to rise (fall). The fact that it is purely forward-looking captures the usual tax-smoothing result that the tax rate will jump to the level required to satisfy the government's budget identity, although we have tilting in the tax rate to capture changes in real interest rates induced by government spending shocks. Eventually, the tax rate will achieve a new long-run value consistent with servicing the new steady-state level of debt.

4.3.3 Intermediate Case

In the intermediate case where $0 < \theta < \infty$, the tax-smoothing condition remains as above, but is combined with a pattern of inflation described by

$$-\theta(\nu_t - 1) + \frac{\mu_{t-1}}{P^m_{t-1}}(1 + \rho P^m_t) - (1 + \rho P^m_t)\tau_t b_{t-1} = 0$$

$$\tau_t b_t - \frac{\mu_t}{P^m_t} - \rho\nu_t\left(\tau_t b_{t-1} - \frac{\mu_{t-1}}{P^m_{t-1}}\right) = 0$$

$$b_t P^m_t - (1 + \rho P^m_t) b_{t-1}\nu_t - g_t - z_t + \tau_t = 0$$

which will deliver initial jumps in inflation, bond prices, and tax rates to ensure fiscal solvency. These first-order conditions also imply that gross inflation returns to 1 in steady state, so the optimal commitment policy makes any inflation only temporary. But there is a continuum of steady-state debt levels, each with an associated optimal tax rate, that are consistent with the steady state of the first-order conditions under commitment.

When we consider a variant on the third case where taxes are no longer available for tax smoothing, either for political reasons or because the tax rate has reached the peak of the Laffer curve, the relevant optimality conditions become

$$\lambda_t P^m_t - \beta E_t(1 + \rho P^m_{t+1})\nu_{t+1}\lambda_{t+1} = 0$$

$$-\theta(\nu_t - 1) + \tilde{\mu}_{t-1}(1 + \rho P^m_t)c_t^{-\sigma} - (1 + \rho P^m_t)\lambda_t b_{t-1} = 0$$

$$\lambda_t b_t - \tilde{\mu}_t c_t^{-\sigma} - \rho\nu_t(\lambda_t b_{t-1} - \tilde{\mu}_{t-1} c_t^{-\sigma}) = 0$$

where the tax rate is fixed at $\overline{\tau}$.

Here the unit root in government debt is no longer present because taxes cannot adjust to support a new steady-state debt level, and inflation cannot influence future surpluses. Instead, inflation must be adjusted to ensure fiscal solvency by returning debt to the steady-state level consistent with the unchanged tax rate. The pattern of inflation also depends on the maturity structure of the inherited debt stock. To see this more clearly we consider the perfect foresight solution in the face of a transfers shock in which the first-order condition for debt implies that $\lambda_t = \lambda_{t+1}$ since $g_t = g^*$. Combining the second and third conditions yields

$$\nu_t(\nu_t - 1) = \left[1 + (\rho P^m_t)^{-1}\right]\beta\nu_{t+1}(\nu_{t+1} - 1)$$

which describes the dynamics of inflation. Inflation rises following a fiscal shock that would otherwise make debt initially higher and then decline toward its steady-state value. The rate of convergence depends on the inverse of the maturity parameter multiplied by the bond price, which initially falls, but then recovers as the period of inflation passes. When $\rho = 0$ the inflation only occurs in the initial period, but becomes more protracted the longer is the maturity of government debt. Similar inflation dynamics are observed when taxes are smoothed, although the magnitude of the initial jump in inflation will be reduced to the extent that tax rates rise to stabilize debt at a higher level in the face of a given shock.

4.4 Numerical Results

The grid-based approach to solving the stochastic version of the model under the simple rules works well when the economy has a well-defined steady state to which it returns. With commitment policies the model enters a new steady state following the realization of a shock, which makes the model difficult to solve using these techniques. For this reason, when considering commitment we restrict attention to perfect foresight equilibrium paths following an initial shock. These paths are computed as follows. We guess the new steady-state value of debt and solve the steady state of the Ramsey problem conditional on that guess. This serves as a terminal condition on the model solution 800 periods in the future. The Ramsey first-order conditions are then solved for 800 periods conditional on this guess for the ultimate steady state. If the solution exhibits a discontinuity between the final period of the solution and the imposed terminal condition, the steady-state guess is revised. This process continues until the guessed new steady state is indeed the steady state to which the economy now settles.

We begin by considering the same transfers shock considered above for various degrees of maturity and different initial debt-to-GDP ratios. The autocorrelated shock to transfers reduces the discounted value of future surpluses and requires a monetary and/or fiscal adjustment. These adjustments are plotted in Fig. 7 for various initial debt-to-GDP ratios and debt maturities. The first column starts from an initial debt-to-GDP ratio of zero. When debt is initially zero and the initial tax rate of $\tau = 0.39$ can support the initial level of transfers and public consumption, under the optimal policy there is no inflation, regardless of the maturity of debt. This is due to the fact that surprise changes in inflation or bond prices only help satisfy the government's intertemporal budget identity if there is already an initial debt stock for them to act on. Even though the debt that will be issued as a result of the transfer shock is of different maturities across the experiments reported in the first column of the figure, this will not affect the optimal policy response to the transfers shock when there is initially no debt. The tax rate jumps to a permanently higher level to support a higher steady-state debt level, as under Barro's (1979) original tax-smoothing result.

The second column begins from an initial steady state with a debt-to-GDP ratio of 25% (and a supporting initial tax rate of $\tau = 0.4$). Now there is mild use of inflation to offset the effects of the transfers shock. Inflation is smaller but more sustained the longer is the average maturity of debt. As maturity lengthens, inflation surprises play an increasingly important role in stabilizing debt, with smaller adjustments in taxes. At higher debt levels, the role of inflation and maturity grows in importance as substitutes for distorting taxes. Ultimately, the increase in inflation is unwound (it serves no purpose as the initial debt stock matures) and there is a permanent increase in both the debt stock and tax rates. These examples underscore that optimal policy is highly state dependent, particularly with respect to the level and maturity of debt at the time the shock hits.

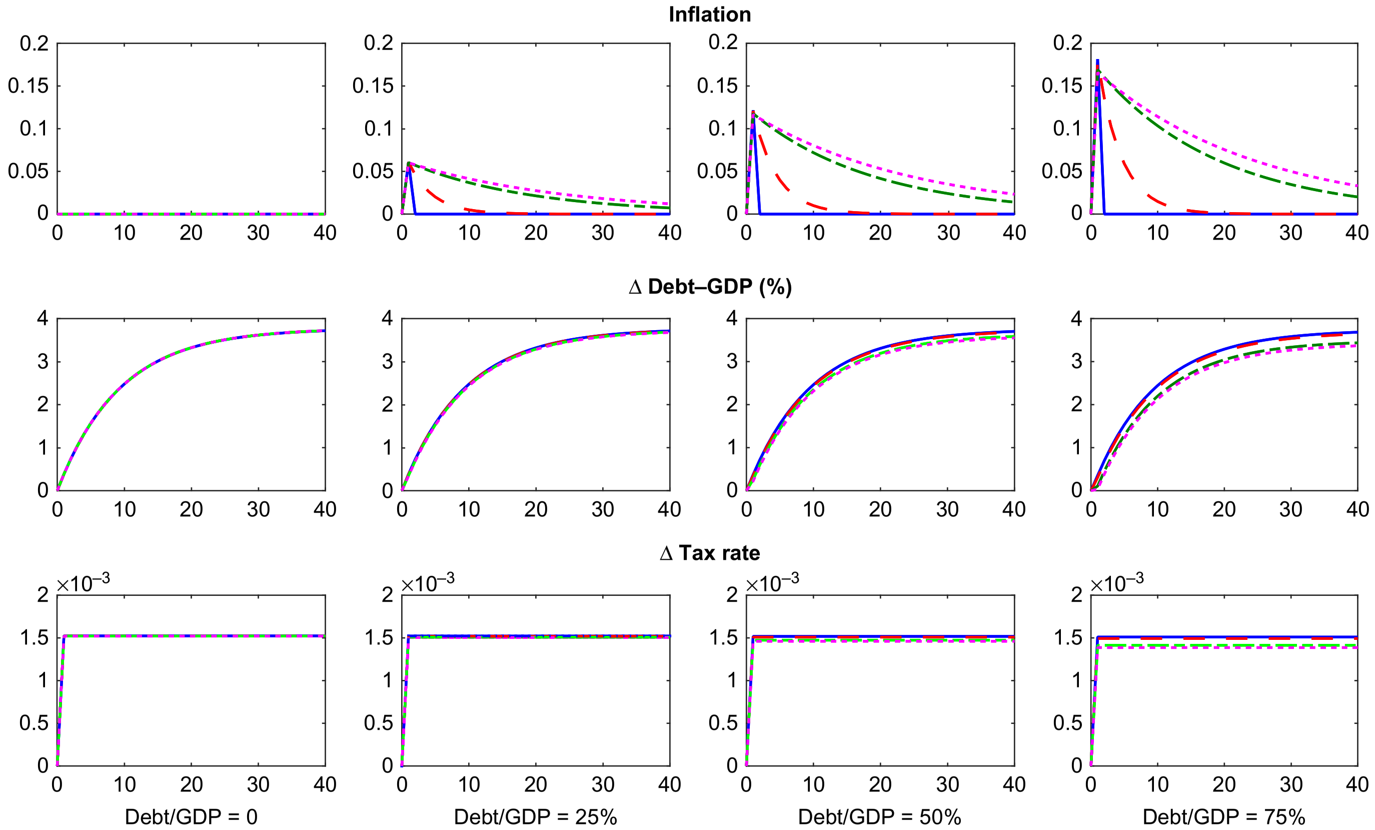

Fig. 7 Optimal policy in response to higher transfers with different debt levels and maturities. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), 4-year debt (*dot-dashed lines*), and 5-year debt (*dotted lines*).

When we turn to government spending shocks in Fig. 8, the story is similar except that now, through the stochastic discount factor, public consumption tilts the optimal path of taxes and affects the magnitude of the fiscal and inflation adjustments needed to satisfy the debt valuation equation. With no initial stock of debt, the subsequent debt maturity structure is irrelevant and the optimal policy does not generate any inflation. But for a positive initial debt level, the spike in inflation for one-period debt is several orders of magnitude larger than for the portfolio of bonds with an average maturity of 8 years. With only short debt, the inflation is immediately eliminated, while the slight rise in inflation is sustained in the presence of longer term debt. Sustained inflation decreases bond prices that reduce the value of debt to for the more mature bonds, permitting the policymaker to reduce the required jump in the tax rate needed to support the higher level of steady-state debt. Interestingly, the higher tax rates during the period of raised public consumption end up reducing the new steady-state level of debt so that the new steady-state tax rate is actually lower than before the shock. This contrasts to the case of the transfer shock where debt levels were raised following the shock.

Fig. 9 reports optimal responses to news of a sustained increase in government spending 5 years in the future. Initially inflation falls and the tax rate jumps down in support of a debt level that is ultimately lower, despite the increase in government spending. This occurs because the policymaker raises the tax rate for the duration of the rise in public consumption to avoid the rapid accumulation of government debt in a period when real interest rates are relatively high. Bond prices rise as the anticipated increase in government spending approaches and then drop dramatically when the spending is realized.

In this experiment the cost of inflation is quite high, $\theta = 10$. A lower cost would lead to greater reliance on the use of monetary policy and innovations in the anticipated path of prices to stabilize debt. As we show later, even this relatively conservative weight on the costs of inflation still generates a sizeable endogenous inflation bias when we consider time-consistent policy.

4.5 Ramsey Policy with a General Maturity Structure

Although the geometrically declining maturity structure is a tractable and plausible description of the profile of government debt for many economies, it is useful to broaden the analysis with a more general description of the maturity structure. This generalization refines the description of the role of optimal inflation surprises in stabilizing debt and begins to consider the role of debt management in insulating the government's finances from fiscal shocks. We employ Cochrane's (2001) notation, allowing the bond valuation equation to be written as in (19) in Section 2.2.1. The government's optimization problem becomes

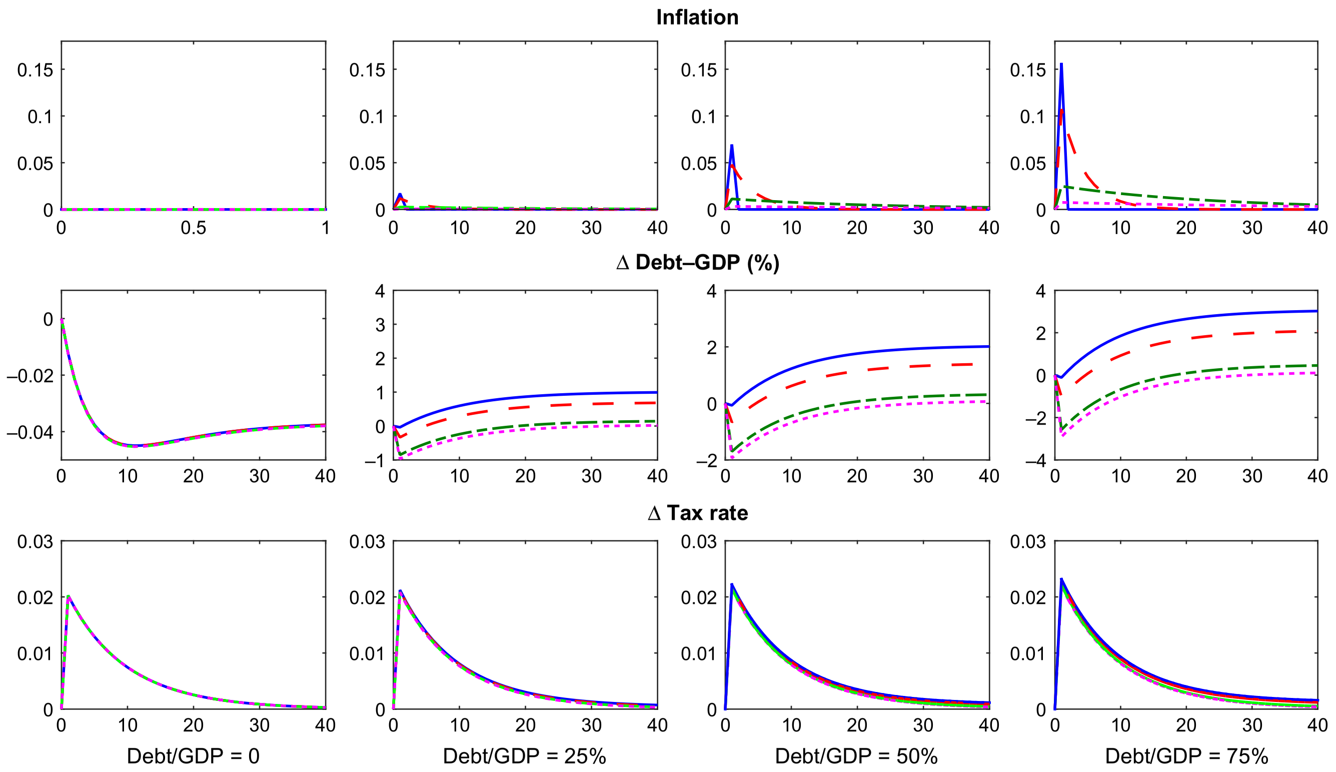

Fig. 8 Optimal policy in response to higher government spending with different debt levels and maturities. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), 4-year debt (*dotted–dashed lines*), and 5-year debt (*dotted lines*).

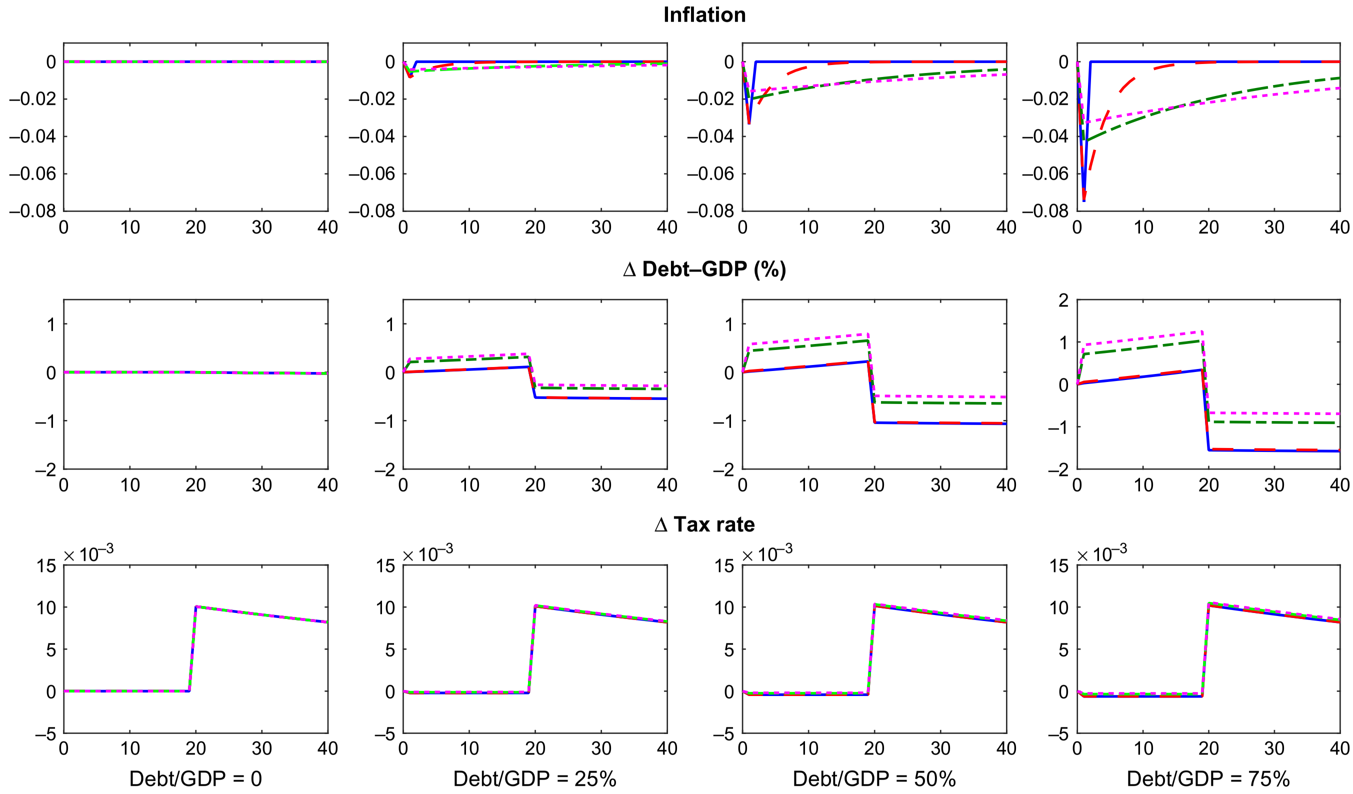

Fig. 9 Optimal policy in response to an anticipated increase in government spending with different debt levels and maturities. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), 4-year debt (*dotted–dashed lines*), and 5-year debt (*dotted lines*).

$$L_0 = E_0 \sum_{t=0}^{\infty} \beta^t \left[-\frac{1}{2}(\tau_t^2 + \theta(\nu_t - 1)^2) \right.$$
$$\left. + \lambda_t \left(-\sum_{j=0}^{\infty} E_t \left[\beta^j u'(c_{t+j}) \prod_{s=0}^{j} \nu_{t+s} \right] \left[\frac{B_t(t+j)}{P_{t-1}} - \frac{B_{t-1}(t+j)}{P_{t-1}} \right] - u'(c_t)(\tau_t - g_t - z_t) \right) \right]$$

The first-order condition for taxation is

$$-\tau_t = u'(c_t)\lambda_t$$

The debt management problem optimally chooses the maturity structure of debt issued in period t which is repayable at future dates, $B_t(t + j)$, to yield the optimality condition

$$-\beta^t \lambda_t \beta^j E_t u'(c_{t+j}) \prod_{s=0}^{j} \nu_{t+s} \frac{1}{P_{t-1}} = -\beta^{t+1} E_t \lambda_{t+1} \beta^{j-1} u'(c_{t+j}) \prod_{s=0}^{j} \nu_{t+s} \frac{1}{P_{t-1}}$$

which can be simplified as

$$\frac{\tau_t}{u'(c_t)} E_t u'(c_{t+j}) \prod_{s=0}^{j} \nu_{t+s} = E_t \frac{\tau_{t+1}}{u'(c_{t+1})} u'(c_{t+j}) \prod_{s=0}^{j} \nu_{t+s}$$

which implies

$$E_t \left[\left[\frac{u'(c_t)}{u'(c_{t+1})} \tau_{t+1} - \tau_t \right] \frac{u'(c_{t+j})}{u'(c_t)} \frac{P_{t-1}}{P_{t+j}} \right] = 0$$

The covariance between the payoff of debt instrument of maturity j periods and next period's tax rate is zero (Bohn, 1990). This is the hedging across states that Angeletos (2002) and Buera and Nicolini (2004) explore. By structuring debt in this way the policymaker minimizes the fiscal and monetary adjustments required in the face of shocks; those policy adjustments then depend on the magnitude and maturity of the outstanding debt stock. To see how debt management can mitigate the need for adjusting tax rates and generating inflation in the face of fiscal shocks, we construct a simple example in the following section where the policymaker can completely insulate the government's finances from government spending shocks.

The final first-order condition is for deflation

$$-\beta^t \theta(\nu_t - 1)\nu_t + \sum_{i=0}^{t} \beta^i \lambda_i \left(-\sum_{j=0}^{\infty} \left[\beta^j u'(c_{i+j}) \prod_{s=0}^{j} \nu_{i+s} \right] \left[\frac{B_i(i+j)}{P_{i-1}} - \frac{B_{i-1}(i+j)}{P_{i-1}} \right] \right)$$

This can be combined with the condition for debt management and quasi-differenced to obtain, under perfect foresight

$$(\nu_t - 1)\nu_t = \beta(\nu_{t+1} - 1)\nu_{t+1} + \theta^{-1}\lambda_0 u'(c_t)\left[\frac{B_{-1}(t)}{P_t}\right]$$

This expression highlights more clearly the link between inflation and the maturity structure of the predetermined debt stock than does the geometrically declining maturity structure. The inflation dynamics under the optimal policy are in a very similar form to the nonlinear new Keynesian Phillips curve when price stickiness results from Rotemberg (1982) quadratic adjustment costs. The key difference is that the forcing variable is the element of the predetermined debt stock that matures in period t. Deflation/inflation anticipates the rate at which the debt stock issued at time $t = -1$ when the plan was formulated, matures. This makes current inflation reflect the discounted value of future debt as it matures. As debt matures, the effectiveness of inflation diminishes and inflation falls: the optimal rate of inflation jumps and gradually erodes until all the initial outstanding debt stock has matured. Notice that this Ramsey plan for inflation is only affected by debt dated at time $t = -1$, and the maturity structure of debt issued after this initial period is irrelevant in a perfect foresight environment. Future maturities will affect the government's ability to insure against fiscal shocks in a stochastic environment. We can see this latter point more clearly by considering a simple example.

4.6 Commitment and Hedging

Angeletos (2002) and Buera and Nicolini (2004) argue that debt maturity should be structured to insure the economy against shocks by having the government issue long-term liabilities, but hold an almost offsetting portfolio of short-term assets (the net difference being the government's overall level of indebtedness). In the face of fluctuating spending needs and interest rates, bond prices adjust to help finance debt without requiring any change in taxation. In these papers the short and long positions are constant over time, so that they do not require active management, although numerically they are extremely large positions (for example, five or six times the value of GDP in Buera and Nicolini, 2004). This approach amounts to another way to introduce the contingency in overall debt payments even though these individual assets/liabilities are not state contingent.

To construct a simple example of the use of debt management for hedging purposes we consider an environment where taxes and transfers are at their steady-state values ($\tau_{t+j} = \tau^*$ and $z_{t+j} = z^*$). Government spending can either take the value of $g^h > g^*$, with probability 1/2, or $g^l < g^*$ with complementary probability. Government debt takes the form of a single-period bond of quantity b^s issued in period t, repayable in period $t + 1$, and a portfolio of longer term bonds of geometrically declining maturity, so that the quantity of debt issued in period t maturing in period $t + j$ is $\rho^j b^m$. With a single *i.i.d.* shock all that is required for complete hedging is that the maturity structure contains both one- and two-period debt to enable us to perfectly hedge, as in Buera and Nicolini. With additional *i.i.d.* shock processes, complete hedging is not possible, as we would require some persistence in the shock process and longer term debt. Because we wish to contrast this case with a scenario where a time-consistent policymaker seeks to use debt management for the purposes of hedging and mitigating time-consistency problems, we allow for a combination of longer term bonds and short-term bonds in which varying proportions of the two types can act as a proxy for changes in average debt maturity. In this example, transfer shocks, which amount to shocks that do not directly affect bond prices and interest rates, cannot be completed hedged, although movements in inflation as part of the optimal policy response could provide some hedging opportunities.

Generalizing the Ramsey policy considered above to include a single-period nominal bond as well as the portfolio of bonds with geometrically declining maturity, the system of first-order conditions to be solved as part of the Ramsey problem is

$$-\theta(\nu_t-1)+\widetilde{\mu}_{t-1}(1+\rho P_t^m)c_t^{-\sigma}+\widetilde{\gamma}_{t-1}c_t^{-\sigma}-(1+\rho P_t^m)\tau_t b_{t-1}-\tau_t b_{t-1}^s=0$$

$$\tau_t b_t-\widetilde{\mu}_t c_t^{-\sigma}-\rho\nu_t(\tau_t b_{t-1}-\widetilde{\mu}_{t-1}c_t^{-\sigma})=0\tau_t b_t^s-\widetilde{\gamma}_t c_t^{-\sigma}=0$$

$$\tau_t P_t^m-\beta E_t(1+\rho P_{t+1}^m)\nu_{t+1}\tau_{t+1}=0$$

$$\tau_t P_t^s-\beta E_t\nu_{t+1}\tau_{t+1}=0$$

$$\beta E_t\frac{(1+\rho P_{t+1}^m)}{P_t^m}\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}\nu_{t+1}-1=0$$

$$\beta E_t\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}\nu_{t+1}-P_t^s=0$$

$$b_t P_t^m+b_t^s P_t^s-(1+\rho P_t^m)b_{t-1}\nu_t-b_{t-1}^s\nu_t-g_t-z^*+\tau_t=0$$

$$g_t=g^i,\quad i=h,l\,\text{with prob }1/2$$

where $\widetilde{\mu}_{t-1}=\frac{\mu_{t-1}}{P_{t-1}^m c_{t-1}^{-\sigma}},\widetilde{\gamma}_{t-1}=\frac{\gamma_{t-1}}{P_{t-1}^s c_{t-1}^{-\sigma}}$, and γ_t is the Lagrange multiplier associated with the pricing of single-period bonds, $P_t^s=\beta E_t\left(\frac{c_{t+1}}{c_t}\right)^{-\sigma}\nu_{t+1}$. There are four state variables—$\widetilde{\mu}_{t-1},\widetilde{\gamma}_{t-1},b_t,b_t^s$—the first two of which capture the history dependence in policymaking under commitment. Despite the complexity of these first-order conditions, the policymaker can fulfill this Ramsey program with a constant tax rate and no inflation by buying an appropriate quantity of single-period assets paid for by issuing longer term bonds. Shocks to public consumption then induce fluctuations in the prices of these assets/liabilities which perfectly insulate the government's finances.

With *i.i.d.* fluctuations in government spending, the current level of spending is also a state variable: we are either in the high- or in the low-government spending regime and may exit that regime with a probability of 1/2 each period.

The pricing equation for geometrically declining coupon bonds is

$$P_t^m = \beta E_t (1 + \rho P_{t+1}^m) \left(\frac{c_{t+1}}{c_t} \right)^{-\sigma} \nu_{t+1}$$

With government spending fluctuating between high and low states, bond prices will fluctuate depending on the spending state. Define $u_{ij} = \frac{u'(1-g^i)}{u'(1-g^j)} = \frac{(1-g^i)^{-\sigma}}{(1-g^j)^{-\sigma}}$, $i,j = l,h$, and $i \neq j$ bond prices in spending regime i, $i = h,l$ are given by

$$\begin{aligned} P_i^m &= \beta \frac{1}{2} (1 + \rho P_i^m) + \beta \frac{1}{2} (1 + \rho P_j^m) u_{ji} \\ &= A_i + B_i P_j^m \end{aligned}$$

where $A_i = (1 - \frac{1}{2}\beta\rho)^{-1} (\frac{1}{2}\beta + \frac{1}{2}\beta u_{ji})$ and $B_i = (1 - \frac{1}{2}\beta\rho)^{-1} \frac{1}{2}\beta\rho u_{ji}$, $i, j = l, h$, and $i \neq j$, which can be solved as

$$P_i^m = \frac{A_i + B_i A_j}{1 - B_i B_j}$$

For one-period debt this reduces to

$$P_i^s = \frac{1}{2}\beta + \frac{1}{2}\beta u_{ji}$$

Optimal hedging uses these fluctuations in bond prices to construct portfolio of government debt that negates the need to vary taxes or induce inflation surprises, despite the random movements in government consumption.

The flow budget identity conditional on the government spending regime, but with constant tax rates and no inflation, is

$$P_i^m b^m + P_i^s b^s = (1 + \rho P_i^m) b^m + b^s - (\tau^* - g^i - z^*)$$

We choose b^m and b^s to ensure this equation holds regardless of the government spending regime, so that the government does not need to issue or retire debt as it moves between low and high spending regimes. This portfolio is given by

$$\begin{bmatrix} b^m \\ b^s \end{bmatrix} = - \begin{bmatrix} P_i^m (1-\rho) - 1 & P_i^s - 1 \\ P_j^m (1-\rho) - 1 & P_j^s - 1 \end{bmatrix}^{-1} \begin{bmatrix} \tau^* - g^i - z^* \\ \tau^* - g^j - z^* \end{bmatrix}$$

We can achieve the same portfolio by considering the debt valuation equation in a given period, which is contingent on the government spending state. If government spending is currently high, that equation is

$$b^s(u'(c^h)) + b^m(u'(c^h)) + \sum_{j=1}^{\infty}(\rho\beta)^j\left[\frac{1}{2}u'(c^l) + \frac{1}{2}u'(c^h)\right]b^m$$
$$= u'(c^h)(\tau^* - g^h - z^*) + \sum_{j=1}^{\infty}\beta^j\left[\frac{1}{2}u'(c^l)(\tau^* - g^l - z^*) + \frac{1}{2}u'(c^h)(\tau^* - g^h - z^*)\right]$$

and if government spending is low it is

$$b^s(u'(c^l)) + b^m(u'(c^l)) + \sum_{j=1}^{\infty}(\rho\beta)^j\left[\frac{1}{2}u'(c^l) + \frac{1}{2}u'(c^h)\right]b^m$$
$$= u'(c^l)(\tau^* - g^l - z^*) + \sum_{j=1}^{\infty}\beta^j\left[\frac{1}{2}u'(c^l)(\tau^* - g^l - z^*) + \frac{1}{2}u'(c^h)(\tau^* - g^h - z^*)\right]$$

subtracting one from the other implies

$$[b^s + b^m](u'(c^h) - u'(c^l)) = u'(c^h)(\tau^* - g^h - z^*) - u'(c^l)(\tau^* - g^l - z^*) \tag{40}$$

Without any change in taxation or inflation, government solvency is ensured, provided that debt maturing in the current period has the value implied by this equation. Assuming a sufficiently low level of net indebtedness, the primary budget will swing between deficit and surplus as government spending moves from high to low regimes, implying that the right side of (40) is negative. Since $u'(c^h) > u'(c^l)$, this condition requires that the Ramsey policymaker buys short-term assets to such an extent that $b^s < -b^m$. The budget identity is insulated from the effects of government spending shocks, which can be absorbed by bond prices without any need to issue new debt, change taxes, or generate inflation surprises.

The size of the longer term liabilities must, equivalently, satisfy the solvency conditions conditional on the current level of government consumption. For example

$$b^s(u'(c^h)) + b^m(u'(c^h)) + \sum_{j=1}^{\infty}(\rho\beta)^j\left[\frac{1}{2}u'(c^l) + \frac{1}{2}u'(c^h)\right]b^m$$
$$= u'(c^h)(\tau^* - g^h - z^*) + \sum_{j=1}^{\infty}\beta^j\left[\frac{1}{2}u'(c^l)(\tau^* - g^l - z^*) + \frac{1}{2}u'(c^h)(\tau^* - g^h - z^*)\right]$$

which can be written as

$$\frac{\rho\beta}{1-\rho\beta}\left[\frac{1}{2}u'(c^l) + \frac{1}{2}u'(c^h)\right]b^s + b^s u'(c^h) + b^m u'(c^h)$$
$$= \frac{\beta}{1-\beta}\left[\frac{1}{2}u'(c^l)(\tau^* - g^l - z^*) + \frac{1}{2}u'(c^h)(\tau^* - g^h - z^*)\right] + u'(c^h)(\tau^* - g^h - z^*)$$

This expression can either define the steady-state level of long-term debt given the tax rate or the tax rate given the long-term debt stock. Either interpretation is consistent with a steady-state solution to the Ramsey tax-smoothing plan where the solution of the remainder of the Ramsey problem is $\tau_t = \tau^*$, $z_t = z^* = 0.18y$, $\nu_t = 1$, $\frac{\gamma_i}{P_i^s} = \tau^* b^s$, $\frac{\mu_i}{P_i^m} = \tau^* b^m$, $i = h, l$ with probability of 1/2. In other words, the steady-state tax rate can support the average level of government spending, steady-state transfers, and the steady-state net debt stock, while fluctuations in bond prices mitigate the need for further tax adjustments to compensate for fluctuations in government spending.

Fig. 10 reveals the pattern of bond returns and the underlying asset positions for a series of random draws across the two spending regimes. The figure's bottom right panel describes a particular realization of the government spending shocks. Despite these movements in spending the budget identity can be satisfied with a constant tax rate and no inflation surprises by buying short-term assets that are funded by issuing longer term debt. The portfolio that achieves this implies that the government holds short-term assets of around 22% of GDP, with longer term liabilities of around 70% of GDP and a net debt of around 48%. Although large, these positions are less than those typically found for richer stochastic processes, where positions often exceed the economy's total endowment by several factors (Buera and Nicolini, 2004). Since the ability to hedge relies on variation in the yield curve, having longer term liabilities to set against the short-term assets is most effective. Then a portfolio of single-period assets matched with 1-year liabilities requires far more short-term assets, compared to a portfolio made up of the same assets and bonds

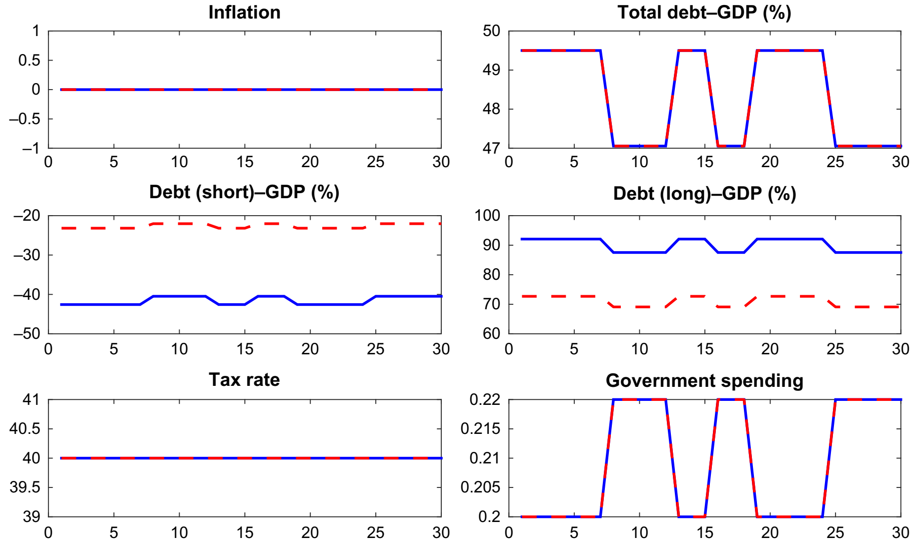

Fig. 10 Optimal hedging under commitment. 1-year debt (*solid lines*) and 5-year debt (*dashed lines*).

with an average maturity of 5 years. Hedging in this way implies that a positive shock to government spending, which raises the primary deficit, actually leads to a reduction in the value of government indebtedness, rather than to an increase. This is a general prediction of models that have achieved financial market completeness which Marcet and Scott (2009) use as the basis of an empirical test, but the data strongly reject.

Faraglia et al. (2008) extend Buera and Nicolini's analysis to move away from an endowment economy to consider a production economy with capital. This makes the size of the extreme portfolio positions even larger, and now the liability/asset positions are no longer constant, but highly volatile, possibly even reversing the issue-long-buy-short recommendation. Because yield premia are not very volatile, they are therefore not very effective as a source of insurance. They then consider what happens if the government is unsure about the specification of some element of the model. The sensitivity of results to small changes in model specification means that it is often better to run a balanced budget than run the risk of getting the portfolio composition wrong. Similarly, even modest transaction costs would make it undesirable to construct such huge portfolios.

4.7 Discretion

A large part of the literature that extends Lucas and Stokey's (1983) analysis focuses on the importance of having access to state-contingent debt either directly or by using inflation surprises and debt management to render state dependent the real payoffs from government debt. When the policymaker can replicate the Ramsey policy in Lucas and Stokey through such devices, there remains the issue of whether the underlying policy is time consistent. In the original Lucas and Stokey model, the Ramsey policy can be made time consistent by adhering to a particular debt maturity structure. Lucas and Stokey then conjecture that allowing debt to be nominal would make the policy problem trivial: positive debt would be costlessly deflated by positive surprise inflation and negative debt would be adjusted by surprise deflation to the level sufficient to support the first-best allocation (the interest on the debt paying for government consumption, consistent with any fiscal taxes/ subsidies required by offset other market distortions). This reasoning suggests that the only interesting case is when the outstanding debt stock is zero.

Persson et al. (1987) initiated a debate exploring the Lucas and Stokey conjecture.[al] Alvarez et al. (2004) conclude that the Lucas and Stokey structure of state-contingent indexed debt, in combination with a condition that net nominal debt is zero so that government debt liabilities equal the stock of money, can ensure the time consistency of the original Lucas and Stokey Ramsey policy in a monetary economy that follows the Friedman rule. As Persson et al. (2006) note, these conditions essentially reduce the monetary version of the Lucas and Stokey economy to its real version.

[al] Persson et al. (2006) chart the course of this debate.

Bohn (1988) argues that in issuing nominal debt the policymaker trades off the ability to use inflation surprises as a hedging device when debt is nominal against the inflation bias that a positive stock of debt creates. In models where the problem is not constructed to mimic the Lucas and Stokey Ramsey policy, the time-consistent policy typically implies a mean reverting steady-state level of debt. Debt can be positive or negative, depending on the nature of the time-inconsistency problem. The issue of the time consistency of policy is also dependent on the cost of inflation surprises. Persson et al. (2006) use beginning- rather than end-of-period money balances in the provision of liquidity services to make unexpected inflation costly, which allows them to construct a time-consistent portfolio of indexed and nominal debt. Martin (2009) adopts the cash–credit good distinction in Lucas and Stokey to generate a cost to inflation which is then balanced against the gains from using inflation to reduce the value of single-period nominal debt. This generates a mean reverting steady-state level of debt under discretion, rather than the random walk in steady-state debt, which is a feature of the Ramsey tax-smoothing policy without state-contingent debt. Martin (2011) combines the Lagos and Wright (2005) monetary search model with fiscal policy and explores the time-consistency problem to find that the welfare costs of an inability to commit are small. This conclusion likely reflects the nature of the costs of surprise inflation; as noted earlier, when Schmitt-Grohé and Uribe (2004) introduce even a tiny degree of nominal inertia, the time-inconsistent Ramsey policy tilts very firmly in favor of price stability, away from the Friedman rule and the use of inflation surprises.

We now turn to consider the impact on the balance between monetary and fiscal policy of constraining the policymaker to be time consistent. We continue to use the endowment economy where inflation is assumed to be costly as a shortcut to introducing nominal inertia.

The policymaker cannot make credible promises about how they will behave in the future in order to improve policy trade-offs today. However, even in this simple model there is an endogenous state variable in the form of government debt, so that policy actions today will affect future expectations through the level of debt that the policy bequeaths to the future. We define the auxiliary variable

$$M(b_{t-1},g_{t-1}) = (1+\rho P_t^m)\nu_t(c_t)^{-\sigma}$$

to write the Bellman equation of the associated policy problem as

$$\begin{aligned} V(b_{t-1},g_{t-1}) = &-\frac{1}{2}(\tau_t^2+\theta(\nu_t-1)^2)+\beta E_t V(b_t,g_t) \\ &+\mu_t\left(\beta\frac{c_t^\sigma}{P_t^m}E_t M(b_t,g_t)-1\right) \\ &+\lambda_t(b_t P_t^m-(1+\rho P_t^m)b_{t-1}\nu_t-g_t-z_t+\tau_t) \end{aligned}$$

We have replaced the expectations in the bond-pricing equation with the auxiliary variable to indicate that the policymaker cannot influence those expectations directly by making policy commitments. But those expectations are a function of the state variables. We take government spending and transfers to be exogenous autoregressive processes.

The implies the first-order conditions

$$
\begin{aligned}
\tau_t &: -\tau_t + \lambda_t = 0 \\
\nu_t &: -\theta(\nu_t - 1) - \lambda_t(1 + \rho P_t^m) b_{t-1} = 0 \\
P_t^m &: -\frac{\mu_t}{P_t^m} + \lambda_t(b_t - \rho b_{t-1}\nu_t) = 0 \\
b_t &: \frac{\mu_t}{P_t^m} c_t^\sigma \beta E_t \frac{\partial M(b_t, g_t)}{\partial b_t} + \lambda_t P_t^m + \beta E_t \frac{\partial V(b_t, g_t)}{\partial b_t} = 0
\end{aligned}
$$

From the envelope theorem

$$
\frac{\partial V(b_{t-1}, g_{t-1})}{\partial b_{t-1}} = -(1 + \rho P_t^m)\nu_t \lambda_t
$$

which can be led one period and substituted into the first-order condition for government debt

$$
\frac{\mu_t}{P_t^m} c_t^\sigma \beta E_t \frac{\partial M(b_t, g_t)}{\partial b_t} + \lambda_t P_t^m - \beta E_t(1 + \rho P_{t+1}^m)\nu_{t+1}\tau_{t+1} = 0
$$

Combining the condition for the bond price P_t^m with the Fisher equation implies

$$
\frac{\mu_t}{P_t^m} = \lambda_t(b_t - \rho \nu_t b_{t-1})
$$

which can be used to eliminate $\frac{\mu_t}{P_t^m}$ from the condition for debt. The system to be solved for $\{P_t^m, \nu_t, \tau_t, b_t, g_t\}$ is

$$
\begin{aligned}
\nu_t &: -\theta(\nu_t - 1) - \tau_t(1 + \rho P_t^m) b_{t-1} = 0 \\
b_t &: \tau_t(b_t - \rho \nu_t b_{t-1}) \beta c_t^\sigma E_t \frac{\partial M(b_t, g_t)}{\partial b_t} + \tau_t P_t^m - \beta E_t(1 + \rho P_{t+1}^m)\nu_{t+1}\tau_{t+1} = 0
\end{aligned}
$$

along with the bond-pricing equation and the government's budget constraint.

The first-order condition for inflation is now

$$
-\theta(\nu_t - 1) = (1 + \rho P_t^m) b_{t-1} \tau_t
$$

Under commitment, inflation persisted only for as long as the maturity structure of the predetermined debt stock at the time a shock hit. Under time-consistent policy, outside of the policymaker's bliss point (of zero inflation and no taxation), with a nonzero debt stock there will always be a state-dependent mix of taxation and inflation. A positive stock of debt delivers positive inflation, regardless of the maturity structure of that debt. This reflects the inflation bias inherent in the time-consistent policy in the presence of nominal debt.

We can see some more differences between discretion and commitment by contrasting the equivalent expressions describing the evolution of the tax rate. Under commitment we obtain the standard tax-smoothing result adjusted for the tilting implied by variations in the stochastic discount factor

$$\tau_t P_t^m = \beta E_t (1 + \rho P_{t+1}^m) \nu_{t+1} \tau_{t+1}$$

The equivalent condition under discretion is

$$\tau_t P_t^m = \beta E_t (1 + \rho P_{t+1}^m) \nu_{t+1} \tau_{t+1} - \tau_t (b_t - \rho \nu_t b_{t-1}) \beta c_t^\sigma E_t \frac{\partial M(b_t, g_t)}{\partial b_t}$$

The additional term captures the effects of the tax rate on expectations of inflation and bond prices through the level of debt carried into the future. Increased debt raises expected inflation and lowers expected bond prices, so $E_t \frac{\partial M(b_t, g_t)}{\partial b_t} < 0$. This captures the debt-contingent nature of the time-consistency problem facing the policymaker. As debt levels rise the policymaker faces a greater temptation to utilize surprise inflation to reduce the debt burden. Economic agents anticipate this and raise their inflationary expectations until the temptation to induce surprises is offset. However, unlike in the standard analysis of the inflationary bias problem this bias is not static since the policymaker can raise additional distortionary taxes to reduce debt and its associated inflation. Therefore the additional term in the above expression raises the tax rate above the level implied by the tax-smoothing condition observed under commitment. Where the tax rate under commitment was carefully constructed to allow debt levels to permanently rise, under discretion the tax rate prevents debt from rising permanently.[am] Moreover, the rate at which the policymaker reduces debt under discretion depends crucially on the term, $(b_t - \rho \nu_t b_{t-1})$ which in turn depends on the maturity structure of the debt stock. Effectively the lower bond prices mean the policymaker must issue more bonds to finance a given deficit, but pays less to buy back the existing debt stock. As debt maturity is increased this latter effect comes to dominate the former and the speed of debt reduction is reduced. Therefore, in contrast to the random walk in steady-state debt observed under commitment, the time-consistent policymaker returns debt to a steady-state value that is very close to zero, but slightly negative where the speed of adjustment depends crucially on average debt maturity. This cannot be seen entirely analytically, so we

[am] Calvo and Guidotti (1992) label this the "debt aversion" effect and Leith and Wren-Lewis (2013) call it the "debt stabilization bias."

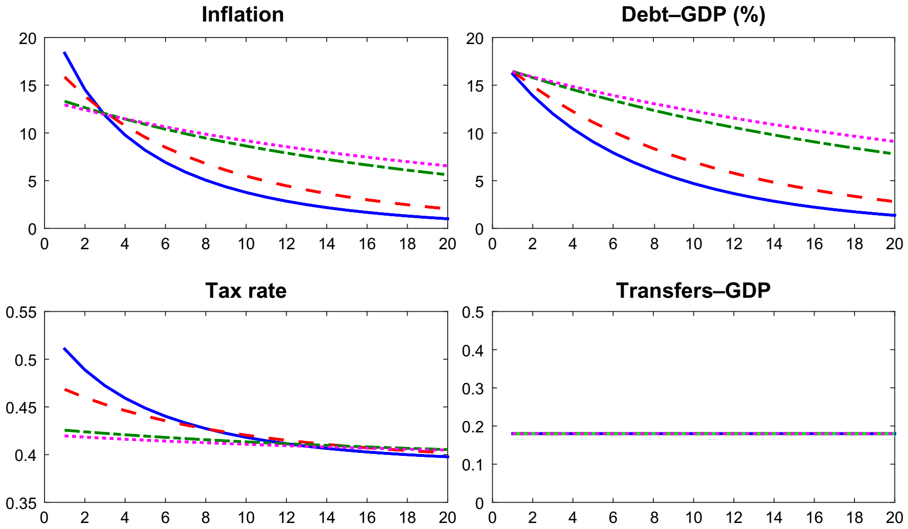

Fig. 11 Optimal time-consistent policy when debt is above its steady-state level. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), 5-year debt (*dotted–dashed lines*), and 7-year debt (*dotted lines*).

need to analyze the numerical solution to the time-consistent policy problem to gain further insight.

The numerical solution under discretion is radically different from that under commitment (Fig. 11). Under commitment, policy allows the steady-state level of debt to follow a random walk and the use of inflation to offset shocks is relatively modest. Under discretion there is a unique steady state at which the policy supporting the steady-state debt level is time consistent, and this occurs at a slightly negative debt stock with a mild deflation. The negative steady-state debt stock falls far short of the negative debt levels that would be needed to support the first-best allocation—that is, the stock of government-held assets generates interest income sufficient to pay for all transfers and government spending without levying any distortionary taxes. Private-sector expectations ensure that the policymaker does not accumulate such a level of assets. Bondholders know that once the government has accumulated a positive stock of assets, it has an incentive to introduce surprise deflation to increase the real value of those assets. This knowledge reduces agents' inflation expectations until the policymaker no longer wishes to introduce such deflationary surprises. Accumulating more assets would then worsen this incentive to deflate confronting the policymaker with a trade-off between accumulating assets to reduce tax rates and the expected deflation that the accumulation of assets implies. In the steady state a balance is struck with a mild deflation and small negative debt stock, although both are extremely close to zero.

At positive debt levels there is a significant desire to reduce debt through inflation surprises. Economic agents anticipate this and raise their inflationary expectations.

Positive debt levels raise inflation in a highly nonlinear way because they introduce a state-dependent inflationary bias which can be very large. Even modest debt-to-GDP ratios can imply double-digit inflation. This is a surprising outcome since the same model and parameterization under commitment imply no inflation at all in the absence of shocks and only small inflation with shocks and positive debt levels.

As noted earlier, the policymaker's desire to mitigate this bias leads to a deviation from tax smoothing where the policymaker raises distortionary taxation above the tax-smoothing level to not only stabilize debt but reduce it toward its steady-state value. Debt maturity lessens this debt stabilization bias problem so that for a given debt-to-GDP ratio inflation is lower, the longer is debt maturity. The debt stabilization bias is heavily dependent on the magnitude of the government debt stock. When debt is high, the efficacy of surprise inflation—either current inflation or through bond prices—is also much higher and this raises the government's incentives to use this device to stabilize debt. As a result the debt stabilization bias rises dramatically with debt levels.

In the absence of innovations to the fiscal surplus, this higher inflation does not actually stabilize debt. As in the original inflation bias problem, there is a pure cost in the form of higher inflation which does not generate any reduction in debt.[an] But unlike the original inflation bias problem, in our case the magnitude of the bias is endogenous and depends on the size and maturity of the government debt. The policymaker can choose to reduce debt through taxation to gradually reduce the bias. Under discretion the reduction in debt can be a quite rapid, particularly when the debt stock is large and of short maturity. The costs of the policymaker being unable to commit in this context are not that debt is unstable, but that the policymaker too aggressively returns government debt to its steady-state level following shocks. This message resonates when thinking about actual fiscal austerity policies in many countries after the 2008 global financial crisis.

4.8 Debt Management under Discretion

The above results highlight the time-consistency issues created by nominal debt. The existing optimal policy literature also considers time-consistency issues in relation to debt management issues. Specifically, in the Lucas and Stokey model with state-contingent debt, the maturity structure is key in ensuring that the Ramsey policy described in Lucas and Stokey is time consistent. At the same time, the optimal hedging analysis shows that the maturity structure can create a portfolio of government bonds that features the right state-contingent payoffs even when the underlying bonds are not state contingent. In the context of a real model, Debortoli et al. (2014) also allow the government to hold

[an] Analogously, in Barro and Gordon (1983) this additional inflation does not reduce unemployment.

short-term assets and longer term liabilities (which are individually not state contingent), but require the policy to be time-consistent. They show that the optimal policy results in a relatively flat maturity structure that offsets the costs of not being able to commit even though this removes the tilting in maturity that is beneficial in terms of insurance effects.

To assess the trade-offs between optimal hedging and time consistency, we use the same model that delivered complete hedging of government expenditure shocks under commitment and solve that model under discretion. In introducing single-period bonds to the time-consistent policy problem we need to define an additional auxiliary variable

$$N(b_{t-1}, b_{t-1}^s, g_{t-1}) = \nu_t (c_t)^{-\sigma}$$

All expectations are now a function of three state variables, longer term bonds, b_{t-1}, single-period bonds, b_{t-1}^s and government spending, g_{t-1}, which will either equal $0.22y$ in the high spending regime, or $0.2y$ in the low spending case.

The policy problem is

$$\begin{aligned} V(b_{t-1}, b_{t-1}^s, g_{t-1}) = & -\frac{1}{2}(\tau_t^2 + \theta(\nu_t - 1)^2) + \beta E_t V(b_t, b_t^s, g_t) \\ & + \mu_t (\beta \frac{c_t^\sigma}{P_t^m} E_t M(b_t, b_t^s, g_t) - 1) \\ & + \gamma_t (\beta E_t \frac{c_t^\sigma}{P_t^s} E_t N(b_t, b_t^s, g_t) - 1) \\ & + \lambda_t (b_t P_t^m + b_t^s P_t^s - (1 + \rho P_t^m) b_{t-1} \nu_t - b_{t-1}^s \nu_t - g_t + \tau_t - z_t) \end{aligned}$$

which has an additional constraint associated with the pricing of short-term bonds, and the government's flow budget identity contains both single-period and declining coupon bonds. After applying the envelope theorem this implies the first-order conditions. For inflation

$$-\theta(\nu_t - 1) = \tau_t [(1 + \rho P_t^m) b_{t-1} + b_{t-1}^s]$$

The level of inflation depends on the total level of indebtedness across short and long bonds, so that a positive level of net indebtedness implies an inflationary bias. As before, this bias serves no purpose in terms of reducing the real debt burden, but reflects economic agents' expectations that if inflation were any lower, the policy would be tempted to introduce a surprise inflation to facilitate debt reduction.

The tax-smoothing conditions are

$$\begin{aligned} \tau_t P_t^m = & \beta E_t (1 + \rho P_{t+1}^m) \nu_{t+1} \tau_{t+1} - \tau_t (b_t - \rho \nu_t b_{t-1}) \beta c_t^\sigma E_t \frac{\partial M(b_t, b_t^s, g_t)}{\partial b_t} \\ & - \tau_t b_t^s \beta c_t^\sigma E_t \frac{\partial N(b_t, b_t^s, g_t)}{\partial b_t} \end{aligned}$$

and

$$\tau_t P_t^s = \beta E_t \nu_{t+1} \tau_{t+1} - \tau_t (b_t - \rho \nu_t b_{t-1}) \beta c_t^\sigma E_t \frac{\partial M(b_t, b_t^s, g_t)}{\partial b_t^s}$$
$$- \tau_t b_t^s \beta c_t^\sigma E_t \frac{\partial N(b_t, b_t^s, g_t)}{\partial b_t^s}$$

The first two terms of these expressions reflect the same tax-smoothing conditions found under commitment, where the choice of short-term assets and longer term bonds could satisfy these conditions while perfectly insulating the government's finances from the fluctuations in government spending. The final two terms in each condition capture the impact that another unit of short or long debt has on long- and short-term bond prices through the impact of debt on inflation expectations. These effects highlight the incentives that the policymaker has to reduce indebtedness to reduce inflation, given the inflationary bias problem created by a positive stock of government debt. The magnitude of the effect of reducing either short- or long-term debt by one bond may vary depending on the relative proportions of the two bonds. In other words, by varying the relative proportions of single period and longer term debt, the policymaker can vary the average debt maturity and thereby influence the inflationary bias problem implied by a given level of indebtedness.

Solving the model without switching in government spending generates a steady state with near-zero debt and inflation (Fig. 12). Introducing government spending switches induces fluctuations in all variables. The movements in spending are largely matched with movements in tax rates (even though these could have been eliminated by issuing an

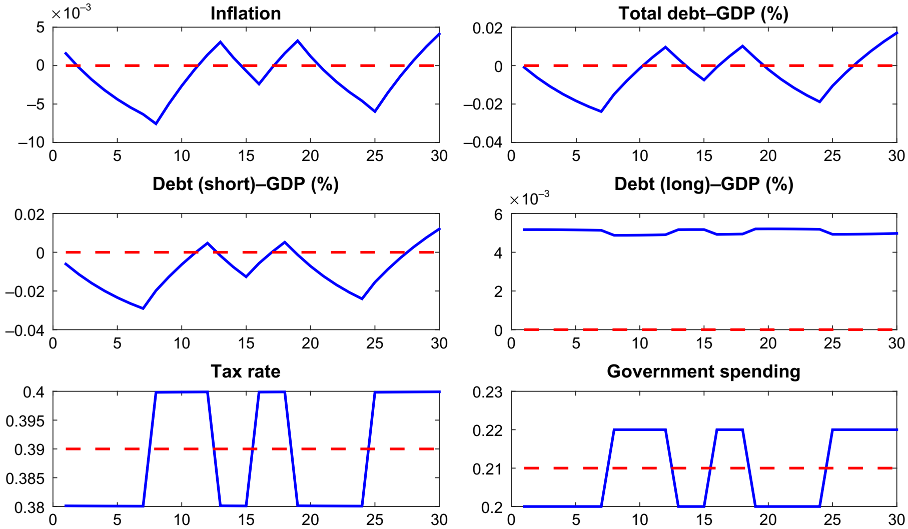

Fig. 12 Hedging under discretion. With government spending switching (*solid lines*) and without government spending switching (*dashed lines*).

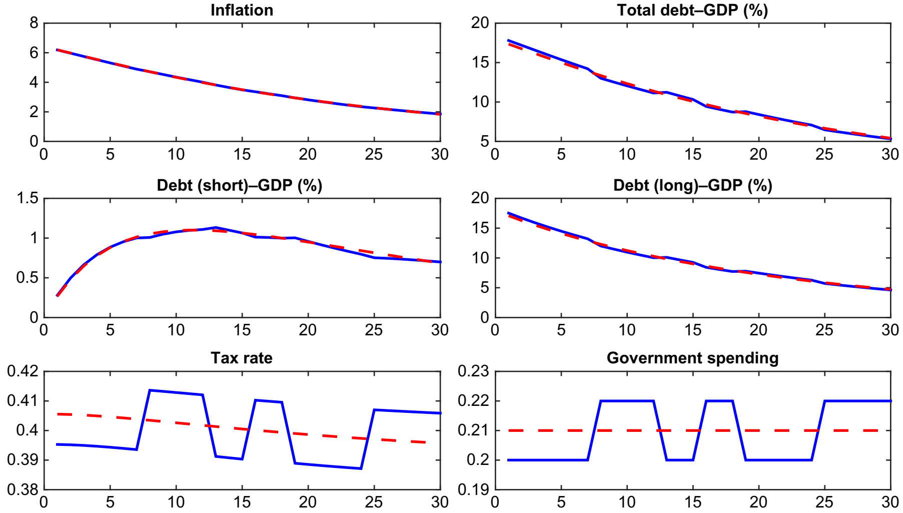

Fig. 13 Hedging and time-consistent policy. With government spending switching (*solid lines*) and without government spending switching (*dashed lines*).

appropriately constructed portfolio of short-term assets and longer term liabilities), although with some increase in the debt/deficit when we are in the high spending regime. The stochastic steady-state asset and liability positions are only slightly positive for assets, and slightly negative for liabilities, but quite distant from the magnitude of the positions required for perfect hedging. Inflation follows the level of indebtedness, giving rise to a positive (negative) inflation bias when the level of indebtedness is positive (negative).

Starting from a positive level of indebtedness, Fig. 13 plots the mix of short- and long-term debt as the economy transitions toward the stochastic steady-state. Calvo and Guidotti's (1992) debt aversion appears as the policymaker fairly rapidly reduces indebtedness in an attempt to eliminate the inflationary bias that debt induces. The fluctuations in debt induced by the changing spending regime are small relative to the general debt dynamics implied by the transition to steady state. The fact that the single-period debt does not rise dramatically when overall indebtedness increases implies that there is an effective lengthening of maturity as overall debt levels increase. This echoes the results of Calvo and Guidotti, which are also discussed in Missale (1999).

5. PRODUCTION ECONOMIES WITH OPTIMAL MONETARY AND FISCAL POLICIES

5.1 The Model

Until now our analysis of optimal policy has been based on a simple flexible price endowment economy, where we have captured the costs of inflation and distortionary taxation by adding quadratic terms in these variables to the policymaker's objective function. We now attempt to generalize these results by considering a production economy where households supply labor to imperfectly competitive firms who are subject to quadratic costs in changing prices as in Rotemberg (1982). The government levies a tax on sales to finance exogenous processes for transfers and government consumption. The policymaker aims to maximize the utility of the representative household. This section therefore endogenizes the welfare costs of both inflation and distortionary taxation. We also widen the scope for monetary and fiscal policy interactions because monetary policy not only generates revaluations of government bonds but also affects real debt service costs and the size of the tax base. Changes in distortionary taxation not only influence the government's budget identity, but they also affect production decisions and have a direct cost-push effect on inflation.

This basic setup is similar to that in Benigno and Woodford (2004) and Schmitt-Grohé and Uribe (2004) but with some differences.[ao] We model price stickiness using Rotemberg's (1996) adjustment costs rather than Calvo (1983) pricing because this reduces the number of state variables when solving the model nonlinearly. We also consider a richer maturity structure rather than single-period bonds.

5.1.1 Households

There is a continuum of households of size one. We assume complete asset markets so that through risk sharing households face the same budget constraint. The typical household seeks to maximize

$$E_0 \sum_{t=0}^{\infty} \beta^t \left(\frac{c_t^{1-\sigma}}{1-\sigma} - \frac{N_t^{1+\varphi}}{1+\varphi} \right)$$

where c and N are a consumption aggregate and labor supply, respectively. The consumption basket is made up of a continuum of differentiated products, $c_t = (\int_0^1 c(j)_t^{\epsilon-1/(\epsilon)} dj)^{\epsilon/(\epsilon-1)}$, and the basket of public consumption takes the same form.

The budget constraint at time t is given by

$$\int_0^1 P_t(j) c_t(j) dj + P_t^m B_t^m = \Pi_t + (1 + \rho P_t^m) B_{t-1}^m + W_t N_t + Z_t \tag{41}$$

where $P_t(j)$ is the price of variety j, Π is the representative household's share of profits in the imperfectly competitive firms (after tax), W are wages, and Z are lump-sum transfers and the bonds the household can invest in are the geometrically declining coupon bonds used above.

We maximize utility subject to the budget constraint (41) to obtain the optimal allocation of consumption across time and the associated pricing of declining coupon bonds

[ao] Leeper and Zhou (2013) study a linear-quadratic version of this setup.

$$\beta E_t\left[\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\left(\frac{P_t}{P_{t+1}}\right)\left(1+\rho P_{t+1}^{m}\right)\right]=P_t^{m}$$

Notice that when these reduce to single-period bonds, $\rho=0$, the price of these bonds is $P_t^m=R_t^{-1}$.

The second first-order condition relates to the labor supply decision

$$\left(\frac{W_t}{P_t}\right)=N_t^{\varphi}c_t^{\sigma}$$

5.1.2 Firms

Firms produce output using to a linear production function, $y(j)_t=AN(j)_t$, where $a_t=\ln(A_t)$ is time varying and stochastic, such that the real marginal costs of production are $mc_t=\frac{W_t}{P_tA_t}$. Household demand for their product is given by $y(j)_t=\left(\frac{P(j)_t}{P_t}\right)^{-\epsilon}y_t$ and firms are also subject to quadratic adjustment costs in changing prices

$$v_t^jP_t=\frac{\phi}{2}\left(\frac{p_t(j)}{\pi^{*}p_{t-1}(j)}-1\right)^2P_ty_t$$

where $\pi^{*}=1$ is the steady-state gross inflation rate. In a symmetric equilibrium where $p_t(j)=P_t$ the first-order condition for firms' profit maximization implies

$$(1-\theta)(1-\tau_t)+\theta mc_t-\phi\frac{\pi_t}{\pi^{*}}\left(\frac{\pi_t}{\pi^{*}}-1\right)+\phi\beta E_t\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\frac{\pi_{t+1}}{\pi^{*}}\frac{y_{t+1}}{y_t}\left(\frac{\pi_{t+1}}{\pi^{*}}-1\right)=0$$

which is the nonlinear version of the Phillips curve and includes the effects of a distortionary tax on sales revenues, τ_t.

5.1.3 Equilibrium

Goods market clearing requires, for each good j

$$y(j)_t=c(j)_t+g(j)_t+v(j)_t$$

which allows us to write

$$y_t\left[1-\frac{\phi}{2}\left(\frac{\pi_t}{\pi^{*}}-1\right)^2\right]=c_t+g_t$$

There is also market clearing in the bonds market where the longer term bond portfolio evolves according to the government's budget identity which we now describe.

5.1.4 Government Budget Identity

Combining the series of the representative consumer's flow budget constraints, (41), and noting the equivalence between factor incomes and national output, we obtain the government's flow budget identity

$$P_t^m b_t = (1+\rho P_t^m)\frac{b_{t-1}}{\pi_t} - y_t\tau_t + g_t - z_t$$

where real debt is defined as $b_t \equiv \frac{B_t^M}{P_t}$.

5.2 Commitment Policy in the New Keynesian Model

Setting up the Lagrangian

$$\begin{aligned} L_t \; &= E_0\sum_{t=0}^{\infty}\beta^t\Bigg[\left(\frac{c_t^{1-\sigma}}{1-\sigma}-\frac{N_t^{1+\varphi}}{1+\varphi}\right)+\lambda_{1t}\left(y_t\left(1-\frac{\phi}{2}\left(\frac{\pi_t}{\pi*}-1\right)^2\right)-c_t-g_t\right) \\ &\quad +\lambda_{2t}\left(\beta\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\left(\frac{P_t}{P_{t+1}}\right)(1+\rho P_{t+1}^m)-P_t^m\right) \\ &\quad +\lambda_{3t}\left((1-\theta)(1-\tau_t)+\theta y_t^{\varphi}c_t^{\sigma}A_t^{-1-\varphi}-\phi\pi_t(\pi_t-1)+\phi\beta\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\pi_{t+1}\frac{y_{t+1}}{y_t}(\pi_{t+1}-1)\right) \\ &\quad +\lambda_{4t}\left(P_t^M b_t-(1+\rho P_t^M)\frac{b_{t-1}}{\pi_t}+y_t\tau_t-g_t-tr_t\right)\Bigg] \end{aligned}$$

and differentiating with respect to $\{c_t, y_t, \tau_t, P_t^m, b_t^m, \pi_t\}$ yield the first-order conditions for the Ramsey program. Those conditions are sufficiently complex to afford little additional insight that was not already gained from the analysis of the comparable problem for our simple endowment economy. But when we solve the model numerically, several interesting results relating to the optimal monetary and fiscal policy mix emerge.

5.3 Numerical Results

The first experiment considers a transfers shock at different initial levels of debt (Fig. 14).[ap] Transfers start at 18% of GDP and then increase with an autocorrelated shock, but do not respond further to GDP. When, as in the first column, the initial debt level is zero the maturity structure of the debt issued after the shock has hit is irrelevant. There is an initial one-period burst in inflation caused by the rise in the tax rate and not fully offset by the tightening of monetary policy. Then a coordinated use of monetary and fiscal policy stabilizes debt at its new steady-state level. The tax rate does not jump immediately to its new steady state, but follows a dynamic path which captures the movement in the real interest rate in the sticky-price economy, while monetary policy ensures that inflation is zero outside of the initial period.

Moving to column 2, at a higher initial debt level radically different policy responses emerge that depend on debt levels and maturity structures. As in Leith and Wren-Lewis (2013) with single-period debt and a sufficiently high debt stock, the transfers shock

[ap] In all cases we solve the model nonlinearly under perfect foresight following an initial perturbation from the steady state.

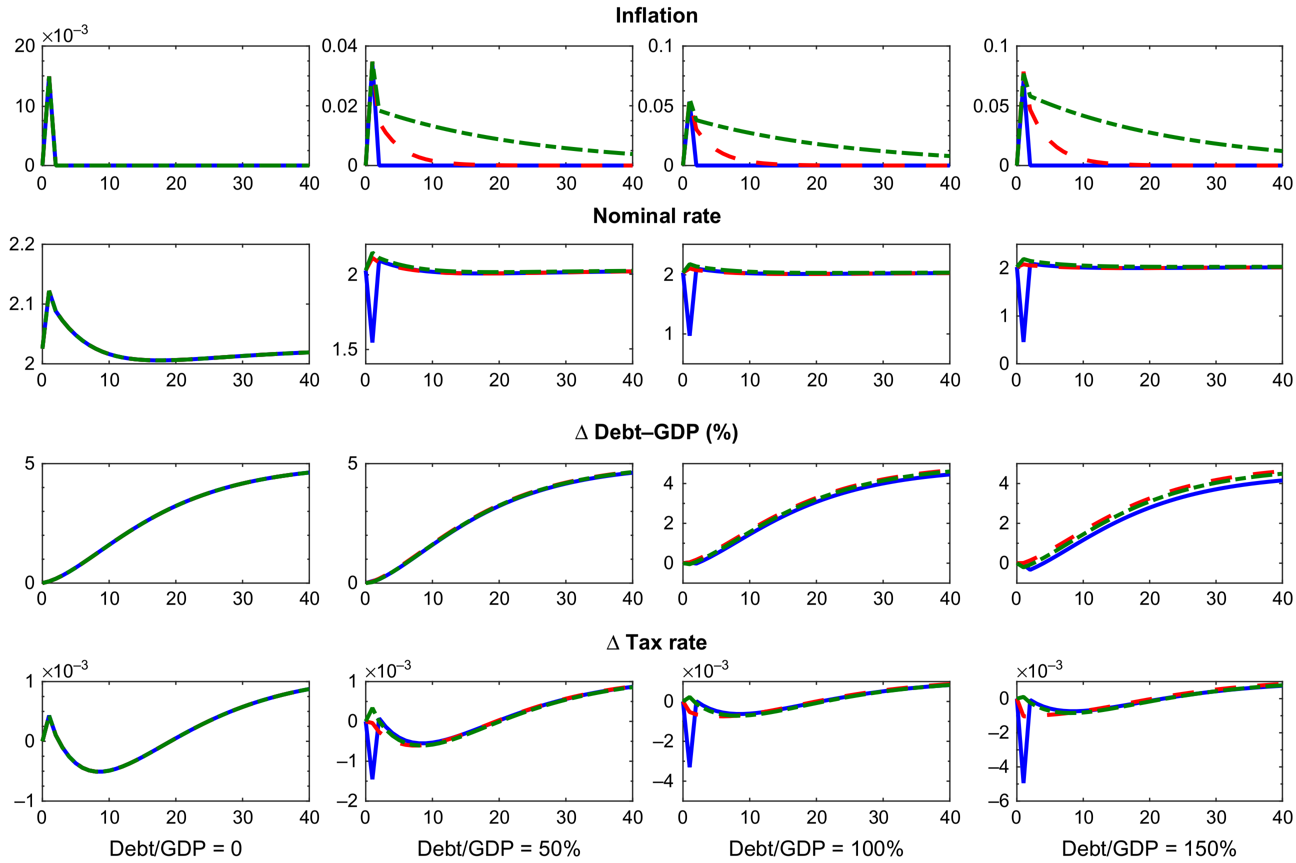

Fig. 14 Optimal policy response to higher transfers with different debt levels and maturities. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), and 4-year debt (*dotted–dashed lines*).

results in the policymaker relaxing monetary policy to reduce debt service costs and fuel the initial burst in inflation. Monetary policy stabilizes the debt—just as in the fiscal theory—while tax rates fall to moderate the rise in inflation. Thereafter a combination of monetary and fiscal policy stabilizes the debt without generating any further inflation. When the debt is of longer term maturity (1 or 5 years), the initial policy response is quite different, with a tighter monetary policy and higher tax rates. The initial rise in inflation extends beyond the first period to help stabilize debt through reduced bond prices.

We now turn to the government spending shock in Fig. 15. The first column sets the initial tax rate at $\tau = 0.39$, sufficient to pay for both the initial value of transfers and public consumption, so there is no debt. In this case, as in the simple endowment economy, debt maturity does not matter and the policy response is the same regardless of the maturity of the debt. Unlike the endowment economy, there is surprise inflation, but this plays no direct role in stabilizing debt. Here the inflation reflects initial jumps in tax rates and interest rates that deliver the optimal balance between monetary and fiscal policy. There is a tax-smoothing jump in taxation that would fuel inflation, but which is offset by a tighter monetary policy that makes inflation zero after the initial period. As private consumption recovers, the tax rate rises, and ultimately there is a high tax rate to support an increased level of debt.

As we increase the initial level of debt, maturity structure generates differences in policy responses. As before, longer maturity delivers a smaller, but more sustained increase in inflation that stabilizes debt by reducing bond prices. But there are differences in the policy mix behind this result. When initial debt to GDP is just under 50%, with only single-period debt the policymaker actually cuts taxes to reduce the inflationary consequences of the government spending shock.

At higher initial debt, more radical differences in the policy mix arise across maturities. Sticky prices mean that not only surprises in the path of inflation influence debt dynamics: the policymaker can also influence real ex-ante interest rates and, through the Phillips curve, the size of the tax base. At a debt level near 100%, we observe a substantial fall in both tax rates and interest rates when debt is only single period. This amounts to a reversal of the conventional assignment of monetary and fiscal policy: monetary policy acts to stabilize debt by cutting real interest rates, while fiscal policy mitigates the inflationary consequences of this by reducing tax rates. For an average debt maturity of 5 years we retain the conventional assignment, with tax rates rising and monetary policy tightening to offset the rise in inflation that higher tax rates would generate.

5.4 An Independent Central Bank

Two key features of jointly optimal policy are worth highlighting. First, price-level control, which is typically a feature of optimal monetary policy in the new Keynesian model, is absent in the presence of fiscal policy and the associated tax-smoothing objective.

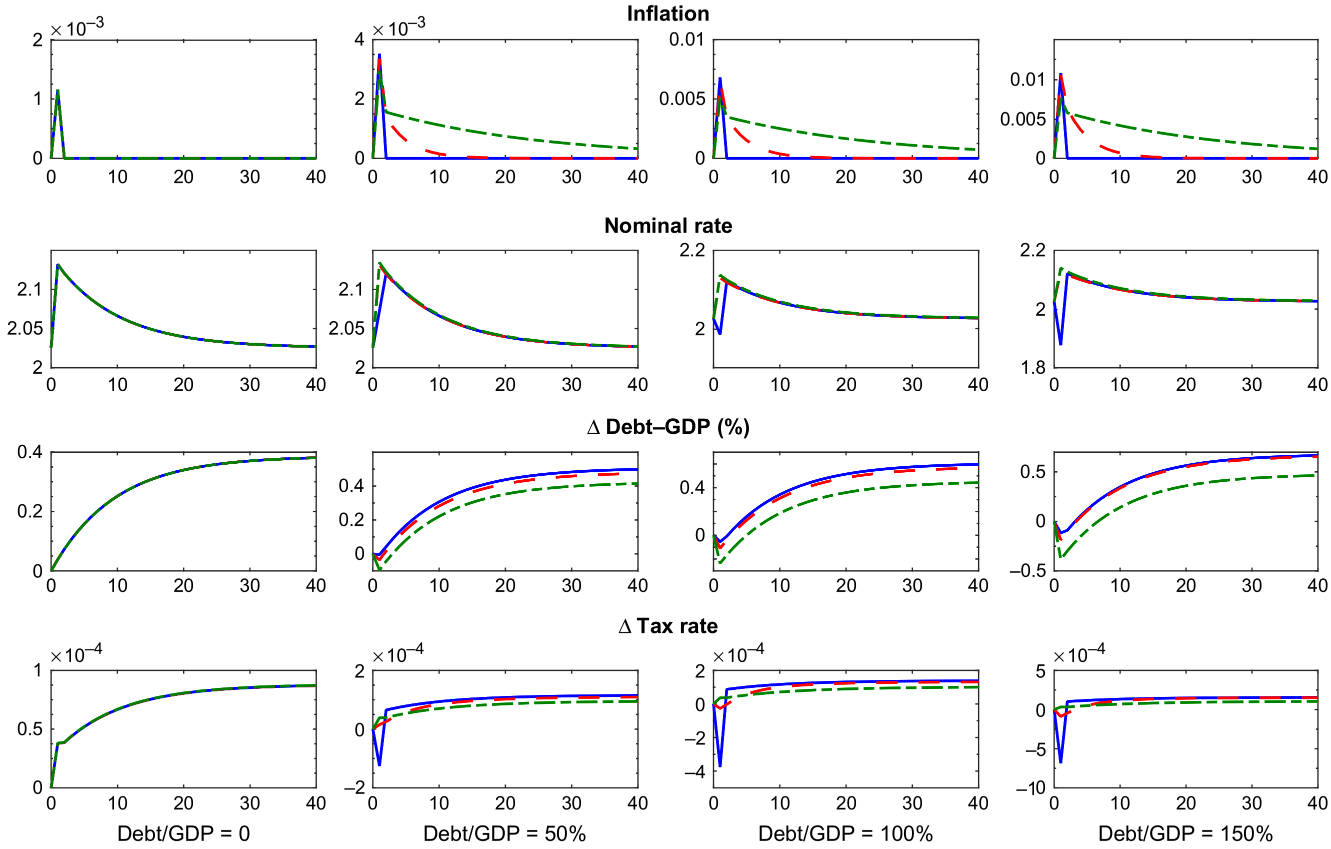

Fig. 15 Optimal policy response to an increase in government spending with different debt levels and maturities. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), and 4-year debt (*dotted–dashed lines*).

Typical analyses have policymakers commit not only to return inflation to target after a shock hits but also to return the *price level* back to its preshock level. This commitment reduces inflation expectations and improves the trade-off between stabilization of inflation and the real economy. When fiscal policy enters the picture, the initial inflation becomes a desirable means of stabilizing debt through the revaluation effects that are a distinguishing feature of the fiscal theory.

Second, the policy mix depends on the size and maturity of government debt. With short maturity and high debt levels, optimal policy reverses the usual policy assignment—raising taxes and interest rates in the face of higher transfers or government consumption—and instead cuts interest rates to reduce debt interest dynamics and cuts taxes to offset the inflation that the relaxation in monetary policy would otherwise induce. Many economists would be uncomfortable with using monetary policy as a tool of fiscal stabilization in this way and would argue in favor of independent central banks to avoid this policy mix.

We assess the implications of independent monetary policy by deriving the optimal fiscal policy conditional on a given monetary policy rule. We assume that the central bank follows a simple Taylor rule with a coefficient on inflation of $\alpha_\pi = 1.5$. The fiscal authority faces the same optimization described earlier, but with the additional constraint that monetary policy follows this rule. Fig. 16 reports that the policy response to higher government spending exhibits some notable differences from the outcome when monetary and fiscal policies are jointly optimal. Inflation's increase is far more prolonged under an independent central bank. When monetary and fiscal policy operate cooperatively, even for the largest stock of debt we analyzed, inflation is less than half that observed when decoupling monetary from fiscal policy. This gives rise to the second surprising result. The active independent monetary policy results in the fiscal policymaker *cutting* rather than raising taxes in response to the government spending shock. The magnitude of the tax cut increases with the stock of debt, but does not vary much across maturities. Optimal fiscal policy counteracts the higher debt service costs that active monetary policy generates by cutting tax rates. This offsets the increase in inflation and under the policy rule mitigates the rise in real interest rates. Because this action is more important the higher the debt, the magnitude of the tax cuts increases with rising debt levels. Similar inflation paths across all debt levels imply that the value of longer maturity debt gets reduced through revaluation effects by more than the other maturities. This also has the implication that the spillovers from monetary policy shocks to the government's finances are likely to be greater at higher and longer maturity debt levels.

These results point to the ubiquity of a central feature of the fiscal theory—debt revaluation through surprise changes in inflation and bond prices. Whether policies are jointly optimal or optimal fiscal policy is constrained by an independent central bank, debt revaluation continues to characterize optimal policy behavior.

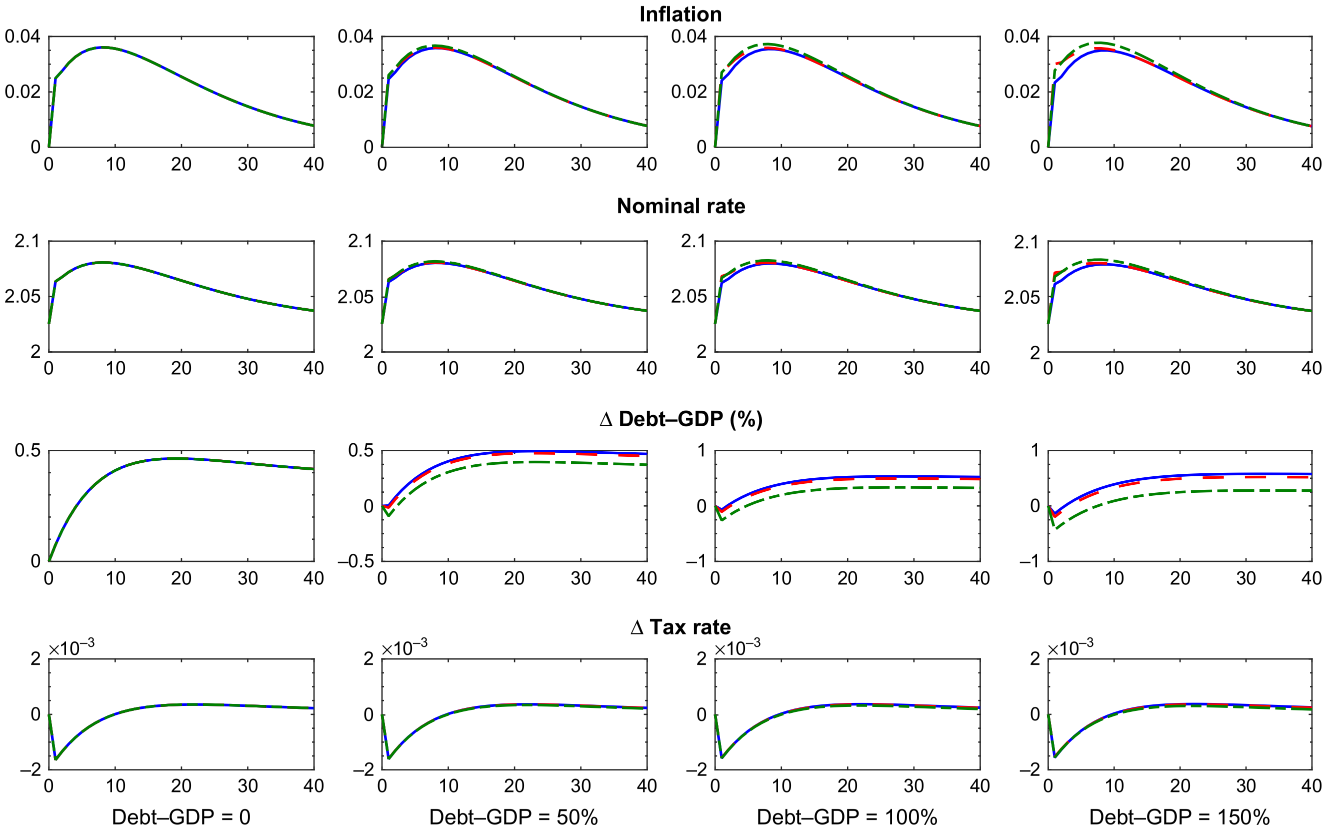

Fig. 16 Optimal fiscal policy response to an increase in government spending with an independent central bank. 1-period debt (*solid lines*), 1-year debt (*dashed lines*), and 4-year debt (*dotted–dashed lines*).

5.5 Discretion in the New Keynesian Economy

This subsection turns to optimal discretionary policy, following the setup in Leeper et al. (2015a). That setup employs a new Keynesian model in which the tax applies to labor income rather than sales revenue and government spending is treated as an endogenous policy instrument rather than an exogenous stream of purchases that need to be financed. There are no transfers. The policy under discretion is a set of decision rules for $\{c_t, y_t, \pi_t, b_t, \tau_t, g_t, P_t^M\}$ that maximize

$$V(b_{t-1}, A_t) = \max\left\{\frac{c_t^{1-\sigma}}{1-\sigma} + \chi\frac{g_t^{1-\sigma_g}}{1-\sigma_g} - \frac{(y_t/A_t)^{1+\varphi}}{1+\varphi} + \beta E_t[V(b_t, A_{t+1})]\right\}$$

subject to the resource constraint

$$y_t\left(1 - \frac{\phi}{2}\left(\frac{\pi_t}{\pi^*} - 1\right)^2\right) - c_t - g_t$$

the Phillips curve

$$(1-\epsilon) + \epsilon(1-\tau_t)^{-1} y_t^{\varphi} c_t^{\sigma} A_t^{-1-\varphi} - \phi\frac{\pi_t}{\pi^*}\left(\frac{\pi_t}{\pi^*} - 1\right) + \phi\beta c_t^{\sigma} y_t^{-1} E_t\left[c_{t+1}^{-\sigma}\frac{\pi_{t+1}}{\pi^*}\left(\frac{\pi_{t+1}}{\pi^*} - 1\right)\right] = 0$$

and the government's budget identity

$$\begin{aligned}
&\beta E_t\left[\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\left(\frac{P_t}{P_{t+1}}\right)\left(1+\rho P_{t+1}^M\right)\right] b_t \\
&= \left\{1 + \rho\beta E_t\left[\left(\frac{c_t}{c_{t+1}}\right)^{\sigma}\left(\frac{P_t}{P_{t+1}}\right)\left(1+\rho P_{t+1}^M\right)\right]\right\}\frac{b_{t-1}}{\pi_t} \\
&- \left(\frac{\tau_t}{1-\tau_t}\right)\left(\frac{y_t}{A_t}\right)^{1+\varphi} c_t^{\sigma} + g_t
\end{aligned}$$

where we have used the bond-pricing equation to eliminate the current value of the portfolio of bonds.

Leeper et al. (2015a) solve the nonlinear system consisting of seven first-order conditions and the three constraints to yield the time-consistent optimal policy using the Chebyshev collocation method. In contrast to the case of commitment where steady-state inflation is zero, discretion implies a steady state with a mildly negative debt stock and a mild deflation. Fig. 17 shows that starting from high debt levels produces significant policy differences across differing bond maturities. These impulse responses reflect the time-consistent adjustment from a high debt level to the ultimate steady-state debt level, which is slightly negative. The most notable element in these dynamic paths is the very high levels of inflation. This inflation does not serve to reduce the real value of debt; instead, it reflects the state-dependent inflationary bias problem generated by high

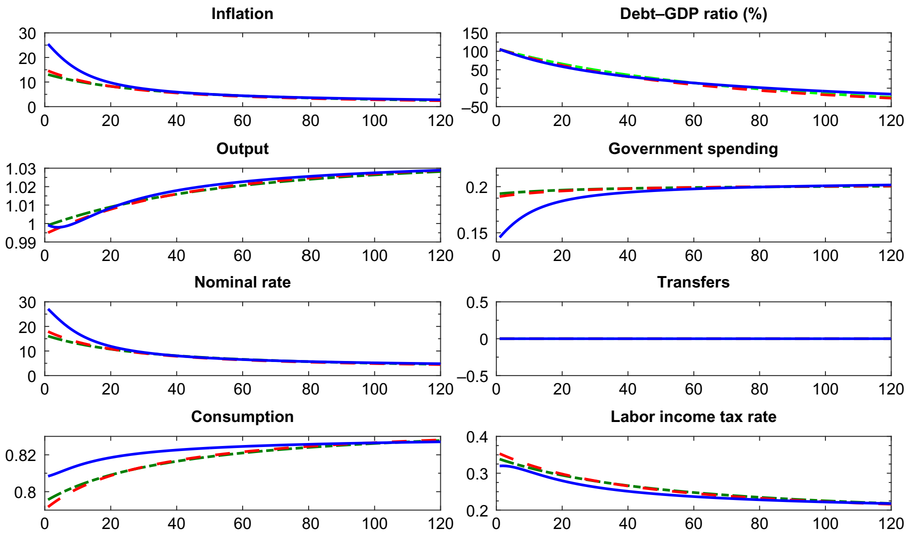

Fig. 17 New Keynesian model under discretionary policy. 1-year debt (*solid lines*), 5-year debt (*dashed lines*), and 8-year debt (*dotted–dashed lines*).

debt levels. When debt levels are raised, the policymaker faces a temptation to use surprise inflation or surprise reductions in bond prices to reduce the real value of government debt. Knowing this, economic agents raise their inflationary expectations until this temptation is no longer present. At empirically plausible debt levels, this temptation is very strong and very high rates of inflation are required to ensure the policy remains time consistent. The shorter the debt maturity, the greater the temptation to inflate and reduce debt levels quickly—what we label "the debt stabilization bias." The steady-state economy eventually achieves a small negative long-run optimal value for debt and a slight undershooting of the inflation target. This falls far short of the accumulated level of assets that would be needed to finance government consumption and eliminate tax and other distortions.

6. EMPIRICAL CONSIDERATIONS

The chapter's emphasis to this point reflects the bulk of the literature on the fiscal theory in its theoretical focus. This section discusses a set of empirical considerations that arise from work on monetary and fiscal interactions. First, we briefly explain why it is difficult to distinguish whether time series data were generated by regime M or by regime F. Then we turn to both reduced form and structural evidence about the prevailing policy regime, including work on regime-switching policies. We end the section by clarifying some common misperceptions about the nature of equilibrium under regime F.

6.1 Distinguishing Regimes M and F

It is well established that regimes M and F can generate equivalent (or nearly equivalent) equilibrium processes. Cochrane (1999) discusses this point and Woodford's (1999) comments on Cochrane's paper elaborate on the issue in some detail. Leeper and Walker (2013) display a simple theoretical example in which the two regimes are observationally equivalent.

Observational equivalence of the two regimes may be surprising. After all, Sections 2 and 3 went to great length to show that monetary and fiscal disturbances produce strikingly different dynamic responses in the two regimes. To understand the equivalence, consider the linearized new Keynesian model that Section 3.1 describes. That model's economic state in period t is the triple $X_t \equiv (\varepsilon_t^M, \varepsilon_t^F, \hat{b}_{t-1})$ and in regime M, each endogenous variable—including the policy variables $\hat{R}_t$ and $\hat{s}_t$—is a linear function of X_t in equilibrium. But those mappings from X_t to the policy variables are consistent with regime F policy behavior: the interest rate depends only on ε_t^M and the surplus depends on ε_t^F.[aq]

Some critics argue that this equivalence result renders the fiscal theory "untestable" and therefore empirically vacuous. Naturally, *equivalence* implies that the conventional view—regime M—is also "untestable." But the critics' nihilism is unwarranted. Observational equivalence merely implies that *in the absence of identifying restrictions* it is impossible to discern which regime produced observed data. But this is nearly a truism. No set of simple correlations—among debt, deficits, inflation, and interest rates—can tell us whether the underlying policy behavior comes from regime M or regime F.[ar]

Yet correlation-based "tests" of the fiscal theory abound in the literature. Canzoneri et al. (2001b) argue that if a positive shock to surpluses both raises future surpluses and lowers the real value of government debt, regime M prevails; if the positive surplus shock raises the value of debt, then regime F prevails. Cochrane (1999) succinctly explains why this is not a "test" of regime. Like any asset, government debt has both a "backward-looking" and a "forward-looking" representation. Let $b_t \equiv B_t/P_t$ denote the real market value of debt. Debt's law of motion—the budget identity—yields the backward view

$$b_{t+1} = r_{t+1}(b_t - s_t)$$

where $r_{t+1} \equiv R_t P_t / P_{t+1}$ is ex-post real return on bonds between t and $t + 1$ and s_t is the primary surplus at t. Higher s_t seems to imply a lower value for debt at $t + 1$. But the forward view, which determines the asset value of debt yields

[aq] If the economy starts with an initial level of debt, the $\{\hat{s}_t\}$ process must be chosen to be consistent with that level.

[ar] Much of the evidence that Friedman and Schwartz (1963a,b) compiled in favor of the quantity theory sought to show that erratic monetary policy drove nominal income movements. But that evidence came from efforts to *identify* "exogenous" or "autonomous" changes in the money stock, as Sims (1972) later showed. Friedman and Schwartz recognized that reduced form correlations alone cannot establish causality.

$$b_t = E_t \sum_{j=0}^{\infty} \left(\frac{1}{r}\right)^j s_{t+j} \tag{42}$$

to suggest that a persistent increase in surpluses raises the value of debt.[as] Evidently, manipulations of identities do not impose enough structure to distinguish between regimes.

A second branch of the correlation-based "testing" literature follows Bohn (1998) in using limited information techniques to estimate

$$s_t = \gamma b_{t-1} + \delta' Z_t + \varepsilon_t^F \tag{43}$$

where s_t is the primary surplus at t, b_{t-1} is the real value of government debt at $t-1$, Z_t is a vector of control variables, and ε_t^F is a possibly serially correlated disturbance. This line of work interprets estimates of (43) as descriptions of fiscal policy behavior.[at] When $\hat{\gamma} > 0$, researchers infer that fiscal behavior is passive, while if $\hat{\gamma} >$ net real interest rate, fiscal policy reacts sufficiently to stabilize debt. Based on such estimates, researchers conclude the economy resides in regime M, so the fiscal theory does not apply.[au]

Missing from this analysis is the bond valuation equation, which is an equilibrium condition that holds regardless of the prevailing policy regime. As condition (42) makes clear, b_{t-1} must be positively correlated with future surpluses *in any equilibrium*. When (43) is estimated without imposing this equilibrium condition, estimates of γ are subject to simultaneous equations bias.

Leeper and Li (2015) use a linearized variant on the endowment economy in Section 2 to study the nature of the simultaneity bias. If the policy disturbance is serially uncorrelated or a lagged dependent variable is added to the regression in (43), then the limited information procedure is valid only if the underlying monetary and fiscal policies are in regime M. Serious biases can arise when data are equilibria in regime F. The sign and severity of bias in $\hat{\gamma}$ depend on monetary policy behavior: the weaker is the reaction of monetary policy to inflation, the stronger is the positive bias. In periods like the aftermath of the 2008 financial crisis, when central banks pegged the nominal interest rate, estimates of γ are more likely to imply a strong response of surpluses to debt. This finding is consistent with Bohn's (1998) estimates, which rarely find evidence that the surplus response is weak.

There are two natural solutions to the simultaneous equations bias. The first is to impose the bond valuation equation on estimates of the fiscal rule, as Chung and

[as] For convenience, (42) assumes a constant real return.

[at] See, for example, Mendoza and Ostry (2008). Ghosh et al. (2012) employ such estimates to compute a country's "fiscal space." Woodford (1999) raises issues with this interpretation.

[au] Canzoneri et al. (2001b) estimate an unrestricted bivariate VAR for the primary surplus and the real value of debt, a technique that is equivalent to estimating a version of (43).

Leeper (2007) and Hur (2013) do in a structural VAR, and estimate monetary and fiscal rules jointly. The second solution is to estimate a fully specified DSGE model.

6.2 Some Suggestive Empirical Evidence

A complete account of empirical evidence about policy regime is beyond the scope of this chapter, so we will briefly recount two kinds of evidence that regime F has prevailed in some historic periods. The first is suggestive evidence that points to empirical facts that are consistent with regime F; then we turn to more formal econometric analysis.

Cochrane (1999) was the first to suggest that U.S. post-World War II inflation could be interpreted through the lens of the fiscal theory. He stresses that readily available fiscal data do not line up well with the theoretical concepts and constructs a data series for the real market value of government debt, from which he infers two different real primary surplus series. Not surprisingly, substantial differences emerge between the primary surplus and conventionally measured surplus (inclusive of debt service), particularly in periods of high debt or high interest rates. He further contrasts his computed surplus series with the Treasury's reported net-of-interest surplus, which does not account for capital gains and losses incurred from bond transactions. Cochrane's calculations make the broad methodological point that scrutiny of regime F equilibria requires careful data construction.

But Cochrane's substantive contribution lies in interpreting the data correlations. He specifies an exogenous—regime F—process for primary surpluses from which he computes the real value of debt as the present value of those artificial surpluses. Processes are chosen to match correlations in the data. Simulations produce observed gross movements in post-war U.S. inflation when the equilibrium price-level sequence emerges from the debt valuation equation.[av] As it happens, the chosen processes would pass either the Bohn (1998) or the Canzoneri et al. (2001b) "test" that those authors claim refutes the fiscal theory. Cochrane's analysis illustrates the difficulties in distinguishing between regimes M and F.[aw]

Woodford (2001) argues that Federal Reserve policy from before World War II until the Treasury-Fed Accord in March 1951 is a clear example in which monetary policy was explicitly assigned the task of maintaining the value of government debt, as it is in regime F. Beginning in April 1942, as Woodford writes

[av] Shim (1984) is an early effort to use VAR analysis to find cross-country evidence of a link between fiscal deficit innovations and inflation.

[aw] Cochrane (2011b) uses the government debt valuation condition to interpret monetary and fiscal policy actions in the wake of the 2008 global recession. He argues that recent policy developments suggest that in coming years the equilibrium condition is likely to have a stronger influence on economies than it has in the past.

> *The yield on ninety-day Treasury bills was pegged at 3/8 of a percent; this peg was maintained through June 1947, and … until that point the price of bills was completely fixed, as the Treasury offered both to buy and sell bills at that price. An intention was also announced of supporting one-year Treasury certificates at a price corresponding to a 7/8 percent annual yield; this policy continued after 1947, though at a slightly higher yield. Finally, the prices of twenty-five-year Treasury bonds were supported at a price corresponding to a 2 and 1/2 percent annual yield; this price floor was maintained up until the time of the "Accord."*
>
> **(Woodford, 2001, pp. 672–673)**

Woodford, however, seems to regard regime F as the exception, arising during wartime and in special circumstances when monetary policy is subordinated to fiscal needs.

Loyo (1999) uses Brazil in the late 1970s and the early 1980s as an example where the fiscal consequences of monetary policy led to explosive inflation. His case does not fall into either of the two regimes in which a determinate bounded equilibrium exists. Instead, Loyo argues that a combination of active fiscal policy and active monetary policy that aggressively sought to combat inflation by raising interest rates strongly in response to inflation produced exactly the phenomenon that Section 3.2.2 describes. Higher interest rates raised bondholders' interest receipts which, in the absence of commensurately higher taxes, raised wealth and aggregate demand. Higher demand increased inflation still further, to which monetary policy responded by raising interest rates, setting off an explosive cycle that produced double-digit inflation rates *per month*. Importantly, this hyperinflation arose with no appreciable change in real seigniorage revenues, as Loyo documents. Loyo's work illustrates a theme that runs through the chapter. If fiscal behavior is active, refusing to raise surpluses to stabilize government debt, more aggressive inflation fighting by the central bank exacerbates the problem: when monetary policy is passive, it amplifies shocks more as it becomes more active; if it is active, those shocks lead to ever-increasing inflation. An alternative monetary policy rule—one that merely pegged the nominal interest rate, for example—would have prevented the explosive inflation.

As of 2015, Brazil may be poised to rerun the experience that Loyo describes. Brazil's 1988 Constitution mandates that government benefits are indexed to inflation, effectively putting 90% of expenditures out of the legislature's reach. With sizeable tax adjustments apparently politically unviable, the gross-of-interest budget deficit reached over 10% of GDP in 2015. Consumer price inflation rose steadily through the year to breach double digits by year-end, despite the Banco Central do Brasil's aggressive antiinflationary efforts that raised the policy interest rate to 14.25% in the second half of 2015 (Banco Central do Brasil, 2015). As *The Economist* (2016) put it: "Fiscal dominance has left arcane discussions among economic theorists and burst onto newspaper columns." As in the period that Loyo studies, rising inflation is driven by the combination of active fiscal behavior and single-minded inflation targeting by the central bank. Coupling that fiscal behavior with passive monetary policy, as in regime F, would not generate explosive inflation rates.

Another recurring theme of the chapter's theory is that debt revaluation effects are a ubiquitous feature of both ad hoc and optimal policy rules. Sims (2013) calculates that since 1960 the surprise gains and losses on U.S. government debt as a percentage of GDP are similar in magnitude to the fluctuations in the deficit relative to GDP: debt revaluations are an important aspect of monetary–fiscal dynamics.[ax] Similarly, Akitoby et al. (2014) calculate that there would be substantial reductions in debt-to-GDP ratios for several developed economies from raising inflation targets to 6%. But Hilscher et al. (2014) argue that it is important to account for the maturity structure of the debt which is actually held by the private sector when undertaking such calculations, concluding that for the United States this may be lower than the maturity of the overall debt stock. Sections 4.4 and 5.3 found that the efficacy of using revaluation effects as a tool of optimal policy increases with both the size and the maturity of the outstanding debt stock. This suggests that the recent increase in debt-to-GDP ratios in most advanced economies raises the likelihood that such revaluation effects may become an increasingly important feature of policy. This does not establish that revaluation effects of the magnitude that Sims reports can come only from regime F-style policies. Instead, it points toward an important source of fiscal financing that formal macro models must confront.

6.3 Some Formal Empirical Evidence

Sims (1998) argues that to assess which part of the policy space—regime M or F—is empirically relevant, it is essential to embed alternative descriptions of policy within a general equilibrium model before taking them to the data. This leads to a more direct attack on the empirical problem of discerning policy regime, as well as the possibility of "testing" which regime is most consistent with observed data.

Leeper and Sims (1994) is an early attempt to estimate a DSGE model with a complete specification of monetary and fiscal policy. Real and nominal rigidities made the analogs to regimes M and F lie in a complicated geometry and the numerical search algorithm had to traverse regions of the parameter space in which either no equilibrium exists or the equilibrium is indeterminate—both cases where the likelihood function is not defined. These difficulties prevented the paper from reaching a conclusion about which policy combination yielded the best fit.[ay]

Bayesian estimation methods have permitted researchers to overcome some of the limitations of earlier work to make progress on the question of the prevailing regime. Expanding on the money-only specification of Smets and Wouters (2007), the models

[ax] See also Taylor (1995), King (1995), and Hall and Sargent (2011) for discussions of and estimates of revaluation effects.

[ay] Leeper (1989) is an even earlier effort that uses a calibrated DSGE model to ask whether impulse response functions from regime M or regime F best match empirical responses. When agents are endowed with foresight about future fiscal actions, there is weak evidence in favor of regime F.

fill in fiscal details and impose the government's budget identity to estimate monetary and fiscal behavior jointly with private behavior. Traum and Yang (2011) impose priors that are centered on either regime M or regime F for various subperiods of U.S. data from 1955 to 2007 and find that the data least prefer the parameter space associated with regime F.

Using a simpler new Keynesian model, but with a maturity structure for government bonds, Tan (2014) argues that rejection of regime F stems from a test procedure that Geweke (2010) calls the "strong interpretation." The strong interpretation takes literally all the cross-equation restrictions of a fully specified dynamic general equilibrium model, which necessarily includes any and all possible sources of misspecification. When Tan employs the methods that DeJong et al. (1996) and Del Negro and Schorfheide (2004) developed, which take the DSGE model as a prior for a VAR, he finds that data no longer strongly prefer regime M. Tan argues that tests of model fit that are robust to misspecification no longer find compelling support for one regime over the other.

Leeper et al. (2015b) estimate medium-scale models that include additional fiscal details—government consumption that may complement or substitute for private consumption, a maturity structure for government debt, explicit rules for several fiscal instruments, and steady-state distorting taxes. For U.S. data covering 1955–2014, even under the strong interpretation, marginal data densities suggest nearly equivalent fits under the two regimes for the full sample and for pre- and post-Volcker subsamples. Details of model specification are as important as policy rules for determining the relative fit of the two regimes.

That paper also reports estimated revaluation effects that arise from government spending expansions that are initially financed by selling debt (partially reproduced in Table 4). These are analogous to the first two columns in Table 2, but the estimated model also includes many other sources of financing—capital, labor and consumption

Table 4 Reports 90% credible intervals around posterior modes

tax revenues, real interest rates, government transfers, and endogenous government spending. Over the full sample and the post-Volcker subsample, the 90% credible intervals display substantial overlap for both inflation and bond prices, suggesting no large differences in revaluation effects in the two regime. Intervals do not overlap in the pre-Volcker period, with larger revaluation effects in regime F for both components.

Both the theory in this chapter and the empirical evidence just cited make clear that revaluation effects that stabilize the value of government bonds are not solely the preserve of regime F. Even in the endowment economy with policy described by simple rules in Section 2, monetary policy and government spending shocks both induce revaluation effects in the two policy regimes. Optimal policy exercises show that it is desirable to use a combination of surprise inflation and tax smoothing to stabilize the economy in the face of fiscal shocks, blurring the lines between the M and F regimes. Such exercises also suggest that the balance between inflationary and fiscal financing is also highly state dependent. In richer production economies subject to nominal inertia, the range of monetary and fiscal policy interactions is far wider: monetary and fiscal policy jointly determine the extent to which there are inflation surprises, movements in real interest rates and bond prices and changes in the tax base. The relative magnitudes of these effects, though, depend on the nature of the policy regime and on the level and maturity of the debt stock.

6.4 Regime-Switching Policies

A growing body of work estimates Markov-switching policy rules and embeds them in otherwise conventional DSGE models. Davig and Leeper (2006) find recurring switches between active and passive monetary and fiscal rules, with some periods in which both policies are active or passive. In a rational expectations model in which agents are endowed with knowledge of the policy process, no single monetary–fiscal mix determines the nature of the equilibrium. Instead, expectations of future policy regimes spill-over to affect the current equilibrium. In a new Keynesian model with lump-sum taxes, Davig and Leeper show that even if regime M currently prevails, a tax cut can produce quantitatively important increases in output and the price level. The effects are still larger conditional on being in regime F.

Gonzalez-Astudillo (2013) uses limited information Bayesian methods to estimate a new Keynesian model with monetary and fiscal policy rules whose coefficients are time varying and interdependent. He finds that monetary policy switches more frequently than fiscal policy—a result that contrasts with findings from Markov-switching models—and that the policies are interdependent. But other findings align closely to models with recurring Markov switching: a monetary contraction reduces inflation in the short run, but raises it over longer horizons; lump-sum tax changes always affect output and inflation.

Kliem et al. (2016) find some provocative reduced-form support for time-varying fiscal effects. Using U.S. data from 1900 to 2011, they discovered that the low-frequency correlation between inflation and the fiscal stance—defined as the ratio of primary deficits to government debt—is significantly positive most of the time until 1980 when it becomes zero. They attribute the shift in correlation to a change in monetary policy behavior.

Those authors extend their analysis in Kliem et al. (2015) to include Germany and Italy and to interpret their findings with an estimated DSGE model. Germany never exhibits a significant low-frequency correlation between fiscal stance and inflation, while in Italy the correlation is positive until the Banca d' Italia gained its independence in the 1990s.

Bianchi (2012) and Bianchi and Ilut (2014) estimate a simple new Keynesian model with fiscal policy, habits, and inflation inertia and that also allows for switches in monetary and fiscal policy rules. Bianchi permits a circular movement across three regimes where policy can transition from the conventional assignment (active monetary policy/passive fiscal policy) through the fiscal theory assignment of passive monetary/active fiscal policy, to an unstable regime where both monetary and fiscal policy are active. He finds that the 1960s and 1970s featured a combination of passive monetary and active fiscal policy, before the Volcker disinflation resulted in a combination of active monetary and fiscal policies. Only around 1990 did fiscal policy turn passive. Bianchi and Ilut model a slightly different set of policy transitions that allows the two stable regimes (active monetary/passive fiscal and passive monetary/active fiscal) to briefly transition through the unstable, doubly active, regime. In their estimates, regime F prevails until before monetary policy turns active in 1979 and fiscal policy turns passive shortly afterward (by 1982). These papers suggest that regime M, though not always in place historically, has been the predominant regime in the United States from at least the early 1990s until the financial crisis.

Chen et al. (2015) build on this work in two ways. First, they allow additional permutations of policy in which monetary and fiscal policy may be simultaneously passive and they make the nature of transitions across regimes less restrictive. Their estimates find that the switch to regime M after the Volcker disinflation is far less certain, with both monetary and fiscal policy repeatedly falling outside regime M, even in the recent data.

Second, Chen et al. move away from ad hoc rules for policy to permit monetary and, in some exercises, fiscal policy to be chosen optimally. Monetary policy turns out to be both optimal and time-consistent, but with switches in the degree of anti-inflation conservatism. Those switches imply that monetary policy was not only less conservative in the 1970s, but also intermittently during the 1960s and briefly after the financial market turmoil from the stock market crash of 1987, the Russian default in 1998, and the dot-com crash. At the same time, fiscal policy can rarely be described as optimal (except in the early 1990s), and instead tends to move between an active and passive rule. For the bulk of the period between 1954 and the 2008 financial crisis, fiscal policy was primarily active with the only sustained periods of passive fiscal policy from the late 1950s until the late 1960s, between 1995 and 2000, and briefly between 2005 and the financial crisis. These estimates imply that regime M is the exception rather than the norm.

More subtle findings in Chen et al. emerge from examining the roles of the maturity structure and the level of debt in determining optimal policy. Sections 4.4 and 5.3 found that the Ramsey plan does resemble regime M in periods when debt levels are low and maturity is long: monetary policy was tightened to stabilize inflation in the face of a government spending shock, while tax rates were raised to stabilize debt. But as debt levels rise, especially when maturity is short, policy assignments get reversed: monetary policy responds weakly to higher inflation from increased government spending to reduce debt service costs and stabilize debt, while tax rates are cut to stabilize inflation. In contrast, under the institutional design of policy with an independent central bank that follows an active Taylor rule, the Ramsey policy actually cuts taxes in the face of the same government spending shock, reducing inflation and offsetting the increase in debt service costs that active monetary policy induces. Despite this anti-inflationary policy on the part of the fiscal policymaker, the equilibrium rate of inflation when the central bank was independent is an order of magnitude higher than when monetary and fiscal policy were jointly optimal. Evidently, the nature of the policy interactions in theory is complex and state contingent, as it appears to be in the empirical regime-switching literature.

Empirical evidence and optimal policy argue that regime M is not the only relevant monetary–fiscal policy mix. Interactions between monetary and fiscal policy are both pervasive and changeable. Understanding the nature of the policy dynamics—both the interactions between monetary and fiscal authorities and the political conflict that drives fiscal policy choices—is likely to be critical to identifying and understanding the evolution of observed policy regimes.

6.5 Common Misperceptions

Economists generally agree that historical episodes of high and volatile inflation rates inevitably have fiscal roots. Building on Sargent and Wallace's (1981) unpleasant monetarist arithmetic logic, Sargent (1986) makes a forceful historical case for hyperinflation's fiscal roots. The association between fiscal dominance—exogenous primary surpluses in Sargent and Wallace—and rampant inflation outcomes is so ingrained that many macroeconomists also believe that regime F fiscal behavior—a weak response of surpluses to debt—necessarily produces bad economic performance.[az]

That belief is unfounded. Bad economic policies can produce bad economic outcomes in any policy regime. And regime F is no more susceptible to undesirable

[az] Cochrane (2005) and Leeper and Walker (2013) give detailed descriptions of how the fiscal theory differs from unpleasant monetarist arithmetic.

equilibria than any other monetary–fiscal mix. Both the theoretical and the empirical results we have reviewed underscore this point.

Fiscal dominance can produce explosive inflation, as Loyo (1999) argues happened in Brazil. But explosiveness is the outgrowth of monetary behavior that is incompatible with fiscal dominance. When fiscal policy is active, ever-increasing inflation arises when the central bank aggressively raises the policy interest rate in a misguided effort to combat inflation. The active fiscal behavior transforms higher interest rates into more rapid growth in nominal government debt, higher aggregate demand, and higher inflation.

Perhaps ironically, Cochrane (2011a), Sims (2013), and Del Negro and Sims (2015) argue that many of the monetary anomalies in the theoretical literature arise primarily because money-only analyses trivialize the role that fiscal policy can play in delivering stable price-level behavior. Those anomalies include Obstfeld and Rogoff's (1983) speculative hyperinflations and Benhabib et al.'s (2002) deflationary traps. Fiscal policy can rule out both cases by adopting behavior that deviates in some fashion from typical regime M fiscal behavior. To eliminate hyperinflations, surpluses need to rise proportionately to excess inflation outside inflation's target range.[ba] To ensure that the economy will not get mired in a deflationary trap, fiscal policy must commit to running deficits or shrinking primary surpluses until inflation reaches its target. Both of these policy functions make fiscal choices explicitly contingent on inflation outcomes.

Monetary policy alone is powerless to eliminate these undesirable equilibria. Ruling out those equilibria requires fiscal policy to deviate from purely passive behavior that centers entirely on debt stabilization.

Skeptics who question whether the economic mechanisms in regime F have ever been observed point to instances in which government debt has grown rapidly, while inflation has been low and steady as *prima facie* evidence that inflation is solely a monetary phenomenon. But this criticism is akin to treating the income velocity of money as constant and finding cases where monetary expansions were not followed by higher nominal spending.

Consider the U.S. experience in the aftermath of the financial crisis. Nominal government debt grew from $4.4 trillion to $10.6 trillion from December 2007 and December 2014, a growth rate of 240% that raised the debt–GDP ratio from 30.5% to 61.0%.[bb] Despite this massive growth in debt, U.S. consumer price inflation averaged 1.9% between 2008 and 2014. With the Federal Reserve pegging the federal funds rate near zero from December 2008 onward, monetary policy behavior appears to have been

[ba] Cochrane (2011a) points out that hyperinflations do not violate any equilibrium conditions, so they are perfectly reasonable equilibria. They are also likely to be welfare reducing and undesirable.

[bb] These numbers come from the Federal Reserve Bank of Dallas's privately held gross federal debt and the U.S. Department of Commerce's annual nominal GDP data. Congressional Budget Office (2015) reports that federal debt held by the public rose from 35% to 74% over the same period.

passive, as in regime F. But the theory in this chapter predicts that if the debt expansion is not associated with higher taxes, private-sector wealth increases, raising aggregate demand and inflation. Where is the inflation that the fiscal theory predicts?

Like constant velocity, simple expositions of the fiscal theory serve pedagogical purposes, but severely constrain the theory's empirical predictions. Missing from the simple theory is that debt's value derives from the *present value* of expected surpluses and that the present value also depends on the expected path of real discount rates. Real interest rates have been decidedly negative in the United States. Kiley (2015) estimates that the real federal funds rate was negative from the onset of the recession through the middle of 2015. Even yields on 5-year Treasury inflation-indexed securities were negative or hovering around zero from September 2010 through 2015, reaching a nadir of −1.47% in October 2012. To the extent that these low rates flowed into real discount rates applied to government debt, the expected present value of surpluses was very high indeed over this period, even in the absence of any anticipated increases in primary surpluses. And along with the low real interest rates that the Federal Reserve sought to achieve, the crisis brought a flight to quality in which investors fled from nongovernment-insured asset classes to government securities, which drove down real treasury bond yields.

Any demand stimulus created by the nominal debt expansion would be offset, at least in part, by the increase in the value of debt that low real discount rates induce. It would take a careful quantitative analysis to make this case convincingly, but we see no a priori refutation of regime F from these observations.

If anything, the logic of the fiscal theory may help to explain the anomaly of why inflation did not fall *as much* as conventional money-only models predicted. The lack of persistent deflation during the recent recession caused some prominent economists to question the validity of conventional Phillips curve models where inflation is driven by measures of economic slack.[bc] Del Negro et al. (2015) argue that conventional models with a new Keynesian Phillips curve can account for the lack of deflation despite a large negative output gap provided prices are sufficiently sticky and inflation expectations remain anchored at positive levels. In their model, the anchoring comes from the anticipation that monetary policy will achieve future rates of inflation that are close to target. An alternative hypothesis is that expectations of future inflationary financing of the large increases in government debt are providing the necessary anchor.

A second canonical example thrown up by skeptics is Japan. Since 1993, Japanese government debt has risen from 75% to 230% of GDP, while inflation has averaged a mere 0.21%. For 20 years beginning in 1995, the Bank of Japan's overnight call rate has been below 0.5% and at 0.1% or lower for more than 12 of those years. Evidently, Japanese monetary policy has been passive. Once again, where is the inflation that the fiscal theory predicts?

[bc] For example, Hall (2011) and Ball and Mazumder (2011).

Japan is a complicated case. Real interest rates have been low, just as in the United States recently, but there is more to the story.[bd] Japan is the poster child for inconsistency in macroeconomic policies, as Krugman (1998), Ito (2006), Ito and Mishkin (2006), and Hausman and Wieland (2014) document. Fiscal policies have see-sawed between stimulus and austerity. Even as Prime Minister Abe appeared to announce an end to the inconsistency and Japanese economic activity and inflation were showing signs of life, Japan raised the consumption tax rate from 5% to 8% in April 2014. Consumer price inflation fell from 2.7% in 2014 to below 1% in 2015 (Leeper, 2016).

Japan has been mired in the trade-off between fiscal sustainability and economic reflation. To a fiscal theorist, Japan's obsession with government debt reduction is puzzling. Central to a regime F equilibrium is that agents' expectations are anchored on fiscal policies that do not raise surpluses when debt expands. Unsettled fiscal policies like those in Japan are unlikely to have so anchored expectations, so it is not clear that Japan resides in regime F; there may be no contradiction of the fiscal theory to explain.

7. PRACTICAL IMPLICATIONS

Viewing practical issues through the joint lenses of monetary and fiscal policies sheds fresh light on policy problems. That new light can also lead to sharply different perspectives on these problems.

7.1 Inflation Targeting

Nearly 30 countries with independent central banks have embraced numerical inflation targeting as the operating principle for monetary policy. Very few of these countries sought simultaneously to adopt fiscal policies that are compatible with the chosen inflation targets. This discussion of the policy interactions that are prerequisites for successful inflation targeting does not depend on the prevailing monetary–fiscal regime, so it applies whether policies reside in regime M or regime F.

The derivations rely on a few generic first-order conditions, a government budget identity, and the condition that optimizing households will not want to over- or under-accumulate assets. For this reason, the results have broad implications that extend well beyond the details of particular models. Consider an economy with a geometrically decaying maturity structure of zero-coupon nominal government bonds. The government's budget identity is

[bd] Imakubo et al. (2015) calculate that real yields on zero-coupon bonds at 1-, 2-, and 3-year maturities fluctuated between 0.5% and −0.5% from the middle of 1995 until 2012, when they fell to almost −2.0% in 2014.

$$\frac{P_t^m B_t^m}{P_t} = \frac{(1+\rho P_t^m) B_{t-1}^m}{P_t} - s_t$$

Letting $Q_{t,t+k} \equiv \beta^k \frac{u'(c_{t+k})}{u'(c_t)} \frac{P_t}{P_{t+k}}$, asset-pricing conditions yield

$$\frac{1}{R_t} = E_t Q_{t,t+1}$$
$$P_t^m = E_t Q_{t,t+1}(1+\rho P_{t+1}^m)$$

and the term structure relationship is

$$P_t^m = E_t \sum_{k=0}^{\infty} \rho^k \left(\prod_{j=0}^{k} \frac{1}{R_{t+j}} \right)$$

These conditions deliver the usual bond valuation equation

$$\frac{(1+\rho P_t^m) B_{t-1}^m}{P_t} = E_t \sum_{i=0}^{\infty} \beta^i \frac{u'(c_{t+i})}{u'(c_t)} s_{t+i}$$

Rewrite the valuation equation by replacing $(1+\rho P_t^m)$ using

$$1+\rho P_t^m = 1 + E_t \sum_{k=1}^{\infty} (\beta\rho)^k \frac{u'(c_{t+k})}{u'(c_t)} \frac{P_t}{P_{t+k}}$$

and, for simplicity, assume a constant-endowment economy, so $\frac{u'(c_{t+i})}{u'(c_t)} = 1$, to generate

$$\left[\sum_{k=0}^{\infty} (\beta\rho)^k \left(\prod_{j=1}^{k} \frac{1}{\pi_{t+j}} \right) \right] \frac{B_{t-1}^m}{P_t} = E_t \sum_{k=0}^{\infty} \beta^k s_{t+k} \tag{44}$$

Imagine an economy that takes as given variables dated $t-1$ and earlier, but commits to hitting an inflation target in all subsequent dates, so $\pi_{t+k} \equiv \pi^*$ for $k \geq 0$. Valuation equation (44) becomes

$$\frac{B_{t-1}^m / P_{t-1}}{EPV_t(s)} = \pi^* - \beta\rho \tag{45}$$

where $EPV_t(s) \equiv E_t \sum_{k=0}^{\infty} \beta^k s_{t+k}$.

This expression imposes stringent conditions on the expected present value of primary surpluses, though not on the surplus path, if the inflation target is to be achieved. For given initial real debt, if the economy adopts a policy of "too high" surpluses, then the inflation target that is achievable is lower than the desired target, π^*. Another way of seeing the tension between monetary and fiscal policy in this equation is to note that the condition requires the fiscal policymaker to adopt a debt target, which it passively adjusts surpluses to achieve. This means that any period of austerity that raises surpluses must induce a subsequent relaxation of policy to bring $EPV_t(s)$ in line with the outstanding debt stock and the inflation target. An austerity program that never took its foot off the gas would undermine the inflation target just as surely as would a myopic fiscal policymaker prone to runaway deficits. Are current fiscal frameworks consistent with such targets?

Both before and since the recent crisis, policymakers have been adopting fiscal rules designed to reverse increases in government debt. For example, following its banking crisis of 1992 Sweden adopted two fiscal rules: a net lending target of 1% of GDP over the economic cycle and a nominal expenditure ceiling 3 years ahead. This ceiling is consistent with ensuring that government expenditure falls as a share of GDP. Similarly, the "debt brake" in Switzerland requires that central government expenditure cannot grow faster than average revenue growth, while the German debt brake introduced in 2011 imposes a limit on federal net lending of 0.35% of GDP. In the United Kingdom, the 2015 Charter for Budget Responsibility requires the government to run a primary surplus in "normal" times. All these measures aim not only to stabilize the debt-to-GDP ratio but to ensure that it is falling over time. And to the extent that the rules are maintained, the pace of debt reduction should increase over time as less of any surplus is devoted to servicing the existing stock of debt. Because these rules fail to include provisions to target a long-run debt-to-GDP ratio, which would relax austerity measures as that target was approached, the rules run the risk of chronically undershooting the inflation target.

From a theoretical perspective, the rules do not make surpluses contingent on debt or the price level. This makes fiscal behavior active, placing it in regime F. When the fiscal policymaker adopts an active rule, as Section 2.3 shows, the monetary authority's ability to control inflation depends crucially on the maturity structure of the outstanding debt and on the nature of its policy response. With a pegged nominal interest rate, inflationary expectations remain consistent with the inflation target and surprise deviations from that target provide the revaluation effects needed to stabilize debt. But if the central bank attempts to come as close to active as possible by setting $\alpha_\pi = \beta$, the rate of inflation follows a random walk, permanently deviating from the inflation target in the face of fiscal shocks. If the policy objective is to smooth the inflationary costs of revaluation effects, then the optimal policy exercises suggest that a persistent deviation from the inflation target is desirable, so long as the persistence matches the maturity structure of the government's debt portfolio. With only single-period debt, there is no advantage in having a prolonged increase or decrease in inflation following a fiscal shock because only the initial period's inflation helps to reduce the real value of government liabilities. But when debt is of longer maturity, allowing inflation to rise and then gradually decline as the predetermined debt stock matures reduces the discounted value of inflationary costs associated with the required revaluation effects.

Successful inflation targeting requires more than a resolute central bank that follows "best practice" monetary policy behavior that includes clear objectives, transparency that leads to effective communications, and accountability. Even with all these elements in place, expression (45) implies that the central bank can achieve π^* only if fiscal policy is compatible with that target. If fiscal behavior requires a long-run inflation rate that differs from π^*, even best practice monetary policy cannot succeed in anchoring long-run inflation expectations or inflation outturns on target.

7.2 Returning to "Normal" Monetary Policy

The financial crisis has seen a substantial increase in debt-to-GDP ratios in many advanced economies, although the immediate need for fiscal adjustment may have been muted due to the reduced debt service costs as real interest rates have fallen since the financial crisis. To see this consider a small change to our policy problem in the endowment economy, in Section 4.2, where we allow the households' discount factor, $\tilde{\beta}_t$, to rise temporarily to $\tilde{\beta} > \beta$, capturing the flight to quality observed in the financial crisis. If we assume government spending is held constant, the policy problem becomes

$$
\begin{aligned}
L_t = E_0 \frac{1}{2} \sum_{t=0}^{\infty} \beta^t [& -\frac{1}{2}(\tau_t^2 + \theta(\nu_t - 1)^2) \\
& + \mu_t(\tilde{\beta}_t E_t \frac{(1+\rho P_{t+1}^m)}{P_t^m} \nu_{t+1} - 1) \\
& + \lambda_t(b_t P_t^m - (1+\rho P_t^m) b_{t-1} \nu_t - g_t - z_t + \tau_t)
\end{aligned}
$$

which yields the first-order conditions

$$
\begin{aligned}
&\tau_t : -\tau_t + \lambda_t = 0 \\
&\nu_t : -\theta(\nu_t - 1) + \mu_{t-1} \frac{(1+\rho P_t^m)}{P_{t-1}^m} \beta^{-1} \tilde{\beta}_{t-1} - (1+\rho P_t^m) \lambda_t b_{t-1} = 0 \\
&P_t^m : -\frac{\mu_t}{P_t^m} + \mu_{t-1} \rho \frac{\nu_t}{P_{t-1}^m} \beta^{-1} \tilde{\beta}_{t-1} + \lambda_t (b_t - \rho \nu_t b_{t-1}) = 0 \\
&b_t : \lambda_t P_t^m - \beta E_t (1+\rho P_{t+1}^m) \nu_{t+1} \lambda_{t+1} = 0
\end{aligned}
$$

Under a perfect foresight equilibrium this implies the tax-smoothing result is recast as

$$
\tau_t = \beta \tilde{\beta}_t^{-1} \tau_{t+1}
$$

which means that the tax rate will be rising during the period in which households have an increased preference for holding government bonds over consumption. Intuitively, the original tax-smoothing result balances the short-run costs of raising taxes to reduce debt against the long-run benefit of lower debt. These costs and benefits are finely balanced with the interest rate on the debt being exactly offset by the policymaker's rate of time preference so that steady-state debt follows a random walk in the face of shocks. When the interest on debt is less than the policymaker's rate of time preference, the policymaker prefers to delay the fiscal adjustment and will allow debt to accumulate, stabilizing debt only after the period of increased household preference for debt holdings has passed.

To the extent that a return to "normal" monetary policy is associated with a rise in debt service costs, optimal policy suggests that efforts to stabilize debt are enhanced at this point. But under the Ramsey policy, inflation surprises to revalue debt are effective only if carried out before the predetermined debt stock matures. Therefore the delay in debt stabilization also reduces the efficacy of promising to raise prices in the future placing more of the burden of adjustment on taxation. At the same time, the higher debt stock that emerges at the point of normalization raises the potential time-inconsistency problems inherent in the Ramsey policy; at this point we may start to see increased pressure to inflate away the debt.

More generally, higher central bank interest rates have powerful fiscal consequences when government debt levels are elevated. In the United States, the Congressional Budget Office (2014) estimates that net interest costs will quadruple between 2014 and 2024 to reach 3.3% of GDP.[be] Those interest costs must be financed somehow—by higher taxes and lower spending now or by faster growth in debt and other adjustments in the future. In light of the political dynamics today in the United States, it is not obvious how those costs will be financed.

Central bankers are well aware of the fiscal consequences of their actions. King (1995) refers to "unpleasant fiscal arithmetic"—a process of monetary disinflation raises real interest rates and destabilizes government debt until the credibility of the disinflation is established. But, he argues, the higher debt may actually undermine that credibility and unpleasant monetarist arithmetic may re-emerge. One interpretation is that King worries about the danger that the fiscal consequences of disinflation may force the central bank to reverse a return to "normal" interest rates.

7.3 Why Central Banks Need to Know the Prevailing Regime

Davig and Leeper (2006), Bianchi (2012), Bianchi and Ilut (2014), and Chen et al. (2015) suggest that there have been switches in the conduct of fiscal policy between passive and active rules. And fiscal switches are not always associated with compensating switches in monetary policy that place the economy in either regime M or regime F. If these policy permutations were permanent, they would either result in indeterminacy (passive

[be] The CBO expects a relatively modest interest in treasury interest rates over that period, with the 10-year rate rising from 2.8 to 4.7 percentage points and the average rate on debt held by the public rising from 1.8 to 3.9 percentage points. Cochrane (2014) considers a scenario in which the Fed raises interest rates to 5% and with them, real interest rates. At a 100% debt–GDP ratio, the increased interest costs amount to $900 billion.

monetary and fiscal policy) or nonexistence of equilibrium (active monetary and fiscal policy). But if policy is expected to return to either the M or F regime sufficiently often, then these policy combinations can still deliver determinate equilibria. So there are four possible permutations of monetary and fiscal policy that may coexist, but only two, if permanent, deliver unique bounded equilibria. The prevailing policy configuration can have profound implications for the conduct of monetary policy, as we illustrate in the endowment economy with Section 2's policy rules.[bf]

Regardless of regime, inflationary dynamics are

$$E_t(\nu_{t+1}-\nu^*)=\frac{\alpha_\pi}{\beta}(\nu_t-\nu^*) \tag{46}$$

Under regime M with an active monetary policy ($\alpha_\pi > \beta$), monetary policy can target inflation in each period, $\nu_t = \nu^*$, while the passive fiscal policy stabilizes debt

$$E_t\left(\frac{b_{t+1}}{R_{t+1}}-\frac{b^*}{R^*}\right)=(\beta^{-1}-\gamma)\left(\frac{b_t}{R_t}-\frac{b^*}{R^*}\right)-E_t\varepsilon^F_{t+1}$$

provided $\gamma > \beta^{-1} - 1$.

Suppose we know the economy will enter this regime in period T, at which point inflation will be at its target $\nu_T = \nu^*$ and the fiscal rule will stabilize whatever debt is inherited at time T. In this case, it does not matter whether or not the monetary policy rule is active or passive prior to period T, since T-step-ahead expected inflation is

$$E_t\nu_{t+T}-\nu^*=\left(\frac{\alpha_\pi}{\beta}\right)^{T-t}(\nu_t-\nu^*)$$

which implies that inflation will be on target between today and period T. If fiscal policy is active, debt will be moving off target between today and period T, but the passive fiscal rule will, from that point on, stabilize debt. If fiscal policy is passive before period T, this would facilitate the debt stabilization prior to T and the targeting of inflation would be uninterrupted by any change of regime at time T.

We now assume that at time T agents anticipate the economy will enter regime F where monetary policy is passive ($\alpha_\pi < \beta$), and fiscal policy does not respond to debt ($\gamma = 0$). Now the period T price level needs to adjust to satisfy the bond valuation equation at time T given the level of inherited nominal debt B_{T-1}. When $\gamma = 0$, the fiscal rule is $s_t = s^* + \varepsilon^F_t$ and the solution for real debt is

$$E_t\frac{B_{T-1}}{R_{T-1}P_{T-1}}=\frac{b^*}{R^*}+\sum_{j=1}^{\infty}\beta^j E_t\varepsilon^F_{T-1+j}$$

[bf] See Davig et al. (2010) and Leeper (2011) for related analyses.

The price level does not jump in period T, but it does adjust in period t when the switch to regime F in period T is first anticipated. The implications for inflation beyond period T depend on how passive the monetary policy rule is. With an interest rate peg, $\alpha = 0$, inflationary expectations remain on target, $E_t\nu_{t+1} = \nu^*$, but there will be innovations to inflation to ensure the bond valuation equation holds in the face of additional fiscal shocks occurring from period T onwards. With some monetary policy response to inflation, $0 < \alpha_\pi < \beta$, the initial jump in the price level will result in a temporary, but sustained rise in inflation whose evolution obeys equation (46). As Section 4 shows, sustaining the rise in inflation enhances the revaluation effect, but the longer is debt maturity, the greater is the reduction in distortions caused by higher inflation.

How does anticipating the F regime in period T affect the conduct of policy prior to period T? With fiscal policy following a rule that may or may not be passive, the expected evolution of government debt follows

$$E_t\left(\frac{B_{t+1}}{R_{t+1}P_{t+1}} - \frac{b^*}{R^*}\right) = (\beta^{-1} - \gamma)\left(\frac{B_t}{R_tP_t} - \frac{b^*}{R^*}\right) - E_t\varepsilon^F_{t+1}$$

We can iterate this forward until period T as

$$E_t\left(\frac{B_{T-1}}{R_{T-1}P_{T-1}} - \frac{b^*}{R^*}\right) = (\beta^{-1} - \gamma)^{T-1-t}\left(\frac{B_t}{R_tP_t} - \frac{b^*}{R^*}\right) + \sum_{j=0}^{T-1-t}(\beta^{-1} - \gamma)^j E_t\varepsilon^F_{t+1+j}$$

which defines the initial debt level $\dfrac{B_t}{R_tP_t}$ required to ensure the economy enters regime F in period T with the appropriate level of debt $\dfrac{B_{T-1}}{R_{T-1}P_{T-1}}$ without any discrete jumps in the price level at that time. This depends upon the extent to which fiscal policy prior to period T acts to stabilize debt as determined by the fiscal feedback parameter, γ, and the expected value of fiscal shocks over that period. If the move to the F regime is sufficiently long in the future and fiscal policy is sufficiently aggressive in stabilizing debt, then there will be little need for surprise inflation in the initial period to ensure the appropriate debt level is bequeathed to the future. But if the switch is more imminent or the fiscal stabilization prior to period T is muted, then an initial jump in prices will be required to ensure the bond valuation equation holds. The inflationary implications of this prior to period T depend on the conduct of monetary policy. If monetary policy is active prior to period T, any initial jump in prices will be explosive until the F regime is established in period T. This happens because the period t price-level jump ensures the bond valuation equation holds, while inflation dynamics are determined by equation (46), which is explosive under an active monetary policy. This is a bounded equilibrium because the process for inflation stabilizes when the policy regime changes in period T. But before period T, the active monetary policy actually destabilizes prices. Postponing the switch to the F regime means that the period of explosive inflation dynamics remains in place for longer.

This analysis has the flavor of a game of chicken between the monetary and fiscal policymakers. The monetary authority can stick to an active monetary policy rule and achieve its inflation target, provided everyone is sure that policy will eventually be supported by a passive fiscal policy which stabilizes debt. Debt dynamics will be unstable in such a scenario until the fiscal authorities relent and adopt a passive fiscal policy. But when there is the suspicion that monetary policy will eventually turn passive to support a fiscal policy that does not stabilize debt, then conventional anti-inflation policies today may actually worsen inflation outcomes.

8. CRITICAL ASSESSMENT AND OUTLOOK

We conclude by examining the areas where further theoretical and empirical work is needed.

8.1 Further Theoretical Developments

This section highlights areas in which additional theoretical work on monetary–fiscal interactions would be fruitful.

8.1.1 Default and the Open Economy

This chapter has focused on closed-economy models, abstracting from issues of sovereign default and open-economy dimensions that have come together in the recent sovereign debt crisis in the Euro Area. In the early applications of the fiscal theory to the open economy, a key issue was whether or not individual country government budget identities were consolidated into a single global bond valuation equation.[bg] If so, with multiple passive monetary policies, each country's price level and exchange rate are indeterminate. In this equilibrium, one country accumulates the debt of another, an outcome whose political equilibrium Sims (1997) argues is unstable. If such equilibria are ruled out, then we return to having a bond valuation equation for each country and fiscal policies in one economy carry implications for outcomes in the second economy. For example, a determinate active/passive policy pair can be achieved across countries rather than within countries (Leith and Wren-Lewis, 2008).

Similar issues arise in a monetary union. With a single passive monetary policy, it is possible to ensure determinacy with only one active fiscal policy (Leith and Wren-Lewis, 2006). These analyses have the troubling feature that the tail seems to wag the dog—a small monetary union member that fails to pursue passive fiscal policy can determine the price level for the entire union. This raises questions about whether these early applications of the fiscal theory to the open economy have appropriately captured

[bg] See Sims (1997), Loyo (1997), Woodford (1998b), Dupor (2000), Canzoneri et al. (2001a), and Daniel (2001).

cross-country heterogeneity—including different price-level processes across member states—and the cross-country implications of the interactions between monetary and fiscal policy. More recent work seeks to model the gross asset/liability positions of countries to capture the kinds of revaluation effects generated by price level and exchange rate movements.[bh] That work finds that the gross asset/liability positions can be several multiples of GDP even when net positions are not, implying that the revaluation effects stressed in this chapter are likely to be both quantitatively important and more complex in open-economy settings.

Recent events highlight the need to bring sovereign default into the analysis. In a model similar to our endowment economy, but augmented with an exogenous default risk, Uribe (2006) demonstrates that default can give rise to fiscal theory-type effects, with anticipated, but delayed defaults potentially destabilizing an active inflation targeting policy in much the same way that anticipating a move to regime F can do.

While many analyses of strategic default focus on real economies—for example, D'Erasmo et al. (2016)—when default through inflation is available as an alternative financing option, it is either assumed to be equivalent to outright default, or possibly less costly if it is less damaging to the balance sheets of a country's banking sector than an outright default (Gros, 2011). Given that inflation is costly, it is not obvious that this will always be the case. A useful line of work would consider the nature of the strategic default decision in environments in which debt revaluations through surprise current inflation and bond prices are possible. Kriwoluzky et al. (2014) is an interesting paper that contrasts outright default for a country engaged in a monetary union with the redenomination of debt following exit from the union. They find that the possibility of exit significantly worsens the preexit/default debt dynamics. Similarly, Burnside et al. (2001) argue that the speculative attacks on fixed-currency regimes in the Asian crisis of 1997 sprung from expectations that large revaluations of debt were required to finance the projected deficits that ongoing bank bailouts were expected to engender. In richer models where default is state dependent and the economic costs of default arise through the impact of default on domestic banks' balance sheets the set of monetary and fiscal interactions is widened further (Bi et al., 2015; Bocola, 2016). There is plenty of scope to deepen our understanding of default vs inflation financing in a sovereign debt crisis.

8.1.2 Better Rules

Analyses of optimal monetary and fiscal policy rules in approximated economies is quite clear about the kinds of simple rules that can mimic the Ramsey policy. Fairly aggressive inflation targeting using an inertial Taylor rule, coupled with a passive fiscal policy that

[bh] See Lane and Milesi-Ferretti (2001) for the first issue of a dataset of external portfolios and Devereux and Sutherland (2011) for a numerical method to endogenously embed such positions in open-economy macro models.

very gradually stabilizes debt, comes close to achieving the welfare levels that the Ramsey policy acquires (Schmitt-Grohé and Uribe, 2007; Kirsanova and Wren-Lewis, 2012). The nonlinear solutions to the optimal policy problem that this chapter described reveal that the policy mix depends crucially on both the level of debt and its maturity. With high levels of short-maturity debt, it is optimal to use monetary policy to stabilize debt and adjust distortionary taxation to mitigate the inflationary consequences of such a policy. This suggests that there may be a family of simple implementable rules which could improve welfare by introducing a degree of state-dependence to the policy mix.

Similarly, studies often seek to assess the importance of automatic stabilizers by adding output to the fiscal rules. Kliem and Kriwoluzky (2014) argue, though, that this is not the most data-coherent specification of policy behavior and that rules conditioned on other macroeconomic variables better capture the cyclical properties of fiscal instruments. Those proposed rules also improve welfare in DSGE models. Taken together, this suggests that there is scope for extending the range of simple rules considered in the literature to find alternatives that are both empirically and normatively more appealing.

8.1.3 Strategic Interactions

Estimates of regime-switching policies find that the policy mix is not always aligned with either regime M or regime F. There are also periods in which policies are in conflict—either doubly active or doubly passive. Introducing strategic interactions between policy authorities into optimal policy analysis may help to put theory in better line with data. Literature that looks at such interactions often relies on linear-quadratic approximation or simplifying assumptions to obtain tractable results.[bi] Blake and Kirsanova (2011) consider the desirability of central bank conservatism in a standard new Keynesian economy augmented with fiscal policy and an associated independent fiscal policymaker. They consider three forms of strategic interaction: either monetary or fiscal leadership, where the leader anticipates the response of the follower, or a Nash equilibrium between the two policymakers. The striking result, which echoes Section 5.4 in which the monetary authority followed a Taylor rule while the fiscal authority optimized, is that central bank conservatism always reduces welfare. Blake and Kirsanova also find that the quantitative results depend on the level of debt around which the economy is linearized. This argues that such analyses could usefully be extended to a nonlinear framework to explore the state dependencies in the strategic monetary and fiscal policy interactions. How robust is the institutional policy design to the strategic interactions implied by independent fiscal and monetary policymakers? To what extent can such interactions explain the observed policy switches in empirical analyses based on simple ad hoc rules?

[bi] Adam and Billi (2008) and Dixit and Lambertini (2003) consider the strategic interactions between monetary and fiscal policymakers, although in abstracting from the existence of government debt they rule out the mechanisms that have been the focus of this chapter.

8.1.4 Political Economy

Theoretical work on optimal policy, particularly fiscal policy, often implies policy behavior that bears little resemblance to observed policy. Benigno and Woodford's (2004) and Schmitt-Grohé and Uribe's (2004) analyses of jointly optimal monetary and fiscal policies suggest that when the policymaker can make credible promises about future actions, the steady-state level of debt should follow a random walk—in response to shocks, debt will be allowed to rise permanently because the short-run costs of reducing debt exactly balance the long-run benefits. This policy prescription is clearly at odds with the mounting concerns over rising debt levels in several advanced economies, which have led the IMF to predict that most governments will be involved with consolidation efforts for several years. The expected pace of consolidation is particularly rapid in the economies that are subject to pressures in the financial markets from worries over fiscal sustainability (International Monetary Fund, 2011).

If instead we assume that policymakers cannot make credible promises about how they behave in the future—policy is constrained to be time-consistent—then the implied policy outcomes can be equally unconvincing: instead of implying that debt should permanently rise following negative fiscal shocks, the theory tends to imply that the policymaker will be tempted to aggressively reduce the debt stock, often at rates that far exceed those observed in practice (Leith and Wren-Lewis, 2013). In standard new Keynesian models, time-consistent policy will not only call for a rapid debt correction, but it will make the long-run equilibrium value of debt negative, as the fiscal authority seeks to accumulate a stock of assets to help offset other frictions in the economy. The analysis in this chapter and in Leeper et al. (2015a), by allowing for a realistically calibrated debt maturity structure, can plausibly slow the pace of fiscal adjustments to levels which are not obviously inconsistent with those observed. And by assuming that the fiscal policymaker discounts the future more highly than households, as a crude means of capturing the short-termism that political frictions can engender, Leeper et al. (2015a) find that the time-consistent policy can support reversion to plausible debt–GDP ratios.

Although an inability to commit can go some way toward explaining this discrepancy between actual policy and the normative prescriptions of the theoretical literature, it seems likely that the political dimensions of policymaking are also important. Political economy aspects of actual fiscal policy have recently been laid bare in the abandoning of fiscal rules in Europe during the financial crisis, the brinkmanship over the raising of the debt ceiling in the United States, and the withholding or awarding of bail-out funds to Greece and other Eurozone economies from the Troika composed of the European Commission, the ECB, and the IMF. In this vein the New Political Economy literature seeks to identify mechanisms that can explain the trends in debt–GDP levels in many developed economies in recent decades.

Alesina and Passalacqua (2016) identify several reasons why governments may pursue policies that raise government debt to suboptimally high levels: (1) fiscal illusion—voters misunderstand the budget identity and are enticed to vote for a party that supports unsustainable tax cuts or spending increases; (2) political business cycles—voters are unsure of the competence of potential governments, so fiscal policy can be used by incumbents to signal competence; (3) delayed stabilization—political factions squabble over who bears the costs of fiscal consolidations, thereby delaying debt stabilization; (4) debt as a strategic variable—political parties use debt to tie the hands of their political opponents when they are out of office; (5) bargaining over policy in heterogeneous legislatures; (6) rent seeking by politicians; and (7) intergenerational redistributions. Some of these mechanisms are more naturally located in majoritarian systems—for example, political business cycles and strategic use of debt—while others are more likely to be associated with continuous strategic interactions between political actors outside of election periods—for example, delayed stabilizations and bargaining within legislatures—which are a feature of proportional/multiparty systems or heterogeneity within parties under a two-party system.

This New Political Economy literature typically does not consider monetary and fiscal policy interactions of the type considered in this chapter, so there is a need to integrate the two literatures. Political conflict inherent in the conduct of fiscal policy may explain why it is possible to obtain a data-coherent optimal policy description of monetary policy—albeit with fluctuations in the degree of monetary policy conservatism—while a similar description for fiscal policy is less easily achieved with policy switching between active and passive rules, with only short-lived periods in which policy is optimal (Chen et al., 2015).

Despite the difficulty of allowing for strategic interactions between the monetary and fiscal policymakers, this may not be going far enough if we are to understand the evolution of the monetary–fiscal policy mix. While treating an independent central bank as a single policymaker may be an acceptable approximation, it is less obvious that fiscal policy is best described by the actions of a single benevolent policymaker. A longer term research goal is to tractably integrate the New Political Economy literature into the analysis of monetary and fiscal policy interactions. Can we explain the changing nature of those interactions?

Political frictions vary substantially across countries. For example, in the United States and the United Kingdom debt levels fell fairly consistently following World War II until the early 1980s, before expanding consistently under Republican administrations in the United States, while not having such a clear partisan pattern in the United Kingdom. The current Conservative government in the United Kingdom is promising an aggressive austerity policy which seeks to run a permanent surplus from 2017. Any use of political frictions to explain the dynamics of debt and other macro variables must also explain such cross-country differences, particularly since it is not obvious that U.S. Republicans and U.K. Conservatives have fundamentally different views on the optimal size of the state.

8.1.5 Money

By focusing on cashless economies we have side-stepped the literature that considers the role of inflation as a tool of public finance vs its impact on money as a medium of exchange (Phelps, 1973). More recent research finds that the nature of the time-consistency problem facing a policymaker who issues nominal debt can depend crucially on the effects of inflation on the transactions technology (Martin, 2009, 2011; Niemann et al., 2013). We have also ignored the central bank's balance sheet, which precludes an analysis of fiscal aspects of unconventional monetary policies which have been discussed in Sims (2013), Del Negro and Sims (2015), and Reis (2013, 2015). Analyzing such unconventional monetary policies or technological developments like virtual money within frameworks that allow for interactions between such developments and fiscal policy are obvious areas for further research.

8.2 Further Empirical Work

This section proposes several directions in which to take empirical work on monetary–fiscal interactions.

8.2.1 Data Needs

In the early days of real business cycle research, Prescott (1986) argued that "theory is ahead of measurement," and, in particular, that theory can guide the measurement of key economic time series. This rings especially true for research on how monetary and fiscal policies affect inflation. Empirical applications in which the debt valuation equation plays a central role require observations on objects that are not readily available: the market value of privately held government liabilities—explicit debt and other commitments—the maturity structure of that debt, actual and expected primary surpluses, and actual and expected real discount rates. Compiling such data across countries and across monetary–fiscal regimes is the first step in an empirical agenda on policy interactions.

8.2.2 Identifying Regime

Empirical work surveyed in Section 6 highlights the difficulties in distinguishing whether regime M, regime F, or some other regimes generated observed time series. It remains to thoroughly explore which features of private and policy behavior are critical for breaking the near observational equivalence of regimes. Surprisingly, little work experiments with alternative specifications of policy behavior, particularly in DSGE models. Instead, most researchers—including us—adopt the simple rules that have become "standard." There is ample room for such experimentation.

Closely related is Geweke's (2010) argument that models are inherently incomplete in the sense that they lack "some aspect of a joint distribution over all parameters, latent variables, and models under consideration [p. 3]." For example, central bank money-only models that follow Smets and Wouters (2007) impose a dogmatic prior that places zero probability mass on regime F parameters. This procedure rejects a priori regions of the parameter space that the work reviewed in Section 6.3 finds fit data equally well. As we have seen, monetary policy actions have very different impacts in regimes M and F, so it matters a great deal to a policymaker, who is using model output to reach decisions, whether regime F is even possible. It would be valuable to apply existing tools for confronting model uncertainty to issues of monetary–fiscal regime (Hansen and Sargent, 2007; Geweke, 2010).

A different angle on model fit pursues DeJong and Whiteman's (1991) idea to ask: what type of prior over policy parameters is needed to support the inference that regime M (or regime F) generated the data? This exercise elicits the strength of a researcher's beliefs about regime when the researcher chooses to focus solely on one possible monetary–fiscal mix.

8.2.3 Generalizing Regime Switching

Existing work that estimates DSGE models with recurring policy regime switching tends to make simplifying assumptions about the nature of both private behavior and the policy process. Those assumptions can be systematically relaxed to arrive at more general models usable for policy analysis. And the fit of the models needs to be scrutinized in the manner that, for example, Smets and Wouter's (2007) specification has been. Until the fit of switching models is carefully evaluated, fixed-regime DSGE models will continue to dominate in policy institutions.[bj]

Recent econometric innovations permit estimation of endogenous regime change (Chang et al., 2015a). That technique treats policy regime as a latent process akin to time-varying probabilities of regime change. Generalizations of those methods to multivariate settings with multiple regimes that switch nonsynchronously could be integrated with DSGE models in which agents learn about the prevailing regime. Setups like that could shed empirical light on endogenous interactions among monetary and fiscal regimes, such as those that arise from the strategic interactions and political economy dynamics that Sections 8.1.3 and 8.1.4 mention.[bk]

8.2.4 Historical Analyses

Friedman and Schwartz (1963a) set the standard for historical analyses of monetary policy. But fiscal policy plays almost no role in their narrative. Stein (1996) is an excellent account of the evolution of fiscal policy in the United States, but his goals are different,

[bj] Sims and Zha (2006) is an exception, though they consider only monetary switching.

[bk] Chang et al. (2015b) estimate single-equation models of U.S. monetary and fiscal behavior to infer how an endogenous switch in one policy's regime predicts and switch in the other policy's regime. Empirical work along these lines connects more clearly to theory than do estimates in which regimes change exogenously.

so he does not connect the fiscal actions on which he reports to macroeconomic activity. A thorough analysis of the monetary–fiscal history of a country that brings to bear modern macroeconomic theory is a bit ambitious, though sorely needed. Short of a "Monetary *and Fiscal* History" that parallels Friedman and Schwartz, there are a great many historical episodes that can be reinterpreted in light of monetary–fiscal interactions.

Across countries there have been many short- and long-lived periods in which central banks have pegged interest rates, yet inflation has remained stable, as Cochrane (2015) points out. This observation seems to contradict Friedman's (1968) warning that pegged rates produce ever-increasing inflation. Has fiscal behavior played a role in delivering stable prices during interest rate pegs?

It would be instructive to bring fiscal behavior explicitly into a reexamination of the gold standard. What are the fiscal requirements of maintaining a fixed parity under the classical gold standard? Or of resuming convertibility after a suspension? Bordo and Hautcoeur (2007) contrast the French and British experiences after they suspended during World War I. Bordo (2011) suggests that France adopted a passive monetary/active fiscal policy mix that lead to substantially larger price-level increases in France than in Britain, which pursued active monetary and passive fiscal policies.

What role has fiscal policy played in accommodating or ending deflationary episodes? These have been well documented—Temin and Wigmore (1990), Bernanke and James (1991), Bordo and Filardo (2005), and Velde (2009) for example—but in the absence of an analytical understanding of how fiscal policy behaves under a gold standard, discussions of policy interactions remain informal (Eggertsson, 2008; Jalil and Rua, 2015).

How have large runups of government debt been financed historically? Hall and Sargent (2011, 2014) have made substantial progress on this important question in recent years.[bl] Although historically most large debt expansions were associated with wars, advanced economies since the financial crisis—and quite possibly going forward—are experiencing nonwar-related debt growth. What does history teach about how policy can best respond to high levels of government debt?

8.3 A Final Word

Macroeconomists have an unfortunate history of arguing over whether monetary or fiscal policy in *the* primary force behind inflation.[bm] If a reader leaves this chapter with a single message, that message should be: the fiscal theory and the quantity theory—or its recent manifestation, the Wicksellian theory—are parts of a more general theory of price-level determination in which monetary and fiscal policies always interact with private-sector behavior to produce the equilibrium aggregate level of prices. Within a certain

[bl] But see also Bordo and White (1991) on the Napoleonic wars and Sargent and Velde (1995) on the French revolution.

[bm] See, for example, Andersen and Jordan (1968) or Friedman and Heller (1969).

parametric family of monetary and fiscal rules, the two seemingly distinct perspectives arise from different regions of the policy parameter space, but there is no sense in which one view is "right" and the other is "wrong." Ultimately, it is an empirical question whether we can discern whether and under what circumstances one view is the dominant factor in inflation dynamics.

We would also encourage macroeconomists to entertain the possibility that both views are "right" most of the time and that the process of price-level determination is more complex than benchmark theories have so far described.

ACKNOWLEDGMENTS

This chapter has benefited from collaborations and discussions with many coauthors and colleagues and we thank them. We also thank Jon Faust, Ding Liu, Jim Nason, Charles Nolan, Fei Tan, and Todd Walker for conversations and Bob Barsky, John Cochrane, John Taylor, and Harald Uhlig for comments.

Abstract

We provide explicit solutions for government spending multipliers during a liquidity trap and within a fixed exchange regime using standard closed and open-economy New Keynesian models. We confirm the potential for large multipliers during liquidity traps. For a currency union, we show that self-financed multipliers are small, always below unity, unless the accompanying tax adjustments involve substantial static redistribution from low to high marginal propensity to consume agents, or dynamic redistribution from future to present non-Ricardian agents. But outside-financed multipliers which require no domestic tax adjustment can be large, especially when the average marginal propensity to consume on domestic goods is high or when government spending shocks are very persistent. Our solutions are relevant for local and national multipliers, providing insight into the economic mechanisms at work as well as the testable implications of these models.

1. INTRODUCTION

Economists generally agree that macroeconomic stabilization should be handled first and foremost by monetary policy. Yet monetary policy can run into constraints that impair its effectiveness. For example, the economy may find itself in a liquidity trap, where interest rates hit zero, preventing further reductions in the interest rate. Similarly, countries that belong to currency unions, or states within a country, do not have the option of an independent monetary policy. Some economists advocate for fiscal policy to fill this void, increasing government spending to stimulate the economy. Others disagree, and the issue remains deeply controversial, as evidenced by vigorous debates on the magnitude of fiscal multipliers. No doubt, this situation stems partly from the lack of definitive empirical evidence, but, in our view, the absence of clear theoretical benchmarks also plays an important role. Although various recent contributions have substantially furthered our understanding, to date, the implications of standard macroeconomic models have not been fully worked out. This is the goal of this chapter. By clarifying the theoretical mechanisms in a unified way, we hope that it will help stimulate more research to validate or invalidate different aspects of the models.

We solve for the response of the economy to changes in the path for government spending during liquidity traps or within currency unions using standard New Keynesian closed and open-economy monetary models. A number of features distinguish our approach and contribution. First, our approach departs from the existing literature by focusing on *fiscal multipliers* that encapsulate the effects of spending for any path for government spending, instead of solving for a particular multiplier associated with the expansion of a single benchmark path for spending (eg, an autoregressive shock process to spending). Second, we obtain simple closed-form solutions for these multipliers. The more explicit and detailed expressions help us uncover the precise mechanisms underlying the effects of fiscal policy and allow us to deliver several new results.

Third, our analysis confirms that constraints on monetary policy are crucial, but also highlights that the nature of the constraint is also important. In particular, we draw a sharp contrast between a liquidity trap, with a binding zero-lower bound, and a currency union, with a fixed exchange rate.

Finally, in addition to nominal rigidities and constraints on monetary policy, we stress the importance of incorporating financial frictions for the analysis of fiscal policy. We do so by extending the benchmark models to include both incomplete markets and non-Ricardian borrowing constrained consumers, allowing for high and heterogeneous marginal propensities to consume out of current income. These financial market imperfections may be especially relevant in the aftermath of a financial crisis, situations where fiscal stimulus is often considered.

Our analysis has obvious implications for the interpretation of recent empirical studies on national and local multipliers. The empirical literature adopts different definitions of summary fiscal multipliers. For example, one popular notion used in many empirical studies consists in computing the ratio of some (discounted or not) average of the impulse responses of output and government spending in response to an innovation in government spending, up to some horizon (in practice 2 or 3 years). We show how our results can be used to compute such numbers analytically, and also discuss alternative definitions of summary fiscal multipliers.

Our results confirm that, in these standard models, fiscal policy can be especially potent during a liquidity trap. In the standard Ricardian model, the multiplier for output is always greater than one. We explicit the way in which the mechanism works through inflation. Higher government spending during a liquidity trap stimulates inflation. With fixed nominal interest rates, this reduces real interest rates which increases current private consumption. The increase in consumption in turn leads to more inflation, creating a feedback loop. The fiscal multiplier is increasing in the degree of price flexibility, which is intuitive given that the mechanism relies on the response of inflation. We show that in the model, backloading spending leads to larger effects; the rationale is that inflation then has more time to affect spending decisions.

For a country or region in a currency union, by contrast, government spending is less effective at increasing output. In particular, in the standard Ricardian model, we show that private consumption is crowded out by government spending, so that the multiplier is less than one. Moreover, price flexibility diminishes the effectiveness of spending, instead of increasing it. We explain this result using a simple argument that illustrates its robustness. Government spending leads to inflation in domestically produced goods and this loss in competitiveness depresses private spending.

It may seem surprising that fiscal multipliers are less than one when the exchange rate is fixed, contrasting with multipliers above one in liquidity traps. We show that even though in both cases the nominal interest rate is fixed, there is a crucial difference: a fixed exchange rate implies a fixed nominal interest rate, but the reverse is not true. Indeed, we prove that the liquidity trap analysis implicitly combines a shock to government spending with a one-off devaluation. The positive response of consumption relies entirely on this devaluation. A currency union rules out such a devaluation, explaining the difference in the response of consumption.

In the context of a country in a currency union, our results uncover the importance of transfers from outside—from other countries or regions. In the short run, when prices have not fully adjusted, positive transfers from outside increase the demand for home goods, stimulating output. We compute "transfer multipliers" that capture the response of the economy to such transfers. We show that these multipliers may be large when there is a high degree of home bias (ie, low degree of openness).

Note that the analysis of outside transfers requires some form of market incompleteness. Otherwise, with complete financial markets, any outside transfer would be completely undone by private insurance arrangements with outsiders. Such an extreme offset is unlikely to be realistic. Thus, we modify the standard open-economy model, which assumes complete markets, to consider the case with incomplete markets.

Understanding the effect of outside transfers is important because such transfers are often tied to government spending. This is relevant for the literature estimating local multipliers, which exploits cross-sectional variation, examining the effects of government spending across regions, states, or municipalities, within a country. In the US federal military spending allocated to a particular state is financed by the country as a whole. The same is true for exogenous differences, due to idiosyncratic provisions in the law, in the distribution of a federal stimulus package. Likewise, idiosyncratic portfolio returns accruing to a particular state's coffers represent a windfall for this state against the rest.

When changes in spending are financed by such outside transfers, the associated multipliers are a combination of self-financed multipliers and transfer multipliers. As a result, multipliers may be substantially larger than one even in a currency union. This difference is more significant when the degree of home bias is large, since this increases the marginal propensity to spend on home produced goods.

The degree of persistence in government spending is also important. Because agents seek to smooth consumption over time, the more temporary the government spending shock, the more the per-period transfer that accompanies the increase in spending is saved in anticipation of lower per-period transfers in the future. As a result, the difference in the effects on current output between outside-financed and self-financed government spending can be large for relatively persistent shocks, but may be small if shocks are relatively temporary. However, as we shall see, this distinction is blurred in the presence of liquidity constraints.

We explore non-Ricardian effects from fiscal policy by introducing hand-to-mouth consumers in addition to permanent income consumers. We think of this as a tractable way of modeling liquidity constraints. Both in a liquidity trap and in a currency union, government spending now has additional effects because of the differences in marginal propensities to consume of both groups of agents.

First, the incidence of taxes across these two groups matters, and redistribution from low marginal propensity to consume permanent-income agents to high marginal propensity to consume hand-to-mouth agents increases output. Second, since the model is non-Ricardian, the timing of taxes matters.

Both these effects can play a role independently of government spending. Indeed, one may consider tax changes without any change in government spending. However, changes in government spending must be accompanied by changes in taxes. As a result, whether government spending is, at the margin, debt-financed or tax-financed matters. Likewise, the distributional makeup of tax changes, across marginal propensities to consume, also matters. These effects can potentially substantially increase fiscal multipliers, both in liquidity traps and for countries or regions in a currency union. In particular, they may raise the multipliers above one for a region within a currency union.

Most importantly, liquidity constraints significantly magnify the difference between self-financed and outside-financed fiscal multipliers for temporary government spending shocks. Intuitively, a higher marginal propensity to consume implies that a greater part of the outside transfer is spent in the short run, contributing towards an increase in fiscal multipliers.

Overall, this discussion brings back the old Keynesian emphasis on the marginal propensity to consume. In particular, for temporary government spending shocks, the difference between self-financed and outside-financed fiscal multipliers is large when the average marginal propensity to consume on domestic goods is large—either due to a large number of liquidity constrained agents or due to a high degree of home bias in spending.

Finally, we show how to bridge our results for small open economies in a currency union and closed economies in a liquidity trap by simultaneously considering the effects government spending in all the countries within a currency union, depending on whether the currency union is in a liquidity trap or whether the central bank of the union can target inflation by adjusting interest rates.

Related Literature

Our chapter is related to several strands of theoretical and empirical literatures. We will discuss those that are most closely related.

We contribute to the literature that studies fiscal policy in the New Keynesian model in liquidity traps. Eggertsson (2011), Woodford (2011), and Christiano et al. (2011) show that fiscal multipliers can be large at the zero lower bound, while Werning (2012) studies optimal government spending with and without commitment to monetary policy. Gali and Monacelli (2008) study optimal fiscal policy in a currency union, but they conduct an exclusively normative analysis and do not compute fiscal multipliers. The results and simulations reported in Corsetti et al. (2011), Nakamura and Steinsson (2011), and Erceg and Linde (2012) show that fiscal multipliers are generally below one under fixed exchange rates yet higher than under flexible exchange rates (away from the zero bound), somewhat validating the conventional Mundell–Flemming view that fiscal policy is more effective with fixed exchange rates (see, eg, Dornbusch, 1980). Our solutions extend these results and help sharpen the intuition for them, by discussing the role of implicit devaluations and transfers. Gali et al. (2007) introduce hand-to-mouth consumers and study the effects of government spending under a Taylor rule in a closed economy. Our setup extends such an analysis to liquidity traps and currency unions in an open economy. Cook and Devereux (2011) study the spillover effects of fiscal policy in open economy models of the liquidity trap. We also examine this question but focus on a different context, that of a currency union, depending on whether it is or not in a liquidity trap.

Our chapter is also related to a large empirical literature on fiscal multipliers. Estimating national fiscal multipliers poses serious empirical challenges. The main difficulties arise from the endogeneity of government spending, the formation of expectations about future tax and spending policies, and the reaction of monetary policy. Most of the literature tries to resolve these difficulties by resorting to Structural VARs. Some papers use military spending as an instrument for government spending. The relevant empirical literature is very large, so we refer the reader to Ramey (2011) for a recent survey. Estimating fiscal multipliers in liquidity traps is nearly impossible because liquidity traps are rare. The closest substitute is provided by estimates that condition of the level of economic activity. Some authors (see, eg, Gordon and Krenn, 2010; Auerbach and Gorodnichenko, 2012) estimate substantially larger national multipliers during deep recessions, but the magnitude of these differential effects remains debated (see, eg, Barro and Redlick, 2009).

States or regions within a country offer an attractive alternative with plausible exogenous variations in spending. Indeed the literature on local multipliers has recently been very active, with contributions by Clemens and Miran (2010), Cohen et al. (2010), Serrato and Wingender (2010), Shoag (2010), Acconcia et al. (2011), Chodorow-Reich et al. (2011), Fishback and Kachanovskaya (2010), and Nakamura and Steinsson (2011). These papers tend to find large multipliers. Our chapter helps interpret these findings. Government spending at the local level in these experiments is generally tied to transfers from outside. It follows that these estimates may be interpreted as combining spending and transfer multipliers, as we define them here.

2. MULTIPLIERS AND SUMMARY MULTIPLIERS

We first set the stage by taking a purely statistical perspective and use it discuss the connection between theory and empirical work.

Suppose one has isolated a relationship between output and government spending encoded in the dynamic response of both variables to a particular structural shock of interest. One may then summarize this relationship into a single "fiscal multiplier" number in a number of ways. Of course, the entire impulse response contains strictly more information, but the multiplier may be a convenient way to summarize it. In the rest of this chapter, we derive the response of output to *any* spending shock for a set of standard macroeconomic models. The implications of each model are encoded in a set of coefficients or loadings, which can be mapped into dynamic responses to output for any impulse from spending.

2.1 Responses and Shocks

2.1.1 Impulse Responses

Suppose we have two time series $\{\hat{g}_t, \hat{y}_t\}$ for government spending and output respectively and that these series (after detrending) are stationary. Assume we can write these two series as a linear function of current and past shocks

$$\hat{g}_t = \hat{A}^g(L)\hat{\varepsilon}_t = \sum_{j=1}^{J} A^{gj}(L)\varepsilon_t^j = \sum_{j=1}^{J}\sum_{k=0}^{\infty}\psi_k^{gj}\varepsilon_{t-k}^j$$

$$\hat{y}_t = \hat{A}^y(L)\hat{\varepsilon}_t = \sum_{j=1}^{J} A^{yj}(L)\varepsilon_t^j = \sum_{j=1}^{J}\sum_{k=0}^{\infty}\psi_k^{yj}\varepsilon_{t-k}^j$$

where the vector of shocks $\hat{\varepsilon}_t = (\varepsilon_t^1, \varepsilon_t^2, \ldots, \varepsilon_t^J)'$ have zero mean and are uncorrelated over time, $\mathbb{E}[\varepsilon_t] = 0$ and $\mathbb{E}[\hat{\varepsilon}_t \hat{\varepsilon}_s'] = 0$ for $t \neq s$. Let us next isolate the effect of one particular shock $j \in J$ and define the components $\{g_t, y_t\}$ explained by this shock. Dropping the j subscript we write this as

$$g_t = A^g(L)\varepsilon_t = \sum_{k=0}^{\infty} \psi_k^g \varepsilon_{t-k} \tag{1a}$$

$$y_t = A^y(L)\varepsilon_t = \sum_{k=0}^{\infty} \psi_k^y \varepsilon_{t-k} \tag{1b}$$

where ε_t is a scalar shock with zero mean and is uncorrelated over time, $\mathbb{E}[\varepsilon_t] = 0$ and $\mathbb{E}[\varepsilon_t \varepsilon_s] = 0$ for $t \neq s$. The natural interpretation is that this particular shock, ε_t, is an exogenous structural shock to government spending. The coefficients $\{\psi_k^i\}$ are the impulse response functions (IRFs) to this shock. The responses can then be interpreted as encompassing a causal relationship. Strictly speaking, however, most of the discussion below does not require this interpretation.

2.1.2 VARs and Instruments

One way to obtain the decomposition of the series described above is using a structural VAR approach. To see this, suppose the original variables $\hat{g}_t$ and $\hat{y}_t$ are part of a VAR, which may include $J-2$ other variables (eg, inflation and interest rates). Suppose ε_t is one of the shocks. By definition, this shock is white noise and is orthogonal to the remaining $J-1$ shocks in the VAR at all leads and lags. In practice, the shock ε_t may be identified using structural assumptions, such as short-run or long-run restrictions. Under appropriate conditions, the shock may then acquire the economic interpretation of a fiscal shock and the response to output can be interpreted as an estimate of the causal relationship between spending and output.

Alternatively, the decomposition may result from an external instrumental variable. Suppose we have a scalar time series $\{z_t\}$ and let the Wold representation of z_t be[a]

$$z_t = A^z(L)\varepsilon_t = \sum_{k=0}^{\infty} \psi_k^z \varepsilon_{t-k}.$$

Thus, the shock ε_t is defined and identified as the innovation from the Wold representation of the instrument z_t. Now project $(\hat{g}_t, \hat{y}_t)$ linearly onto contemporaneous and lagged values of z_t, obtaining the predictors g_t and y_t (with residuals $\tilde{g}_t$ and $\tilde{y}_t$). These can then be represented as in (1). Once again, if the instrument is deemed exogenous to other economic fundamental shocks, then this shock may acquire economic interpretation as a fiscal shock and the response of output and spending can be interpreted as an estimate of the causal relationship between these variables.

2.2 Summary Multipliers

The sequences $\{\psi_k^g, \psi_k^y\}$ provide a full characterization of the joint behavior of $\{y_t\}$ and $\{g_t\}$, with respect to the shock $\{\varepsilon_t\}$. Suppose one insists on summarizing this

[a] Abstracting from the deterministic component.

relationship by a single number, called a "fiscal multiplier." First define the contemporaneous multiplier

$$m_k = \frac{\psi_k^y}{\psi_k^g}$$

indexed by $k = 0, 1, \ldots$ A general summary multiplier may take a ratio of the form

$$M^y = \frac{\sum\limits_{k=0}^{\infty} \lambda_k^y \psi_k^y}{\sum\limits_{k=0}^{\infty} \lambda_k^g \psi_k^g} = \frac{\sum\limits_{k=0}^{\infty} \lambda_k^y \psi_k^g}{\sum\limits_{k=0}^{\infty} \lambda_k^g \psi_k^g} \sum_{k=0}^{\infty} m_k \omega_k$$

where $\omega_k = \lambda_k^y \psi_k^g / \sum_{k=0}^{\infty} \lambda_k^y \psi_k^g$ is a weight that adds up to unity. A simple case is to add up the unweighted the reaction over the first N periods,

$$M^y = \frac{\sum\limits_{k=0}^{N} \psi_k^y}{\sum\limits_{k=0}^{N} \psi_k^g} = \sum_{k=0}^{N} m_k \omega_k,$$

where $\omega_k = \psi_k^g / \sum_{k=0}^{N} \psi_k^g$.

2.2.1 Regression Based Summary Multipliers: OLS and IV

Another popular way to proceed in obtaining a summary fiscal multiplier is regress output on spending and to take the coefficient on spending as a summary multiplier. Consider the relationship

$$\hat{y}_t = \beta^{OLS} \hat{g}_t + u_t^{OLS},$$

where $\mathbb{E}[\hat{g}_t u_t^{OLS}] = 0$ and

$$\beta^{OLS} \equiv \frac{\mathbb{E}[\hat{g}_t \hat{y}_t]}{\mathbb{E}[\hat{g}_t^2]} = \frac{\sum\limits_{j=1}^{J} \sum\limits_{k=0}^{\infty} \psi_k^{yj} \psi_k^{gj}}{\sum\limits_{j=1}^{J} \sum\limits_{k=0}^{\infty} \left(\psi_k^{gj}\right)^2} = \sum_{j=1}^{J} \sum_{k=0}^{\infty} m_k^j \omega_k^j.$$

where

$$m_k^j = \frac{\psi_k^{yj}}{\psi_k^{gj}}, \qquad \omega_k^j \equiv \frac{(\psi_k^{gj})^2}{\sum\limits_{l=0}^{\infty} (\psi_l^{gj})^2}.$$

Thus, the population regression recovers a weighted average of the k-multipliers associated with each shock j.

Consider next an instrumental variable regression

$$\hat{y}_t = \beta^{IV}\hat{g}_t + u_t^{IV}$$

where $\mathbb{E}[z_t u_t^{IV}] = 0$ and

$$\beta^{IV} \equiv \beta^{OLS} \equiv \frac{\mathbb{E}[y_t z_t]}{\mathbb{E}[g_t z_t]} = \frac{\sum\limits_{k=0}^{\infty} \psi_k^y \psi_k^z}{\sum\limits_{k=0}^{\infty} \psi_k^g \psi_k^z} = \sum_{k=0}^{\infty} m_k \omega_k,$$

with weights

$$\omega_k \equiv \frac{\psi_k^g \psi_k^z}{\sum\limits_{l=0}^{\infty} \psi_l^g \psi_k^z}.$$

These weights are positive if ψ_k^g and ψ_k^z take the same sign.[b]

2.3 Connection to Models

As we will show, the implications of a model for fiscal spending can be encoded in a sequence of theoretical multipliers $\{\alpha_{t,k}\}$, where the element $\alpha_{t,k}$ represents the predicted response of output in period t to government spending in period k. This response is calculated as the first-order effect by linearizing the model.

What is the connection between $\{\alpha_{t,k}\}$ and the impulse responses $\{\psi_k^g\}$ and $\{\psi_k^g\}$ discussed above? Suppose we can interpret ε_t as an exogenous shock to the path for spending as summarized by $\{\psi_k^g\}$ and we can interpret the change in spending as a having causal endogenous response in output summarized by $\{\psi_t^y\}$. In the model both responses would be related by

$$\psi_k^y = \sum_{k'=0}^{\infty} \psi_{k'}^g \alpha_{k,k'},$$

for all $t = 0, 1, \ldots$ Given the theoretical multipliers, this relationship give us the output response $\{\psi_k^y\}$ for any given government spending response $\{\psi_t^g\}$.

Under what conditions can we invert this relationship and identify the theoretical multipliers $\{\alpha_{t,k}\}$ from the responses $\{\psi_k^g\}$ and $\{\psi_k^y\}$? For a single pair of $\{\psi_k^g\}$ and $\{\psi_k^y\}$ the answer is generally negative. For any given k the $\alpha_{k,\cdot}$ sequence is not identified: we can only identify the value of the sum $\sum_{k'=0}^{\infty} \psi_{k'}^g \{\alpha_{k,k'}\}$.

[b] In some cases, for example, Nakamura and Steinsson (2011), the IV regressions are run in differences. It is straightforward to adjust the calculations above in this case.

Without further information identification would only be possible if we had multiple responses, $\{\psi_k^g\}$ restrictions, $\{\psi_k^y\}$, that is, multiple spending shocks.

A special case obtains if the response is purely forward looking, as is the case in some of the simplest macroeconomic models. To see this, assume that $\alpha_{t,k} = \alpha_{0,k-t}$ for $k=t,t+1,\ldots$ and $\alpha_{t,k} = 0$ for $k=1,2,\ldots,t-1$. Then we have

$$\psi_t^y = \sum_{k=t}^{\infty} \psi_k^g \alpha_{0,\,k-t}.$$

Then we can identify the entire sequence $\{\alpha_{0,k-t}\}$ from the pair of sequences $\{\psi_k^g\}$ and $\{\psi_k^y\}$, provided we satisfy a standard rank condition (so that the set of sequences $\{\psi_{k-t}^g\}$ for $t \in \{0,1,\ldots\}$ are linearly independent).

3. A CLOSED ECONOMY

We consider a one-time shock to the current and future path of spending that is realized at the beginning of time $t=0$ that upsets the steady state. To simplify and focus on the impulse response to this shock, we abstract from ongoing uncertainty at other dates.[c] We adopt a continuous time framework. This is convenient for some calculations but is completely inessential to any of our results.

The remainder of this section specifies a standard New Keynesian model environment; readers familiar with this setting may wish to skip directly to Section 4.

Households

There is a representative household with preferences represented by the utility function

$$\int_0^{\infty} e^{-\rho t}\left[\frac{C_t^{1-\sigma}}{1-\sigma} + \chi\frac{G_t^{1-\sigma}}{1-\sigma} - \frac{N_t^{1+\phi}}{1+\phi}\right] dt,$$

where N_t is labor, and C_t is a consumption index defined by

$$C_t = \left(\int_0^1 C_t(j)^{\frac{\epsilon-1}{\epsilon}} dj\right)^{\frac{\epsilon}{\epsilon-1}},$$

where $j \in [0, 1]$ denotes an individual good variety. Thus, ϵ is the elasticity between varieties produced within a given country. We denote by $P_t(j)$ is the price of variety j, and by

$$P_t = \left(\int_0^1 P_t(j)^{1-\epsilon} dj\right)^{\frac{1}{1-\epsilon}}$$

the corresponding price index.

[c] Since we are interested in a first order approximation of the equilibrium response to shocks, which can be solved by studying the log-linearized model, the presence of ongoing uncertainty would not affect any of our calculation or conclusions (we have certainty equivalence).

Households seek to maximize their utility subject to the budget constraints

$$\dot{D}_t = i_t D_t - \int_0^1 P_t(j) C_t(j) dj + W_t N_t + \Pi_t + T_t$$

for $t \geq 0$ together with a no-Ponzi condition. In this equation, W_t is the nominal wage, Π_t represents nominal profits and T_t is a nominal lump sum transfer. The bond holdings of home agents are denoted by D_t and the nominal interest rate for the currency union is denoted by i_t.

Government

Government consumption G_t is an aggregate of varieties just as private consumption,

$$G_t = \left(\int_0^1 G_t(j)^{\frac{\epsilon-1}{\epsilon}} dj \right)^{\frac{\epsilon}{\epsilon-1}}.$$

For any level of expenditure $\int_0^1 P_t(j) G_t(j) dj$, the government splits its expenditure across these varieties to maximize G_t. Spending is financed by lump-sum taxes. Ricardian equivalence holds, so that the timing of these taxes is irrelevant.

Firms

A typical firm produces a differentiated good with a linear technology

$$Y_t(j) = A_t N_t(j),$$

where A_t is productivity in the home country.

We allow for a constant employment tax $1 + \tau^L$, so that real marginal cost is given by $\frac{1+\tau^L}{A_t}\frac{W_t}{P_t}$. We take this employment tax to be constant in our model, as in standard in the literature. The tax rate is set to offset the monopoly distortion so that $\tau^L = -\frac{1}{\varepsilon}$. However, none of our results hinge on this particular value.

We adopt the standard Calvo price-setting framework. In every moment a randomly flow ρ_δ of firms can reset their prices. Those firms that reset choose a reset price P_t^r to solve

$$\max_{P_t^r} \int_0^\infty e^{-\rho_\delta s - \int_0^s i_{t+z} dz} \left(P_t^r Y_{t+s|t} - (1+\tau^L) W_t \frac{Y_{t+s|t}}{A_t} \right),$$

where $Y_{t+k|t} = \left(\frac{P_t^r}{P_{t+k}} \right)^{-\epsilon} Y_{t+k}$, taking the sequences for W_t, Y_t and P_t as given.

3.1 Equilibrium Conditions

We now summarize equilibrium conditions for the home country. Market clearing in the goods and labor market requires that:

$$Y_t = C_t + G_t,$$

$$N_t = \frac{Y_t}{A_t}\Delta_t,$$

where Δ_t is an index of price dispersion $\Delta_t = \int_0^1 \left(\frac{P_{H,t}(j)}{P_{H,t}}\right)^{-\epsilon}$. The Euler equation

$$\sigma\frac{\dot{C}_t}{C_t} = i_t - \pi_t - \rho$$

ensures the agents' intertemporal optimization, where $\pi_t = \dot{P}_t/P_t$ is inflation.

The natural allocation is a reference allocation that prevails if prices are flexible and government consumption is held constant at its steady state value G. We denote the natural allocation with a bar over variables.

We omit the first-order conditions for the price-setting problem faced by firms here. We shall only analyze a log-linearized version of the model which collapses these equilibrium conditions into the New Keynesian Phillips curve presented below.

4. NATIONAL MULTIPLIERS IN A LIQUIDITY TRAP

To obtain multipliers, we study the log-linearized equilibrium conditions around the natural allocation with constant government spending. Define

$$c_t = (1-\mathcal{G})(\log(C_t) - \log(\bar{C}_t)) \approx \frac{C_t - \bar{C}_t}{Y},$$

$$y_t = \log Y_t - \log \bar{Y}_t \approx \frac{Y_t - \bar{Y}_t}{Y} \qquad g_t = \mathcal{G}(\log G_t - \log G) \approx \frac{G_t - G}{Y},$$

where $\mathcal{G} = \frac{G}{Y}$. So that we have, up to a first order approximation,

$$y_t = c_t + g_t.$$

The log linearized system is then

$$\dot{c}_t = \hat{\sigma}^{-1}(i_t - \pi_t - \bar{r}_t), \tag{2}$$

$$\dot{\pi}_t = \rho\pi_t - \kappa(c_t + (1-\xi)g_t), \tag{3}$$

where $\hat{\sigma} = \frac{\sigma}{1-\mathcal{G}}$, $\lambda = \rho_\delta(\rho + \rho_\delta)$, $\kappa = \lambda(\hat{\sigma} + \phi)$ and $\xi = \frac{\hat{\sigma}}{\hat{\sigma} + \phi}$. Eq. (2) is the Euler equation and Eq. (3) is the New Keynesian Philips curve. Here, $\bar{r}_t$ is the natural rate of interest, defined as the real interest rate that prevail at the natural allocation, ie, Eq. (2) with $c_t = 0$ for all $t \geq 0$ implies $i_t - \pi_t = \bar{r}_t$ for all $t \geq 0$.

It will prove useful to define the following two numbers ν and $\bar{\nu}$ (the eigenvalues of the system):

$$\nu = \frac{\rho - \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2} \qquad \bar{\nu} = \frac{\rho + \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2}.$$

If prices were completely flexible, then consumption and labor are determined in every period by two static conditions: the labor consumption condition and the resource constraint. Spending affects the solution and gives rise to the neoclassical multiplier $1 - \xi$, which is positive but less than 1 and entirely due to a wealth effect on labor supply.

From now on, we take as given a path for the interest rate $\{i_t\}$ summarizing monetary policy. To resolve or sidestep issues of multiplicity one can assume that there is a date T such that $c_t = g_t = \pi_t = 0$ and $i_t = \bar{r}_t$ for $t \geq T$.[d] A leading example is a liquidity trap scenario where $i_t = 0$ and $\bar{r}_t < 0$ for $t < T$. However, although this is a useful interpretation but is not required for the analysis below.

Remark 1 Suppose $c_T = 0$ for some date T, then

$$c_t = \int_t^T \left(i_{t+s} - \pi_{t+s} - \bar{r}_{t+s}\right) ds,$$

so that given the inflation path $\{\pi_t\}$ the consumption path $\{c_t\}$ is independent of the spending path $\{g_t\}$.

This remark highlights that the mechanism by which government spending affects consumption, in the New Keynesian model, is inflation which affects the real interest rate. One can draw two implications from this. First, other policy instruments that affect inflation, such as taxes, may have similarly policy effects. Second, empirical work on fiscal multipliers has not focused on the role inflation plays and it may be interesting to test the predicted connection between output and inflation present in New Keynesian models.

4.1 Fiscal Multipliers Solved

Since the system is linear it admits a closed form solution. We can express any solution with government spending as

$$c_t = \tilde{c}_t + \int_0^\infty \alpha_s^c g_{t+s} ds, \tag{4a}$$

[d] Note that T may be arbitrarily large and will have no impact on the solution provided below. Indeed, the characterization of the equilibrium is valid even without selecting an equilibrium this way: one just interprets c^* and π^* below any equilibrium in the set of equilibrium attained when $g_t = 0$ for all t. The solution then describes the entire set of equilibria for other spending paths $\{g_t\}$.

$$\pi_t = \tilde{\pi}_t + \int_0^\infty \alpha_s^\pi g_{t+s} ds, \tag{4b}$$

where $\{\tilde{c}_t, \tilde{\pi}_t\}$ are equilibria with $g_t = 0$ for all t. We focus on the integral term $\int_0^\infty \alpha_s^i g_{t+s} ds$ for $i = c$, π as a measure of the effects of fiscal policy $g \neq 0$. We assume the integrals are well defined, although we allow and discuss the case where it is $+\infty$ or $-\infty$ below.

Focusing on consumption, we call the sequence of coefficients $\{\alpha_s^c\}$ *fiscal multipliers*. It is crucial to note that these are *total private consumption multipliers* and not *output multipliers*. Indeed, output is given by

$$y_t = \tilde{y}_t + g_t + \int_0^\infty \alpha_s^c g_{t+s} ds.$$

Whereas the natural benchmark for consumption multipliers is 0, that for output multipliers is 1.

The coefficients α_s^c do not depend on calendar time t, nor do they depend on the interest rate paths $\{i_t\}$ and $\{r_t\}$. Thus, the impact on consumption or output, given by the term $\int_0^\infty \alpha_s^c g_{t+s} ds$, depends only on the future path for spending summarized weighted by $\{\alpha_s^c\}$.

There are two motivations for adopting $\int_0^\infty \alpha_s^c g_{t+s} ds$ as a measure of the impact of fiscal policy, one more practical, the other more conceptual.

1. The more practical motivation applies if the economy finds itself in a liquidity trap with nominal interest rates immobilized at zero, at least for some time. Fiscal multipliers $\{\alpha_s^c\}$ can then be used to predict the effects of fiscal policy. To see this, suppose the zero lower bound is binding until T so that $i_t = 0$ for $t < T$; suppose that after T monetary policy delivers an equilibrium with zero inflation, so that $\pi_t = 0$ for $t \geq T$. As is well known, the resulting equilibrium without government spending ($g_t = 0$ for all t) features a negative consumption gap and deflation: $\tilde{c}_t$, $\tilde{\pi}_t < 0$ for $t < T$ (see, eg, Werning, 2012).

   Now, consider a stimulus plan that attempts to improve this outcome by setting $g_t > 0$ for $t < T$ and $g_t = 0$ for $t \geq T$. Then $\int_0^\infty \alpha_s^c g_{t+s} ds = \int_0^{T-t} \alpha_s^c g_{t+s} ds$ is precisely the effect of the fiscal expansion on consumption c_t, relative to the outcome without the stimulus plan $\tilde{c}_t$.

   More generally, suppose that after the trap spending may be nonzero and that monetary may or may not be described as securing zero inflation. Even in this case, we may still use fiscal multipliers to measure the impact of fiscal policy during the liquidity trap: one can write $c_t = c_T + \int_0^{T-t} \alpha_s^c g_{t+s} ds$ for $t < T$, where the c_T encapsulates the combined effects of fiscal and monetary policy after the trap $t \geq T$.

2. More conceptually, our fiscal multipliers provide a natural decomposition of the effects of the fiscal policy, over what is attainable by monetary policy alone.

   Eqs. (4a) and (4b) characterize the entire set of equilibria for $g \neq 0$ by providing a one-to-one mapping between equilibria with $g = 0$. Both $\tilde{c}_t$ and $\tilde{\pi}_t$ are equilibria with

$g = 0$ and are affected by monetary policy, as summarized, among other things, by the interest rate path $\{i_t\}$.

We can represent these facts as a relationship between the set of equilibria with and without government spending,

$$\mathcal{E}_g = \mathcal{E}_0 + \alpha \cdot g,$$

where $\mathcal{E}_0$ represents the set of equilibria when $g_t = 0$ for all t, while $\mathcal{E}_g$ is the set of equilibria for a given path for spending $g = \{g_t\}$. Here $\alpha = \{\alpha_s^c, \alpha_s^\pi\}$ collects the fiscal multipliers and the cross product $\alpha \cdot g$ represents the integrals $\int_0^\infty \alpha_s^i g_{t+s} ds$ for $i = c, \pi$. The set $\mathcal{E}_g$ is a displaced version of $\mathcal{E}_0$ in the direction $\alpha \cdot g$. Each equilibrium point in $\mathcal{E}_0$ is shifted in parallel by $\alpha \cdot g$ to another equilibrium point in $\mathcal{E}_g$ and it shares the same nominal interest rate path $\{i_t\}$. This last fact is unimportant for this second conceptual motivation, since the focus is on comparing the two sets, not equilibrium points. Instead, the important issue is that $\alpha \cdot g$ measures the influence of government spending on the set of equilibria. This provides a conceptual motivation for studying the multipliers α, since they summarize this influence. In other words, without spending one can view monetary policy as selecting from the set $\mathcal{E}_0$, while with government spending monetary policy can choose from $\mathcal{E}_g$. The effects of fiscal policy on the new options is then precisely determined by the shift $\alpha \cdot g$. Fig. 1 represents this idea pictorially.[e]

Our first result delivers a closed-form solution for fiscal multipliers. Using this closed form one can characterize the multiplier quite tightly.

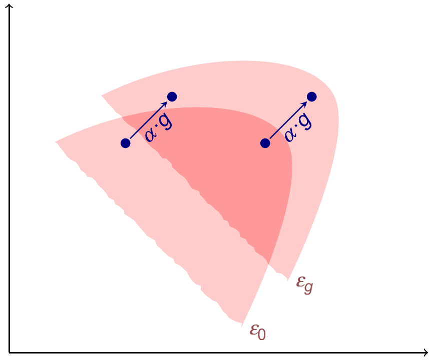

Fig. 1 A schematic depiction of the set of equilibria without government spending and the set of equilibria for a given spending path $\{g_t\}$.

[e] The figure is purposefully abstract and meant to convey the notion of a parallel shift only, so we have not labeled either axis and the shape of the sets is purely for illustrative purposes.

Proposition 1 (Closed Economy Multipliers) *The fiscal multipliers are given by*

$$\alpha_s^c = \hat{\sigma}^{-1}\kappa(1-\xi)e^{-\bar{\nu}s}\left(\frac{e^{(\bar{\nu}-\nu)s}-1}{\bar{\nu}-\nu}\right).$$

The instantaneous fiscal multiplier is zero $\alpha_0^c = 0$, *but the fiscal multipliers are positive, increasing and convex for large* s *so that* $\lim_{s\to\infty}\alpha_s^c = \infty$.

The left panel of Fig. 2 displays these consumption multipliers α_s^c as a function of s for a standard calibration. The proposition states that current spending has no effect on consumption: $\alpha_0^c = 0$. By implication, changes in spending that are very temporary are expected to have negligible effects on consumption and have an output multiplier that is near unity. As stated earlier, the effects of government spending on consumption work through inflation. Current spending does affect the current inflation rate and thus affects the growth rate of consumption. However, since this higher inflation is so short lived the lower growth rate for consumption has no significant stretch of time to impact the level of consumption.

In contrast, spending that takes place in the far future can have a very large impact. The further out into the future, the larger the impact, since α_s^c is increasing in s. Indeed, in the limit the effect becomes unbounded, since $\lim_{s\to\infty}\alpha_s^c = \infty$. The logic behind these results is that spending at $s > 0$ increases inflation over the entire interval of time $[0, s]$. This then lowers the real interest over this same time interval and lowers the growth rate of consumption. Since the long-run consumption level is fixed, the lower growth rate raises the level of consumption. This rise in consumption in turn leads to higher inflation, creating a feedback cycle. The larger the interval $[0, s]$ over which these effect have time to act, the larger is the effect on consumption.

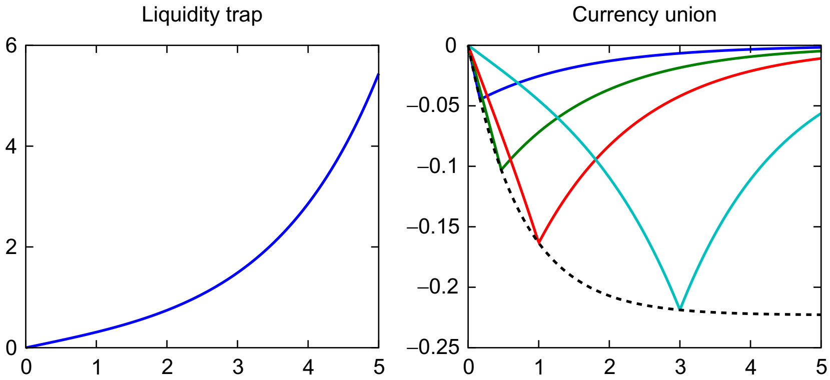

Fig. 2 Liquidity trap and currency union consumption multipliers α_s^c and $\alpha_{s-t}^{c,t,CM}$ as a function of s. Each curve for $\alpha_{s-t}^{c,t,CM}$ is plotted for different values of t ∈{0.25, 0.5, 1, 3}. The black dashed line shows the lower envelope. Parameters are $\sigma = 1$, $\eta = \gamma = 1$, $\varepsilon = 6$, $\phi = 3$, $\lambda = 0.14$, and $\alpha = 0.4$.

The fact that fiscal multipliers are unbounded as $s \to \infty$ stands in strong contrast to the zero multiplier at $s = 0$. It also has important implications. For example, a positive path for spending $\{g_t\}$ that is very backloaded can create a very large response for consumption. This is the case if the shock to spending is very persistent.

Example 1 (AR(1) Spending) Suppose $g_t = g e^{-\rho_g t}$, then if $\rho_g > -\nu > 0$ the response of consumption c_t is finite and given by

$$\int \alpha_s^c g e^{-\rho_g (t+s)} ds = \frac{\hat{\sigma}^{-1} \kappa (1-\xi)}{(\rho_g + \nu)(\rho_g + \bar{\nu})} g e^{-\rho_g t}.$$

The condition $\rho_g > -\nu > 0$ requires spending to revert to zero fast enough to prevent the integral from being infinite.

Some paths for spending imply an infinite value for $\int_0^\infty \alpha_s^c g_s ds$. For instance, this is the case in the example above when $\rho_g < -\nu$. How should one interpret such cases? Technically, this may invalidate our approximation. However, we think the correct economic conclusion to draw is that spending will have an explosive positive effect on consumption. One way to see this is to truncate the path of spending $\{g_t\}$, by setting $g_t = 0$ for all $t \geq T$ for some large T. This ensures that $\int_0^T \alpha_s^c g_s ds$ is finite but the response is guaranteed to be very large if the cutoff is large.

Next, we ask how fiscal multipliers are affected by the degree of price stickiness. Departures from the neoclassical benchmark, where the consumption multiplier is negative, require some stickiness in prices. Perhaps surprisingly, the resulting Keynesian effects turn out to be decreasing in the degree of price stickiness.

Proposition 2 (Price Stickiness) *The fiscal multipliers* $\{\alpha_s^c\}$

1. *are zero when prices are rigid* $\kappa = 0$*;*
2. *are increasing in price flexibility* κ*;*
3. *converge to infinity,* $\alpha_s^c \to \infty$*, in the limit as prices become fully flexible so that* $\kappa \to \infty$.

The logic for these results relies on the fact that spending acts on consumption through inflation. At one extreme, if prices were perfectly rigid then inflation would be fixed at zero and spending has no effect on consumption. As prices become more flexible spending has a greater impact on inflation and, hence, on consumption. Indeed, in the limit as prices become perfectly flexible, inflation becomes so responsive that the effects on consumption explode.

Recall that our fiscal multipliers are calculated under the assumption that the path for interest rates remains unchanged when spending rises. These results seem less counterintuitive when one realizes that such a monetary policy, insisting on keeping interest rates unchanged, may be deemed to be looser when prices are more flexible and inflation reacts more. Of course, this is precisely the relevant calculation when the economy finds itself in a liquidity trap, so that interest rates are up against the zero lower bound.

We capture backloading by a first order dominant shift in the cumulative distribution of spending for a given net present value of output. Backloading leads to a higher path of consumption at every point in time. This is simply because backloading gives more time to the feedback loop between output and inflation to play out.

When applied in a liquidity trap setting it is important to keep in mind the correct interpretation of this result. Our calculations compare spending paths at constant interest rates. In a liquidity trap, this translates to changes in spending before the end of the liquidity trap. If spending is delayed past the liquidity trap this affects consumption differently. For example, if after the end of the trap T monetary policy targets zero inflation, then government spending lowers consumption at T. This feeds back to consumption at $t = 0$, according to $c_t = c_T + \int_0^{T-t} \alpha_s^c g_{t+s} ds$ for $t < T$, lowering the impact on consumption and potentially reversing it. We conclude that backloading spending within the trap increases summary multipliers, but delaying spending past the trap reduce it.

4.2 Summary Fiscal Multipliers Again

Up to now we have discussed properties of fiscal multipliers $\{\alpha_s^c\}$. Usually, fiscal multipliers are portrayed as a single number that summarizes the impact of some change in spending on output or consumption, perhaps conditional on the state of the economy or monetary policy. This requires collapsing the entire sequence of fiscal multipliers $\{\alpha_s^c\}$ into a single number $\bar{\alpha}$, which we shall call a *summary fiscal multiplier,* such as

$$M^c = \frac{\int_0^\infty \lambda_t^c \int_0^\infty \alpha_s^c g_{t+s} ds\, dt}{\int_0^\infty \lambda_t^g g_t dt},$$

where $\{\lambda_t^c\}$ and $\{\lambda_t^g\}$ are weights. It is most natural to consider symmetric weights, with $\lambda_t^g = \lambda_t^c = \lambda_t$, which assume from now on. The simplest weight sets $\lambda_t = 1$ for $t \leq \tau$ and $\lambda_t = 0$ for $t > \tau$, which then computes the ratio of the total responses over the interval $[0, \tau]$. Another possibility is to set $\lambda_t = e^{-\rho t}$, to compute the ratio of the present value responses over the entire horizon.[f]

Note that since $y_t = c_t + g_t$ we have that the output multiplier (defined analogously to the consumption multiplier) is simply[g]

$$M^y = M^c + 1.$$

As this discussion makes clear there are many possibilities for summary multipliers and no universal criteria to select them. Instead, one can adapt the summary multiplier to the

[f] The empirical counterpart of such an infinite-horizon calculation is, however, impractical.

[g] That is, we define

$$M^y = \frac{\int_0^\infty \lambda_t \left(\int_0^\infty \alpha_s^c g_{t+s} ds + g_t\right) dt}{\int_0^\infty \lambda_t g_t dt}.$$

application and relevant policy at hand. The characterizations provided in the previous section have implications for any of these measures. Namely,

i if spending $\{g_t\}$ converges to being concentrated at $t = 0$ then $M^c \to 0$;

ii the more backloaded is government spending for a given net present value, the higher is M^c;

iii the multiplier M^c is increasing in flexibility, it is zero with rigid prices $\kappa = 0$ and goes to infinity in the limit of flexible prices $\kappa \to \infty$.

Example 2 Suppose we have an autoregressive spending path $g_t = ge^{-\rho_g t}$ for $\rho_g > 0$. The summary multiplier is independent of g_0 and given by

$$M^c = \frac{\int_0^\infty \lambda_t \int_0^\infty \alpha_s^c g_{t+s} ds\, dt}{\int_0^\infty \lambda_t g_t dt} = \frac{\int_0^\infty \lambda_t \int_0^\infty \alpha_s^c e^{-\rho_g(t+s)} ds\, dt}{\int_0^\infty \lambda_t e^{-\rho_g t} dt} = \int_0^\infty \alpha_s^c e^{-\rho_g s} ds.$$

Higher values of ρ_g shift weight towards the future. More persistence leads to higher summary multipliers.

4.3 Endogenous Spending: Policy Shocks vs Policy Rules

Up to now we have considered exogenous changes in government spending and their impact on output—a fiscal policy shock. Many stimulus policies, however, are best thought of as responding endogenously to the state of the economy—a fiscal policy rule.

Since the state of the economy depends on the model parameters, this implies that model parameters may play a double role when evaluating fiscal policy rules, as opposed to evaluating fiscal policy shocks.

In this short section we briefly touch on this issue using two examples. Formally, a change in parameters may affect both the structural fiscal multipliers $\{\alpha_t^c\}$, as we have discussed, and the path for government spending $\{g_t\}$. Both may have effects on output and summary fiscal multipliers.

Example 3 Christiano et al. (2011) compute summary fiscal multipliers in a liquidity trap. They assume a policy for government spending that increases spending by a constant amount as long the economy remains in the liquidity trap. They vary the degree of price flexibility and the duration of the liquidity trap and compute the fiscal multiplier (see Fig. 2).

Their summary multiplier is equivalent to computing the initial output response divided by the initial spending increase. Their results suggest that parameter values that make the recession worse also lead to larger multipliers. In some cases, this follows because the parameters affect the fiscal multipliers $\{\alpha_s^c\}$ directly. For example, this is the case for the degree of price flexibility κ. Higher price flexibility makes the recession worse and leads to higher fiscal multipliers, as shown in Proposition 2.

However, in other cases their conclusion rely on the indirect effects that these parameters have on the policy experiment $\{g_t\}$ itself. Indeed, this may affect summary multipliers even when our multipliers $\{\alpha_s^c\}$ are unchanged. Their setup features Poisson uncertainty regarding the length of the trap, but the same logic applies in a deterministic setting, when the liquidity trap has a known duration T.[h]

Suppose the economy is in a liquidity trap with zero interest rates for $t \leq T$ and returns to the natural allocation $c_t = g_t = 0$ for $t \geq T$. Consider fiscal policy interventions that increase spending during the trap, $g_t = g$ for $t \leq T$ and $g_t = 0$ for $t > T$. Higher T then leads to a deeper recession (see Werning, 2012) but has no effect on fiscal multipliers $\{\alpha_t^c\}$. However, the summary impact multiplier computed as

$$\frac{\int_0^T \alpha_s^c g \, ds}{g} = \int_0^T \alpha_s^c \, ds,$$

is increasing and convex in T. A longer liquidity trap increases this summary multiplier even though spending at any point in time is equally effective (α_s^c unchanged). It would be wrong to conclude that a stimulus plan with a fixed duration $\tau \leq T$ (a policy *shock*), such as a year or two, becomes more powerful when T increases. Rather, if $g_t = g$ for all $t \leq T$ (a policy rule) when T increases, then the effect on output is larger simply because the increase in T extends the time frame over which a fixed increase in spending g takes place, leading to an increase in the cumulative change in spending, Tg. Since cumulative spending increases, the impact effect would be larger even if, counter to the model, α_s^c were constant. Moreover, this effect is amplified because the extension backloads spending, and Proposition 1 shows that this is particularly effective since α_s^c is increasing in s.

Example 4 Another perspective is provided when g_t is set as a linear function of current consumption

$$g_t = -\Psi c_t,$$

for some $\Psi > 0$. Then the Phillips curve becomes

$$\dot{\pi}_t = \rho \pi_t - \kappa(c_t + (1-\xi)g_t) = \rho \pi_t - \kappa(1-(1-\xi)\Psi)c_t.$$

Suppose further that $\Psi = (1-\xi)^{-1}$, so that spending "fills the gap" and $c_t + (1-\xi)g_t = 0$. We maintain the assumption that $c_t = g_t = 0$ for $t \geq T$. Inflation is then zero for all $t \geq 0$ and the outcome for consumption is *as if* prices were completely rigid. Now, with this fiscal policy in place, consider different values for price flexibility κ. Neither the outcome for consumption $\{c_t\}$ nor the spending path $\{g_t\}$ depend on κ. Thus, in this special case, for given T, the fiscal rule can be interpreted as a fiscal shock, since it is independent of κ.

[h] Their parameter p, which represents the probability of remaining in the trap, has an effect similar to T in our deterministic setting.

However, the benchmark equilibrium outcome without spending, ie, $g_t = 0$, is decreasing in price flexibility κ (see Werning, 2012). Thus, fiscal policy has a greater effect on consumption when prices are more flexible. This is consistent with Proposition 2 regarding the effects of price flexibility on $\{\alpha_s^c\}$.

5. AN OPEN ECONOMY MODEL OF A CURRENCY UNION

We now turn to open economy models similar to Farhi and Werning (2012a,b) which in turn build on Gali and Monacelli (2005, 2008).

The model focuses on a continuum of regions or countries that share a common currency. One interpretation is that these regions are states or provinces within a country. Our analysis is then directly relevant to the literature estimating "local" multipliers, exploiting cross-sectional variation in spending behavior across states in the United States to estimate the effects on income and employment. Another interpretation is to member countries within a currency union, such as the European Monetary Union (EMU). Our analysis then sheds light on the debates over fiscal policy, stimulus vs austerity, for periphery countries.

For concreteness, from now on we will refer to these economic units (regions or countries) simply as countries. We focus on the effects around a symmetric steady state after a fiscal policy is realized in every country. A crucial ingredient is how private agents share risk internationally. We consider the two polar cases: (i) incomplete markets, where agents can only trade a risk-free bond; and (ii) complete markets with perfect risk sharing. These two market structures have different implications for fiscal multipliers.

5.1 Households

There is a continuum measure one of countries $i \in [0, 1]$. We focus attention on a single country, which we call "home" and can be thought of as a particular value $H \in [0, 1]$. We will focus on a one time shock, so that all uncertainty is realized at $t = 0$. Thus, we can describe the economy after the realization of the shock as a deterministic function of time.

In every country, there is a representative household with preferences represented by the utility function

$$\int_0^\infty e^{-\rho t}\left[\frac{C_t^{1-\sigma}}{1-\sigma} + \chi\frac{G_t^{1-\sigma}}{1-\sigma} - \frac{N_t^{1+\phi}}{1+\phi}\right]dt,$$

where N_t is labor, and C_t is a consumption index defined by

$$C_t = \left[(1-\alpha)^{\frac{1}{\eta}} C_{H,t}^{\frac{\eta-1}{\eta}} + \alpha^{\frac{1}{\eta}} C_{F,t}^{\frac{\eta-1}{\eta}}\right]^{\frac{\eta}{\eta-1}},$$

where $C_{H,t}$ is an index of consumption of domestic goods given by

$$C_{H,t} = \left(\int_0^1 C_{H,t}(j)^{\frac{\epsilon-1}{\epsilon}} dj \right)^{\frac{\epsilon}{\epsilon-1}},$$

where $j \in [0, 1]$ denotes an individual good variety. Similarly, $C_{F,t}$ is a consumption index of imported goods given by

$$C_{F,t} = \left(\int_0^1 C_{i,t}^{\frac{\gamma-1}{\gamma}} di \right)^{\frac{\gamma}{\gamma-1}},$$

where $C_{i,t}$ is, in turn, an index of the consumption of varieties of goods imported from country i, given by

$$C_{i,t} = \left(\int_0^1 C_{i,t}(j)^{\frac{\epsilon-1}{\epsilon}} dj \right)^{\frac{\epsilon}{\epsilon-1}}.$$

Thus, ϵ is the elasticity between varieties produced within a given country, η the elasticity between domestic and foreign goods, and γ the elasticity between goods produced in different foreign countries. An important special case obtains when $\sigma = \eta = \gamma = 1$. We call this the Cole–Obstfeld case, in reference to Cole and Obstfeld (1991).

The parameter α indexes the degree of home bias, and can be interpreted as a measure of openness. Consider both extremes: as $\alpha \to 0$ the share of foreign goods vanishes; as $\alpha \to 1$ the share of home goods vanishes. Since the country is infinitesimal, the latter captures a very open economy without home bias; the former a closed economy barely trading with the outside world.

Households seek to maximize their utility subject to the budget constraints

$$\dot{D}_t = i_t D_t - \int_0^1 P_{H,t}(j) C_{H,t}(j) dj - \int_0^1 \int_0^1 P_{i,t}(j) C_{i,t}(j) dj di + W_t N_t + \Pi_t + T_t$$

for $t \geq 0$. In this equation, $P_{H,t}(j)$ is the price of domestic variety j, $P_{i,t}$ is the price of variety j imported from country i, W_t is the nominal wage, Π_t represents nominal profits and T_t is a nominal lump-sum transfer. All these variables are expressed in the common currency. The bond holdings of home agents is denoted by D_t and the common nominal interest rate within the union is denoted by i_t.

We sometimes allow for transfers across countries that are contingent on shocks. These transfers may be due to private arrangements in complete financial markets. or due to government arrangements. These transfers can accrue to the government or directly to the agents. This is irrelevant since lump-sum taxes are available. For example, we sometimes consider the assumption of complete markets where agents in different countries can perfectly share risks in a complete set of financial markets. Agents form international portfolios, the returns of which result in international transfers that are contingent on the realization of the shock. A different example is in

Section 8 where we consider government spending in the home country paid for by a transfer from the rest of the world. In this case, we have in mind a direct transfer to the government of the home country, or simply spending paid for and made by the rest of the world.

5.2 Government

Government consumption G_t is an aggregate of different varieties. Importantly, we assume that government spending is concentrated exclusively on domestic varieties

$$G_t = \left(\int_0^1 G_t(j)^{\frac{\epsilon-1}{\epsilon}} dj \right)^{\frac{\epsilon}{\epsilon-1}}.$$

For any level of expenditure $\int_0^1 P_{H,t}(j) G_t(j) dj$, the government splits its expenditure across varieties to maximize government consumption G_t. Spending is financed by lump-sum taxes. The timing of these taxes is irrelevant since Ricardian equivalence holds in our basic model. We only examine a potentially non-Ricardian setting in Section 7 where we introduce hand-to-mouth consumers into the model.

5.3 Firms

5.3.1 Technology

A typical firm in the home economy produces a differentiated good using a linear technology

$$Y_t(j) = A_{H,t} N_t(j),$$

where $A_{H,t}$ is productivity in the home country. We denote productivity in country i by $A_{i,t}$.

We allow for a constant employment tax $1 + \tau^L$, so that real marginal cost deflated by Home PPI is $\frac{1+\tau^L}{A_{H,t}} \frac{W_t}{P_{H,t}}$. We take this employment tax to be constant and set to offset the monopoly distortion so that $\tau^L = -\frac{1}{\varepsilon}$, as is standard in the literature. However, none of our results hinge on this particular value.

5.3.2 Price-Setting Assumptions

We assume that the Law of One Price holds so that at all times, the price of a given variety in different countries is identical once expressed in the same currency.

We adopt the Calvo price setting framework, where in every period, a randomly flow ρ_δ of firms can reset their prices. Those firms that get to reset their price choose a reset price P_t^r to solve

$$\max_{P_t^r} \int_0^\infty e^{-\rho_\delta s - \int_0^s i_{t+z} dz} \left(P_t^r Y_{t+s|t} - (1+\tau^L) W_t \frac{Y_{t+s|t}}{A_{H,t}} \right),$$

where $Y_{t+k|t} = \left(\frac{P_t^r}{P_{H,t+k}} \right)^{-\epsilon} Y_{t+k}$, taking the sequences for W_t, Y_t, and $P_{H,t}$ as given.

5.4 Terms of Trade and Real Exchange Rate

It is useful to define the following price indices: the home Consumer Price Index (CPI) is

$$P_t = [(1-\alpha) P_{H,t}^{1-\eta} + \alpha P_t^{*1-\eta}]^{\frac{1}{1-\eta}},$$

the home Producer Price Index (PPI)

$$P_{H,t} = \left[\int_0^1 P_{H,t}(j)^{1-\epsilon} dj \right]^{\frac{1}{1-\epsilon}},$$

and P_t^* is the price index for imported goods. The terms of trade are defined by

$$S_t = \frac{P_t^*}{P_{H,t}}.$$

Similarly let the real exchange rate be

$$\mathcal{Q}_t = \frac{P_t^*}{P_t}.$$

5.5 Equilibrium Conditions

We now summarize the equilibrium conditions. For simplicity of exposition, we focus on the case where all foreign countries are identical. Because agents face the same sequence of interest rates optimal consumption satisfies

$$C_t = \Theta C_t^* \mathcal{Q}_t^{\frac{1}{\sigma}},$$

where Θ is a relative Pareto weight which might depend on the realization of the shocks, and C_t^* is union-wide consumption. The goods market clearing condition is

$$Y_t = (1-\alpha) C_t \left(\frac{\mathcal{Q}_t}{S_t} \right)^{-\eta} + \alpha S_t^\gamma C_t^* + G_t.$$

We also have the labor market clearing condition

$$N_t = \frac{Y_t}{A_{H,t}} \Delta_t,$$

where Δ_t is an index of price dispersion $\Delta_t = \int_0^1 \left(\frac{P_{H,t}(j)}{P_{H,t}} \right)^{-\epsilon}$ and the Euler equation

$$\sigma\frac{\dot{C}_t}{C_t} = i_t - \pi_t - \rho,$$

where $\pi_t = \dot{P}_t/P_t$ is CPI inflation. Finally, we must include the country-wide budget constraint

$$N\dot{F}A_t = (P_{H,t}Y_t - P_tC_t) + i_tNFA_t,$$

where NFA_t is the country's net foreign assets at t, which for convenience, we measure in home numeraire. We impose a standard no-Ponzi condition, $e^{-\int_0^t i_s ds}NFA_t \rightarrow 0$ as $t \rightarrow \infty$.

Absent transfers or insurance across countries NFA_0 must be equal to zero. Instead, when markets are complete we require that $\Theta = 1$. We then solve for the initial value of NFA_0 that is needed, for each shock realization. This value can be interpreted as an insurance transfer from the rest of the world.

Finally with Calvo price setting we have the equations summarizing the first-order condition for optimal price setting. We omit these conditions since we will only analyze a log-linearized version of the model.

6. NATIONAL AND LOCAL FISCAL MULTIPLIERS IN CURRENCY UNIONS

To compute local multipliers, we study the log-linearized equilibrium conditions around a symmetric steady state with zero inflation. We denote the deviations of total private consumption (by domestic and foreigners), output, and public consumption on domestic goods relative to steady state output by

$$c_t = (1-\mathcal{G})(\log(Y_t - G_t) - \log(Y-G)) \approx \frac{Y_t - G_t - (Y-G)}{Y},$$

$$y_t = \log(Y_t) - \log(Y) \approx \frac{Y_t - Y}{Y} \qquad g_t = \mathcal{G}(\log G_t - \log G) \approx \frac{G_t - G}{Y},$$

where $\mathcal{G} = \frac{G}{Y}$ denotes the steady state share of government spending in output. Then we have, up to a first order approximation,

$$y_t = c_t + g_t,$$

Note that c_t does not represent private domestic total consumption (of home and foreign goods); instead it is private consumption (domestic and foreign) of domestic goods. In a closed economy the two coincide, but in an open economy, for our purposes, the latter is more relevant and convenient.

The log linearized system can then be written as a set of differential equations

$$\dot{\pi}_{H,t} = \rho\pi_{H,t} - \kappa(c_t + (1-\xi)g_t) - \lambda\hat{\sigma}\alpha(\omega-1)c_t^* - (1-\mathcal{G})\lambda\hat{\sigma}\alpha\omega\theta, \tag{5}$$

$$\dot{c}_t = \hat{\sigma}^{-1}(i_t^* - \pi_{H,t} - \rho) - \alpha(\omega - 1)\dot{c}_t^*, \tag{6}$$

with an initial condition and the definition of the variable θ,

$$c_0 = (1 - \mathcal{G})(1 - \alpha)\theta + c_0^*, \tag{7}$$

$$\theta = (1 - \mathcal{G})\int_0^{+\infty} e^{-\rho s}\rho \frac{(\omega - \sigma)}{\omega + (1 - \alpha)(1 - \sigma)} c_s ds + (1 - \mathcal{G}) \frac{1 - \alpha + \alpha\omega}{\omega + (1 - \alpha)(1 - \sigma)} \frac{\rho}{\alpha} \mathrm{nfa}_0, \tag{8}$$

and either

$$\mathrm{nfa}_0 = 0 \tag{9}$$

if markets are incomplete or

$$\theta = 0 \tag{10}$$

if markets are complete, where $\mathrm{nfa}_0 = \frac{NFA_0}{Y}$ is the normalized deviation of the initial net foreign asset position from ($\mathrm{nfa}_0 = 0$ at the symmetric steady state) and $\theta = \log\Theta$ is the wedge in the log-linearized Backus–Smith equation ($\theta = 0$ at the symmetric steady state). In these equations, we have used the following definitions: $\lambda = \rho_\delta(\rho + \rho_\delta)$, $\kappa = \lambda(\hat{\sigma} + \phi)$, $\xi = \frac{\hat{\sigma}}{\hat{\sigma} + \phi}$,

$$\omega = \sigma\gamma + (1 - \alpha)(\sigma\eta - 1),$$
$$\hat{\sigma} = \frac{\sigma}{1 - \alpha + \alpha\omega} \frac{1}{1 - \mathcal{G}}.$$

Eq. (5) is the New Keynesian Philips Curve. Eq. (6) is the Euler equation. Eq. (7) is derived from the requirement that the terms of trade are predetermined at $t = 0$ because prices are sticky and the exchange rate is fixed. Finally Eq. (8) together with either (9) or (10) depending on whether markets are incomplete or complete, represents the country budget constraint. In the Cole–Obstfeld case $\sigma = \eta = \gamma = \Omega = 1$, so that the complete and incomplete markets solutions coincide. Away from the Cole–Obstfeld case, the complete and incomplete markets solutions differ. The incomplete markets solution imposes that the country budget constraint (8) with $\mathrm{nfa}_0 = 0$, while the complete markets solution solves for the endogenous value of nfa_0 that ensures that the country budget constraint (8) holds with $\theta = 0$. This can be interpreted as an insurance payment from the rest of the world.

These equations form a linear differential system with forcing variables $\{g_t, g_t^*, i_t^*\}$. It will prove useful to define the following two numbers ν and $\bar{\nu}$ (the eigenvalues of the system):

$$\nu = \frac{\rho - \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2} \qquad \bar{\nu} = \frac{\rho + \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2}.$$

6.1 Domestic Government Spending

We first consider the experiment where the only shock is domestic government spending, so that $i_t^* = \rho$, $g_t^* = y_t^* = c_t^* = 0$. Note that if $g_t = 0$ throughout then $\theta = 0$ and $y_t = c_t = 0$. We shall compute the deviations from this steady state when $g_t \neq 0$.

The assumptions one makes about financial markets can affect the results. We consider, in turn, both the cases of complete markets and incomplete markets.

6.1.1 Complete Markets

We start by studying the case where markets are complete. This assumption is representative of most of the literature, and is often adopted as a benchmark due to its tractability. The key implication is that consumption is insured against spending shocks. In equilibrium, private agents make arrangements with the rest of the world to receive transfers when spending shoots up and, conversely, to make transfers when spending shoots down. As a result, government sending shocks to not affect consumption on impact. Formally, we have $\theta = 0$, so the system becomes

$$\begin{aligned} \dot{\pi}_{H,t} &= \rho \pi_{H,t} - \kappa(c_t + (1-\xi)g_t), \\ \dot{c}_t &= -\hat{\sigma}^{-1} \pi_{H,t}, \end{aligned}$$

with initial condition

$$c_0 = 0.$$

Because the system is linear, we can write

$$\begin{aligned} c_t &= \int_{-t}^{\infty} \alpha_s^{c,t,CM} g_{t+s} ds, \\ \pi_{H,t} &= \int_{-t}^{\infty} \alpha_s^{\pi,t,CM} g_{t+s} ds, \end{aligned}$$

where the superscript *CM* stands for complete markets. Note two important differences with the closed economy case. First, there are both forward- and backward-looking effects from government spending; the lower bound in these integrals is now given by $-t$ instead of 0. At every point in time, consumption is pinned down by the terms of trade which depend on past inflation. Second, the multipliers depend on calendar time t.

It is important to remind the reader that the sequence of coefficients $\{\alpha_s^{c,t,CM}\}$ represents a notion of fiscal multiplier for total private consumption of domestic goods (by domestic and foreigners) and not for domestic output, which is given by

$$y_t = g_t + \int_{-t}^{\infty} \alpha_s^{c,t,CM} g_{t+s} ds.$$

Whereas the natural benchmark for consumption multipliers is 0, that for output multipliers is 1.

Proposition 3 (Open Economy Multipliers, Complete Markets) *Suppose that markets are complete, then the fiscal multipliers are given by*

$$\alpha_s^{c,t,CM} = \begin{cases} -\hat{\sigma}^{-1}\kappa(1-\xi)e^{-\nu s}\dfrac{1-e^{(\nu-\bar{\nu})(t+s)}}{\bar{\nu}-\nu} & s<0, \\ -\hat{\sigma}^{-1}\kappa(1-\xi)e^{-\bar{\nu}s}\dfrac{1-e^{-(\bar{\nu}-\nu)t}}{\bar{\nu}-\nu} & s\geq 0. \end{cases}$$

It follows that

1. *for $t=0$ we have $\alpha_s^{c,t,CM}=0$ for all s;*

2. *for $t>0$ we have $\alpha_s^{c,t,CM}<0$ for all s;*

3. *for $t\to\infty$ we have $\alpha_{s-t}^{c,t,CM}\to 0$ for all s;*

4. *spending at zero and infinity have no impact: $\alpha_{-t}^{c,t,CM}=\lim_{s\to\infty}\alpha_s^{c,t,CM}=0$.*

The right panel of Fig. 2 displays consumption multipliers for a standard calibration. Consumption multipliers are very different in an open economy with a fixed exchange rate. For starters, part (1) says that the initial response of consumption is always zero, simply restating the initial condition above that $c_0=0$. This follows from the fact that the terms of trade are predetermined and complete markets insure consumption.

Part (2) proves that the consumption response at any other date is actually negative. Note that the Euler equation and the initial condition together imply that

$$c_t = -\hat{\sigma}^{-1}\log\frac{P_{H,t}}{P_H}.$$

Government spending increases demand, leading to inflation, a rise in $P_{H,t}$. In other words, it leads to an appreciation in the terms of trade and this loss in competitiveness depresses private demand, from both domestic and foreign consumers. Although we have derived this result in a specific setting, we expect it to be robust. The key ingredients are that consumption depends negatively on the terms of trade and that government spending creates inflation.

It may seem surprising that the output multiplier is necessarily less than one whenever the exchange rate is fixed, because this contrasts sharply with our conclusions in a closed economy with a fixed interest rate. They key here is that a fixed exchange rate implies a fixed interest rate, but the reverse is not true. We expand on this idea in the next section.

Part (3) says that the impact of government spending at any date on private consumption vanishes in the long run. This exact long run neutrality relies on the assumption of complete markets; otherwise, there are potential long-run neoclassical wealth effects from accumulation of foreign assets.

Part (4) says that spending near zero and spending in the very far future have negligible impacts on consumption at any date. Spending near zero affects inflation for a trivial amount of time and thus have has insignificant effects on the level of home prices. Similarly, spending in the far future has vanishing effects on inflation at any date.

Example 5 (AR(1) Spending) Suppose that $g_t = ge^{-\rho_g t}$ and that markets are complete. Then

$$c_t = -ge^{\nu t}\frac{1-e^{-(\nu+\rho_g)t}}{\nu+\rho_g}\frac{\hat{\sigma}^{-1}\kappa(1-\xi)}{\bar{\nu}+\rho_g}.$$

For $g > 0$, this example shows that c_t is always negative. In other words, in the open economy model with complete markets, output always expands less than the increase in government spending. The intuition is simple. Because the terms of trade are predetermined, private spending on home goods is also predetermined so that $c_0 = 0$. Government spending initially leads to inflation because the total (public and private) demand for home goods is increased in the short run. With fixed nominal interest rates, inflation depresses real interest rates, leading to a decreasing path of private consumption of domestic goods, so that c_t becomes negative. The inflationary pressures are greatest at $t = 0$ and they then recede over time as public and private demand decrease. Indeed at some point in time, inflation becomes negative and in the long run, the terms of trade return to their steady state value. At that point, private consumption of domestic goods $\hat{c}_t$ reaches its minimum and starts increasing, returning to 0 in the long run. The crucial role of inflation in generating $c_t < 0$ is most powerfully illustrated in the rigid price case. When prices are entirely rigid, we have $\kappa = 0$ so that $c_t = 0$ throughout.[i]

An interesting observation is that the openness parameter α enters Proposition 3 or Example 5 only through its effect on $\hat{\sigma}$.[j] As a result, in the Cole–Obstfeld case $\sigma = \eta = \gamma = 1$ and the private consumption multipliers $\alpha_s^{c,t,CM}$ are completely independent of openness α. Away from the Cole–Obstfeld case, $\alpha_s^{c,t,CM}$ depends on α, but its dependence can be positive or negative depending on the parameters.[k]

Next, we ask how fiscal multipliers are affected by the degree of price stickiness.

Proposition 4 (Price Stickiness) *The fiscal multipliers $\{\alpha_s^{c,t,CM}\}$ depend on price flexibility as follows:*

1. *when prices are rigid so that $\kappa = 0$, we have $\alpha_s^{c,t,CM} = 0$ for all s and t;*

[i] Note that the above calculation is valid even if $\rho_g < 0$, as long as $\bar{\nu} + \rho_g > 0$. If this condition is violated, then c_t is $-\infty$ for $g > 0$ and $+\infty$ for $g < 0$.

[j] Recall that $\hat{\sigma} = \frac{\sigma}{1+\alpha[(\sigma\gamma-1)+(\sigma\eta-1)-\alpha(\sigma\eta-1)]}\frac{1}{1-\mathcal{G}}$.

[k] For example, when $\sigma\eta > 1$ and $\sigma\gamma > 1$, $\alpha_s^{c,t,CM}$ is increasing in α for $\alpha \in [0, \min\{\frac{(\sigma\gamma-1)+(\sigma\eta-1)}{2(\sigma\eta-1)}, 1\}]$ and decreasing in α for $\alpha \in [\min\{\frac{(\sigma\gamma-1)+(\sigma\eta-1)}{2(\sigma\eta-1)}, 1\}, 1]$.

2. *when prices become perfectly flexible $\kappa \to \infty$, then for all t, the function $s \to \alpha_s^{c,t,CM}$ converges in distributions to $-(1-\xi)$ times a Dirac distribution concentrated at $s=0$, implying that $\int_{-t}^{\infty} \alpha_s^{c,t,CM} g_{t+s} ds = -(1-\xi) g_t$ for all (continuous and bounded) paths of government spending $\{g_t\}$.*

Unlike in the liquidity trap, fiscal multipliers do not explode when prices become more flexible. In a liquidity trap, government spending sets into motion a feedback loop between consumption and inflation: government spending increases inflation, which lower real interest rates, increases private consumption, further increasing inflation, etc. ad infinitum. This feedback loop is nonexistent in a currency union: government spending increases inflation, appreciates the terms of trade, reduces private consumption, reducing the inflationary pressure. Instead, the allocation converges to the flexible price allocation $c_t = -(1-\xi)g_t$ when prices become very flexible. At the flexible price allocation, private consumption is entirely determined by contemporaneous government spending. Hence the function $\alpha_s^{c,t,CM}$ of s converges in distributions to $-(1-\xi)$ times a Dirac function at $s=0$. This implies that fact that for $s=0$, $\lim_{\kappa\to\infty}\alpha_s^{c,t,CM} = -\infty$ and for $s \neq 0$, $\lim_{\kappa\to\infty}\alpha_s^{c,t,CM} = 0$.

One can reinterpret the neoclassical outcome with flexible prices as applying to the case with rigid prices and a flexible exchange rate that is adjusted to replicate the flexible price allocation. The output multiplier is then less than one. The first result says that with rigid prices but fixed exchange rates, output multipliers are equal to one. In this sense, the comparison between fixed with flexible exchange rates confirms the conventional view from the Mundell–Flemming model that fiscal policy is more effective with fixed exchange rates (see, eg, Dornbusch, 1980). This is consistent with the simulation findings in Corsetti et al. (2011).

6.1.2 Incomplete Markets

We now turn our attention to the case where markets are incomplete. Although the complete market assumption is often adopted for tractability, we believe incomplete markets may be a better approximation to reality in most cases of interest.

A shock to spending may create income effects that affect consumption and labor responses. The complete markets solution secures transfers from the rest of the world that effectively cancel these income effects. As a result, the incomplete markets solution is in general different from the complete market case. One exception is the Cole–Obstfeld case, where $\sigma = \eta = \gamma = 1$.

With incomplete markets, the system becomes

$$\begin{aligned}\dot{\pi}_{H,t} &= \rho\pi_{H,t} - \kappa(c_t + (1-\xi)g_t) - (1-\mathcal{G})\lambda\hat{\sigma}\alpha\omega\theta,\\ \dot{c}_t &= -\hat{\sigma}^{-1}\pi_{H,t},\end{aligned}$$

with initial condition

$$c_0 = (1-\mathcal{G})(1-\alpha)\theta,$$
$$\theta = (1-\mathcal{G})\int_0^{+\infty} e^{-\rho s}\rho\frac{(\omega-\sigma)}{\omega+(1-\alpha)(1-\sigma)}c_s ds.$$

We denote the consumption multipliers with a superscript *IM*, which stands for incomplete markets. We denote by $\hat{t}$ the time such that

$$\frac{e^{\nu\hat{t}}}{1-e^{\nu\hat{t}}} = \omega\frac{\hat{\sigma}}{\hat{\sigma}+\phi}\frac{\alpha}{1-\alpha}.$$

We also define

$$\hat{\Sigma} = (1-\mathcal{G})(1-\alpha)\frac{1}{\bar{\nu}} + (1-\mathcal{G})\frac{\hat{\sigma}}{\hat{\sigma}+\phi}\alpha\omega\frac{1}{\rho}\frac{\nu}{\bar{\nu}}.$$

Note that $\bar{\Omega}=0$ in the Cole–Obstfeld case.

Proposition 5 (Open Economy Multipliers, Incomplete Markets) *Suppose that markets are incomplete, then fiscal multipliers are given by*

$$\alpha_s^{c,t,IM} = \alpha_s^{c,t,CM} + \delta_s^{c,t,IM},$$

where $\alpha_s^{c,t,CM}$ *is the complete markets consumption multiplier characterized in Proposition 3 and*

$$\delta_s^{c,t,IM} = \rho\left[\frac{1-\alpha}{\alpha}e^{\nu t} - \lambda\hat{\sigma}\omega\kappa^{-1}(1-e^{\nu t})\right] \times \frac{\alpha\frac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}}{1-\hat{\Sigma}\frac{1}{1-\mathcal{G}}\rho\frac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}}(1-\xi)e^{-\rho(t+s)}(1-e^{\nu(t+s)}).$$

The difference $\delta_s^{c,t,IM}$ *is* 0 *in the Cole–Obstfeld case* $\sigma=\eta=\gamma=1$. *Away from the Cole–Obstfeld case, the sign of* $\delta_s^{c,t,IM}$ *is the same as the sign of* $\left(\frac{\omega}{\sigma}-1\right)(t-\hat{t})$*; moreover,* $\delta_{-t}^{c,t,IM}=0$ *and* $\lim_{s\to\infty}\delta_s^{c,t,IM}=0$.

The difference between the complete and incomplete market solution vanishes in the Cole–Obstfeld case. Although, away from the this case $\delta_s^{c,t,IM}$ is generally nonzero, it necessarily changes signs (both as a function of *s* for a given *t*, and as a function of *t*, for a given *s*). In this sense, incomplete markets cannot robustly overturn the conclusion of Proposition 3 and guarantee positive multipliers for consumption.

With complete markets

$$\theta = 0,$$

while with incomplete markets

$$\theta = \int_0^{+\infty} e^{-\rho s}(1-\mathcal{G})\rho\frac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}c_t ds.$$

This means that with complete markets, home receives an endogenous transfer nfa_0 from the rest of the world following a government spending shock. In the Cole–Obstfeld case, this transfer is zero, but away from this case, this transfer is nonzero. The difference between these two solutions can then be obtained as the effect of this endogenous transfer.

6.2 Understanding Closed vs Open Economy Multipliers

Fig. 2 provides a sharp illustration of the difference between a liquidity trap and a currency union. In a liquidity trap, consumption multipliers are positive, increase with the date of spending, and become arbitrarily large for long-dated spending. By contrast, in a currency union, consumption multipliers are negative, V-shaped and bounded as a function of the date of spending, and asymptote to zero for long-dated spending.

Before continuing it is useful to pause to develop a deeper understanding of the key difference between the closed and open economy results. The two models are somewhat different—the open economy features trade in goods and the closed economy does not—yet they are quite comparable. Indeed, we will highlight that the crucial difference lies in monetary policy, not model primitives. Although a fixed exchange rate implies a fixed nominal interest rate, the converse is not true.

To make the closed and open economies more comparable, we consider the limit of the latter as $\alpha \to 0$. This limit represents a closed economy in the sense that preferences display an extreme home bias and trade is zero. To simplify, we focus on the case of complete markets so that $\theta = 0$. Even in this limit case, the closed and open economy multipliers differ. This might seems surprising since, after all, both experiments consider the effects of government spending for a fixed nominal interest rate. To understand the difference, we allow for an initial devaluation.

Consider then the open economy model in the closed-economy limit $\alpha \to 0$ and let e_0 denote the new value for the exchange rate after the shock in log deviations relative to its steady-state value (so that $e_0 = 0$ represents no devaluation). The only difference introduced in the system by such one-time devaluation is a change the initial condition to[1]

$$c_0 = \hat{\sigma}^{-1} e_0.$$

[1] The full system allowing for a flexible exchange rate and an independent monetary policy i_t is (with $\theta = 0$ and $c_t^* = 0$)

$$\begin{aligned} \dot{\pi}_{H,t} &= \rho \pi_{H,t} - \kappa(c_t + (1-\xi) g_t), \\ \dot{c}_t &= \hat{\sigma}^{-1}(i_t - \pi_{H,t} - \rho), \\ \dot{e}_t &= i_t - i_t^*, \end{aligned}$$

with initial condition

$$c_0 = \hat{\sigma}^{-1} e_0.$$

If we set $i_t = i_t^*$ then $\dot{e}_t = 0$ so that $e_t = e_0$, which amounts to a one-time devaluation.

The exchange rate devaluation e_0 depreciates the initial terms of trade one for one and increases the demand for home goods through an expenditure switching effect. Of course, this stimulative effect is present in the short run, but vanishes in the long run once prices have adjusted. A similar intuition for the effect of fiscal policy on the exchange rate in a liquidity trap is also discussed in Cook and Devereux (2011).

Now if in the closed economy limit of the open economy model, we set the devaluation e_0 so that $\hat{\sigma}^{-1}e_0$ exactly equals the initial consumption response $\int_0^\infty \alpha_s^c g_{t+s} ds$ of the closed economy model, ie,

$$e_0 = \int_0^\infty \kappa(1-\xi)e^{-\bar{\nu}s}\left(\frac{e^{(\bar{\nu}-\nu)s}-1}{\bar{\nu}-\nu}\right)g_s ds, \tag{11}$$

then we find exactly the same response for consumption and inflation as in the closed economy model. This means that if we combined the government spending shock with an initial devaluation given by (11), then the multipliers of the closed economy limit of the open economy model would coincide with those of the closed economy model.[m]

This analysis shows that the policy analysis conducted for our closed economy model implicitly combines a shock to government spending with a devaluation.[n] In contrast, our open economy analysis assumes fixed exchange rates, ruling out such devaluations. The positive response of consumption in the closed economy model relies entirely on this one-time devaluation. Thus, the key difference between the two models is in monetary policy, not whether the economy is modeled as open or closed. Indeed, we have taken the closed-economy limit $\alpha \to 0$, but the results hold more generally: the degree of openness α matters only indirectly through its impact on $\hat{\sigma}$, ν and $\bar{\nu}$ and in the Cole–Obstfeld case, α actually does not even affect these parameters.

7. LIQUIDITY CONSTRAINTS AND NON-RICARDIAN EFFECTS

In this section, we explore non-Ricardian effects of fiscal policy in a closed and open economy setting. To do so, we follow Campbell and Mankiw (1989), Mankiw (2000), and Gali et al. (2007) and introduce hand-to-mouth consumers, a tractable

[m] Note that the size of this devaluation is endogenous and grows without bound as prices become more flexible, ie, as κ increases. This explains why large multipliers are possible with high values of κ in the closed economy model: they are associated with large devaluations.

[n] To see what this implies, suppose the spending shock has a finite life so that $g_t = 0$ for $t \geq T$ for some T and that monetary policy targets inflation for $t \geq T$. In the closed economy model, inflation is always positive and the price level does not return to its previous level. In contrast, in the open economy model with a fixed exchange rate (no devaluation) inflation is initially positive but eventually negative and the price level returns to its initial steady state value. Indeed, if $g_t > 0$ for $t < T$ and $g_t = 0$ for $t \geq T$ for some T, then inflation is strictly negative for $t \geq T$ and the price level falls towards its long run value asymptotically.

way of modeling liquidity constraints. The latter paper studied the effects of government spending under a Taylor rule in a closed economy. Instead, our focus here is on liquidity traps and currency unions.

7.1 Hand-to-Mouth in a Liquidity Trap

The model is modified as follows. A fraction $1-\chi$ of agents are optimizers, and a fraction χ are hand-to-mouth. Optimizers are exactly as before. Hand-to-mouth agents cannot save or borrow, and instead simply consume their labor income in every period, net of lump-sum taxes. These lump-sum taxes are allowed to differ between optimizers (T_t^o) and hand-to-mouth agents (T_t^r). We define

$$t_t^o = \frac{T_t^o - T^o}{Y} \qquad t_t^r = \frac{T_t^r - T^r}{Y},$$

where T^o and T^r are the per-capita steady state values of T_t^o and T_t^r.

We log-linearize around a steady state where optimizers and hand-to-mouth consumers have the same consumption and supply the same labor. In the appendix, we show that the model can be summarized by the following two equations

$$\begin{aligned}\dot{c}_t &= \tilde{\sigma}^{-1}(i_t - \bar{r}_t - \pi_t) + \tilde{\Theta}_n \dot{g}_t - \tilde{\Theta}_\tau \dot{t}_t^r,\\ \dot{\pi}_t &= \rho\pi_t - \kappa[c_t + (1-\xi)g_t],\end{aligned}$$

where $\tilde{\sigma}$, $\tilde{\Theta}_n$ and $\tilde{\Theta}_\tau$ are positive constants defined in the appendix, which are increasing in χ and satisfy $\tilde{\Theta}_n = \tilde{\Theta}_\tau = 0$ and $\tilde{\sigma} = \hat{\sigma}$ when $\chi = 0$. The presence of hand-to-mouth consumers introduces two new terms in the Euler equation, one involving government spending and the other one involving taxes—both direct determinants of the consumption of hand-to-mouth agents. These terms drop out without hand-to-mouth consumers, since $\chi = 0$ implies $\tilde{\Theta}_n = \tilde{\Theta}_\tau = 0$ and $\tilde{\sigma} = \hat{\sigma}$.

As before we define

$$\tilde{\nu} = \frac{\rho - \sqrt{\rho^2 + 4\kappa\tilde{\sigma}^{-1}}}{2} \qquad \tilde{\tilde{\nu}} = \frac{\rho + \sqrt{\rho^2 + 4\kappa\tilde{\sigma}^{-1}}}{2}.$$

We write the corresponding multipliers with a HM superscript to denote "hand-to-mouth."

Proposition 6 (Closed Economy Multipliers, Hand-to-Mouth) *With hand-to-mouth consumers, we have*

$$c_t = \tilde{c}_t + \tilde{\Theta}_n g_t - \tilde{\Theta}_\tau t_t^r + \int_0^\infty \alpha_s^{c,HM} g_{t+s}\, ds - \int_0^\infty \gamma_s^{c,HM} t_{t+s}^r\, ds,$$

where

$$\alpha_s^{c,HM} = \left(1 + \frac{\widetilde{\Theta}_n}{1-\xi}\right)\widetilde{\alpha}_s^{c,HM} \qquad \gamma_s^{c,HM} = \frac{\widetilde{\Theta}_\tau}{1-\xi}\widetilde{\alpha}_s^{c,HM}.$$

$$\widetilde{\alpha}_s^{c,HM} = \widetilde{\sigma}^{-1}\kappa(1-\xi)e^{-\widetilde{\bar{\nu}}s}\left(\frac{e^{(\widetilde{\bar{\nu}}-\widetilde{\nu})s}-1}{\widetilde{\bar{\nu}}-\widetilde{\nu}}\right).$$

In these expressions, g_t and t_t^r can be set independently of each other because the government can always raise the necessary taxes on optimizing agents by adjusting t_t^o, so that total taxes $t_t = \chi t_t^r + (1-\chi)t_t^o$ are sufficient to balance the government budget over time

$$0 = \int_0^\infty (t_t - g_t)e^{-\rho t}dt.$$

If there are additional constraints on the tax system, then g_t and t_t^r become linked. For example, imagine that tax changes on optimizing and hand-to-mouth have to be identical so that $t_t^o = t_t^r = t_t$. In this case, taxes on hand-to-mouth agents satisfy

$$0 = \int_0^\infty (t_t^r - g_t)e^{-\rho t}dt.$$

Imagine in addition that the government must run a balanced budget, then we must have $t_t^o = t_t^r = t_t = g_t$. In this case, taxes on hand-to-mouth agents satisfy

$$t_t^r = g_t.$$

The presence of hand-to-mouth consumers affects the closed-form solution by modifying the coefficients on spending and adding new terms. The terms fall under two categories: the terms $\widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau t_t^r$ capturing the concurrent effects of spending and the integral terms $\int_0^\infty \alpha_s^{c,HM} g_{t+s}ds - \int_0^\infty \gamma_s^{c,HM} t_{t+s}^r ds$ capturing the effects of future government spending and future taxes.

The concurrent terms appear because, with hand-to-mouth consumers, current fiscal policy has a direct and contemporaneous impact on spending. They represent traditional Keynesian effects, which are independent of the degree of price flexibility κ. The integral terms capture the effects of future fiscal policy through inflation. They represent New Keynesian terms, which scale with the degree of price flexibility κ, and disappear when prices are perfectly rigid $\kappa = 0$.

Let us start by discussing the concurrent terms $\widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau t_t^r$. First, the term $-\widetilde{\Theta}_\tau t_t^r$ captures the fact that a reduction in current taxes on hand-to-mouth consumers increases their total consumption directly by redistributing income towards them, away from either unconstrained consumers, who have a lower marginal propensity to consume, or from future hand-to-mouth consumers. Second, the term $\tilde{\Theta}_n g_t$ captures the fact that higher current government spending increases labor income and hence consumption of hand-to-mouth consumers, who have a higher marginal propensity to consume than optimizers. Even when government spending is balanced so that $g_t = \chi t_t^o + (1-\chi)t_t^r$ and taxes are levied equally on optimizers and hand-to-mouth agents so that $t_t^r = g_t$, the sum of the concurrent terms is not exactly zero because of the different effects of government spending and taxes on real wages.

In this case, since $\tilde{\Theta}_\tau = \tilde{\Theta}_n \frac{\mu}{1+\phi}$, the sum of the concurrent terms $\tilde{\Theta}_n g_t - \tilde{\Theta}_\tau t_t^r = \left(1 - \frac{\mu}{1+\phi}\right)\tilde{\Theta}_n g_t$ is likely to be positive in typical calibrations where steady state markups $\mu - 1$ are small compared to ϕ. This is because with sticky prices and flexible wages, real wages increase following increases in government spending, which reduces profit. With heterogeneous marginal propensities to consume, the incidence of this loss across agents matters for private spending, and hence for multipliers, and as we shall see below, these effects can be very large. We refer the reader to the appendix for a complete characterization of fiscal multipliers when these profit effects are taken out (profit offset).

We now turn to the integral terms $\int_0^\infty \alpha_s^{c,HM} g_{t+s} ds - \int_0^\infty \gamma_s^{c,HM} t_{t+s}^r ds$, lower taxes on hand-to-mouth consumers in the future, or higher government spending in the future, stimulates total future consumption.[o] This increases inflation, reducing the real interest rate which increases the current consumption of optimizing agents. This, in turn, stimulates spending by hand-to-mouth consumers. These indirect effects all work through inflation.

Going back to the example where tax changes on hand-to-mouth agents and optimizers discussed above $t_t^o = t_t^r = t_t$, our formulas reveal that the timing of deficits matters. Front-loading fiscal surpluses reduces multipliers through the New Keynesian effects, but increases multipliers early on (and lowers them eventually) through the Keynesian effects.

It is important to understand how these results depend on fixed interest rates, due, say, to a binding zero lower bound. Away from this bound, monetary policy could be chosen

[o] Note that there are conflicting effects of the fraction of hand-to-mouth consumers χ on $\alpha_s^{c,HM} = \left(1 + \frac{\tilde{\Theta}_n}{1-\xi}\right)\tilde{\alpha}_s^{c,HM}$ with $\tilde{\alpha}_s^{c,HM} = \tilde{\sigma}^{-1}\kappa(1-\xi)e^{-\tilde{\tilde{\nu}}s}\left(\frac{e^{(\tilde{\tilde{\nu}}-\tilde{\nu})s}-1}{\tilde{\tilde{\nu}}-\tilde{\nu}}\right)$. On the one hand, future spending increases future output and hence current inflation more when χ is higher, as captured by the multiplicative term $1 + \frac{\tilde{\Theta}_n}{1-\xi}$ which increases with χ. On the other hand, a given amount of inflation leads to less intertemporal substitution when χ is higher, because hand-to-mouth consumers do not substitute intertemporally, as captured by the term $\tilde{\sigma}^{-1}$ which decreases with χ. Overall, for plausible simulations, we find that the former effect tends to be stronger, and potentially much stronger, than the latter. Similar comments apply to the term $\gamma_s^{c,HM}$, which is always positive for $\chi > 0$ but is zero for $\chi = 0$.

to replicate the flexible price allocation with zero inflation. The required nominal interest rate is impacted by the presence of hand-to-mouth consumer

$$i_t = \tilde{\sigma}\left[(1-\xi) + \tilde{\Theta}_n\right]\dot{g}_t + \tilde{\sigma}\,\tilde{\Theta}_\tau \dot{t}^r_t,$$

but consumption is not

$$c_t = -(1-\xi)g_t.$$

Hence away from the zero bound, we get the neoclassical multiplier, which is determined completely statically and does not depend on the presence of hand-to-mouth consumers.[p] In contrast, whenever monetary policy does not or cannot replicate the flexible price allocation, then hand-to-mouth consumers do make a difference for fiscal multipliers. Gali et al. (2007) consider a Taylor rule which falls short of replicating the flexible price allocation. Here, we have focused on fixed interest rates, motivated by liquidity traps.

7.2 Hand-to-Mouth in a Currency Union

We now turn to the open economy version with hand-to-mouth agents.

7.2.1 Complete Markets

We start with the case of complete markets for optimizers. In the appendix, we show that the system becomes

$$\begin{aligned}\dot{\pi}_{H,t} &= \rho\pi_{H,t} - \tilde{\kappa}(c_t + (1-\tilde{\xi})g_t) - (1-\mathcal{G})\lambda\,\tilde{\sigma}\tilde{\alpha}\tilde{\omega}\theta - \tilde{\kappa}\tilde{\tilde{\Theta}}_\tau t^r_t,\\ \dot{c}_t &= -\tilde{\sigma}^{-1}\pi_{H,t} + \tilde{\Theta}_n\dot{g}_t - \tilde{\Theta}_\tau \dot{t}^r_t,\end{aligned}$$

with initial condition

$$c_0 = \tilde{\Theta}_n g_0 - \tilde{\Theta}_\tau t^r_0,$$

for some constants $\tilde{\kappa}$, $\tilde{\alpha}$, $\tilde{\omega}$,$\tilde{\sigma}$, $\tilde{\Theta}_n$, $\tilde{\Theta}_\tau$ and $\tilde{\tilde{\Theta}}_\tau$ defined in the appendix. Importantly $\tilde{\sigma}$, $\tilde{\Theta}_n$, $\tilde{\Theta}_\tau$ are increasing in χ and $\tilde{\Theta}_n$ and $\tilde{\Theta}_\tau$ are decreasing in α. When $\chi = 0$ we have $\tilde{\kappa} = \kappa$, $\tilde{\alpha} = \alpha$, $\tilde{\omega} = \omega$,$\tilde{\sigma} = \hat{\sigma}$, $\tilde{\Theta}_n = 0$, $\tilde{\Theta}_\tau = 0$ and $\tilde{\tilde{\Theta}}_\tau = 0$. As usual, we define

$$\tilde{\nu} = \frac{\rho - \sqrt{\rho^2 + 4\tilde{\kappa}\,\tilde{\sigma}^{-1}}}{2} \qquad \tilde{\bar{\nu}} = \frac{\rho + \sqrt{\rho^2 + 4\tilde{\kappa}\,\tilde{\sigma}^{-1}}}{2}.$$

[p] Note, however, that hand-to-mouth agents might change the associated allocation of optimizers. They just don't matter for the aggregate allocation.

Proposition 7 (Open Economy Multipliers, Hand-to-Mouth, Complete Markets) *With hand-to-mouth agents and complete markets for optimizers, we have*

$$c_t = \tilde{\Theta}_n g_t - \tilde{\Theta}_\tau t_t^r + \int_{-t}^{\infty} \alpha_s^{c,t,HM,CM} g_{t+s} ds - \int_{-t}^{\infty} \gamma_s^{c,t,HM,CM} t_{t+s}^r ds,$$

where

$$\alpha_s^{c,t,HM,CM} = \left(1 + \frac{\tilde{\Theta}_n}{1 - \tilde{\xi}}\right) \tilde{\alpha}_s^{c,t,HM,CM}, \qquad \gamma_s^{c,t,HM,CM} = \frac{\tilde{\Theta}_\tau - \tilde{\tilde{\Theta}}_\tau}{1 - \tilde{\xi}} \tilde{\alpha}_s^{c,t,HM,CM},$$

$$\tilde{\alpha}_s^{c,t,HM,CM} = \begin{cases} -\tilde{\sigma}^{-1} \tilde{\kappa}(1 - \tilde{\xi}) e^{-\tilde{\nu} s} \dfrac{1 - e^{(\tilde{\nu} - \tilde{\bar{\nu}})(t+s)}}{\tilde{\bar{\nu}} - \tilde{\nu}} & s < 0, \\[2ex] -\tilde{\sigma}^{-1} \tilde{\kappa}(1 - \tilde{\xi}) e^{-\tilde{\bar{\nu}} s} \dfrac{1 - e^{-(\tilde{\bar{\nu}} - \tilde{\nu})t}}{\tilde{\bar{\nu}} - \tilde{\nu}} & s \geq 0. \end{cases}$$

Just as in the closed economy case, hand-to-mouth consumers introduce additional Keynesian effects and New Keynesian effects through cumulated inflation, where the former are independent of price flexibility κ while the latter scale with price flexibility κ and disappear when prices are perfectly rigid so that $\kappa = 0$. Just as in the closed economy case, the Keynesian effects increase consumption in response to contemporaneous positive government spending shocks and decrease consumption in response to contemporaneous increases in taxes on hand-to-mouth agents. The difference with the closed economy case is that the New Keynesian effects tend to depress consumption in response to positive government spending shocks. A pure illustration of the Keynesian effect is initial consumption c_0 (for which New Keynesian effects are 0), which is not 0 anymore, but instead $c_0 = \tilde{\Theta}_n g_0 - \tilde{\Theta}_\tau t_0^r$. Importantly $\tilde{\Theta}_n$ and $\tilde{\Theta}_\tau$ are decreasing with the degree of openness α, simply because higher values of α reduce the marginal propensity to consume on domestic goods of hand-to-mouth agents, capturing the "leakage abroad" of fiscal policy.

7.2.2 Incomplete Markets

We now treat the case of incomplete markets for optimizers. We refer the reader to the appendix for the definitions of the constants $\tilde{\Omega}_n$, $\tilde{\Omega}_c$, Σ.

Proposition 8 (Open Economy Multipliers, Hand-to-Mouth, Incomplete Markets) *With hand-to-mouth agents and incomplete markets for optimizers, we have*

$$c_t = \tilde{\Theta}_n g_t - \tilde{\Theta}_\tau t_t^r + \int_{-t}^{\infty} \alpha_s^{c,t,HM,IM} g_{t+s} ds - \int_{-t}^{\infty} \gamma_s^{c,t,HM,IM} t_{t+s}^r ds,$$

where

$$\alpha_s^{c,t,HM,IM} = \alpha_s^{c,t,HM,CM} + \delta_s^{c,t,HM,IM},$$
$$\gamma_s^{c,t,HM,IM} = \gamma_s^{c,t,HM,CM} + \epsilon_s^{c,t,HM,IM},$$

with

$$\begin{aligned}\delta_s^{c,t,HM,IM} = \rho\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}}e^{\widetilde{\nu}t} - (1-\mathcal{G})\lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\tilde{\nu}t}\right)\right] \\ \times\frac{\widetilde{\alpha}}{1-\Sigma\widetilde{\Omega}_c}\left[e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_n}{\rho} + e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\widetilde{\Theta}_n\right. \\ \left.+\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\left(1-\widetilde{\xi}\right)\left(1+\frac{\widetilde{\Theta}_n}{1-\widetilde{\xi}}\right)e^{-\rho(t+s)}\left(1-e^{\tilde{\nu}(t+s)}\right)\right],\end{aligned}$$

$$\begin{aligned}\epsilon_s^{c,t,HM,IM} = -\rho\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}}e^{\widetilde{\nu}t} - \lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\tilde{\nu}t}\right)\right] \\ \times\frac{\widetilde{\alpha}}{1-\Sigma\widetilde{\Omega}_c}\left[e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_\tau}{\rho} - e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\widetilde{\Theta}_\tau\right. \\ \left.+\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\left(1-\widetilde{\xi}\right)\frac{\widetilde{\widetilde{\Theta}}_\tau-\widetilde{\Theta}_\tau}{1-\widetilde{\xi}}e^{-\rho(t+s)}\left(1-e^{\tilde{\nu}(t+s)}\right)\right].\end{aligned}$$

The difference between the complete and incomplete market solution $\delta_s^{c,t,HM,IM}$ and $\epsilon_s^{c,t,HM,IM}$ are generally nonzero, can be understood along the same lines as in Section 6 in the absence of hand-to-mouth agents, generally switch signs with t and s, but do not substantively overturn the forces identified in the case of complete markets.

8. OUTSIDE-FINANCED FISCAL MULTIPLIERS

Up to this point, in our open economy analysis of currency unions, we have assumed that each country pays for its own government spending. Actually, with complete markets it does not matter who is described as paying for the government spending, since regions will insure against this expense. In effect, any transfers across regions arranged by governments are undone by the market. With incomplete markets, however, who pays matters. Transfers between regions cannot be undone and affect the equilibrium. Thus, for the rest of this section we assume incomplete markets.

We first examine what happens when the domestic country doesn't pay for the increase in domestic government spending. We show that this can make an important difference and lead to larger multipliers. This is likely to be important in practice: indeed, a large part of the "local multiplier" literature considers experiments where government spending is not paid by the economic region under consideration.

8.1 Outside-Financed Fiscal Multipliers with No Hand-to-Mouth

We first start with the case where there are no hand-to-mouth agents. The only difference with the results with incomplete markets from Section 6.1 is that we now have

$$\theta = (1-\mathcal{G})\int_0^{+\infty} e^{-\rho s}\rho\frac{(\omega-\sigma)}{\omega+(1-\alpha)(1-\sigma)}c_s ds + (1-\mathcal{G})\frac{1-\alpha+\alpha\omega}{\omega+(1-\alpha)(1-\sigma)}\frac{\rho}{\alpha}\mathrm{nfa}_0,$$

where

$$\mathrm{nfa}_0 = \int_0^{\infty} e^{-\rho t} g_t dt$$

is the transfer from foreign to home that pays for the increase in government spending. In the Cole–Obstfeld case $\sigma = \eta = \gamma = \Omega = 1$.

We denote the consumption multipliers with a superscript *PF*, which stands for "paid for" by foreigners.

Proposition 9 (Outside-Financed Open Economy Multipliers) *When domestic government spending is outside-financed, the fiscal multipliers are given by the same expressions as in Proposition 5 with the difference that*

$$\alpha_s^{c,t,PF} = \alpha_s^{c,t,IM} + \delta_s^{c,t,PF},$$

where $\alpha_s^{c,t,IM}$ is the incomplete markets consumption multiplier characterized in Proposition 5 and

$$\delta_s^{c,t,PF} = \rho\left[\frac{1-\alpha}{\alpha}e^{\nu t} - \lambda\hat{\sigma}\omega\kappa^{-1}(1-e^{\nu t})\right] \times \frac{1}{1-\hat{\Sigma}\frac{1}{1-\mathcal{G}}\rho\frac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}}\frac{1-\alpha+\alpha\omega}{\omega+(1-\alpha)(1-\sigma)}e^{-\rho(t+s)}.$$

The sign of $\delta_s^{c,t,PF}$ is the same as that of $(\hat{t}-t)$ and $\lim_{s\to\infty}\delta_s^{c,t,PF} = 0$.

In the Cole–Obstfeld case $\sigma = \eta = \gamma = 1$, the expression simplifies to

$$\delta_s^{c,t,PF} = \left[e^{\nu t}\frac{1-\alpha}{\alpha} - (1-e^{\nu t})\frac{1}{1-\mathcal{G}}\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\right]\rho e^{-\rho(t+s)}.$$

The intuition is most easily grasped by considering the Cole–Obstfeld case, which we focus on for now. When government spending is outside-financed, there is an associated transfer to domestic agents. Because agents are permanent-income consumers, only the net present value of the per-period transfer matters, which in turn depends on the persistence of the shock to government spending. The effects of this transfer is captured by the term $\delta_s^{c,t,PF}$, which is higher, the higher the degree of home bias (the lower α). Indeed, more generally, we can compute net-present-value transfer multipliers for pure transfers nfa_0 unrelated to government spending[q]:

$$c_t = \beta^{c,t}\text{nfa}_0$$

with

$$\beta^{c,t} = \left[e^{\nu t}\frac{1-\alpha}{\alpha} - \left(1-e^{\nu t}\right)\frac{1}{1-\mathcal{G}}\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\right]\rho.$$

We can also compute the effects of net-present-value transfers on inflation $\beta^{\pi,t} = -\nu e^{\nu t}\left[\rho\frac{1-\alpha}{\alpha} + \rho\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\right]$ and on the terms of trade $\beta^{s,t} = -\left[1-e^{\nu t}\right]\left[\rho\frac{1-\alpha}{\alpha} + \rho\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\right]$ (note that the terms of trade gap equals accumulated inflation $s_t = -\int_0^t \pi_{H,s}ds$). The presence of the discount factor ρ in all these expressions is natural because what matters is the annuity value ρnfa_0 of the transfer.

Net-present-value transfers have opposite effects on output in the short and long run. In the short run, when prices are rigid, there is a Keynesian effect due to the fact that transfers stimulate the demand for home goods: $\beta^{c,0} = \rho\frac{1-\alpha}{\alpha}$. In the long run, when prices adjust, the neoclassical wealth effect on labor supply lowers output: $\lim_{t\to\infty}\beta^{c,t} = -\rho\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}$. In the medium run, the speed of adjustment, from the Keynesian short-run response to the neoclassical long-run response, is controlled by the degree of price flexibility κ, which affects ν.[r]

Note that the determinants of the Keynesian and neoclassical wealth effects are very different. The strength of the Keynesian effect hinges on the relative expenditure share of home goods $\frac{1-\alpha}{\alpha}$: the more closed the economy, the larger the Keynesian effect. The strength of the neoclassical wealth effect depends on the elasticity of labor supply $\frac{1}{\phi}$: the more elastic labor supply, the larger the neoclassical wealth effect.

Positive net-present-value transfers also increase home inflation. The long-run cumulated response in the price of home produced goods equals $\rho\frac{1-\alpha}{\alpha} + \rho\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}$.

[q] In the particular case that we study here, transfers occur concurrently with an increase in government spending and exactly pay for the increase in government spending $\text{nfa}_0 = \int_0^\infty e^{-\rho t}g_t dt$.

[r] Note that ν is decreasing in κ, with $\nu = 0$ when prices are rigid ($\kappa = 0$), and $\nu = -\infty$ when prices are flexible ($\kappa = \infty$).

The first term $\rho\frac{1-\alpha}{\alpha}$ comes from the fact that transfers increase the demand for home goods, due to home bias. The second term $\rho\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}$ is due to a neoclassical wealth effect that reduces labor supply, raising the wage. How fast this increase in the price of home goods occurs depends positively on the flexibility of prices through its effect on ν.[s]

These effects echo the celebrated Transfer Problem controversy of Keynes (1929) and Ohlin (1929). With home bias, a transfer generates a boom when prices are sticky, and a real appreciation of the terms of trade when prices are flexible. The neoclassical wealth effect associated with a transfer comes into play when prices are flexible, and generates an output contraction and a further real appreciation.

In the closed economy limit we have $\lim_{\alpha\to 0}\beta^{c,t}=\infty$. In the fully open economy limit we have $\lim_{\alpha\to 0}\beta^{c,t}=0$. The intuition is that the Keynesian effect of transfers is commensurate with the relative expenditure share on home goods $\frac{1-\alpha}{\alpha}$. This proposition underscores that transfers are much more stimulative than government spending, the more so, the more closed the economy. This robust negative dependence of transfer multipliers $\beta^{c,t}$ on openness α should be contrasted with the lack of clear dependence on openness of government spending multipliers $\alpha_s^{c,t,CM}$ noted above (indeed in the Cole–Obstfeld case, $\alpha_s^{c,t,CM}$ is independent of α).

Example 6 (Outside-Financed Spending, Cole–Obstfeld, AR(1)) Suppose that $g_t=ge^{-\rho_g t}$ and that domestic government spending is outside-financed. In the Cole–Obstfeld case $\sigma=\eta=\gamma=1$, we have

$$c_t=g\left[e^{\nu t}\frac{1-\alpha}{\alpha}-(1-e^{\nu t})\frac{1}{1-\mathcal{G}}\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\right]\frac{\rho}{\rho+\rho_g}$$
$$-ge^{\nu t}\left(\frac{1-e^{-(\nu+\rho_g)t}}{\nu+\rho_g}\right)\kappa(1-\xi)\frac{1-\mathcal{G}}{\bar{\nu}+\rho_g}.$$

Moreover we have $c_0=g\frac{1-\alpha}{\alpha}\frac{\rho}{\rho+\rho_g}$ and $\lim_{t\to\infty}c_t=-g\frac{1}{1-\mathcal{G}}\frac{1}{\frac{1}{1-\mathcal{G}}+\phi}\frac{\rho}{\rho+\rho_g}$.

Note that the second term on the right-hand side of the expression for c_t in Example 6 is simply the term identified in Example 5 in the complete markets case. The first term arises precisely because government spending is now paid for by foreign.

It is particularly useful to look at the predictions of this proposition for $t=0$ and $t\to\infty$. In the case of a stimulus $g>0$, we have $c_0>0>\lim_{t\to\infty}c_t$. Following a positive stimulus shock, we can get $c_0>0$ and actually $c_t>0$ for some time (because $\theta>0$) and eventually $c_t<0$. The conclusion would be that an unpaid for fiscal stimulus at

[s] Recall that ν is decreasing in the degree of price flexibility κ.

home has a larger consumption multiplier in the short run and smaller in the long run. This is true as long as there is home bias $\alpha < 1$. The reason is that the associated transfer redistributes wealth from foreign to home consumers. This increases the demand for home goods because of home bias. In the neoclassical model with flexible prices, there would be an appreciation of the terms of trade and a reduction in the output of home goods because of a neoclassical wealth effect. With sticky prices, prices cannot adjust in the short term, and so this appreciation cannot take place right away, and so the output of home goods increases. In the long run, prices adjust and we get the neoclassical effect.

The lesson of this section is that we can partly overturn the conclusion of Proposition 3 when government spending is outside-financed. When the degree of home bias $1-\alpha$, is high, or when increases in government spending are very persistent, then local multipliers estimates that involve increases in government spending that are not self-financed are potentially substantially inflated compared to the counterfactual of self-financed increases in government spending.

8.2 Outside-Financed Fiscal Multipliers with Hand-to-Mouth

We now turn to the case where there are hand-to-mouth agents.

Proposition 10 (Outside-Financed Open Economy Multipliers, Incomplete Markets, Hand-to-Mouth) *With hand-to-mouth agents, when domestic government spending is outside-financed, the fiscal multipliers are given by the same expressions as in Proposition 8 with the difference that*

$$\alpha_s^{c,t,HM,PF} = \alpha_s^{c,t,HM,IM} + \delta_s^{c,t,PF},$$

where

$$\delta_s^{c,t,HM,PF} = \rho\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}} e^{\widetilde{\nu} t} - \lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\widetilde{\nu} t}\right)\right]\frac{1}{1-\Sigma\widetilde{\Omega}_c}\frac{\widetilde{\alpha}(1-\mathcal{G})\widetilde{\Omega}_f}{\rho}e^{-\rho(t+s)}.$$

When domestic government spending is outside-financed, the question of the incidence of the accompanying transfer across domestic optimizers and hand-to-mouth agents naturally arises. These distributive effects are entirely captured by the adjustment in the taxes t_t^r paid by hand-to-mouth agents.

From now on, we focus on the benchmark case where taxes and the accompanying per-period transfer are distributed equally on optimizers and hand-to-mouth agents and where the domestic government runs a balanced budget, because this case is the most relevant to think about most of the estimates in the local multipliers literature where regions correspond to states with limited de jure or de facto ability to borrow.

When domestic government spending is self-financed, we have $t_t^o = t_t^r = g_t$, and instead when government spending is outside-financed, we have $t_t^o = t_t^r = 0$. Comparing fiscal multipliers when government spending is self-financed vs outside-financed, the effect of reduced taxes on optimizers in the latter case is captured by the corrective term

$\delta_s^{c,t,PF}$, while the effect of reduced taxes on hand-to-mouth agents is captured by the reduction in t_t^r from g_t to zero. In particular, in the short run before prices can fully adjust, both effects increase fiscal multipliers, the first effect for reasons already discussed in the case without hand-to-mouth agents in Section 8.1, the second effect because hand-to-mouth agents have a higher marginal propensity to consume than optimizers.

The presence of hand-to-mouth agents magnifies the difference between self-financed and outside-financed fiscal multipliers for temporary government spending shocks, simply because hand-to-mouth agents spend more of the temporary implicit transfer from foreigners that separate these two experiments in the short run, the more so, the more temporary the government spending shock.

Overall, this analysis shows that when the average marginal propensity to consume on domestic goods, as captured by the fraction of hand-to-mouth agents χ and by the degree of home bias $1-\alpha$, is high, or when increases in government spending are very persistent, then local multipliers estimates that involve increases in government spending that are not self-financed are potentially substantially inflated compared to the counterfactual of self-financed increases in government spending.

9. TAKING STOCK: SOME SUMMARY MULTIPLIER NUMBERS

In this section, we provide numerical illustrations for the forces that we have identified in the chapter. We report summary multipliers $M^Y = 1 + M^C$ in liquidity traps and currency unions, computed as the ratio of the average response of output over the 2 years following the increase in spending to the average increase in government spending over the same period. Our baseline calibration features $\chi = 0$, $\sigma = 1$, $\epsilon = 6$, $\phi = 3$, and $\mathcal{G} = 0.3$ for liquidity traps and $\chi = 0$, $\sigma = 1$, $\eta = \gamma = 1$, $\epsilon = 6$, $\phi = 3$, $\mathcal{G} = 0.3$, and $\alpha = 0.4$ for currency unions. We take the government spending shock to be constant for $\tau_g = 1.25$ years (5 quarters) and zero afterwards.[t] We then explore variations with higher values of χ. In all these experiments, we maintain the assumption that taxes fall equally on hand-to-mouth agents and on optimizers, and that markets are incomplete. In the deficit financed experiments, taxes are increased (discretely) only after three years, and are then constant for 1.25 years before reverting to zero. The first part of Table 1 corresponds to the case of perfectly rigid prices $\lambda = 0$ (infinite price duration), the second part to $\lambda = 0.12$ (price duration of 2.9 years), and $\lambda = 1.37$ (price duration of 0.9 year).

We start with the case of perfectly rigid prices in the first part of Table 1. This table presents summary multipliers in liquidity traps and currency unions, depending on whether

[t] This shock has the same duration $\frac{\tau_g}{2} = \frac{1}{\rho_g}$ as an AR(1) with a coefficient with $\rho_g = 1.6$ (corresponding to a quarterly mean-reversion coefficient of 0.7), but dies off completely in finite time (after 1.6 years), leading to more reasonable values for liquidity trap multipliers when prices are somewhat flexible (the tail of the shock matters a great deal in this case because α_s^c and $\widetilde{\alpha}_s^{c,HM}$ increase exponentially with the horizon s).

Table 1 Summary output multipliers

or not they are tax-financed (taxes equal to government spending in every period), deficit-financed (taxes are raised only 3 years after the increase in spending, and then mean-revert at the same rate as spending), or outside-financed (no change in taxes). For all these cases, we also report multipliers for different values of the profit-offset coefficient o: 0, 0.5, and 1. This profit-offset coefficient is equal to the share of marginal profits per agent which is transferred to each hand-to-mouth agent: when it is equal to 0, hand-to-mouth agents are completely shielded from the impact of government spending on profits, and when it is equal to 1, they are impacted exactly like optimizers. This is important because with sticky prices and flexible wages, real wages increase following increases in government spending, so that profits increase less than proportionately with output, while labor income increases more than proportionately. With heterogeneous marginal propensities to consume, the incidence of this loss across agents matters for private spending, and hence for multipliers, and as we shall see below, these effects can be very large. While our analysis in the main text of the paper is confined to the case $o = 0$, the appendix gives a full treatment of the arbitrary o case. We also vary the fraction of hand-to-mouth agents χ between 0 and 0.75.

The results are as follows. We start with our baseline calibration. The multiplier is always 1 in a liquidity trap, independently of whether government spending is tax- or debt-financed. In a currency union, the multiplier is 1 independently of whether government spending is tax- or debt-financed, but it increases to 1.1 when it is outside-financed.

We then depart from the baseline increasing the fraction of hand-to-mouth agents χ from 0 to 0.25, 0.5, and 0.75. We start with the case of full profit offset $o = 1$ and explain the role of profit offset later. In a liquidity trap, the tax-financed multiplier remains at 1 irrespective of χ. The deficit-financed multiplier increases with χ to 1.2 ($\chi = 0.25$), 1.7 ($\chi = 0.5$), or 3.1 ($\chi = 0.75$). Turning to currency unions, the tax-financed multiplier is 1 irrespective of χ. The deficit-financed multiplier increases with χ to 1.1 ($\chi = 0.25$), 1.3 ($\chi = 0.5$), or 1.8 ($\chi = 0.75$). Finally the outside-financed multiplier increases with χ to 1.3 ($\chi = 0.25$), 1.5 ($\chi = 0.5$), or 2.7 ($\chi = 0.75$). Importantly, the difference between outside- and self-financed multipliers is now larger than in our baseline, and the deficit-financed multiplier is in between these two multipliers.

In general, lower values of the profit offset coefficient o lead to higher multipliers. This is because with no profit offset, the contemporaneous reduction in profits resulting from the increase in government spending acts like a redistribution from low marginal propensity to consume optimizers toward high marginal propensity to consume hand-to-mouth agents, which increases output (and vice versa for the increase in taxes). This effect, which can be very large, disappears with full profit offset. The * in Table 1 indicates that the feedback loop between output and the distributive effects of profits on agents with different marginal propensities to consume is so powerful that it "blows up". When it occurs, our formulas cease to apply and the correct interpretation is that multipliers are positive infinite.

We continue with the case of sticky but not perfectly rigid prices in the second and third parts of Table 1, where we run through the exact same experiments as in the first part of Table 1. The key differences are as follows. First, in the case of liquidity traps, tax-financed multipliers are a lot higher than with rigid prices, illustrating the power of the positive feedback loop between inflation and output. Deficit-financed multipliers can be a lot lower than with rigid prices and can actually be negative when there are enough hand-to-mouth agents because the positive feedback loop for front-loaded government spending is weaker than the more back-loaded negative one for taxes (in this case, lower profit offset reduces multipliers, potentially leading to negative infinite values indicated by $-*$). Second, in the case of currency unions, multipliers are lower than with rigid prices, but the difference is not as large as in the case of liquidity traps. This is because in this case, there is no feedback loop between output and inflation since inflation lowers spending instead of increasing it, because of its accumulated effect appreciates the terms of trade and rebalances spending away from home goods toward foreign goods.

Although this is not illustrated in the table, we briefly comment on the role of the persistence of shocks and of the openness of the economy. In liquidity traps, more persistent government spending shocks tend to increase tax-financed multipliers because of the feedback loop between output and inflation (in fact tax-financed multipliers can become infinite when prices are not entirely rigid, even without hand-to-mouth agents). They increase deficit-financed multipliers with no hand-to-mouth agents but can decrease them with enough hand-to-mouth agents and somewhat flexible prices because the feedback loop between output and inflation is more potent for back-loaded taxes than for front-loaded government spending. In currency unions, more persistent government spending shocks tend to decrease tax-financed and deficit-financed multipliers, but to increase outside-financed multipliers when prices are rigid enough. In currency unions, multipliers tend to increase when the economy is more closed (α is lower) when government spending is outside-financed and prices are not too flexible or when it is deficit-financed and larger than one (less leakage abroad).

Our simulations are illustrative and do not attempt to explore a wide range of possible parameters. For example, we have kept the fraction of hand-to-mouth agents at a modest level. Likewise, we only explore a relatively open economy. Overall, even within this limited range, our results show that fiscal multipliers are somewhat sensitive to various primitive parameters, as well as the nature of the fiscal experiment. Differences were found comparing completely rigid prices to standard degrees of price stickiness, especially for the liquidity trap case. The presence of hand-to-mouth agents also affects the responses significantly. Perhaps most surprisingly, distributional impacts appear to be crucial. First, there is the difference between tax-financed, deficit-financed, and outside-financed spending. Second, there is the difference in the responses obtained depending on the way profits are redistributed. As explained earlier, this effect relies on the model prediction that profits relative to labor earnings are countercyclical. Thus, this effect could be mitigated if wages, which are flexible in our standard New Keynesian model, were also assumed to be sticky.

Theoretically, in currency unions, outside-financed multipliers can be much larger than deficit-financed multipliers, especially when the economy is relatively closed and government spending shocks are relatively persistent. However, in our simulations with relatively open economies and relatively transitory government spending shocks (which capture the characteristics of many local multiplier studies), these differences are not very large. Since deficit-financed multipliers tend to be larger in liquidity traps than in currency unions (because there is less "leakage" abroad) with rigid enough prices, it would appear that outside-financed multipliers in currency unions (as estimated in the local multipliers literature) may provide a rough lower bound for national multipliers deficit-financed in liquidity traps with rigid enough prices. When prices are more flexible, the comparison is more delicate and the rough lower bound need not apply.

10. COUNTRY SIZE, AGGREGATION, AND FOREIGN GOVERNMENT SPENDING

So far, we have focused on the case where the country undertaking the fiscal stimulus is a small (infinitesimal) part of the currency union—this is implied by our modeling of countries as a continuum. Here, we relax this assumption. To capture country size, we interpret i as indexing regions and we imagine that countries $i \in [0, x]$ are part of a single country. They undertake the same fiscal stimulus g_t^i. We denote with a $- \ i \in (x, 1]$ the index of a typical region that is not undertaking fiscal stimulus so that $g_t^{-i} = 0$. We consider two situations: (1) monetary policy i_t^* at the union level achieves perfect inflation targeting (2) monetary policy at the union level is passive because the union is in a liquidity trap where interest rates i_t^* are at the zero lower bound. For simplicity, we focus on the Cole–Obstfeld case throughout.

10.1 Inflation Targeting at the Union Level

The aggregates variables satisfy

$$g_t^* = \int_0^1 g_t^i di = x g_t^i,$$

$$c_t^* = \int_0^1 c_t^i di = x c_t^i + (1-x) c_t^{-i},$$

$$\pi_t^* = \int_0^1 \pi_t^i di = x \pi_t^i + (1-x)] \pi_t^{-i}.$$

As long as the zero lower bound is not binding, monetary policy at the union level can be set to target zero inflation $\pi_t^* = 0$. The required interest rate i_t^* is

$$i_t^* - \rho = -\hat{\sigma}(1-\xi)x\dot{g}_t^i,$$

and the corresponding value of c_t^* is

$$c_t^* = -(1-\xi)xg_t^i.$$

The allocation for regions in the country undertaking the stimulus solves

$$\begin{aligned}\dot{\pi}_t^i &= \rho\pi_t^i - \kappa(c_t^i + (1-\xi)g_t^i),\\ \dot{c}_t^i &= -(1-\xi)x\dot{g}_t^i - \hat{\sigma}^{-1}\pi_t^i,\end{aligned}$$

$$c_0^i = -(1-\xi)xg_0^i.$$

Similarly the allocation for regions not undertaking the stimulus solves

$$\dot{\pi}_t^{-i} = \rho\pi_t^{-i} - \kappa c_t^{-i},$$

$$\dot{c}_t^{-i} = -(1-\xi)x\dot{g}_t^i - \hat{\sigma}^{-1}\pi_t^{-i},$$

$$c_0^{-i} = -(1-\xi)xg_0^i.$$

In the Cole–Obstfeld case, we define

$$\alpha_s^{c,t,CM*} = \begin{cases} \hat{\sigma}^{-1}\kappa(1-\xi)e^{-\nu s}\dfrac{1-e^{(\nu-\bar{\nu})(t+s)}}{\bar{\nu}-\nu} & s<0,\\ \hat{\sigma}^{-1}\kappa(1-\xi)e^{-\bar{\nu}s}\dfrac{1-e^{(\nu-\bar{\nu})t}}{\bar{\nu}-\nu} & s\geq 0.\end{cases}$$

Proposition 11 (Large Countries, Union-Wide Inflation Targeting) *Suppose that the zero bound is not binding at the union level and that monetary policy targets union-wide inflation $\pi_t^* = 0$. Then in the Cole–Obstfeld case, we have*

$$c_t^i = -x(1-\xi)g_t^i + (1-x)\int_{-t}^{\infty}\alpha_s^{c,t,CM}g_{t+s}^i ds,$$

$$c_t^{-i} = -(1-\xi)xg_t^i + x\int_{-t}^{\infty}\alpha_s^{c,t,CM*}g_t^i ds.$$

Let us first focus on the regions in the country undertaking the spending. This proposition shows that for regions in the country undertaking the stimulus, the effects on private spending on domestic goods are simply a weighted average of the effect $-(1-\xi)g_t^i$ that would arise if the country undertaking the stimulus could set monetary policy to target their own domestic inflation $\pi_t^i = 0$, and the effect that arises if the country is a small (infinitesimal) part of a currency union, with weights given by x and $1-x$, where x is the relative size of the country undertaking the stimulus.

Let us now turn to the regions in countries not undertaking the spending. There are both direct effects and indirect effects. The indirect effects work through inflation, which affect the terms of trade and, hence, the demand for the goods produced by these regions. To isolate the direct effects set $\kappa = 0$, so that there is no inflation and $\alpha_s^{c,t,CM*} = 0$. The demand for home goods is then equal to $c_t^{-i} = -(1-\xi)g_t^* = -(1-\xi)xg_t^i$. When spending rises in regions $i \in [0, x]$, it depresses private spending by agents of these regions, lowering the demand for output in regions $-\ i \in (x, 1]$. When $\kappa > 0$, the indirect effect works through inflation. The lower demand for goods in regions $-\ i \in (x, 1]$ creates deflation in these regions, which makes these economies more competitive. The lower prices then increase the demand for the goods produced by these regions.

Example 7 (Union-Wide Inflation Targeting, AR(1)) Suppose that $g_t^i = g^i e^{-\rho_g t}$, then we have

$$c_t^{-i} = -e^{\nu t}(1-\xi)xg^i \left[1 - \frac{1 - e^{-(\nu+\rho_g)t}}{\rho_g + \nu} \frac{\rho_g(\rho + \rho_g)}{\rho_g + \bar{\nu}}\right].$$

This implies that c_0^{-i} is negative if g^i is positive. If $\rho_g + \nu < 0$ then c_t^{-i} will remain negative. If instead $\rho_g + \nu > 0$ then c_t^{-i} starts out negative, but eventually switches signs.

This results suggests that a temporary increase in government spending abroad accompanied by monetary tightening to ensure no union-wide inflation induces a recession at home. This fits a common narrative regarding the post German reunification in the early 90s. The fiscal expansion was combined with a monetary contraction in Germany, so as to avoid inflation. The quasi-fixed exchange rate arrangements of the EMS forced other countries to follow suit and tighten monetary policy, negatively affecting their economic performance.

10.2 Zero Bound at the Union Level

If the zero bound binds at the union level, then c_t^* is given by

$$c_t^* = x \int_0^\infty \alpha_s^c g_{t+s}^i ds.$$

The allocation for regions in the country undertaking the stimulus solves

$$\dot{\pi}_t^i = \rho \pi_t^i - \kappa(c_t^i + (1-\xi)g_t^i),$$
$$\dot{c}_t^i = -\hat{\sigma}^{-1}\pi_t^i,$$
$$c_0^i = x \int_0^\infty \alpha_s^c g_{t+s}^i ds.$$

Similarly the allocation for regions not undertaking the stimulus solves

$$\dot{\pi}_t^{-i} = \rho \pi_t^{-i} - \kappa c_t^{-i},$$
$$\dot{c}_t^{-i} = -\hat{\sigma}^{-1}\pi_t^{-i},$$

$$c_0^{-i} = x \int_0^{\infty} \alpha_s^c g_{t+s}^i ds.$$

Proposition 12 (Large Countries, Union-Wide Zero Bound) *Suppose that the zero bound is binding at the union level, then in the Cole–Obstfeld case, we have*

$$c_t^i = x \int_0^{\infty} \alpha_s^c g_{t+s}^i ds + (1-x) \int_{-t}^{\infty} \alpha_s^{c,t,CM} g_{t+s}^i ds,$$

$$c_t^{-i} = x e^{\nu t} \int_0^{\infty} \alpha_s^c g_s^i ds.$$

Similarly to Proposition 11, this proposition shows that for the country undertaking the stimulus, the effects on private spending on domestic goods are simply a weighted average of the effect $\int_0^{\infty} \alpha_s^c g_{t+s}^i ds$ that would arise if the country undertaking the stimulus were a closed economy at the zero lower bound, and the effect that arises if the country were a small (infinitesimal) part of a currency union, with weights given by x and $1 - x$, where x is the relative size of the country undertaking the stimulus.

In contrast to the inflation targeting case, when the zero lower bound binds, an increase in government spending by regions $i \in [0, x]$ increases the demand for the goods of regions $-i \in (x, 1]$. This is natural since we now have a general expansion in private demand because inflation reduces real interest rates.[u]

11. CONCLUSION

We have explored the economic response to changes in government spending in a few benchmark models. Relative to the existing literature, our contribution is to characterize the dynamics of these responses analytically in some detail, rather than summarizing the effects in a single "summary multiplier." We have done so by defining the multipliers to be the partial derivative of private spending at any point in time, to public spending at any other date. We have also attempted to be relatively exhaustive in incorporating various elements that are important, but sometimes missing in standard analyses. In particular, we considered both closed and open economies and incorporated hand-to-mouth agents in both these frameworks. Most importantly, our analysis is the first to emphasize different forms of financing for the government spending shock, including tax-financed, deficit-financed, and outside-financed. It is our hope that our approach and analysis will prove useful in interpreting and unifying the large theoretical and empirical research on fiscal multipliers.

[u] These findings on the spillover effects of fiscal policy complement the results in Cook and Devereux (2011) who focus on different configurations than us: they show that the spillover effects of fiscal policy at home on foreign when home is in a liquidity trap are negative with flexible exchange rates, but positive with fixed exchange rates. In this section, we focus on fixed exchange rates in a currency union and show how these spillover effects switch signs depending on whether the union is in a liquidity trap or targets inflation.

APPENDICES

Appendix A

This appendix derives the linear systems of equations to be solved for in order to derive fiscal multipliers in the following cases: liquidity trap; currency union with either complete markets (CM), incomplete markets (IM), and outside-financed government spending (PF). Appendix B then solves these systems equations to derive fiscal multipliers.

In both appendices, the general case with an arbitrary fraction χ of hand-to-mouth agents and with arbitrary profit offset o is derived first, followed by two special cases: no hand-to-mouth agents $\chi = 0$ (as in Sections 1–6) and no profit offset $o = 0$ (as in Sections 1–8).

Compared to the main text, the environment is generalized by allowing hand-to-mouth agents to receive a profit offset which redistributes a share of profits $o \in [0, 1]$ to hand-to-mouth agents:

$$P_t C_t^r = W_t N_t^r + \frac{o}{\chi}\Pi_t - P_t \underline{T}_t^r,$$

with

$$\begin{aligned} P_t \underline{T}_t^r &= P_t T_t^r - \frac{o}{\chi}\Pi_t, \\ \Pi_t &= P_{H,t} Y_t - w_t N_t. \end{aligned}$$

A.1 Liquidity Trap

Assume that $c_t^* = 0, i_t^* = \bar{r}_t$ for all $t \geq 0$. The log-linearized equations are

$$\begin{aligned} \dot{c}_t^o &= (1-\mathcal{G})\sigma^{-1}(i_t - \bar{r}_t - \pi_t), \\ c_t^r &= \frac{WN^r}{Y}\left(w_t + n_t^r\right) - \underline{t}_t^r, \\ w_t &= \frac{\sigma}{1-\mathcal{G}} c_t^r + \phi n_t^r, \\ w_t &= \frac{\sigma}{1-\mathcal{G}} c_t + \phi n_t, \\ c_t &= \chi c_t^r + (1-\chi) c_t^o, \\ n_t &= \chi n_t^r + (1-\chi) n_t^o, \\ \dot{\pi}_t &= \rho \pi_t - \kappa[c_t + (1-\xi) g_t], \\ \underline{t}_t^r &= t_t^r - o\left[\left(1 - \frac{1}{\mu}\right) n_t - \frac{1}{\mu} w_t\right], \end{aligned}$$

where w_t denotes real wages and μ is the steady state markup, with $\lambda = \rho_\delta(\rho + \rho_\delta), \kappa = \lambda(\hat{\sigma} + \phi), \xi = \dfrac{\hat{\sigma}}{\hat{\sigma} + \phi}$.

Combining and rearranging, we get

$$n_t^r = \phi^{-1}\left(w_t - \frac{\sigma}{1-\mathcal{G}}c_t^r\right),$$

$$c_t^r = \frac{WN^r}{Y}\left[\left(1+\phi^{-1}\right)\left(\frac{\sigma}{1-\mathcal{G}}c_t + \phi n_t\right) - \phi^{-1}\frac{\sigma}{1-\mathcal{G}}c_t^r\right] - \underline{t}_t^r,$$

$$c_t^r = \frac{\frac{WN^r}{Y}\left(1+\phi^{-1}\right)\left(\frac{\sigma}{1-\mathcal{G}}c_t + \phi n_t\right) - \underline{t}_t^r}{1+\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}},$$

$$c_t\left[\frac{1-\chi\frac{WN^r}{Y}\frac{\sigma}{1-\mathcal{G}} + (1-\chi)\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}}{1+\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}}\right] = \chi\frac{\frac{WN^r}{Y}\left(1+\phi^{-1}\right)\phi n_t - \underline{t}_t^r}{1+\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}} + (1-\chi)c_t^o,$$

$$c_t = \chi\frac{\frac{WN^r}{Y}\left(1+\phi^{-1}\right)\phi n_t - \underline{t}_t^r}{1-\chi\frac{WN^r}{Y}\frac{\sigma}{1-\mathcal{G}} + (1-\chi)\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}} + (1-\chi)\frac{1+\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}}{1-\chi\frac{WN^r}{Y}\frac{\sigma}{1-\mathcal{G}} + (1-\chi)\phi^{-1}\frac{\sigma}{1-\mathcal{G}}\frac{WN^r}{Y}}c_t^o,$$

$$c_t = \chi\frac{\phi(1+\phi)n_t - \frac{Y}{WN^r}\phi\underline{t}_t^r}{\frac{Y}{WN^r}\phi - \chi\frac{\sigma}{1-\mathcal{G}}\phi + (1-\chi)\frac{\sigma}{1-\mathcal{G}}} + (1-\chi)\frac{\frac{Y}{WN^r}\phi + \frac{\sigma}{1-\mathcal{G}}}{\frac{Y}{WN^r}\phi - \chi\frac{\sigma}{1-\mathcal{G}}\phi + (1-\chi)\frac{\sigma}{1-\mathcal{G}}}c_t^o,$$

$$c_t = \chi(1-\mathcal{G})\frac{\phi(1+\phi)n_t - \mu\phi\underline{t}_t^r}{(1-\mathcal{G})\mu\phi + \sigma - \chi\sigma(1+\phi)} + (1-\chi)\frac{(1-\mathcal{G})\mu\phi + \sigma}{(1-\mathcal{G})\mu\phi + \sigma - \chi\sigma(1+\phi)}c_t^o,$$

and finally

$$c_t = \Theta_n n_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1}\sigma\frac{1}{1-\mathcal{G}}c_t^o,$$

where

$$\bar{\sigma}^{-1} = \sigma^{-1}(1-\chi)(1-\mathcal{G})\frac{(1-\mathcal{G})\mu\phi + \sigma}{\phi(1-\mathcal{G})\mu + \sigma - \chi\sigma(1+\phi)},$$

$$\Theta_n = \chi(1-\mathcal{G})\frac{(1+\phi)\phi}{\phi(1-\mathcal{G})\mu + \sigma - \chi\sigma(1+\phi)},$$

$$\Theta_\tau = \chi(1-\mathcal{G})\frac{\mu\phi}{\phi(1-\mathcal{G})\mu + \sigma - \chi\sigma(1+\phi)},$$

Differentiating, we get

$$c_t = \Theta_n \dot{n}_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1}(i_t - \bar{r}_t - \pi_t),$$

and using $\dot{n}_t = \dot{c}_t + \dot{g}_t$, we find the Euler equation

$$\dot{c}_t = \tilde{\sigma}^{-1}(i_t - \bar{r}_t - \pi_t) + \tilde{\Theta}_n \dot{g}_t - \tilde{\Theta}_\tau \underline{t}_t^r,$$

where

$$\tilde{\sigma}^{-1} = \frac{\bar{\sigma}^{-1}}{1 - \Theta_n},$$

$$\tilde{\Theta}_n = \frac{\Theta_n}{1 - \Theta_n},$$

$$\tilde{\Theta}_\tau = \frac{\Theta_\tau}{1 - \Theta_n}.$$

By definition of t_t^r and using the expression for the wage,

$$\underline{t}_t^r = t_t^r - \frac{o}{\chi}\left[\left(1 - \frac{1}{\mu}\right)(c_t + g_t) - \frac{1}{\mu}\left[\frac{\sigma}{1 - \mathcal{G}} c_t + \phi(c_t + g_t)\right]\right].$$

Thus,

$$\underline{t}_t^r = t_t^r + \psi_c c_t + \psi_n g_t,$$

where

$$\psi_c = -\frac{o}{\chi}\left[1 - \frac{1}{\mu}\left(\frac{\sigma}{1 - \mathcal{G}} + (1 + \phi)\right)\right],$$

$$\psi_n = -\frac{o}{\chi}\left[1 - \frac{1}{\mu}(1 + \phi)\right].$$

Using the Euler equation and the expression for t_t^r, we get

$$[1 - \Theta_n + \Theta_\tau \psi_c]\dot{c}_t = -\bar{\sigma}^{-1}\pi_t + [\Theta_n - \Theta_\tau \psi_n]\dot{g}_t - \Theta_\tau \dot{t}_t^r.$$

Thus,

$$\dot{c}_t = -\underline{\tilde{\sigma}}^{-1}\pi_t + \underline{\tilde{\Theta}}_n \dot{g}_t - \underline{\tilde{\Theta}}_\tau \dot{t}_t^r,$$

where

$$\underline{\tilde{\sigma}}^{-1} = \frac{1}{\underline{\tilde{\Theta}}_c}\bar{\sigma}^{-1},$$

$$\underline{\tilde{\Theta}}_n = \frac{1}{\underline{\tilde{\Theta}}_c}[\Theta_n - \Theta_\tau \psi_n],$$

$$\underline{\tilde{\Theta}}_\tau = \frac{1}{\underline{\tilde{\Theta}}_c}\Theta_\tau,$$

$$\underline{\tilde{\Theta}}_c = 1 - \Theta_n + \Theta_\tau \psi_c.$$

Special case: no hand-to-mouth agents $\chi = 0$

The log-linear system is

$$\begin{aligned}\dot{c}_t &= -\hat{\sigma}^{-1}\pi_t,\\ \dot{\pi}_t &= \rho\pi_t - \kappa[c_t + (1-\xi)g_t],\end{aligned}$$

for all $t \geq 0$.

Special case: no profit offset $o = 0$

The log-linear system is

$$\begin{aligned}\dot{c}_t &= -\widetilde{\sigma}^{-1}\pi_t + \widetilde{\Theta}_n\dot{g}_t - \widetilde{\Theta}_\tau\dot{t}^r_t,\\ \dot{\pi}_t &= \rho\pi_t - \kappa[c_t + (1-\xi)g_t].\end{aligned}$$

for all $t \geq 0$.

A.2 Currency Union

Assume that $c^*_t = 0, i^*_t = \bar{r}_t$ for all $t \geq 0$. The log-linearized equations are

$$c^o_t = (1-\mathcal{G})\theta + \frac{(1-\alpha)(1-\mathcal{G})}{\sigma}s_t,$$

$$y_t = (1-\alpha)\hat{c}_t + (1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]s_t + g_t,$$

$$y_t = n_t,$$

$$\dot{c}^o_t = -(1-\mathcal{G})\sigma^{-1}(\pi_{H,t} + \alpha\dot{s}_t),$$

$$c^r_t = \frac{1}{\mu}\left(w_t + n^r_t\right) - \underline{t}^r_t,$$

$$w_t = \frac{\sigma}{1-\mathcal{G}}c^r_t + \phi n^r_t,$$

$$w_t = \frac{\sigma}{1-\mathcal{G}}\hat{c}_t + \phi n_t,$$

$$\hat{c}_t = \chi c^r_t + (1-\chi)c^o_t,$$

$$n_t = \chi n^r_t + (1-\chi)n^o_t,$$

$$\dot{\pi}_{H,t} = \rho\pi_{H,t} - \lambda(w_t + \alpha s_t),$$

$$\int_0^{+\infty} e^{-\rho t} nx_t dt = -\mathrm{nfa}_0,$$

$$\underline{t}^r_t = t^r_t - \frac{o}{\chi}\left[\left(1-\frac{1}{\mu}\right)n_t + \alpha p_{H,t} - \frac{1}{\mu}w_t\right],$$

with $\mathrm{nfa}_0 = 0$ in the IM case and $\mathrm{nfa}_0 = \int_0^{+\infty} e^{-\rho t}g_t dt$ in the PF case, where $\omega = \sigma\gamma + (1-\alpha)(\sigma\eta - 1)$. Note that we have denoted total consumption of home agents by $\hat{c}_t$ to avoid a confusion with c_t, the total consumption of home goods by private agents (both home and foreign).

Using the expressions for the wage, aggregate consumption, and labor,

$$\hat{c}_t = \Theta_n n_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} c_t^o,$$

where Θ_n, Θ_τ, and $\bar{\sigma}$ have been defined above. Differentiating the Backus–Smith condition, we get (we could have gotten this equation directly from the definition of s_t)

$$\dot{s}_t = -\pi_{H,t}.$$

Now we can get to an equation involving total (home + foreign) consumption of the domestic good $c_t = y_t - g_t$ which yields

$$c_t = (1-\alpha)\hat{c}_t + (1-\mathcal{G})\alpha \left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma} \right] s_t.$$

Differentiating, we get

$$\dot{c}_t = (1-\alpha)\dot{\hat{c}}_t + (1-\mathcal{G})\alpha \left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma} \right] \dot{s}_t,$$

then combining with the equation for $\hat{c}_t$,

$$\dot{c}_t = (1-\alpha) \left[\Theta_n \dot{n}_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} \dot{c}_t^o \right] + (1-\mathcal{G})\alpha \left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma} \right] \dot{s}_t,$$

and replacing $n_t = c_t + g_t$,

$$\dot{c}_t = (1-\alpha) \left[\Theta_n (\dot{c}_t + \dot{g}_t) - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} \dot{c}_t^o \right] + (1-\mathcal{G})\alpha \left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma} \right] \dot{s}_t,$$

and rearranging

$$\dot{c}_t = \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \underline{t}_t^r + \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n} \sigma \frac{1}{1-\mathcal{G}} \dot{c}_t^o + \frac{1}{1-(1-\alpha)\Theta_n} \frac{\alpha(1-\mathcal{G})(\omega+1-\alpha)}{\sigma} \dot{s}_t,$$

where

$$\widetilde{\Theta}_n = \frac{(1-\alpha)\Theta_n}{1-(1-\alpha)\Theta_n},$$

$$\widetilde{\Theta}_\tau = \frac{(1-\alpha)\Theta_\tau}{1-(1-\alpha)\Theta_n},$$

then using the Euler equation for optimizers

$$\dot{c}_t = \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \dot{\underline{t}}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n} [\pi_{H,t} + \alpha \dot{s}_t] + \frac{1}{1-(1-\alpha)\Theta_n} \frac{\alpha(1-\mathcal{G})(\omega+1-\alpha)}{\sigma} \dot{s}_t,$$

and finally combining with the expression for $\dot{s}_t = -\pi_{H,t}$

$$\dot{c}_t = \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \dot{\underline{t}}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}[(1-\alpha)\pi_{H,t}]$$
$$-\frac{1}{1-(1-\alpha)\Theta_n}\frac{\alpha(1-\mathcal{G})(\omega+1-\alpha)}{\sigma}\dot{\pi}_{H,t},$$

which we can rewrite as

$$\dot{c}_t = \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \dot{\underline{t}}_t^r - \frac{\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\left[(1-\alpha)^2 + \alpha\frac{\bar{\sigma}}{\sigma}(1-\mathcal{G})(\omega+1-\alpha)\right]\dot{\pi}_{H,t},$$
$$\dot{c}_t = \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \dot{\underline{t}}_t^r - \widetilde{\sigma}^{-1}\pi_{H,t},$$

where

$$\widetilde{\sigma}^{-1} = \frac{\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\left[(1-\alpha)^2 + \alpha\frac{\bar{\sigma}}{\sigma}(1-\mathcal{G})(\omega+1-\alpha)\right].$$

This is our Euler equation.[v]

To derive an initial condition, we use

$$c_t = (1-\alpha)\hat{c}_t + (1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]s_t,$$
$$\hat{c}_t = \Theta_n n_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1}\sigma\frac{1}{1-\mathcal{G}}c_t^o,$$
$$c_t^o = (1-\mathcal{G})\theta + \frac{(1-\alpha)(1-\mathcal{G})}{\sigma}s_t,$$

and

$$n_t = c_t + g_t,$$

to get

$$c_t = \widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau \underline{t}_t^r + \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}\left((1-\mathcal{G})\theta + \frac{(1-\alpha)(1-\mathcal{G})}{\sigma}s_t\right)$$
$$+\frac{(1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}s_t,$$

and apply it at $t=0$ with $s_0 = 0$ to get

[v] We can check that when there are no hand-to-mouth consumers, this boils down to

$$\dot{c}_t = -\sigma^{-1}(1-\mathcal{G})[1+\alpha(\omega-1)]\pi_t,$$

which is exactly the expression that we found.

$$c_0 = \widetilde{\Theta}_n g_0 - \widetilde{\Theta}_\tau \underline{t}_0^r + \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n} \sigma \frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta.$$

Hence with complete markets, this boils down to the simple condition

$$c_0 = \widetilde{\Theta}_n g_0 - \widetilde{\Theta}_\tau \underline{t}_0^r.$$

Finally we need to compute

$$mc_t = w_t + p_t - p_{H,t} = w_t + \alpha s_t,$$

We have

$$w_t = \frac{\sigma}{1-\mathcal{G}} \hat{c}_t + \phi n_t,$$
$$w_t = \frac{\sigma}{1-\mathcal{G}} \hat{c}_t + \phi (c_t + g_t),$$

which using

$$\hat{c}_t = \Theta_n n_t - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} c_t^o,$$

we can rewrite as

$$w_t = \frac{\sigma}{1-\mathcal{G}} \left(\Theta_n (c_t + g_t) - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} c_t^o \right) + \phi (c_t + g_t),$$
$$w_t = \frac{\sigma}{1-\mathcal{G}} \left[\Theta_n (c_t + g_t) - \Theta_\tau \underline{t}_t^r + \bar{\sigma}^{-1} \sigma \frac{1}{1-\mathcal{G}} \left((1-\mathcal{G})\theta + \frac{(1-\alpha)(1-\mathcal{G})}{\sigma} s_t \right) \right] + \phi (c_t + g_t),$$

so that

$$\begin{aligned} w_t + \alpha s_t = {} & \left(\frac{\sigma \Theta_n}{1-\mathcal{G}} + \phi \right) (c_t + g_t) - \frac{\sigma}{1-\mathcal{G}} \Theta_\tau \underline{t}_t^r + \left(\frac{\sigma}{1-\mathcal{G}} \right)^2 \bar{\sigma}^{-1} (1-\mathcal{G})\theta \\ & + \left[\alpha + \left(\frac{\sigma}{1-\mathcal{G}} \right)^2 \bar{\sigma}^{-1} \frac{(1-\alpha)(1-\mathcal{G})}{\sigma} \right] s_t, \end{aligned}$$

which using

$$\begin{aligned} c_t = {} & \widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau \underline{t}_t^r + \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n} \sigma \frac{1}{1-\mathcal{G}} (1-\mathcal{G})\theta \\ & + \left[\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n} \sigma \frac{1}{1-\mathcal{G}} \frac{(1-\alpha)(1-\mathcal{G})}{\sigma} + \frac{(1-\mathcal{G})\alpha \left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma} \right]}{1-(1-\alpha)\Theta_n} \right] s_t, \end{aligned}$$

i.e.

$$s_t = \frac{c_t - \widetilde{\Theta}_n g_t + \widetilde{\Theta}_\tau \underline{t}_t^r - \dfrac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\dfrac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta}{\dfrac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\dfrac{1}{1-\mathcal{G}}\dfrac{(1-\alpha)(1-\mathcal{G})}{\sigma} + \dfrac{(1-\mathcal{G})\alpha\left[\dfrac{\omega}{\sigma}+\dfrac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}},$$

we can rewrite as

$$\begin{aligned} w_t + \alpha s_t = {} & \left(\frac{\sigma\Theta_n}{1-\mathcal{G}} + \phi\right)(c_t + g_t) - \frac{\sigma}{1-\mathcal{G}}\Theta_\tau \underline{t}_t^r + \left(\frac{\sigma}{1-\mathcal{G}}\right)^2 \bar{\sigma}^{-1}(1-\mathcal{G})\theta \\ & + \frac{\alpha + \dfrac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\dfrac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \dfrac{(1-\mathcal{G})\alpha\left[\dfrac{\omega}{\sigma}+\dfrac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}} \\ & \times \left[c_t - \widetilde{\Theta}_n g_t + \widetilde{\Theta}_\tau \underline{t}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta\right], \end{aligned}$$

$$\begin{aligned} w_t + \alpha s_t = {} & \left(\frac{\sigma\Theta_n}{1-\mathcal{G}} + \phi\right)(c_t + g_t) - \frac{\sigma}{1-\mathcal{G}}\Theta_\tau \underline{t}_t^r + \left(\frac{\sigma}{1-\mathcal{G}}\right)^2 \bar{\sigma}^{-1}(1-\mathcal{G})\theta \\ & + \frac{\alpha + \dfrac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\dfrac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \dfrac{(1-\mathcal{G})\alpha\left[\dfrac{\omega}{\sigma}+\dfrac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}} \\ & \times \left[c_t - \widetilde{\Theta}_n g_t + \widetilde{\Theta}_\tau \underline{t}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta\right]. \end{aligned}$$

We can then replace this expression in to get the New Keynesian Phillips Curve

$$\dot{\pi}_{H,t} = \rho\pi_{H,t} - \lambda(w_t + \alpha s_t).$$

The system is summarized by

$$\begin{aligned} \dot{c}_t &= \widetilde{\Theta}_n \dot{g}_t - \widetilde{\Theta}_\tau \underline{t}_t^r - \widetilde{\sigma}^{-1}\pi_{H,t}, \\ \dot{\pi}_{H,t} &= \rho\pi_{H,t} - \lambda(w_t + \alpha s_t), \\ c_0 &= \widetilde{\Theta}_n g_0 - \widetilde{\Theta}_\tau \underline{t}_0^r + \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta, \end{aligned}$$

and the nfa condition, where

$$
\begin{aligned}
w_t + \alpha s_t = {} & \left(\frac{\sigma\Theta_n}{1-\mathcal{G}} + \phi\right)(c_t + g_t) - \frac{\sigma}{1-\mathcal{G}}\Theta_\tau \underline{t}_t^r + \left(\frac{\sigma}{1-\mathcal{G}}\right)^2 \bar{\sigma}^{-1}(1-\mathcal{G})\theta \\
& + \frac{\alpha + \frac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \frac{(1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}} \\
& \times \left[c_t - \widetilde{\Theta}_n g_t + \widetilde{\Theta}_\tau \underline{t}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta\right].
\end{aligned}
$$

Define $\widetilde{\kappa}$ by

$$
\widetilde{\kappa} = \lambda\left[\frac{\sigma\Theta_n}{1-\mathcal{G}} + \phi + \frac{\alpha + \frac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \frac{(1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}}\right].
$$

Define $\widetilde{\xi}$ by

$$
\widetilde{\kappa}\left(1-\widetilde{\xi}\right) = \lambda\left[\frac{\sigma\Theta_n}{1-\mathcal{G}} + \phi - \frac{\alpha + \frac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \frac{(1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}}\widetilde{\Theta}_n\right].
$$

Define $\widetilde{\alpha}$ by

$$
\widetilde{\alpha} = 1 - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}.
$$

Define $\widetilde{\omega}$ by

$$
\begin{aligned}
\widetilde{\omega} = {} & \frac{1}{(1-\mathcal{G})\widetilde{\sigma}\widetilde{\alpha}} \\
& \times\left[\left(\frac{\sigma}{1-\mathcal{G}}\right)^2\bar{\sigma}^{-1}(1-\mathcal{G}) - \frac{\alpha + \frac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \frac{(1-\mathcal{G})\alpha\left(\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right)}{1-(1-\alpha)\Theta_n}}\frac{(1-\alpha)\bar{\sigma}^{-1}\sigma}{1-(1-\alpha)\Theta_n}\right].
\end{aligned}
$$

Define $\widetilde{\widetilde{\Theta}}_\tau$ by

$$\widetilde{\widetilde{\Theta}}_\tau = \frac{\lambda}{\widetilde{\widetilde{\kappa}}}\left[-\frac{\sigma}{1-\mathcal{G}}\Theta_\tau + \frac{\alpha + \dfrac{\sigma}{1-\mathcal{G}}\bar{\sigma}^{-1}(1-\alpha)}{\dfrac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}(1-\alpha) + \dfrac{(1-\mathcal{G})\alpha\left[\dfrac{\omega}{\sigma} + \dfrac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}}\widetilde{\Theta}_\tau\right].$$

Define Γ_1 by

$$\Gamma_1 = (1-\alpha)^2\bar{\sigma}^{-1} + (1-\mathcal{G})\alpha\left(\frac{\omega}{\sigma} + \frac{1-\alpha}{\sigma}\right),$$

Then we can rewrite the system as

$$\begin{aligned}
\dot{\pi}_{H,t} &= \rho\pi_{H,t} - \widetilde{\kappa}\left(c_t + \left(1-\widetilde{\xi}\right)g_t\right) - (1-\mathcal{G})\lambda\widetilde{\sigma}\widetilde{\alpha}\widetilde{\omega}\theta - \widetilde{\kappa}\widetilde{\widetilde{\Theta}}_\tau \underline{t}_t^r,\\
\dot{c}_t &= -\widetilde{\sigma}^{-1}\pi_{H,t} + \widetilde{\Theta}_n\dot{g}_t - \widetilde{\Theta}_\tau\dot{\underline{t}}_t^r,
\end{aligned}$$

with an initial condition

$$c_0 = (1-\mathcal{G})(1-\widetilde{\alpha})\theta + \widetilde{\Theta}_n g_0 - \widetilde{\Theta}_\tau \underline{t}_0^r,$$

and the nfa condition.

For net exports we get

$$\begin{aligned}
nx_t &= -(1-\mathcal{G})\alpha s_t + y_t - \hat{c}_t - g_t,\\
nx_t &= (1-\mathcal{G})\left[\alpha\frac{\omega}{\sigma} + \alpha\frac{1-\alpha}{\sigma} - \alpha\right]s_t - \alpha\hat{c}_t,\\
nx_t &= (1-\mathcal{G})\left[\alpha\frac{\omega}{\sigma} + \alpha\frac{1-\alpha}{\sigma} - \alpha\right]s_t\\
&\quad -\alpha\left[\Theta_n(c_t+g_t) - \Theta_\tau\underline{t}_t^r + \bar{\sigma}^{-1}\sigma\frac{1}{1-\mathcal{G}}c_t^o\right],
\end{aligned}$$

and finally

$$\begin{aligned}
nx_t &= (1-\mathcal{G})\left[\alpha\frac{\omega}{\sigma} + \alpha\frac{1-\alpha}{\sigma} - \alpha\right]s_t\\
&\quad -\alpha\left[\Theta_n(c_t+g_t) - \Theta_\tau\underline{t}_t^r + \bar{\sigma}^{-1}\sigma\frac{1}{1-\mathcal{G}}\left((1-\mathcal{G})\theta + \frac{(1-\alpha)(1-\mathcal{G})}{\sigma}s_t\right)\right],
\end{aligned}$$

where

$$s_t = \frac{c_t - \widetilde{\Theta}_n g_t + \widetilde{\Theta}_\tau \underline{t}_t^r - \frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}(1-\mathcal{G})\theta}{\frac{(1-\alpha)\bar{\sigma}^{-1}}{1-(1-\alpha)\Theta_n}\sigma\frac{1}{1-\mathcal{G}}\frac{(1-\alpha)(1-\mathcal{G})}{\sigma} + \frac{(1-\mathcal{G})\alpha\left[\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right]}{1-(1-\alpha)\Theta_n}}.$$

Using the Euler equation,

$$p_{H,t} = -s_0 - \frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n](c_t - c_0) + \frac{1}{\Gamma_1}(1-\alpha)\Theta_n(g_t - g_0) - (1-\alpha)\frac{1}{\Gamma_1}\Theta_\tau\left(\underline{t}_t^r - \underline{t}_0^r\right).$$

Using the initial condition for consumption,

$$p_{H,t} = -\frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n]c_t + \frac{1}{\Gamma_1}(1-\alpha)\Theta_n g_t - (1-\alpha)\frac{1}{\Gamma_1}\Theta_\tau \underline{t}_t^r + (1-\alpha)\frac{1}{\Gamma_1}\bar{\sigma}^{-1}\sigma\theta,$$

since $s_0 = 0$.

By definition of $\underline{t}_t^r$ and using the expressions for output, for prices and for the real wage,

$$\begin{aligned}\underline{t}_t^r = t_t^r - \frac{o}{\chi}\Bigg[&\left(1-\frac{1}{\mu}\right)(c_t + g_t)\\ &+\alpha\left[-\frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n]c_t + \frac{1}{\Gamma_1}(1-\alpha)\Theta_n g_t - (1-\alpha)\frac{1}{\Gamma_1}\Theta_\tau \underline{t}_t^r + (1-\alpha)\frac{1}{\Gamma_1}\bar{\sigma}^{-1}\sigma\theta\right]\\ &-\frac{1}{\mu}\left[\frac{\sigma}{1-\mathcal{G}}\frac{1}{1-\alpha}\left[c_t - (1-\mathcal{G})\alpha\left(\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right)s_t\right] + \phi n_t\right]\Bigg].\end{aligned}$$

Using the expression for the terms-of-trade,

$$\begin{aligned}\underline{t}_t^r = t_t^r - \frac{o}{\chi}\Bigg[&\left(1-\frac{1}{\mu}\right)(c_t + g_t)\\ &+\alpha\left[-\frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n]c_t + \frac{1}{\Gamma_1}(1-\alpha)\Theta_n g_t - (1-\alpha)\frac{1}{\Gamma_1}\Theta_\tau \underline{t}_t^r + (1-\alpha)\bar{\sigma}^{-1}\sigma\theta\right]\\ &-\frac{1}{\mu}\frac{\sigma}{1-\mathcal{G}}\frac{1}{1-\alpha}c_t\\ &+\frac{1}{\mu}\sigma\frac{\alpha}{1-\alpha}\left(\frac{\omega}{\sigma}-\frac{1-\alpha}{\sigma}\right)\frac{1}{\Gamma_1}\left[[1-(1-\alpha)\Theta_n]c_t - (1-\alpha)\Theta_n g_t + (1-\alpha)\Theta_\tau \underline{t}_t^r - (1-\alpha)\bar{\sigma}^{-1}\sigma\theta\right]\\ &-\frac{1}{\mu}\phi n_t\Bigg].\end{aligned}$$

Thus,

$$\underline{t}_t^r = \psi_\tau t_t^r + \psi_c c_t + \psi_n g_t + \psi_\theta \theta,$$

where

$$\psi_c = -\frac{o}{\chi}\frac{1}{\hat{\psi}_\tau}\left[\left(1-\frac{1}{\mu}\right) - \alpha\frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n] - \frac{1}{\mu}\left[\frac{\sigma}{1-\alpha}\left[\frac{1}{1-\mathcal{G}} - \alpha\left(\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right)\frac{1}{\Gamma_1}[1-(1-\alpha)\Theta_n]\right]+\phi\right]\right],$$

$$\psi_n = -\frac{o}{\chi}\frac{1}{\hat{\psi}_\tau}\left[\left(1-\frac{1}{\mu}\right) + \alpha\frac{1}{\Gamma_1}(1-\alpha)\Theta_n - \frac{1}{\mu}\left[\sigma\alpha\left(\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right)\frac{1}{\Gamma_1}\Theta_n + \phi\right]\right],$$

$$\psi_\theta = -\frac{o}{\chi}\frac{1}{\hat{\psi}_\tau}\left[\alpha\frac{1}{\Gamma_1}(1-\alpha)\bar{\sigma}^{-1}\sigma - \frac{1}{\mu}\sigma\alpha\left(\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right)\frac{1}{\Gamma_1}\bar{\sigma}^{-1}\sigma\right],$$

$$\psi_\tau = \frac{1}{\hat{\psi}_\tau},$$

$$\hat{\psi}_\tau = 1 - \frac{o}{\chi}\left[\alpha\frac{1}{\Gamma_1}(1-\alpha)\Theta_\tau - \frac{1}{\mu}\sigma\alpha\left(\frac{\omega}{\sigma}+\frac{1-\alpha}{\sigma}\right)\frac{1}{\Gamma_1}\Theta_\tau\right].$$

Using the Euler equation and the expression for $\underline{t}_t^r$,

$$[1-(1-\alpha)\Theta_n + (1-\alpha)\Theta_\tau\psi_c]\dot{c}_t = \Gamma_1\pi_{H,t} + (1-\alpha)[\Theta_n - \Theta_\tau\psi_n]\dot{g}_t - (1-\alpha)\Theta_\tau\psi_\tau t_t^r.$$

Thus,

$$\dot{c}_t = -\underline{\widetilde{\sigma}}^{-1}\pi_{H,t} + \underline{\widetilde{\Theta}}_n\dot{g}_t - \underline{\widetilde{\Theta}}_\tau\dot{t}_t^r,$$

where

$$\begin{aligned}
\underline{\widetilde{\sigma}}^{-1} &= \frac{1}{\underline{\widetilde{\Theta}}_c}\,\Gamma_1,\\
\underline{\widetilde{\Theta}}_n &= (1-\alpha)\frac{1}{\underline{\widetilde{\Theta}}_c}\,[\Theta_n - \Theta_\tau\psi_n],\\
\underline{\widetilde{\Theta}}_\tau &= (1-\alpha)\frac{1}{\underline{\widetilde{\Theta}}_c}\,\Theta_\tau\psi_\tau,\\
\underline{\widetilde{\Theta}}_c &= 1-(1-\alpha)\Theta_n + (1-\alpha)\Theta_\tau\psi_c.
\end{aligned}$$

Using the New Keynesian Phillips Curve and the expression for $\underline{t}_t^r$,

$$\dot{\pi}_{H,t} = \rho\pi_{H,t} - \widetilde{\kappa}\left[c_t + \left(1-\widetilde{\xi}\right)g_t\right] - (1-\mathcal{G})\lambda\widetilde{\sigma}\widetilde{\alpha}\widetilde{\omega}\theta - \widetilde{\kappa}\widetilde{\widetilde{\Theta}}_\tau\left[\psi_\tau t_t^r + \psi_c c_t + \psi_n g_t + \psi_\theta\theta\right].$$

Thus,

$$\dot{\pi}_{H,t} = \rho\pi_{H,t} - \underline{\widetilde{\kappa}}_c c_t - \underline{\widetilde{\kappa}}_n g_t - \underline{\widetilde{\kappa}}_\theta\theta - \underline{\widetilde{\kappa}}_\tau t_t^r,$$

where

$$\underline{\widetilde{\kappa}}_c = \widetilde{\kappa}\left(1 + \widetilde{\widetilde{\widetilde{\Theta}}}_\tau \psi_c\right),$$

$$\underline{\widetilde{\kappa}}_n = \widetilde{\kappa}\left(1 - \widetilde{\xi} + \widetilde{\widetilde{\widetilde{\Theta}}}_\tau \psi_n\right),$$

$$\underline{\widetilde{\kappa}}_\theta = (1 - \mathcal{G})\lambda\widetilde{\sigma}\widetilde{\alpha}\widetilde{\omega} + \widetilde{\kappa}\widetilde{\widetilde{\widetilde{\Theta}}}_\tau \psi_\theta,$$

$$\underline{\widetilde{\kappa}}_\tau = \widetilde{\kappa}\widetilde{\widetilde{\widetilde{\Theta}}}_\tau \psi_\tau.$$

Using the initial condition for consumption and the expression for $\underline{t}_t^r$,

$$c_0 = \Upsilon\theta + \underline{\widetilde{\Theta}}_n g_0 - \underline{\widetilde{\Theta}}_\tau t_0^r,$$

where

$$\Upsilon = \frac{1}{\underline{\widetilde{\widetilde{\Theta}}}_c}\left[(1 - \mathcal{G})(1 - \widetilde{\alpha})[1 - (1 - \alpha)\Theta_n] - (1 - \alpha)\Theta_\tau \psi_\theta\right].$$

Using the expressions for net exports and for $\underline{t}_t^r$,

$$nx_t = \alpha(1 - \mathcal{G})\left[\frac{1}{1 - \alpha}\left(\frac{\omega}{\sigma} + \frac{1 - \alpha}{\sigma}\right) - 1\right]s_t - \frac{\alpha}{1 - \alpha}c_t.$$

Using the expression for the terms-of-trade,

$$\begin{aligned} nx_t = {} & \alpha(1 - \mathcal{G})\left[\frac{1}{1 - \alpha}\left(\frac{\omega}{\sigma} + \frac{1 - \alpha}{\sigma}\right) - 1\right] \\ & \times \frac{1}{\Gamma_1}\left[[1 - (1 - \alpha)\Theta_n]c_t - (1 - \alpha)\Theta_n g_t + (1 - \alpha)\Theta_\tau \underline{t}_t^r - (1 - \alpha)\bar{\sigma}^{-1}\sigma\theta\right] \\ & - \frac{\alpha}{1 - \alpha}c_t. \end{aligned}$$

Thus,

$$\begin{aligned} nx_t = {} & \Omega_c c_t - (1 - \mathcal{G})\frac{\Gamma_2}{\Gamma_1} \\ & \times \left[[(1 - \alpha)\Theta_n - (1 - \alpha)\Theta_\tau \psi_n]g_t - (1 - \alpha)\Theta_\tau \psi_\tau t_t^r + \left[(1 - \alpha)\bar{\sigma}^{-1}\sigma - (1 - \alpha)\Theta_\tau \psi_\theta\right]\theta\right], \end{aligned}$$

where

$$\begin{aligned} \Omega_c &= (1 - \mathcal{G})\frac{\Gamma_2}{\Gamma_1}[1 - (1 - \alpha)\Theta_n + (1 - \alpha)\Theta_\tau \psi_c] - \frac{\alpha}{1 - \alpha}, \\ \Gamma_2 &= \alpha\left[\frac{1}{1 - \alpha}\left(\frac{\omega}{\sigma} + \frac{1 - \alpha}{\sigma}\right) - 1\right]. \end{aligned}$$

Using the expressions for the Pareto weight and for net exports,

$$\theta = \int_0^{+\infty} e^{-\rho s}\left[\widetilde{\boldsymbol{\Omega}}_c c_s + \widetilde{\boldsymbol{\Omega}}_n g_s + \widetilde{\boldsymbol{\Omega}}_\tau t_s^r\right] ds + \widetilde{\boldsymbol{\Omega}}_f \mathrm{nfa}_0,$$

where

$$\begin{aligned}
\widetilde{\boldsymbol{\Omega}}_c &= \rho \frac{\Gamma_1}{\Gamma_2}\frac{\boldsymbol{\Omega}_c}{1-\mathcal{G}}\frac{1}{(1-\alpha)\bar{\sigma}^{-1}\sigma - \Theta_\tau \Psi_\theta},\\
\widetilde{\boldsymbol{\Omega}}_n &= -\rho \frac{(1-\alpha)\Theta_n - (1-\alpha)\Theta_\tau \Psi_n}{(1-\alpha)\bar{\sigma}^{-1}\sigma - \Theta_\tau \Psi_\theta},\\
\widetilde{\boldsymbol{\Omega}}_\tau &= \rho \frac{(1-\alpha)\Theta_\tau \Psi_\tau}{(1-\alpha)\bar{\sigma}^{-1}\sigma - \Theta_\tau \Psi_\theta},\\
\widetilde{\boldsymbol{\Omega}}_f &= \rho \frac{\Gamma_1}{\Gamma_2}\frac{1}{1-\mathcal{G}}\frac{1}{(1-\alpha)\bar{\sigma}^{-1}\sigma - \Theta_\tau \Psi_\theta}.
\end{aligned}$$

Special case: no hand-to-mouth agents $\chi = 0$

The log-linear system is

$$\begin{aligned}
\dot{c}_t &= -\hat{\sigma}^{-1}\pi_{H,t},\\
\dot{\pi}_{H,t} &= \rho \pi_{H,t} - \kappa[c_t + (1-\xi)g_t] - (1-\mathcal{G})\lambda \hat{\sigma}\alpha\omega\theta,
\end{aligned}$$

for all $t \geq 0$, with

$$c_0 = (1-\mathcal{G})(1-\alpha)\theta$$

And

$$\theta = \int_0^{+\infty} e^{-\rho s}\rho(1-\mathcal{G})\frac{\omega - \sigma}{\omega + (1-\alpha)(1-\sigma)} c_s ds + \rho \frac{1}{\alpha}\frac{\alpha\omega + 1 - \alpha}{\omega + (1-\alpha)(1-\sigma)}\frac{1}{1-\mathcal{G}}\mathrm{nfa}_0,$$

where $\kappa = \lambda[\phi + \hat{\sigma}]$, $\xi = \dfrac{\hat{\sigma}}{\phi + \hat{\sigma}}$, $\hat{\sigma} = \dfrac{\sigma}{1-\mathcal{G}}\dfrac{1}{(1-\alpha)+\alpha\omega}$.

Special case: no profit offset $o = 0$

The log-linear system is

$$\begin{aligned}
\dot{c}_t &= -\widetilde{\sigma}^{-1}\pi_{H,t} + \widetilde{\boldsymbol{\Theta}}_n \dot{g}_t - \widetilde{\boldsymbol{\Theta}}_\tau \dot{t}_t^r,\\
\dot{\pi}_{H,t} &= \rho \pi_{H,t} - \widetilde{\kappa}\left[c_t + \left(1 - \widetilde{\xi}\right)g_t\right] - (1-\mathcal{G})\lambda \widetilde{\sigma}\widetilde{\alpha}\widetilde{\omega}\theta - \widetilde{\kappa}\widetilde{\widetilde{\boldsymbol{\Theta}}}_\tau t_t^r,
\end{aligned}$$

for all $t \geq 0$, with

$$c_0 = \frac{1}{1-\boldsymbol{\Theta}_n}[(1-\mathcal{G})(1-\widetilde{\alpha})[1-(1-\alpha)\boldsymbol{\Theta}_n]]\theta + \widetilde{\boldsymbol{\Theta}}_n g_0 - \widetilde{\boldsymbol{\Theta}}_\tau t_0^r$$

and

$$\theta = \int_0^{+\infty} e^{-\rho s} \left[\rho \frac{\Gamma_1}{\Gamma_2} \frac{(1-\mathcal{G})\frac{\Gamma_2}{\Gamma_1}[1-(1-\alpha)\Theta_n] - \frac{\alpha}{1-\alpha}}{1-\mathcal{G}} \frac{1}{(1-\alpha)\bar{\sigma}^{-1}\sigma} c_s - \rho \frac{\Theta_n}{\bar{\sigma}^{-1}\sigma} g_s + \rho \frac{\Theta_\tau}{\bar{\sigma}^{-1}\sigma} t_s^r \right] ds$$
$$+ \rho \frac{\Gamma_1}{\Gamma_2} \frac{1}{1-\mathcal{G}} \frac{1}{(1-\alpha)\bar{\sigma}^{-1}\sigma} \mathrm{nfa}_0.$$

Appendix B

This appendix derives the solutions to the linear systems obtained in Appendix A. The same special cases are considered.

B.1 Liquidity Trap

Define

$$\widetilde{\nu} = \frac{\rho - \sqrt{\rho^2 + 4\kappa \underline{\widetilde{\sigma}}^{-1}}}{2}, \quad \widetilde{\overline{\nu}} = \frac{\rho + \sqrt{\rho^2 + 4\kappa \underline{\widetilde{\sigma}}^{-1}}}{2}.$$

The equilibrium is completely characterized by the following:

$$\dot{X}_t = A X_t + B_t,$$

where

$$X_t = [\pi_t, c_t]^t, \quad A = \begin{bmatrix} \rho & -\kappa \\ -\underline{\widetilde{\sigma}}^{-1} & 0 \end{bmatrix}, \quad B_t = -\kappa(1-\xi) g_t E_1 + \left[\underline{\widetilde{\Theta}}_n \dot{g}_t - \underline{\widetilde{\Theta}}_\tau \dot{t}_t^r \right] E_2,$$

for all $t \geq 0$.

The (unique) solution that satisfies saddle-path stability writes:

$$X_t = \int_t^{+\infty} \kappa(1-\xi) g_s e^{-A(s-t)} E_1 \, ds - \int_t^{+\infty} \left(\underline{\widetilde{\Theta}}_n \dot{g}_s - \underline{\widetilde{\Theta}}_\tau \dot{t}_s^r \right) e^{-A(s-t)} E_2 \, ds.$$

Equivalently, integrating the relevant objects by part,

$$\begin{aligned} X_t = & \int_t^{+\infty} \kappa(1-\xi) g_s e^{-A(s-t)} E_1 \, ds + \left(\underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r \right) E_2 \\ & - \int_t^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r \right) A e^{-A(s-t)} E_2 \, ds \end{aligned}.$$

Thus,

$$c_t = \int_t^{+\infty} \kappa(1-\xi) E_2^t e^{-A(s-t)} E_1 \, ds + \left(\underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r \right) - \int_t^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r \right) E_2^t A e^{-A(s-t)} E_2 \, ds.$$

Note that

$$E_2^t e^{-At} E_1 = \widetilde{\underline{\sigma}}^{-1} \frac{e^{-\tilde{\nu} t} - e^{-\bar{\tilde{\nu}} t}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} \;,\;\; E_2^t A e^{-At} E_2 = -\kappa(1-\xi)\widetilde{\underline{\sigma}}^{-1} \frac{e^{-\tilde{\nu} t} - e^{-\bar{\tilde{\nu}} t}}{\bar{\widetilde{\nu}} - \widetilde{\nu}},$$

for all $t \geq 0$.

Thus,

$$\begin{aligned} c_t = {} & \widetilde{\underline{\Theta}}_n g_t - \widetilde{\underline{\Theta}}_\tau t_t^r \\ & + \kappa \widetilde{\underline{\sigma}}^{-1}\left(1 - \xi + \widetilde{\underline{\Theta}}_n\right) \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} g_s ds \\ & - \kappa(1-\xi)\widetilde{\underline{\sigma}}^{-1} \widetilde{\underline{\Theta}}_\tau \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} t_s^r ds. \end{aligned}$$

Therefore,

$$c_t = \widetilde{\underline{\Theta}}_n g_t - \widetilde{\underline{\Theta}}_\tau t_t^r + \int_0^{+\infty} \alpha_s^{c,HM} g_{t+s} ds - \int_0^{+\infty} \gamma_s^{c,HM} t_{t+s}^r ds,$$

where

$$\begin{aligned} \alpha_s^{c,HM} &= \left(1 + \frac{\widetilde{\underline{\Theta}}_n}{1-\xi}\right) \widetilde{\alpha}_s^{c,HM} \;,\;\; \gamma_s^{c,HM} = \frac{\widetilde{\underline{\Theta}}_\tau}{1-\xi} \widetilde{\alpha}_s^{c,HM}, \\ \widetilde{\alpha}_s^{c,HM} &= \kappa \widetilde{\underline{\sigma}}^{-1}(1-\xi) e^{-\bar{\tilde{\nu}} s} \frac{e^{(\bar{\tilde{\nu}} - \tilde{\nu})s} - 1}{\bar{\widetilde{\nu}} - \widetilde{\nu}}. \end{aligned}$$

Special case: no hand-to-mouth agents $\chi = 0$

Define

$$\nu = \frac{\rho - \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2} \;,\;\; \bar{\nu} = \frac{\rho + \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2}.$$

We have

$$c_t = \int_0^{+\infty} \alpha_s^{c,HM} g_{t+s} ds,$$

where

$$\alpha_s^{c,HM} = \kappa\hat{\sigma}^{-1}(1-\xi) e^{-\bar{\nu} s} \frac{e^{(\bar{\nu} - \nu)s} - 1}{\bar{\nu} - \nu}.$$

Special case: no profit offset $o = 0$

We have

$$c_t = \widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau t_t^r + \int_0^{+\infty} \alpha_s^{c,HM} g_{t+s} ds - \int_0^{+\infty} \gamma_s^{c,HM} t_{t+s}^r ds,$$

where

$$\alpha_s^{c,HM} = \left(1 + \frac{\widetilde{\Theta}_n}{1-\xi}\right)\widetilde{\alpha}_s^{c,HM} \ , \ \ \gamma_s^{c,HM} = \frac{\widetilde{\Theta}_\tau}{1-\xi}\widetilde{\alpha}_s^{c,HM},$$

$$\widetilde{\alpha}_s^{c,HM} = \kappa\widetilde{\sigma}^{-1}(1-\xi)e^{-\bar{\widetilde{\nu}}s}\frac{e^{(\bar{\widetilde{\nu}}-\widetilde{\nu})s}-1}{\bar{\widetilde{\nu}}-\widetilde{\nu}}.$$

B.2 Currency Union

The IM and PF cases are considered here. The results for the CM case are obtained by direct analogy.

Define

$$\widetilde{\nu} = \frac{\rho - \sqrt{\rho^2 + 4\widetilde{\kappa}_c\underline{\widetilde{\sigma}}^{-1}}}{2} \ , \ \ \bar{\widetilde{\nu}} = \frac{\rho + \sqrt{\rho^2 + 4\widetilde{\kappa}_c\underline{\widetilde{\sigma}}^{-1}}}{2}.$$

The equilibrium is completely characterized by the following:

$$\dot{X}_t = AX_t + B_t,$$

With

$$E_2^t X_0 = \Upsilon\theta + \underline{\widetilde{\Theta}}_n g_0 - \underline{\widetilde{\Theta}}_\tau t_0^r,$$

$$\theta = \int_0^{+\infty} e^{-\rho s}\left[\underline{\widetilde{\Omega}}_c c_t + \underline{\widetilde{\Omega}}_n g_t + \underline{\widetilde{\Omega}}_\tau t_t^r\right] ds + \underline{\widetilde{\Omega}}_f \mathrm{nfa}_0,$$

where

$$X_t = [\pi_t, c_t]^t \ , \ \ A = \begin{bmatrix} \rho & -\widetilde{\kappa}_c \\ -\underline{\widetilde{\sigma}}^{-1} & 0 \end{bmatrix} \ , \ \ B_t = -\left(\underline{\widetilde{\kappa}}_n g_t + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_t^r\right)E_1 + \left[\underline{\widetilde{\Theta}}_n \dot{g}_t - \underline{\widetilde{\Theta}}_\tau \dot{t}_t^r\right]E_2,$$

for all $t \geq 0$.

The (unique) solution that satisfies saddle-path stability writes:

$$X_t = \alpha_{\widetilde{\nu}} e^{\widetilde{\nu}t} X_{\widetilde{\nu}} + \int_t^{+\infty}\left(\underline{\widetilde{\kappa}}_n g_s + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_s^r\right)e^{-A(s-t)}E_1 ds - \int_t^{+\infty}\left(\underline{\widetilde{\Theta}}_n \dot{g}_s - \underline{\widetilde{\Theta}}_\tau \dot{t}_s^r\right)e^{-A(s-t)}E_2 ds,$$

with

$$E_2^t X_0 = \Upsilon\theta + \underline{\widetilde{\Theta}}_n g_0 - \underline{\widetilde{\Theta}}_\tau t_0^r,$$
$$\theta = \int_0^{+\infty} e^{-\rho s}\left[\widetilde{\Omega}_c c_t + \widetilde{\Omega}_n g_t + \widetilde{\Omega}_\tau t_t^r\right] ds + \widetilde{\Omega}_f \mathrm{nfa}_0,$$

where $\alpha_{\tilde{\nu}} \in \mathbb{R}$.

Equivalently, integrating the relevant objects by part,

$$X_t = \alpha_{\tilde{\nu}} e^{\tilde{\nu} t} X_{\tilde{\nu}} + \int_t^{+\infty} \left(\underline{\widetilde{\kappa}}_n g_s + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_s^r\right) e^{-A(s-t)} E_1 ds + \left(\underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r\right) E_2$$
$$- \int_t^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r\right) A e^{-A(s-t)} E_2 ds,$$

with

$$E_2^t X_0 = \Upsilon\theta + \underline{\widetilde{\Theta}}_n g_0 - \underline{\widetilde{\Theta}}_\tau t_0^r,$$
$$\theta = \int_0^{+\infty} e^{-\rho s}\left[\widetilde{\Omega}_c c_t + \widetilde{\Omega}_n g_t + \widetilde{\Omega}_\tau t_t^r\right] ds + \widetilde{\Omega}_f \mathrm{nfa}_0.$$

Thus,

$$\Upsilon\theta - \int_0^{+\infty} \left(\underline{\widetilde{\kappa}}_n g_s + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_s^r\right) E_2^t e^{-As} E_1 ds$$
$$+ \int_0^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r\right) A E_2^t e^{-As} E_2 ds = \alpha_{\tilde{\nu}}.$$

Therefore,

$$c_t = \left[\Upsilon\theta - \int_0^{+\infty} \left(\underline{\widetilde{\kappa}}_n g_s + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_s^r\right) E_2^t e^{-As} E_1 ds + \int_0^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r\right) E_2^t A e^{-As} E_2 ds\right] e^{\tilde{\nu} t}$$
$$+ \int_t^{+\infty} \left(\underline{\widetilde{\kappa}}_n g_s + \underline{\widetilde{\kappa}}_\theta \theta + \underline{\widetilde{\kappa}}_\tau t_s^r\right) E_2^t e^{-A(s-t)} E_1 ds + \left(\underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r\right)$$
$$- \int_t^{+\infty} \left(\underline{\widetilde{\Theta}}_n g_s - \underline{\widetilde{\Theta}}_\tau t_s^r\right) E_2^t A e^{-A(s-t)} E_2 ds.$$

Equivalently,

$$c_t = \left[\Upsilon e^{\tilde{\nu} t} - \underline{\widetilde{\kappa}}_\theta \left[e^{\tilde{\nu} t} \int_0^{+\infty} E_2^t e^{-As} E_1 ds - \int_t^{+\infty} E_2^t e^{-A(s-t)} E_1 ds\right]\right] \theta + \underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r$$
$$- \underline{\widetilde{\kappa}}_n \left[e^{\tilde{\nu} t} \int_0^{+\infty} E_2^t e^{-As} E_1 g_s ds - \int_t^{+\infty} E_2^t e^{-A(s-t)} E_1 g_s ds\right]$$
$$+ \underline{\widetilde{\Theta}}_n \left[e^{\tilde{\nu} t} \int_0^{+\infty} E_2^t A e^{-As} E_2 g_s ds - \int_t^{+\infty} E_2^t A e^{-A(s-t)} E_2 g_s ds\right]$$
$$- \underline{\widetilde{\kappa}}_\tau \left[e^{\tilde{\nu} t} \int_0^{+\infty} E_2^t e^{-As} E_1 t_s^r ds - \int_t^{+\infty} E_2^t e^{-A(s-t)} E_1 t_s^r ds\right]$$
$$- \underline{\widetilde{\Theta}}_\tau \left[e^{\tilde{\nu} t} \int_0^{+\infty} E_2^t e^{-As} A E_2 t_s^r ds - \int_t^{+\infty} E_2^t A e^{-A(s-t)} E_2 t_s^r ds\right].$$

Note that

$$E_2^t e^{-At} E_1 = \underline{\widetilde{\sigma}}^{-1} \frac{e^{-\tilde{\nu}t} - e^{-\bar{\tilde{\nu}}t}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} \ , \quad E_2^t A e^{-At} E_2 = -\widetilde{\kappa}_c \underline{\widetilde{\sigma}}^{-1} \frac{e^{-\tilde{\nu}t} - e^{-\bar{\tilde{\nu}}t}}{\bar{\widetilde{\nu}} - \widetilde{\nu}},$$

for all $t \geq 0$.

Thus,

$$c_t = \left[\frac{\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}_\theta} \underline{\widetilde{\sigma}}^{-1} \left(e^{\tilde{\nu}t} - 1 \right) \int_0^{+\infty} e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}} s}{\bar{\widetilde{\nu}} - \widetilde{\nu} ds} \right] \theta + \underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r$$

$$- \left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_n \right) \underline{\widetilde{\sigma}}^{-1} \left[e^{\tilde{\nu}t} \int_0^{+\infty} \frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} g_s ds - \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} g_s ds \right]$$

$$- \left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_\tau \right) \underline{\widetilde{\sigma}}^{-1} \left[e^{\tilde{\nu}t} \int_0^{+\infty} \frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} t_s^r ds - \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} t_s^r ds \right].$$

Using the expression for the Pareto weight θ,

$$c_t = \left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}_\theta} \underline{\widetilde{\sigma}}^{-1} \left(e^{\tilde{\nu}t} - 1 \right) \frac{\widetilde{\nu}^{-1} - \bar{\widetilde{\nu}}^{-1}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} \right] \left(\int_0^{+\infty} e^{-\rho s} \left[\widetilde{\Omega}_c c_s + \widetilde{\Omega}_n g_s + \widetilde{\Omega}_\tau t_s^r \right] ds + \widetilde{\Omega}_f \mathrm{nfa}_0 \right)$$

$$+ \underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r$$

$$- \left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_n \right) \underline{\widetilde{\sigma}}^{-1} \left[e^{\widetilde{\nu t}} \int_0^{+\infty} \frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} g_s ds - \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} g_s ds \right]$$

$$- \left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_\tau \right) \underline{\widetilde{\sigma}}^{-1} \left[e^{\tilde{\nu}t} \int_0^{+\infty} \frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} t_s^r ds - \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} t_s^r ds \right].$$

From Fubini's Theorem, assuming that the integrals are finite,

$$\int_0^{+\infty} e^{-\rho t} \int_t^{+\infty} \frac{e^{-\tilde{\nu}(s-t)} - e^{-\bar{\tilde{\nu}}(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} x_s ds dt = \int_0^{+\infty} e^{-\rho s} \int_0^s \frac{e^{(\rho - \tilde{\nu})(s-t)} - e^{(\rho - \bar{\tilde{\nu}})(s-t)}}{\bar{\widetilde{\nu}} - \widetilde{\nu}} dt x_s ds$$

$$= -\frac{1}{\bar{\widetilde{\nu}}} - \widetilde{\nu} \int_0^{+\infty} e^{-\rho s} \left[(\rho - \widetilde{\nu})^{-1} \left(1 - e^{(\rho - \tilde{\nu})s} \right) - \left(\rho - \bar{\widetilde{\nu}} \right)^{-1} \left(1 - e^{(\rho - \tilde{\nu})s} \right) \right] x_s ds,$$

for each $x \in \{g, t^r\}$.

Note that $\frac{\tilde{\nu}^{-1} - \bar{\tilde{\nu}}^{-1}}{\bar{\tilde{\nu}} - \tilde{\nu}} = -\underline{\widetilde{\kappa}}_c^{-1} \underline{\widetilde{\sigma}}$ by definition of $\widetilde{\nu}, \bar{\widetilde{\nu}}$. Thus,

$$\int_0^{+\infty} e^{-\rho t} c_t dt = \frac{1}{1 - \Sigma \widetilde{\Omega}_c} \left(\int_0^{+\infty} \varsigma_n^t g_s ds + \int_0^{+\infty} \varsigma_\tau^t t_s^r ds + \varsigma_f \mathrm{nfa}_0 \right),$$

where

$$\begin{aligned}
\varsigma_n^t &= \Sigma e^{-\rho t}\widetilde{\Omega}_n + e^{-\rho t}\underline{\widetilde{\Theta}}_n - \left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c\underline{\widetilde{\Theta}}_n\right)\underline{\widetilde{\sigma}}^{-1}\left[\frac{1}{\rho-\widetilde{\nu}}\frac{e^{-\tilde{\nu}t}-e^{-\bar{\bar{\tilde{\nu}}}t}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}\right.\\
&\qquad\left.+\frac{1}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}e^{-\rho t}\left[(\rho-\widetilde{\nu})^{-1}\left(1-e^{(\rho-\tilde{\nu})t}\right)-\left(\rho-\bar{\bar{\widetilde{\nu}}}\right)^{-1}\left(1-e^{(\rho-\bar{\bar{\tilde{\nu}}})t}\right)\right]\right],\\
\varsigma_\tau^t &= \Sigma e^{-\rho t}\widetilde{\Omega}_\tau - e^{-\rho t}\underline{\widetilde{\Theta}}_\tau - \left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c\underline{\widetilde{\Theta}}_\tau\right)\underline{\widetilde{\sigma}}^{-1}\left[\frac{1}{\rho-\widetilde{\nu}}\frac{e^{-\tilde{\nu}t}-e^{-\bar{\bar{\tilde{\nu}}}t}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}\right.\\
&\qquad\left.+\frac{1}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}e^{-\rho t}\left[(\rho-\widetilde{\nu})^{-1}\left(1-e^{-(\rho-\tilde{\nu})t}\right)-\left(\rho-\bar{\bar{\widetilde{\nu}}}\right)^{-1}\left(1-e^{(\rho-\bar{\bar{\tilde{\nu}}})t}\right)\right]\right],\\
\varsigma_f &= \Sigma\widetilde{\Omega}_f,\\
\Sigma &= \Upsilon\frac{1}{\rho-\widetilde{\nu}} - \underline{\widetilde{\kappa}}_\theta\underline{\widetilde{\kappa}}_c^{-1}\left(\frac{1}{\rho}-\frac{1}{\rho-\widetilde{\nu}}\right).
\end{aligned}$$

Therefore,

$$c_t = \underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r + \int_{-t}^{+\infty}\alpha_s^{c,t,HM,IM} g_{t+s}ds - \int_{-t}^{+\infty}\gamma_s^{c,t,HM,IM} t_{t+s}^r ds,$$

where

$$\begin{aligned}
\alpha_s^{c,t,HM,IM} &= \alpha_s^{c,t,HM,CM} + \delta_s^{c,t,HM,IM} + \delta_s^{c,t,HM,PF},\\
\gamma_s^{c,t,HM,IM} &= \gamma_{s0}^{c,t,HM,CM} + \epsilon_s^{c,t,HM,IM},
\end{aligned}$$

with

$$\begin{aligned}
\alpha_s^{c,t,HM,CM} &= -\left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c\underline{\widetilde{\Theta}}_n\right)\underline{\widetilde{\sigma}}^{-1}\left[e^{\widetilde{\nu t}}\frac{e^{-\tilde{\nu}(t+s)}-e^{-\bar{\bar{\tilde{\nu}}}(t+s)}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s}-e^{-\bar{\bar{\tilde{\nu}}}s}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}\right],\\
\gamma_s^{c,t,HM,CM} &= \left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c\underline{\widetilde{\Theta}}_\tau\right)\underline{\widetilde{\sigma}}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)}-e^{-\bar{\bar{\tilde{\nu}}}(t+s)}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s}-e^{-\bar{\bar{\tilde{\nu}}}s}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}\right],\\
\delta_s^{c,t,HM,IM} &= \left(\frac{1}{1-\Sigma\widetilde{\Omega}_c}\widetilde{\Omega}_c\varsigma_n^{t+s} + e^{-\rho(t+s)}\widetilde{\Omega}_n\right)\left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta\underline{\widetilde{\kappa}}_c^{-1}\left(1-e^{\tilde{\nu}t}\right)\right],\\
\epsilon_s^{c,t,HM,IM} &= -\left(\frac{1}{1-\Sigma\widetilde{\Omega}_c}\widetilde{\Omega}_c\varsigma_\tau^{t+s} + e^{-\rho(t+s)}\widetilde{\Omega}_\tau\right)\left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta\underline{\widetilde{\kappa}}_c^{-1}\left(1-e^{\tilde{\nu}t}\right)\right],
\end{aligned}$$

and $\delta_s^{c,t,HM,PF} = 0$ in IM case, and

$$\delta_s^{c,t,HM,PF} = \left(\frac{1}{1-\Sigma\widetilde{\Omega}_c}\widetilde{\Omega}_c\varsigma_f + \widetilde{\Omega}_f\right)\left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta\underline{\widetilde{\kappa}}_c^{-1}\left(1-e^{\tilde{\nu}t}\right)\right]e^{-\rho(t+s)}$$

in PF case.

We can reexpress these as

$$\alpha_s^{c,t,HM,CM} = -\left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_n\right)\underline{\widetilde{\sigma}}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)} - e^{-\bar{\bar{\tilde{\nu}}}(t+s)}}{\bar{\bar{\widetilde{\nu}}} - \widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s} - e^{-\bar{\bar{\tilde{\nu}}}s}}{\bar{\bar{\widetilde{\nu}}} - \widetilde{\nu}}\right],$$

$$\gamma_s^{c,t,HM,CM} = \left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_\tau\right)\underline{\widetilde{\sigma}}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)} - e^{-\bar{\bar{\tilde{\nu}}}(t+s)}}{\bar{\bar{\widetilde{\nu}}} - \widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s} - e^{-\bar{\bar{\tilde{\nu}}}s}}{\bar{\bar{\widetilde{\nu}}} - \widetilde{\nu}}\right],$$

$$\begin{aligned}\delta_s^{c,t,HM,IM} = {} & \left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta \underline{\widetilde{\kappa}}_c^{-1}\left(1 - e^{\tilde{\nu}t}\right)\right] \times \\ & \frac{1}{1 - \Sigma \underline{\widetilde{\Omega}}_c}\Big[e^{-\rho(t+s)}\underline{\widetilde{\Omega}}_n + e^{-\rho(t+s)}\underline{\widetilde{\Omega}}_c \underline{\widetilde{\Theta}}_n \\ & + \underline{\widetilde{\Omega}}_c\left(\underline{\widetilde{\kappa}}_n + \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_n\right)\underline{\widetilde{\sigma}}^{-1}\frac{1}{\widetilde{\kappa}_c \underline{\widetilde{\sigma}}^{-1}} e^{-\rho(t+s)}\left(1 - e^{\tilde{\nu}(t+s)}\right)\Big],\end{aligned}$$

$$\begin{aligned}\epsilon_s^{c,t,HM,IM} = {} & -\left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta \underline{\widetilde{\kappa}}_c^{-1}\left(1 - e^{\tilde{\nu}t}\right)\right] \times \\ & \frac{1}{1 - \Sigma \underline{\widetilde{\Omega}}_c}\Big[e^{-\rho(t+s)}\underline{\widetilde{\Omega}}_\tau - e^{-\rho(t+s)}\underline{\widetilde{\Omega}}_c \underline{\widetilde{\Theta}}_\tau \\ & + \underline{\widetilde{\Omega}}_c\left(\underline{\widetilde{\kappa}}_\tau - \underline{\widetilde{\kappa}}_c \underline{\widetilde{\Theta}}_\tau\right)\underline{\widetilde{\sigma}}^{-1}\frac{1}{\widetilde{\kappa}_c \underline{\widetilde{\sigma}}^{-1}} e^{-\rho(t+s)}\left(1 - e^{\tilde{\nu}(t+s)}\right)\Big],\end{aligned}$$

and $\delta_s^{c,t,HM,PF} = 0$ in the IM case, and

$$\delta_s^{c,t,HM,PF} = \left[\Upsilon e^{\tilde{\nu}t} - \underline{\widetilde{\kappa}}_\theta \underline{\widetilde{\kappa}}_c^{-1}\left(1 - e^{\widetilde{\nu t}}\right)\right]\frac{1}{1 - \Sigma \underline{\widetilde{\Omega}}_c}\underline{\widetilde{\Omega}}_f e^{-\rho(t+s)}$$

in the PF case.

By direct analogy,

$$c_t = \underline{\widetilde{\Theta}}_n g_t - \underline{\widetilde{\Theta}}_\tau t_t^r + \int_{-t}^{+\infty} \alpha_s^{c,t,HM,CM} g_{t+s} ds - \int_0^{+\infty} \gamma_s^{c,t,HM,CM} t_{t+s}^r ds$$

in CM case.

Special case: no hand-to-mouth agents $\chi = 0$

Define

$$\nu = \frac{\rho - \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2}, \quad \bar{\nu} = \frac{\rho + \sqrt{\rho^2 + 4\kappa\hat{\sigma}^{-1}}}{2},$$

and

$$\hat{\Sigma} = (1 - \mathcal{G})(1 - \alpha)\frac{1}{\bar{\bar{\widetilde{\nu}}}} + (1 - \mathcal{G})\frac{\hat{\sigma}}{\phi + \hat{\sigma}}\alpha\omega\frac{1}{\bar{\bar{\widetilde{\nu}}}}\frac{\widetilde{\nu}}{\rho}.$$

Define

$$\alpha_s^{c,t,HM,CM} = -\kappa(1-\xi)\hat{\sigma}^{-1}\left[e^{\nu t}\frac{e^{-\nu(t+s)} - e^{-\bar{\nu}(t+s)}}{\bar{\nu}-\nu} - \mathbb{1}_{s\geq 0}\frac{e^{-\nu s} - e^{-\bar{\nu}s}}{\bar{\nu}-\nu}\right].$$

We have

$$c_t = \int_{-t}^{+\infty} \alpha_s^{c,t,HM,IM} g_{t+s} ds,$$

where

$$\alpha_s^{c,t,HM,IM} = \alpha_s^{c,t,HM,CM} + \delta_s^{c,t,HM,IM} + \delta_s^{c,t,HM,PF},$$

with

$$\delta_s^{c,t,HM,IM} = \rho\left[\frac{1-\alpha}{\alpha}e^{\tilde{\nu}t} - \frac{\hat{\sigma}}{\phi+\hat{\sigma}}\omega\left(1-e^{\tilde{\nu}t}\right)\right] \\ \times \frac{\alpha\dfrac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}}{1-\hat{\Sigma}\rho\dfrac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}\dfrac{1}{1-\mathcal{G}}}(1-\xi)e^{-\rho(t+s)}\left(1-e^{\tilde{\nu}(t+s)}\right),$$

and $\delta_s^{c,t,HM,PF} = 0$ in the IM case, and

$$\delta_s^{c,t,HM,PF} = \rho\left[\frac{1-\alpha}{\alpha}e^{\tilde{\nu}t} - \frac{\hat{\sigma}}{\phi+\hat{\sigma}}\omega\left(1-e^{\widetilde{\nu t}}\right)\right]\frac{\dfrac{\alpha\omega+1-\alpha}{\omega+(1-\alpha)(1-\sigma)}}{1-\hat{\Sigma}\rho\dfrac{\omega-\sigma}{\omega+(1-\alpha)(1-\sigma)}\dfrac{1}{1-\mathcal{G}}}e^{-\rho(t+s)}$$

in the PF case.

Special case: no profit offset $o = 0$

In that case we have

$$\Sigma = (1-\mathcal{G})(1-\widetilde{\alpha})\frac{1}{\bar{\bar{\widetilde{\nu}}}} + (1-\mathcal{G})\lambda\widetilde{\sigma}\widetilde{\alpha}\widetilde{\omega}\widetilde{\kappa}^{-1}\frac{1}{\rho}\frac{\widetilde{\nu}}{\bar{\bar{\widetilde{\nu}}}}.$$

Define

$$\widetilde{\alpha}_s^{c,t,HM,CM} = -\widetilde{\kappa}\left(1-\widetilde{\xi}\right)\widetilde{\sigma}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)} - e^{-\bar{\bar{\tilde{\nu}}}(t+s)}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s} - e^{-\bar{\bar{\tilde{\nu}}}s}}{\bar{\bar{\widetilde{\nu}}}-\widetilde{\nu}}\right].$$

We have

$$c_t = \widetilde{\Theta}_n g_t - \widetilde{\Theta}_\tau t_t^r + \int_{-t}^{+\infty} \alpha_s^{c,t,HM,IM} g_{t+s} ds - \int_{-t}^{+\infty} \gamma_s^{c,t,HM,IM} t_{t+s}^r ds,$$

where

$$\alpha_s^{c,t,HM,IM} = \alpha_s^{c,t,HM,CM} + \delta_s^{c,t,HM,IM} + \delta_s^{c,t,HM,PF},$$
$$\gamma_s^{c,t,HM,IM} = \gamma_s^{c,t,HM,CM} + \epsilon_s^{c,t,HM,IM},$$

with

$$\alpha_s^{c,t,HM,CM} = -\left(1 + \frac{\widetilde{\Theta}_n}{1-\widetilde{\xi}}\right)\widetilde{\kappa}\left(1-\widetilde{\xi}\right)\widetilde{\sigma}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)} - e^{-\bar{\tilde{\nu}}(t+s)}}{\bar{\tilde{\nu}} - \widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\tilde{\nu}} - \widetilde{\nu}}\right],$$

$$\gamma_s^{c,t,HM,CM} = -\frac{\widetilde{\Theta}_\tau - \widetilde{\widetilde{\Theta}}_\tau}{1-\widetilde{\xi}}\widetilde{\kappa}\left(1-\widetilde{\xi}\right)\widetilde{\sigma}^{-1}\left[e^{\tilde{\nu}t}\frac{e^{-\tilde{\nu}(t+s)} - e^{-\bar{\tilde{\nu}}(t+s)}}{\bar{\tilde{\nu}} - \widetilde{\nu}} - \mathbb{1}_{s\geq 0}\frac{e^{-\tilde{\nu}s} - e^{-\bar{\tilde{\nu}}s}}{\bar{\tilde{\nu}} - \widetilde{\nu}}\right],$$

$$\begin{aligned}
\delta_s^{c,t,HM,IM} = \rho &\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}}e^{\tilde{\nu}t} - \lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\tilde{\nu}t}\right)\right] \\
&\times \frac{\widetilde{\alpha}}{1-\Sigma\widetilde{\Omega}_c}\left[e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_n}{\rho} + e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\widetilde{\Theta}_n. \right. \\
&\left. + \frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\left(1-\widetilde{\xi}\right)\left(1+\frac{\widetilde{\Theta}_n}{1-\widetilde{\xi}}\right)e^{-\rho(t+s)}\left(1-e^{\tilde{\nu}(t+s)}\right)\right],
\end{aligned}$$

$$\begin{aligned}
\epsilon_s^{c,t,HM,IM} = -\rho &\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}}e^{\tilde{\nu}t} - \lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\tilde{\nu}t}\right)\right] \\
&\times \frac{\widetilde{\alpha}}{1-\Sigma\widetilde{\Omega}_c}\left[e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_\tau}{\rho} - e^{-\rho(t+s)}\frac{(1-\mathcal{G})\widetilde{\Omega}_c}{\rho}\widetilde{\Theta}_\tau. \right. \\
&\left. + \widetilde{\Omega}_c\left(1-\widetilde{\xi}\right)\frac{\widetilde{\widetilde{\Theta}}_\tau - \widetilde{\Theta}_\tau}{1-\widetilde{\xi}}e^{-\rho(t+s)}\left(1-e^{\tilde{\nu}(t+s)}\right)\right],
\end{aligned}$$

and $\delta_s^{c,t,HM,PF} = 0$ in the IM case, and

$$\delta_s^{c,t,HM,PF} = \rho\left[\frac{1-\widetilde{\alpha}}{\widetilde{\alpha}}e^{\tilde{\nu}t} - \lambda\widetilde{\sigma}\widetilde{\kappa}^{-1}\widetilde{\omega}\left(1-e^{\tilde{\nu}t}\right)\right]\frac{1}{1-\Sigma\widetilde{\Omega}_c}\frac{\widetilde{\alpha}(1-\mathcal{G})\widetilde{\Omega}_f}{\rho}e^{-\rho(t+s)}$$

in the PF case.

Abstract

The question of what is a sustainable public debt is paramount in the macroeconomic analysis of fiscal policy. This question is usually formulated as asking whether the outstanding public debt and its projected path are consistent with those of the government's revenues and expenditures (ie, whether fiscal solvency conditions hold). We identify critical flaws in the traditional approach to evaluate debt sustainability, and examine three alternative approaches that provide useful econometric and model-simulation tools to analyze debt sustainability. The first approach is Bohn's nonstructural empirical framework based on a fiscal reaction function that characterizes the dynamics of sustainable debt and primary balances. The second is a structural approach based on a calibrated dynamic general equilibrium framework with a fully specified fiscal sector, which we use to quantify the positive and normative effects of fiscal policies aimed at restoring fiscal solvency in response to changes in debt. The third approach deviates from the others in assuming that governments cannot commit to repay their domestic debt and can thus optimally decide to default even if debt is sustainable in terms of fiscal solvency. We use these three approaches to analyze debt sustainability in the United States and Europe after the sharp increases in public debt following the 2008 crisis, and find that all three raise serious questions about the prospects of fiscal adjustment and its consequences.

1. INTRODUCTION

The question of what is a sustainable public debt has always been paramount in the macroeconomic analysis of fiscal policy, and the recent surge in the debt of many advanced and emerging economies has made it particularly critical. This question is often understood as equivalent to asking whether the government is solvent. That is, whether the outstanding stock of public debt matches the projected present discounted value of the primary fiscal balance, measuring both at the general government level and including all forms of fiscal revenue as well as all current expenditures, transfers and entitlement payments. This chapter revisits the question of public debt sustainability, identifies critical flaws in traditional ways to approach it, and discusses three alternative approaches that provide useful econometric and model-simulation tools to evaluate debt sustainability.

The first approach is an empirical approach proposed in Bohn's seminal work on fiscal solvency. The advantage of this approach is that it provides a straightforward and powerful method to conduct nonstructural empirical tests. These tests require only data on the primary balance, outstanding debt, and a few control variables. The data are then used to estimate linear and nonlinear *fiscal reaction functions* (FRFs), which map the response of the primary balance to changes in outstanding debt, conditional on the control variables. A positive, statistically significant response coefficient is a sufficient condition for the debt to be sustainable. A key lesson from Bohn's work, however, is that using this or other time-series econometric tools just to test for fiscal solvency is futile, because the intertemporal government budget constraint holds under very weak time-series assumptions that are generally satisfied in the data. In particular, Bohn (2007) showed that the constraint holds if either the debt or revenues and expenditures (including debt service) are integrated of *any* finite order. In light of this result, he proposed shifting the focus to analyzing the characteristics of the FRFs in order to study the dynamics of fiscal adjustment that have maintained solvency.

We provide new FRF estimation results for historical data spanning the 1791–2014 period for the United States, and for a cross-country panel of advanced and emerging economies for the period 1951–2013. The results are largely in line with previous findings showing that the response coefficient of the primary balance to outstanding debt is positive and statistically significant in most countries (ie, the sufficiency condition for debt sustainability is supported by the data).[a] On the other hand, the results provide clear evidence of a large structural shift in the response coefficients since the 2008 crisis, which is reflected in large negative residuals in the FRFs since 2009. The primary balances predicted by the FRF of the United States for the period 2008–14 are much larger than the observed ones, and the debt and primary balance dynamics that FRFs predict after 2014 for both the United States and European economies yield higher primary surpluses and lower debt ratios than what official projections show. Moreover, in the case of the United States, the pattern of consistent primary deficits since 2009 and continuing until at least 2020 in official projections, is unprecedented. In all previous episodes of large increases in public debt of comparable magnitudes (the Civil War, the two World Wars, and the Great Depression), the primary balance was in surplus 5 years after the debt peaked.

Using the estimated FRFs, we illustrate that there are multiple parameterizations of a FRF that support the same expected present discounted value of primary balances, and thus all of them make the same initial public debt position sustainable. However, these multiple reaction functions yield different short- and long-run dynamics of debt and primary balances, and therefore differ in terms of social welfare and their macro effects. At this point, this nonstructural approach reaches its limits. The standard Lucas-critique argument implies that estimated FRFs cannot be used to study the implications of fiscal policy changes. Hence, comparing different patterns of fiscal adjustment requires a structural framework that models explicitly the mechanisms and distortions by which tax and expenditure policies affect the economy, the structure of financial markets the government can access, and the implications of the government's inability to commit to repay its obligations.

The second approach to study debt sustainability that we examine picks up at this point. We use a calibrated two-country dynamic general equilibrium framework with

[a] Formally, the null hypothesis that the response coefficient is nonpositive is rejected at the standard confidence level.

a fully specified fiscal sector to study the effects of alternative fiscal strategies to restore fiscal solvency in the aftermath of large increases in debt, assuming that the government is committed to repay. The model is calibrated to data from the United States and Europe and used to quantify the positive and normative effects of fiscal policies that governments may use seeking to increase the present value of the primary fiscal balance by enough to match the increases in debt observed since 2008 (ie, by enough to restore fiscal solvency). This framework has many of the standard elements of the workhorse open-economy Neoclassical model with exogenous long-run balanced growth, but it includes modifications designed to make the model consistent with the observed elasticity of tax bases. As a result, the model captures more accurately the relevant tradeoffs between revenue-generating capacity and distortionary effects in the choice of fiscal instruments.

The results show that indeed alternative fiscal policy strategies that are equivalent in that they restore fiscal solvency, have very different effects on welfare and macro aggregates. Moreover, some fiscal policy setups fall short from producing the changes in the equilibrium present discounted value of primary balances that are necessary to match the observed increases in debt. This is particularly true for taxes on capital in the United States and labor taxes in Europe. The dynamic Laffer curves for these taxes (ie, Laffer curves in terms of the present discounted value of the primary fiscal balance) peak below the level required to make the higher post-2008 debts sustainable.

We also find that, in line with findings in the international macroeconomics literature, the fact that the United States and Europe are financially integrated economies implies that the revenue-generating capacity of taxation on capital income is adversely affected by international externalities.[b] At the prevailing tax structures, increases in US capital income taxes (assuming European taxes are constant) generate significantly smaller increases in the present value of US primary balances than if the United States implemented the same taxes under financial autarky. The model also predicts that at its current capital tax rate, Europe is in the inefficient side of its dynamic Laffer curve for the capital income tax. Hence, lowering its tax, assuming the United States keeps its capital tax constant, induces externalities that enlarge European fiscal revenues, and thus the present value of European primary balances rises significantly more than if Europe implemented the same taxes under financial autarky. This does not imply that debt is easier to sustain in Europe but that the incentives for tax competition are strong, and hence that the assumption that US taxes would remain invariant is unlikely to hold.

The results from the empirical and structural approach suggest that public debt sustainability analysis needs to be extended to consider the implications of the government's lack of commitment to repay domestic obligations. In particular, the evidence of

[b] There is a large empirical and theoretical literature on international taxation and tax competition examining the effects of these externalities. See for example, Frenkel et al. (1991), Huizinga et al. (2012), Klein et al. (2007), Mendoza and Tesar (1998, 2005), Persson and Tabellini (1995), and Sorensen (2003).

structural changes weakening the response of primary balances to debt post-2008, and the findings that tax increases may not be able to generate enough revenue to restore fiscal solvency and are hampered by international externalities, indicate that the risk of default on domestic public debt should be considered. In addition, the ongoing European debt crisis and the recurrent turmoil around federal debt ceiling debates in the United States demonstrate that domestic public debt is not in fact the risk-free asset that is generally taken to be. The first two approaches to study debt sustainability covered in this chapter are not useful for addressing this issue, because they are built on the premise that the government is committed to repay. Note also that the risk here is not that of external sovereign default, which is the subject of a different chapter in this Handbook and has been widely studied in the literature. Instead, the risk here is the one that Reinhart and Rogoff (2011) referred to as "the forgotten history of domestic debt:" Historically, there have been episodes in which governments have defaulted outright on their domestic public debt, and until very recently the macro literature had paid little attention to these episodes. Hence, the third approach we examine assumes that governments cannot commit to repay domestic debt, and decide optimally to default even if standard solvency conditions hold, and even when domestic debt holders enter in the payoff function of the sovereign making the default decision. Sustainable debt in this setup is the debt that can be supported as a market equilibrium with positive quantity and price, exposed with positive probability to a government default, and with actual episodes in which default is the equilibrium outcome.

In this framework, the government maximizes a social welfare function that assigns positive weight to the welfare of all domestic agents in the economy, including those who are holders of government debt. Defaulting on public debt is useful as a tool for redistributing resources across agents, but is also costly because debt effectively provides liquidity to credit-constrained agents and serves as a vehicle for tax-smoothing and self-insurance.[c] If default is costless, debt is unsustainable for a utilitarian government because default is always optimal. Debt can be sustainable if default carries a cost or if the government's social welfare function has a bias in favor of bond holders. In addition, this second assumption can be an equilibrium outcome under majority voting if the fraction of agents that do not own debt is sufficiently large, because these agents benefit from the consumption-smoothing ability that public debt issuance provides for them, and may thus choose a government biased in favor of bond holders over a utilitarian government. A quantitative application of this setup calibrated to data from Europe shows how the

[c] This view of default costs is motivated by the findings of Aiyagari and McGrattan (1998) on the social value of domestic public debt as the vehicle for self insurance in a model of heterogeneous agents assuming the government is committed to repay. Birkeland and Prescott (2006) show that public debt also has social value as a mechanism for tax smoothing when population growth declines, taxes distort labor, and intergenerational transfers fund retirement. Welfare when public debt is used to save for retirement is larger than in a tax-and-transfer system.

tradeoff between these costs and benefits of default determines sustainable debt. Domestic default occurs with low probability and returns on government debt carry default premia, and in the setup with a government biased in favor of bondholders the sustainable debt is large and rises with the concentration of debt ownership.

The rest of this chapter is organized as follows: Section 2 discusses the classic and empirical approaches to evaluate debt sustainability, including the new FRF estimation results. Section 3 focuses on the structural approach. It examines the quantitative predictions of the two-country dynamic general equilibrium model for the positive and normative effects of fiscal policies aimed at restoring fiscal solvency in response to large increases in debt, including the application to the case of the United States and Europe. Section 4 covers the domestic default approach, with the quantitative example based on European data. Section 5 provides a critical assessment of all three approaches and an outlook with directions for future research. Section 6 summarizes the main conclusions.

2. EMPIRICAL APPROACH

Several articles and conference volumes survey the large literature on indicators of public debt sustainability and empirical tests of fiscal solvency (eg, Buiter, 1985; Blanchard, 1990; Blanchard et al., 1990; Chalk and Hemming, 2000; IMF, International Monetary Fund, 2003; Afonso, 2005; Bohn, 2008; Neck and Sturm, 2008, and Escolano, 2010). These surveys generally start by formulating standard concepts of government accounting, and then build around them the arguments to construct indicators of debt sustainability or tests of fiscal solvency. We proceed here in a similar way, but adopting a general formulation following the analysis of government debt in the textbook by Ljungqvist and Sargent (2012). The advantage of this formulation is that it is explicit about the structure of asset markets, which as we show below turns out to be critical for the design of empirical tests of fiscal solvency.

Consider a simple economy in which output and total government outlays (ie, current expenditures and transfer payments) are exogenous functions of a vector of random variables s denoted $y(s_t)$ and $g(s_t)$, respectively. The exogenous state vector follows a standard discrete Markov process with transition probability matrix $\pi(s_{t+1},s_t)$. Taxes at date t depend on s_t and on the outstanding public debt, but since the latter is the result of the history of values of s up to and including date t, denoted s^t, taxes can be expressed as $\tau_t(s^t)$. In terms of asset markets, this economy has a full set of state-contingent Arrow securities with a j-step ahead equilibrium pricing kernel given by $Q_j(s_{t+j}|s_t) = MRS(c_{t+j},c_t)\pi^j(s_{t+j},s_t)$.[d]

[d] $MRS(c_{t+j},c_t) \equiv \beta^j u'(c(s_{t+j}))/u'(c(s_t))$ is the marginal rate of substitution in consumption between date $t+j$ and date t. Note also that in this simple economy the resource constraint implies that consumption is exogenous and given by $c(s_{t+j}) = y(s_{t+j}) - g(s_{t+j})$.

Public debt outstanding at the beginning of date t is denoted as $b_{t-1}(s_t|s^{t-1})$, which is the amount of date-t goods that the government promised at $t-1$ to deliver if the economy is in state s_t at date t with history s^{t-1}. The government's budget constraint can then be written as follows:

$$\sum_{s_{t+1}} Q_1(s_{t+1}|s_t)b_t(s_{t+1}|s^t)\pi(s_{t+1},s_t) - b_{t-1}(s_t|s^{t-1}) = g(s_t) - \tau_t(s^t).$$

Notice that there are no restrictions on what type of financial instruments the government uses to borrow. In particular, the typical case in which the government issues only risk-free debt is not ruled out. In this case, the above budget constraint reduces to the familiar form: $[b_t(s^t)/R_1(s_t)] - b_{t-1}(s^{t-1}) = g(s_t) - \tau_t(s^t)$, where $R_1(s_t)$ is the one-step-ahead risk-free real interest rate (which at equilibrium satisfies $R_1(s_t)^{-1} = E_t[MRS(c_{t+1},c_t)]$).

Imposing the no-Ponzi game condition $\lim\inf_{j\to\infty} E_t[MRS(c_{t+j},c_t)b_{t+j}] = 0$ on the above budget constraint, and using the equilibrium asset pricing conditions, yields the following intertemporal government budget constraint (IGBC):

$$b_{t-1} = pb_t + \sum_{j=1}^{\infty} E_t[MRS(c_{t+j},c_t)pb_{t+j}], \tag{1}$$

where $pb_t \equiv \tau_t - g_t$ is the primary fiscal balance. This IGBC condition is the familiar fiscal solvency condition that anchors the standard concept of debt sustainability: b_{t-1} is said to be sustainable if it matches the expected present discounted value of the stream of future primary fiscal balances. Hence, the two main goals of most of the empirical literature on public debt sustainability have been: (a) to construct simple indicators that can be used to assess debt sustainability, and (b) to develop formal econometric tests that can determine whether the hypothesis that IGBC holds can be rejected by the data.

2.1 Classic Debt Sustainability Analysis

Classic public debt sustainability analysis focuses on the long-run implications of a deterministic version of the IGBC. This approach uses the government budget constraint evaluated at steady state as a condition that relates the long-run primary fiscal balance as a share of GDP and the debt-output ratio, and defines the latter as the sustainable debt (see Buiter, 1985, Blanchard, 1990, and Blanchard et al., 1990). To derive this condition from the setup described earlier, first remove uncertainty from the government budget constraint with nonstate contingent debt to obtain: $[b_t/(1+r_t)] - b_{t-1} = -pb_t$. Then rewrite the equation with government bonds at face value instead of discount bonds: $b_t - (1+r_t)b_{t-1} = -pb_t$. Finally, apply a change of variables so that debt and primary balances are measured as GDP ratios, which implies that the effective interest rate becomes $r_t \equiv (1+i_t^r)/(1+\gamma_t) - 1$, where i_t^r is the real interest rate and γ_t is the growth rate of GDP (or alternatively use the nominal interest rate and the growth rate of nominal GDP). Solving for the steady-state debt ratio yields:

$$b^{ss} = \frac{pb^{ss}}{r} \approx \frac{pb^{ss}}{i^r - \gamma}. \tag{2}$$

Thus, the steady-state debt ratio $b^{ss}$is the annuity value of the steady state primary balance pb^{ss}, discounted at the long-run, growth-adjusted interest rate. In policy applications, this condition is used either as an indicator of the primary balance-output ratio needed to stabilize a given debt-output ratio (the so-called "debt stabilizing" primary balance), or as an indicator of the sustainable target debt-output ratio that a given primary balance-output ratio can support. There are also variations of this approach that use the constraint $b_t - (1 + r_t)b_{t-1} = -pb_t$ to construct estimates of primary balance targets needed to produce desired changes in debt at shorter horizons than the steady state. For instance, imposing the condition that the debt must decline ($b_t - b_{t-1} < 0$), implies that the primary balance must yield a surplus that is at least as large as the growth-adjusted debt service: $pb_t \geq r_t b_{t-1}$.

The Classic Approach was developed in the 1980s but remains a tool widely used in policy assessments of sustainable debt. In particular, Annex VI of IMF (2013) instructs IMF economists to use a variation of the Blanchard ratio, called the Exceptional Fiscal Performance Approach, as one of three methodologies for estimating maximum sustainable public debt ranges (the other two methodologies introduce uncertainty and are discussed later in this section). This variation determines a country's maximum sustainable primary balance and "appropriate" levels of i^r and γ, and then applies them to the Blanchard ratio to estimate the maximum level of debt that the country can sustain.

The main flaw of the Classic Approach is that it only *defines* what long-run debt is for a given long-run primary balance (or vice versa) if stationarity holds, or *defines* lower bounds on the short-run dynamics of the primary balance. It does not actually connect the outstanding initial debt of a particular period b_{t-1} with b^{ss}, where the latter should be $\lim_{j\to\infty} b_{t+j}$ starting from b_{t-1}, and thus it cannot actually guarantee that b_{t-1} is sustainable in the sense of satisfying the IGBC. In fact, as we show below, for a given b_{t-1} there are multiple dynamic paths of the primary balance that satisfy IGBC. A subset of these paths converges to stationary debt positions, with different values of b^{ss} that vary widely depending on the primary balance dynamics, and there is even a subset of these paths for which the debt diverges to infinity but is still consistent with IGBC!

A second important flaw of the Classic approach is the absence of uncertainty and considerations about the asset market structure. Policy institutions have developed several methodologies that introduce uncertainty into debt sustainability analysis. For example, Barnhill and Kopits (2003) proposed incorporating uncertainty by adapting the value-at-risk (VaR) methodology of the financial industry to debt instruments issued by governments. Their methodology aims to quantify the probability of a negative net worth position for the government. Other methodologies described in IMF (2013) use stochastic time-series simulation tools to examine debt dynamics, estimating models for the individual components of the primary balance or nonstructural vector-autoregression models that include these variables jointly with key macroeconomic aggregates (eg, output growth, inflation) and a set of exogenous variables. The goal is to compute probability density functions of possible debt-output ratios based on forward simulations of the time-series models. The distributions are then used to make assessments of sustainable debt in terms of the probability that the simulated debt ratios are greater or equal than a critical value, or to construct "fan charts" summarizing the confidence intervals of the future evolution of debt. More recently, Ostry et al. (2015) use the fiscal reaction functions estimated by Ghosh et al. (2013) and discussed later in this section to construct measures of "fiscal space," which are intended to show the space a country has for increasing its debt ratio while still satisfying the IGBC.

IMF (2013) proposes two other stochastic tools as part of the framework for quantifying maximum sustainable debt (complementing the deterministic Exceptional Fiscal Performance estimates discussed earlier). The first is labeled the Early Warning Approach. This method computes a threshold debt ratio above which a country is likely to experience a debt crisis. The threshold is optimized with respect to the type-1 (false alarms of crises) and type-2 (missed warnings of crises) errors it produces, by minimizing the sum of the ratio of missed crises to total crises periods and false alarms to total noncrises periods. The second tool, labeled the Uncertainty Approach, is actually the same as the method proposed by Mendoza and Oviedo (2009), to which we turn next.[e]

The stochastic methods reviewed above have the significant shortcoming that, as with the Blanchard ratio, they cannot guarantee that their sustainable debt estimates satisfy the IGBC. Moreover, they introduce uncertainty without taking into account the fact that typically government debt is in the form of non-state-contingent instruments. The setup proposed by Mendoza and Oviedo (2006, 2009) addresses these two shortcomings. In this setup, the government issues non-state-contingent debt facing stochastic Markov processes for government revenues and outlays (ie, asset markets are incomplete). The key assumption is that the government is committed to repay, which imposes a constraint on public debt akin to Ayagari's Natural Debt Limit for private debt in Bewley models of heterogeneous agents with incomplete markets.

Following the simple version of this framework presented in Mendoza and Oviedo (2009), assume that output follows a deterministic trend, with an exogenous growth rate given by γ, and that the real interest rate is constant. Assume also that the government

[e] IMF (2013) refers to this approach as "a derivative of the exceptional fiscal performance approach and relies on the same underlying concepts and equations." As we explain, however, Blanchard ratios and their variations differ significantly from the debt limits and debt dynamics characterized by Mendoza and Oviedo (2009).

keeps its outlays smooth, unless it finds itself unable to borrow more, and when this happens it cuts its outlays to minimum tolerable levels.[f] Since the government cannot have its outlays fall below this minimum level, it does not hold more debt than the amount it could service after a long history in which $pb(s^t)$ remains at its worst possible realization (ie, the primary balance obtained with the worst realization of revenues, $\tau^{\min}$, and public outlays cut to their tolerable minimum $g^{\min}$), which can happen with positive probability. This situation is defined as a state of fiscal crisis and it sets and upper bound on debt denoted the "Natural Public Debt Limit" (NPDL), which is given by the growth-adjusted annuity value of the primary balance in the state of fiscal crisis:

$$b_t \leq NPDL \equiv \frac{\tau^{\min} - g^{\min}}{i^r - \gamma}. \tag{3}$$

This result together with the government budget constraint yields a law of motion for debt that follows this simple rule: $b_t = \min\left[NPDL, (1 + r_t)b_{t-1} - pb_t\right] \geq \bar{b}$, where $\bar{b}$ is an assumed lower bound for debt that can be set to zero for simplicity (ie, the government cannot become a net creditor).[g]

Notice that NPDL is lower for governments that have (a) higher variability in public revenues (ie, lower $\tau^{\min}$ in the support of the Markov process of revenues), (b) less flexibility to adjust public outlays (higher $g^{\min}$), or (c) lower growth rates and/or higher real interest rates. The stark differences between NPDL and b^{ss} from the classic debt sustainability analysis are also important to note. The expressions are similar, but the two methods yield sharply different implications for debt sustainability: The classic approach will always identify as sustainable debt ratios that are unsustainable according to the NPDL, because in practice b^{ss} uses the average primary fiscal balance, instead of its worst realization, and as a result it yields a long-run debt ratio that violates the NPDL. Moreover, while b^{ss} cannot be related to the IGBC, the debt rule $b_t = \max\left[NPDL, (1 + r_t)b_{t-1} - pb_t\right] \geq \bar{b}$ always satisfies the IGBC, because debt is bounded above at the NPDL, which guarantees that the no-Ponzi game condition cannot be violated. Note also, however, that the NPDL is a measure of the largest debt that a government can maintain, and not an estimate of the long-run average debt ratio or of the stationary debt ratio.

[f] This is a useful assumption to keep the setup simple, but is not critical. Mendoza and Oviedo (2006) model government expenditures entering a CRRA utility function as an optimal decision of the government, and here the curvature of the utility function imposes the debt limit in the same way as in Bewley models.

[g] This debt rule has an equivalent representation as a lower bound on the primary balance: $pb_t \geq (1 + r_t)b_{t-1} - NPDL$. On the date of a fiscal crisis, b_t hits NPDL. The next period, if the lowest realization of revenues is drawn again, pb_{t+1} hits $\tau^{\min} - g^{\min}$. Debt and the primary balance remain unchanged until higher revenue realizations are drawn, and the larger surpluses reduce the debt. See section III.3 of Mendoza and Oviedo (2009) for stochastic simulations of a numerical example.

The NPDL can be turned into a policy indicator by characterizing the probabilistic processes of the components of the primary balance together with some simplifying assumptions. On the revenue side, the probabilistic process of tax revenues reflects the uncertainty affecting tax rates and tax bases. This uncertainty includes domestic tax policy variability, the endogenous response of the economy to that variability, and other factors that can be largely exogenous to the domestic economy (eg, the effects of fluctuations in commodity prices and commodity exports on government revenues). On the expenditure side, government expenditures adjust partly in response to policy decisions, but the manner in which they respond varies widely across countries, as the literature on procyclical fiscal policy in emerging economies has shown (eg, see Alesina and Tabellini, 2005; Kaminsky et al., 2005; Talvi and Vegh, 2005).

The quantitative analysis in Mendoza and Oviedo (2009) treats the revenue and expenditures processes as exogenous, and calibrates them to 1990–2005 data from four Latin American economies.[h] Since the value of the expenditure cuts that each country can commit to is unobservable, they calculate instead the implied cuts in government outlays, relative to each country's average (ie, $g^{\min} - E[g]$), that would be needed so that each country's NPDL is consistent with the largest debt ratio observed in the sample. The largest debt ratios are around 55% for all four countries (Brazil, Colombia, Costa Rica, and Mexico), but the cuts in outlays that make these debt ratios consistent with the NPDL range from 3.8 percentage points of GDP for Costa Rica to 6.2 percentage points for Brazil. This is the case largely because revenues in Brazil have a coefficient of variation of 12.8%, vs 7% in Costa Rica, and hence to support a similar NPDL at a much higher revenue volatility requires higher $g^{\min}$. Mendoza and Oviedo also showed that the time-series dynamics of debt follow a random walk with boundaries at NPDL and $\bar{b}$.

2.2 Bohn's Debt Sustainability Framework

In a series of influential articles published between 1995 and 2011, Henning Bohn made four major contributions to the empirical literature on debt sustainability tests:

1. *IGBC tests that discount future primary balances at the risk-free rates are misspecified, because the correct discount factors are determined by the state-contingent equilibrium pricing kernel (Bohn, 1995).*[i] Tests affected by this problem include those reported in several well-known empirical studies (eg, Hamilton and Flavin, 1986, Hansen et al., 1991, and Gali, 1991). Following Ljungqvist and Sargent (2012), this mispecification

[h] Mendoza and Oviedo (2006) endogenize the choice of government outlays and decentralize the private and public borrowing decisions in a small open economy model with nonstate-contingent assets.

[i] Lucas (2012) raised a similar point in a different context. She argued that the relevant discount rate for government flows should not be the risk-free rate but a cost of capital that incorporates the market risk associated with government activities.

error is easy to illustrate by using the equilibrium risk-free rates ($R_{t+j}^{-1} = E_t\left[MRS(c_{t+j}, c_t)\right]$) to rewrite the IGBC as follows:

$$b_{t-1} = pb_t + \sum_{j=1}^{\infty}\left[\frac{E_t[pb_{t+j}]}{R_{t+j}} + cov_t\left(MRS(c_{t+j}, c_t), pb_{t+j}\right)\right]. \tag{4}$$

Hence, discounting the primary balances at the risk-free rates is only correct if

$$\sum_{j=1}^{\infty} cov_t\left(MRS(c_{t+j}, c_t), pb_{t+j}\right) = 0.$$

This would be true under one of the following assumptions: (a) perfect foresight, (b) risk-neutral private agents, or (c) primary fiscal balances that are uncorrelated with future marginal utilities of consumption. All of these assumptions are unrealistic, and (c) in particular runs contrary to the strong empirical evidence showing that primary balances are not only correlated with macro fluctuations, but show a strikingly distinct pattern across industrial and developing countries: primary balances are procyclical in industrial countries, and acyclical or countercyclical in developing countries. Moreover, Bohn (1995) also showed examples in which this misspecification error leads to incorrect inferences that reject fiscal solvency when it actually does hold. For instance, a rule that maintains g/y and b/y constant in a balanced-growth economy with i.i.d. output growth violates the mispeficied IGBC if mean output growth is greater or equal than the interest rate, but it does satisfy condition (1).

2. *Testing for debt sustainability is futile, because the IGBC holds under very weak assumptions about the time-series processes of fiscal data that are generally satisfied. The IGBC holds if either debt or revenue and spending inclusive of debt service are integrated of finite but arbitrarily high order (Bohn, 2007).* This invalidates several fiscal solvency tests based on specific stationarity and cointegration conditions (eg, Hamilton and Flavin, 1986; Trehan and Walsh, 1988; Quintos, 1995), because neither a particular order of integration of the debt data, nor the cointegration of revenues and government outlays is necessary for debt sustainability. As Bohn explains in the proof of this result, the reason is intuitive: In the forward conditional expectation that forms the no-Ponzi game condition, the j^{th} power of the discount factor asymptotically dominates the expectation $E_t(b_{t+j})$ as $j \rightarrow \infty$ if the debt is integrated of any finite order. This occurs because $E_t(b_{t+j})$ is *at most* a polynomial of order n if b is integrated of order n, while the discount factor is exponential in j, and exponential growth dominates polynomial growth. But perhaps of even more significance is the implication that, since integration of finite order is indeed a very weak condition, testing for fiscal solvency or debt sustainability per se is not useful: The data are all but certain to reject the hypotheses that debt or revenue and spending inclusive of debt service are nonstationary after differencing the

data a finite number of times (usually only once!). Bohn (2007) concluded that, in light of this result, using econometric tools to try and identify in the data fiscal reaction functions that support fiscal solvency and studying their dynamics is "more promising for understanding deficit problems."

3. *A linear fiscal reaction function (FRF) with a statistically significant, positive (conditional) response of the primary balance to outstanding debt is sufficient for the IGBC to hold (Bohn, 1998, 2008).* Proposition 1 in Bohn (2008) demonstrates that this linear FRF is sufficient to satisfy the IGBC:

$$pb_t = \mu_t + \rho b_{t-1} + \varepsilon_t,$$

for all t, where $\rho > 0$, μ_t is a set of additional determinants of the primary balance, which typically include an intercept and proxies for temporary fluctuations in output and government expenditures, and ε_t is i.i.d. The proof only requires that μ_t be bounded and that the present value of GDP be finite. Intuitively, the argument of the proof is that with pb changing by the positive factor ρ when debt rises, the growth of the debt j periods ahead is lowered by $(1-\rho)^j$. Formally, for any small $\rho > 0$, the following holds as $j \to \infty$: $E_t[MRS(c_{t+j}, c_t)b_{t+j}] \approx (1-\rho)^j b_t \to 0$, which in turn implies that the NPG condition and thus the IGBC hold. Note also that while debt sustainability holds for any $\rho > 0$, the long-run behavior of the debt ratio differs sharply depending on the relative values of the mean r and ρ. To see why, combine the FRF and the government budget constraint to obtain the law of motion of the debt ratio $b_t = -\mu_t + (1 + r_t - \rho)b_{t-1} + \varepsilon_t$. Hence, debt is stationary only if $\rho > r$, otherwise it explodes, but as long as $\rho > 0$ it does so at a slow enough pace to still satisfy IGBC.[j] In addition, the IGBC holds for the same value of initial debt for any $\rho > 0$, but, if $\rho > r$, debt converges to a higher long-run average as ρ falls.

The above results also show why the steady-state debt b^{ss} of the classic debt sustainability analysis is not useful for assessing debt sustainability: With the linear FRF, multiple well-defined long-run averages of debt are consistent with debt sustainability, each determined by the particular value of the response coefficient in the range $\rho > r$, and even exploding debt is consistent with debt sustainability if $0 < \rho < r$. Moreover, in the limit as $r \to 0$, the Blanchard ratio of the classic analysis predicts that debt diverges to infinity ($b^{ss} \to \infty$ if pb^{ss} is finite), while the linear FRF predicts that both b and pb are mean-reverting to well-defined long-run averages given by $-\mu/\rho$ and 0. Similarly, notions of a "maximal sustainable interest rate" are meaningless from

[j] Bohn (2007) shows that this result holds for any of the following three assumptions about the interest rate process: (i) $r_t = r$ for all t, (ii) r_t is a stochastic process that is serially uncorrelated with $E_t[r_{t+1}] = r$, or (iii) r_t is any stochastic process with mean r subject only to implicit restrictions such that $b_t = \frac{1}{1+r}E_t[pb_{t+1} + b_{t+1} - (r_{t+1} - r)b_t]$.

the perspective of assessing whether the debt satisfies the IGBC, because $\rho > 0$ is sufficient for IGBC to hold regardless of the value of r.[k]

4. *Empirical tests of the linear FRF based on historical U.S. data and various subsamples reject the hypothesis that $\rho \leq 0$, so IGBC holds (Bohn, 1998, 2008).* In his 2008 article, Bohn constructed a dataset going back to 1791, the start of US public debt after the Funding Act of 1790, and found that the response coefficient estimated with 1793–2003 data is positive and significant, ranging from 0.1 to 0.12. Moreover, looking deeper into the fiscal dynamics he found that economic growth has been sufficient to cover the entire servicing costs of US public debt, but there are structural breaks in the response coefficient. The 1793–2003 estimates are about twice as large as those obtained in Bohn (1998) using data for 1916–2005, which is a period that emphasizes the cold-war era of declining debt but high military spending.

Bohn's framework has been applied to cross-country datasets by Mendoza and Ostry (2008) and extended to include a nonlinear specification allowing for default risk by Ghosh et al. (2013).[l] Mendoza and Ostry found estimates of response coefficients for a panel of industrial countries that are similar to those Bohn (1998) obtained for the United States. In addition, they found that the solvency condition holds for a panel that includes both industrial and developing countries, as well as in a subpanel that includes only the latter. They also found, however, that cross-sectional breaks are present in the data at particular debt thresholds. In the combined panel and the subpanels with only advanced or only developing economies, there are high-debt country groups for which the response coefficient is not statistically significantly different from zero. Ghosh et al. found that the response coefficients fall sharply at high debt levels, and obtained estimates of fiscal space that measure the distance between observed debt ratios and the largest debt ratios that can be supported given debt limits implied by the presence of default risk.

2.3 Estimated Fiscal Reaction Functions and Their Implications

We provide below new estimation results for linear FRFs for the United States using historical data from 1791 to 2014, and for a cross-country panel using data for the 1951–2013 period. Some of the results are in line with the findings of previous studies, but the key difference is that there is a significant break in the response of the primary

[k] This is not the case if the government cannot commit to repay its debt. In external sovereign default models in the vein of Eaton and Gersovitz (1981), for example, the interest rate is an increasing, convex function of the debt stock, and there exists a debt level at which rationing occurs because future default on newly issued debt becomes a certain event.

[l] The same approach has also been used to test for external solvency (ie, whether the present discounted value of the balance of trade matches the observed net foreign asset position). Durdu et al. (2013) conducted cross-country empirical tests using data for 50 countries over the 1970–2006 period and found that the data cannot reject the hypothesis of external solvency, which in this case is measured as a negative response of net exports to net foreign assets.

balance to debt after 2008. We then use the estimation results and the historical data to put in perspective the current fiscal situation of the United States and Europe. In particular, we show that: (a) primary balance adjustment in the United States is lagging significantly behind what has been observed in the aftermath of previous episodes of large increases in debt, (b) observed primary deficits have been much larger than what the FRFs predict, and (c) hypothetical scenarios with alternative response coefficients produce sharply different patterns of transitional dynamics and long-run debt ratios, but they are all consistent with the same observed initial debt ratios (ie, IGBC holds for all of them).

2.3.1 FRF Estimation Results

Table 1 shows estimation results for the FRF of the United States using historical data for the 1791–2014 period. The table shows results for five regression models similar to those estimated in Bohn (1998, 2008). Column (1) shows the base model, which uses as regressors the initial debt ratio, the cyclical component of output, and temporary military expenditures as a measure of transitory fluctuations in government expenditures.[m] Column (2) introduces a nonlinear spline coefficient when the debt is higher than the mean. Column (3) introduces an AR(1) error term. Column (4) adds the squared mean deviation of the debt ratio. Column (5) includes a time trend. Columns (6) and (7) provide modifications that are important for showing the structural instability of the FRF post-2008: Column (6) reruns the base model truncating the sample in last year of the sample used in Bohn (2008) and Column (7) uses a sample that ends in 2008. The signs of the debt, output gap and military expenditures coefficients are the same as in Bohn's regressions, and in particular the response coefficient estimates are generally positive, which satisfies the sufficiency condition for debt sustainability.

In Columns (1)–(5), the point estimates of ρ range between 0.077 and 0.105, which are lower than Bohn's 2008 estimates based on 1793–2003 data, but higher than his (1998) estimates based on 1916–95 data. The ρ estimates are always statistically significant, although only at the 90% confidence level in the base and squared-debt models.

Column (6) shows that if we run the linear FRF over the same sample period as in Bohn (2008), the results are very similar to his (see in particular Column 1 of table 7 in his paper).[n] The point estimate of ρ is 0.105, compared with 0.121 in Bohn's study (both statistically significant at the 99% confidence level). But in our base model of Column (1) we found that using the full sample that runs through 2014 the point estimate of ρ falls to 0.078. Moreover, excluding the post-2008-crisis data in Column (7), the results

[m] We follow Bohn in measuring this temporary component as the residual of an AR(2) process for military expenditures.

[n] They only differ because we defined military expenditures as the sum of expenditures by the Department of Defense and the Veterans Administration for the full sample, excluding international relations, while Bohn includes Veterans starting in 1940 and adds international relations.

"*,""**," and "***" denote that the corresponding coefficient is statistically significant at the 90%, 95%, and 99% confidence levels. Output gap is percent deviation from Hodrick–Prescott trend. Military expenditure includes all Department of Defense and Department of Veterans Affairs outlays.

are very similar to those obtained with the same sample period as Bohn's. Hence, these results suggest that the addition of the post-2008 data, a tumultous period in the fiscal stance of the United States, produces a structural shift in the FRF.[o] Testing formally for this hypothesis, we found that Chow's forecast test rejects strongly the null hypothesis of no structural change in the value of ρ when the post-2008 data are added. Hence, the decline in the estimate of ρ from 0.102 to 0.078 is statistically significant. This change in the response of the primary balance to higher debt ratios may seem small, but it implies that the primary balance adjustment is about 25% smaller, and as we show later this results in large changes in the short- and long-run dynamics of debt.

The regressions with nonlinear features (Column (2) with the debt spline at the mean debt ratio, and Column (4) with the squared deviation from the mean debt ratio) are very different from Bohn's estimates. In Bohn (1998), the FRF with the same spline term has a negative point estimate $\rho = -0.015$ and a large, positive spline coefficient of 0.105 when debt is above its mean, so that for above-average debt ratios the response of the primary balance is stronger than for below-average debt ratios, and becomes positive with a net effect of 0.09, which is consistent with debt sustainability. In contrast, Table 1 shows a ρ estimate of 0.09 with a spline coefficient of -0.14. Hence, these results suggest that the response of the primary balance is weaker for above-average debt ratios, and the net effect is negative at -0.05, which violates the linear FRF's sufficiency condition for debt sustainability. The spline coefficient is not, however, statistically significant. For the squared-debt regressions, Bohn (2008) estimated a positive coefficient of 0.02, while the coefficient shown in Table 1 is only 0.003 (both not statistically significant). Thus, both the debt-spline and debt-squared regressions are also consistent with the possibility of a structural change in the FRF. In particular, the stronger primary balance response at higher debt ratios that Bohn identified in his 1998 and 2008 studies changed to a much weaker response once the data up to 2014 are introduced. The rationale for this is that the large debt increases since 2008 have been accompanied by adjustments in the primary balance that differ sharply from what has been observed in previous episodes of large debt increases, as we illustrate below.

Tables 2–4 show the results of cross-country panel regressions similar to those reported by Mendoza and Ostry (2008) and Ghosh et al. (2013), but expanded to include data for the 1951–2013 period for 25 advanced and 33 emerging economies. The first six columns of results in these tables show three pairs of regression models. Each pair uses a different measure of government expenditures, since the measure based on military expenditures used in the US regressions is unavailable and/or less relevant as a measure of the temporary component of government expenditures in the international dataset.

[o] Bohn (2008) also found evidence of structural shifts when contrasting his results for 1784–2003 with his 1916–95 results, with sharply lower response coefficients for the shorter sample, which he attributed to the larger weight of the cold-war era (in which debt declined while military spending remained high).

Models (1) and (2) use total real government outlays (ie, current expenditures plus all other noninterest expenditures, including transfer payments), models (3) and (4) use the cyclical component of total real outlays, and models (5) and (6) follow Mendoza and Ostry (2008) and use the cyclical component of real government absorption from the national accounts (ie, real current government expenditures). Models (1), (3) and (5) include country-specific AR(1) terms, which Mendoza and Ostry also found important to consider, while model (2), (4), and (6) do not.

Two caveats about the measures of government expenditures used in these regressions. First, they are less representative of unexpected increases in government expenditures, particularly the HP cyclical component because of the double-sided nature of the HP filter. Second, since the primary balance is the difference between total revenues and expenditures, adding the latter as a regressor implies that revenues are the only endogenous component of the dependent variable that can respond to changes in debt. This is less true when we use only the cyclical component of expenditures and/or use only current expenditures instead of total outlays, but it remains a potential limitation. Interestingly, the coefficients on government expenditures do have the same sign as in the US regressions with temporary military expenditures (although they are about half the size), and they are statistically significant at the 99% confidence level. These caveats do imply, however, that the coefficients on government expenditures cannot be interpreted as measuring only the response of the primary balance to unexpected increases in government expenditures, but can reflect also differences in the cyclical stance of fiscal policies and in the degree of access to debt markets (see Mendoza and Ostry, 2008 for a discussion of these issues).

Table 2 shows that, as in Mendoza and Ostry, considering the country-specific AR(1) terms in the cross-country panel is important. The advanced economies' response coefficients are higher and with significantly smaller standard errors when the autocorrelation of error terms is corrected. Hence, we focus the rest of the discussion of the panel results on the results with AR(1) terms.

The advanced economies' response coefficients of the primary balance on debt in the AR(1) models are positive and statistically significant in general. The coefficients are smaller in the regressions that use cyclical components of either total outlays or current expenditures (models (3) and (5)) than in the one that uses the level of government outlays (model (1)), but across the first two the ρ coefficients are similar (0.02 vs 0.028). Following again Mendoza and Ostry, we focus on the regressions that use the cyclical components of current government expenditures.

Comparing the FRFs with country AR(1) terms and using the cyclical component of current government expenditures across the three panel datasets, Tables 2–4 show that the estimates of ρ are 0.028 for advanced economies, 0.053 for emerging economies, and 0.047 for the combined panel. Mendoza and Ostry obtained estimates of 0.02 for advanced economies and 0.036 for both emerging economies and the combined panel.

The results are somewhat different, but the two are consistent in producing larger values of ρ for emerging economies and the combined panel than for advanced economies.

The difference in the response coefficients across advanced and emerging economies highlights important features of their debt dynamics. Condition (4) suggests that countries with procyclical fiscal policy (ie, acyclical or countercyclical primary balances) can sustain higher debt ratios than countries with countercyclical fiscal policy (ie, procyclical primary balances). Yet we observe the opposite in the data: Advanced economies conduct countercyclical fiscal policy and show higher average debt ratios than emerging economies, which display procyclical or acyclical fiscal policy (ie, significantly lower primary balance-output gap correlations). Indeed, the higher ρ of the emerging economies implies that these countries converge to lower mean debt ratios in the long run. As Mendoza and Ostry (2008) concluded, this higher ρ is not an indicator of "more sustainable" fiscal policies in emerging economies, but evidence of the fact that past increases in debt of a given magnitude in these countries require a stronger conditional response of the primary balance, and hence less reliance on debt markets, than in advanced economies.

2.3.2 Implications for Europe and the United States

Public debt and fiscal deficits rose sharply in several advanced economies after the 2008 global financial crisis, in response to both expansionary fiscal policies and policies aimed at stabilizing financial systems. To put in perspective the magnitude of this recent surge in debt, it is useful to examine Bohn's historical dataset of public debt and primary balances for the United States. Defining a public debt crisis as a year-on-year increase in the public debt ratio larger than twice the historical standard deviation, which is equivalent to more than 8.15 percentage points in Bohn's dataset, we identify five debt crisis events (see Fig. 1): The two world wars (World War I with an increase of 28.7 percentage points of GDP over 1918–19 and World War II with 59.3 percentage points over 1943–45), the Civil War (19.7 percentage points over 1862–63), the Great Depression (18.5 percentage points over 1932–33), and the Great Recession (22.3 percentage points over 2009–10). The Great Recession episode is the third largest, ahead of the Civil War and the Great Depression episodes.

Fig. 2 illustrates the short-run dynamics of the US primary fiscal balance after each of the five debt crises. Each crisis started with large deficits, ranging from 4% of GDP for the Great Depression to nearly 20% of GDP for World War II, but the Great Recession episode is unique in that the primary balance remains in deficit 4 years after the crisis. In the three war-related crises, a large primary deficit turned into a small surplus within 3 years. By contrast, the latest baseline scenario from the Congressional Budget Office (*Updated Budget and Economic Outlook: 2015–2025*, January 2015), projects that the US primary balance will continue in deficit for the next 10 years. The primary deficit is projected to shrink to 0.6% of GDP in 2018 and then hover near 1% through 2025. In addition,

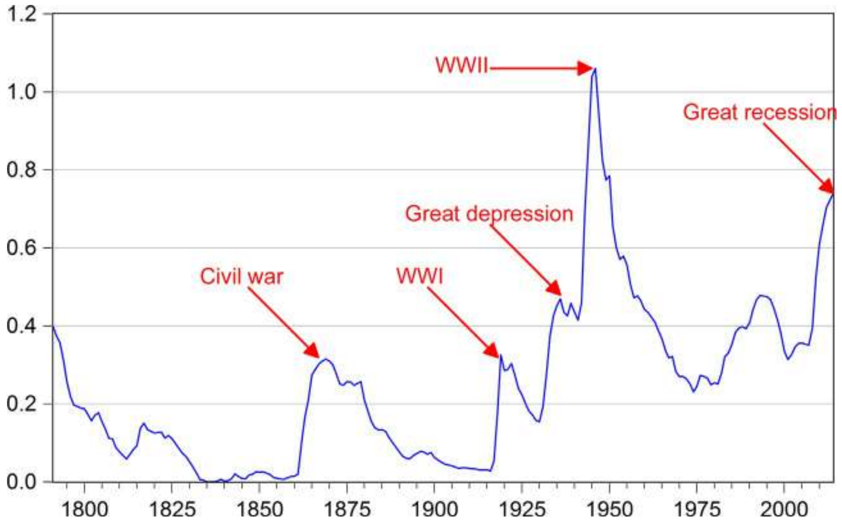

Fig. 1 US government debt as percentage of GDP.

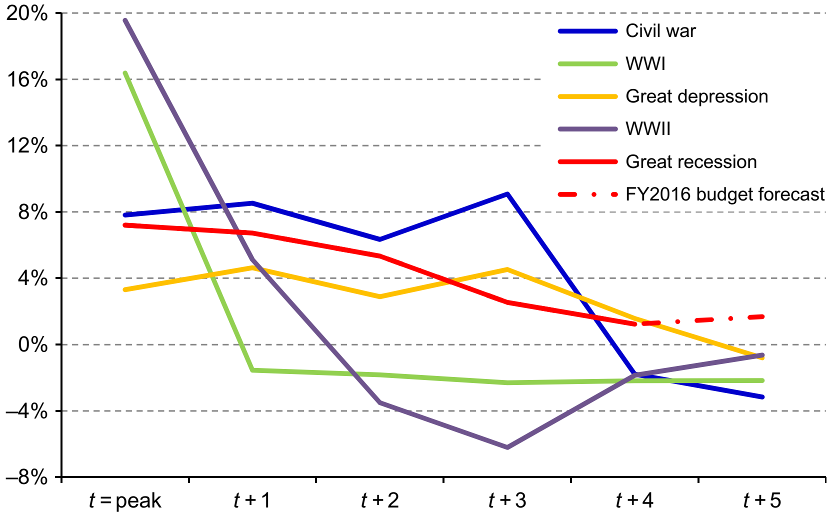

Fig. 2 US government deficits after debt crises.

relative to the Great Depression, the first three deficits of the Great Recession were nearly twice as large, and by 5 years after the debt crisis of the Great Depression the United States had a primary surplus of nearly 1% of GDP. In summary, the post-2008 increase in public debt has been of historic proportions, and the absence of primary surpluses in both the 4 years after the surge in debt and the projections for 2015–25 is *unprecedented* in US history.

Many advanced European economies have not fared much better. Weighted by GDP, the average public debt ratio of the 15 largest European economies rose from 38% to 58% between 2007 and 2011. The increase was particularly large in the five countries at the center of the European debt crisis (Greece, Ireland, Italy, Portugal and Spain), where the debt ratio weighted by GDP rose from 75% to 105%, but even in some of the largest European economies public debt rose sharply (by 33 and 27 percentage points in the United Kingdom and France, respectively).

The estimated FRFs can be used to examine the implications of these rapid increases in public debt ratios for debt sustainability and for the short- and long-run dynamics of debt and deficits. Consider first the regression residuals. Fig. 3 shows the residuals of the US fiscal reaction function estimated in the base model (1) of Table 1, and Fig. 4 shows rolling residuals from the same regression. These two plots show that the residuals for 2008–14 are significantly negative, and much larger in absolute value than the residuals in the rest of the sample period. In fact, the residuals for 2009–11 are twice as large as the corresponding minus-two-standard-error bound. Thus, the primary deficits observed during the post-2008 years have been much larger than what the FRFs predicted, even after accounting for the larger deficits that the FRFs allow on account of the depth of the recession and expansionary government expenditures. These large residuals are of course consistent with the results documented earlier showing evidence of structural change in the FRF when the post-2008 data are added.

The structural change in the FRF can also be illustrated by comparing the actual primary balances from 2009 to 2014 and the government-projected primary balances for

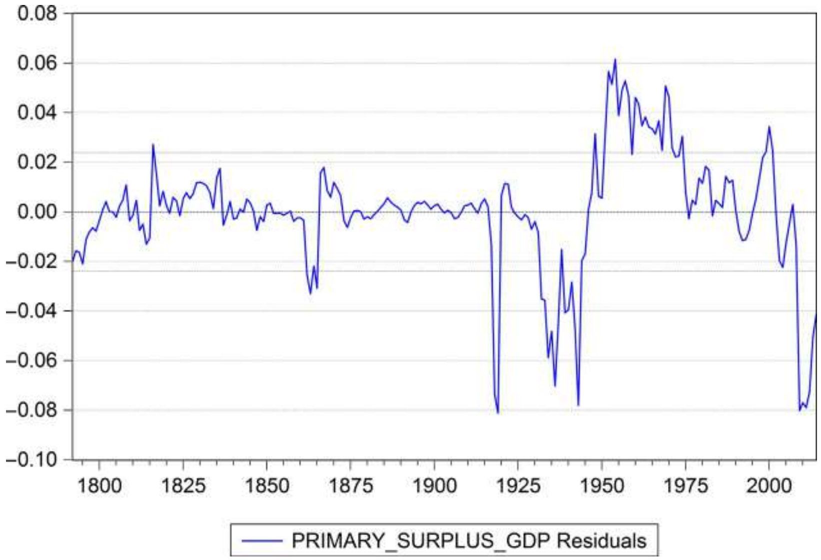

Fig. 3 Residuals for the US fiscal reaction function. *Note*: This residuals correspond to the Base Model (1) in Table 1. The dotted lines are at two s.d. above and below zero.

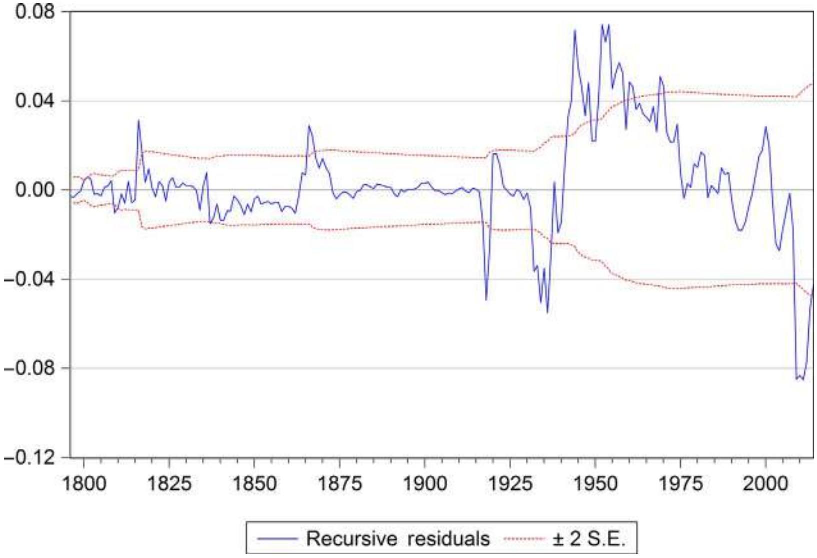

Fig. 4 Rolling residuals for the US fiscal reaction function. *Note*: For each sample 1791-*t*, the baseline specification, model (1) in Table 1, is estimated and the residual at time *t* is reported together with the 2 standard deviation band for the errors in that sample.

2015 to 2020 in the *President's Budget for Fiscal Year 2016* with the out-of-sample forecast that the FRF estimated with data up to 2008 in Column (7) of Table 1 produces (see Fig. 5). To construct this forecast, we use the observed realizations of the cyclical components of output and government expenditures from 2009 to 2014, and for 2015 to 2020 we use again data from the projections in the *President's Budget*.

As Fig. 5 shows, for the period 2009–14, the primary balance showed deficits significantly larger than what the FRF predicted, and also much larger than the deficit at the minus-two-standard-error bound of the forecast band. The mean forecast of the FRF predicted a rising primary surplus from zero to about 4% of GDP between 2009 and 2014, while the data showed deficits narrowing from 8% to about 2% of GDP. In addition, the primary deficits projected in the *President's Budget* are also much larger than predicted by the mean forecast of the FRF, with the projections at or below the minus-two-standard error band. Bohn (2011) warned that already by 2011 there were signs of a likely structural break, because his estimated FRFs called for primary surpluses when the debt ratio surpassed 55–60%, while the 2012 *Budget* projected large and persistent primary deficits at debt ratios much higher than those.

The estimated FRF results can also be used to study projected time-series paths for public debt and the primary balance as of the latest actual observations (2014). To simulate the debt dynamics, we use the law of motion for public debt that results from combining the government budget constraint and the FRF mentioned earlier: $b_t = -\mu_t + (1 + r_t - \rho)b_{t-1} + \varepsilon_t$. We consider baseline scenarios in which we use estimated

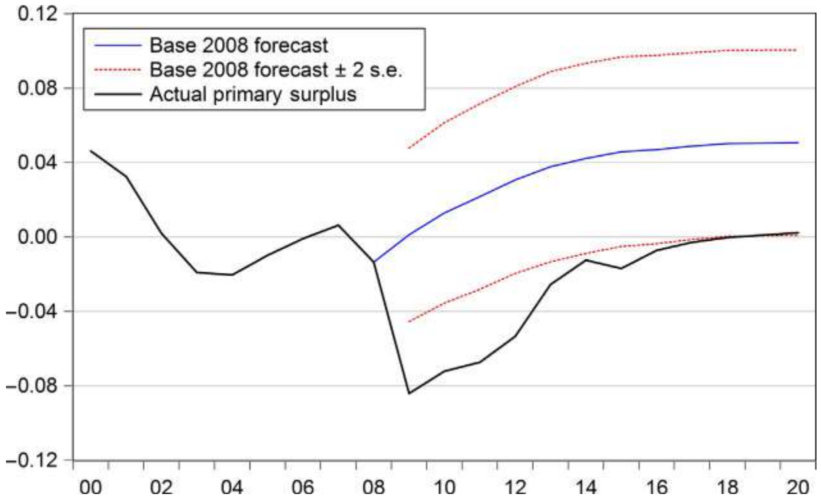

Fig. 5 US primary surplus actual value and 2008 based forecast. *Note*: The forecast is based on model (7) in Table 1 which has the sample restricted to 1791–2008. Given actual values of debt-to-GDP ratio, GDP gap, and military expenditure a forecast of the primary surplus to GDP ratio is generated for the sample 2009–20. Actual variables from 2015 onward correspond to estimates included in The president's budget for fiscal year 2016. Chow's forecast test rejects the null hypothesis of no structural change starting in 2009 with 99.9% confidence.

ρ coefficients for Europe and the United States, and simulate forward starting from the 2014 observations. For the United States, we used model (3) in Table 1. For Europe, we use model (5) from Table 2 and take a simple cross-section average among European industrialized countries. Projections of the future values of the fluctuations in output and government expenditures are generated with simple univariate AR models. In addition, we compare these baseline projection scenarios with scenarios in which we lower the response coefficient to half of the regression estimates or lower the intercept of the FRFs. Recall from the earlier discussion that changing these parameters, as long as $\rho > 0$, generates the same present discounted value of the primary balance as the baseline scenarios, but as we show below the transitional dynamics and long-run debt ratios they produce are very different. These simulations also require assumptions about the values of the real interest rate and the growth rate that determine $1 + r$. For simplicity, we assume that $r = 0$, which rules out the range in which debt can grown infinitely large but still be consistent with the IGBC (ie, the range $0 < \rho < r$), and it also implies that primary balances converge to zero in the long run.[p]

[p] Real interest rates on government debt and rates of output growth in large industrial countries are low but with expectations of an eventual increase. Rather than taking a stance on the difference between the two, we just assumed here that they are equal.

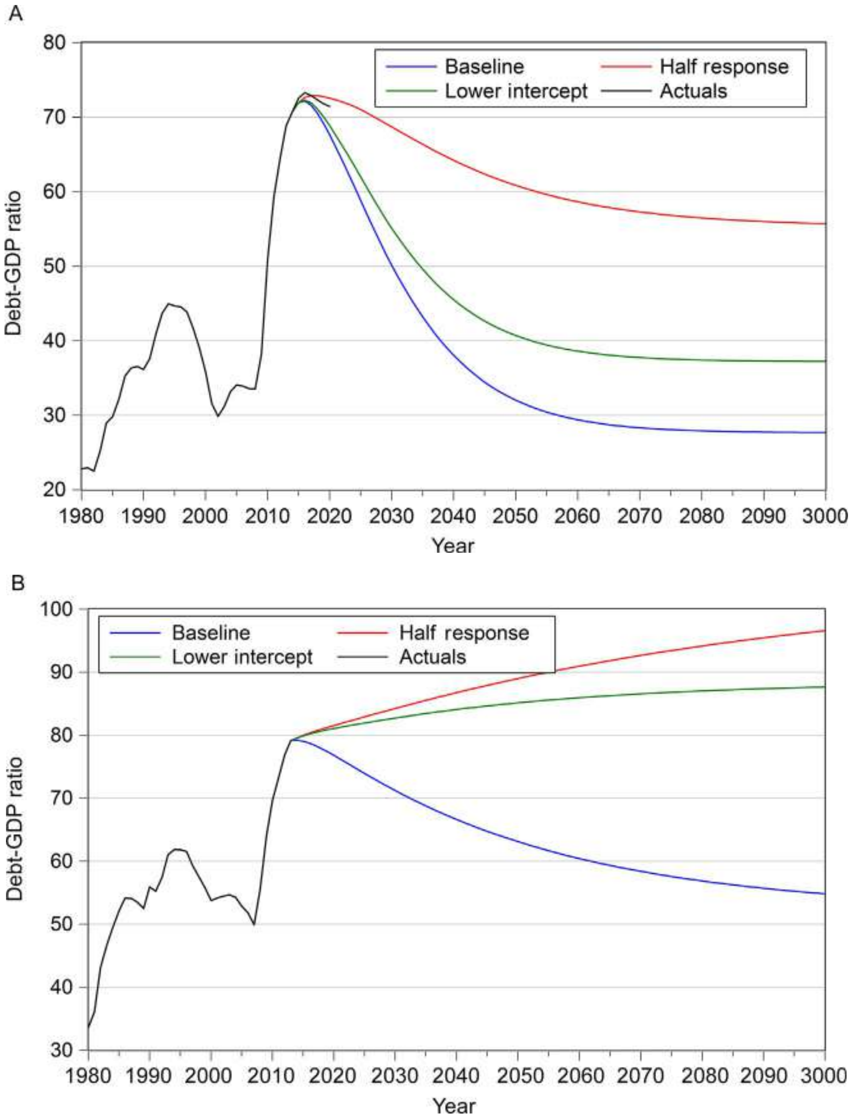

Fig. 6 Debt-to-GDP actuals and simulations since 2014. (A) US debt to GDP. (B) Europe debt to GDP. *Note*: For the United States: Model (3) in Table 1 is used in conjunction with estimated AR(2) processes for the output gap and military expenditure, plus the government budget constraint. For Europe: Model (5) in Table 2 is used in conjunction with estimated AR(1) processes for the output gap and government consumption gap in each country, and a simple average among advanced European countries is taken.

Fig. 6 and 7 show the projected paths of debt ratios and primary balances for the base-line and the alternative scenarios, for both the United States and Europe. These plots show that under the baseline scenario the countries should be reporting primary surpluses that will decline monotonically over time, and should therefore display a monotonically

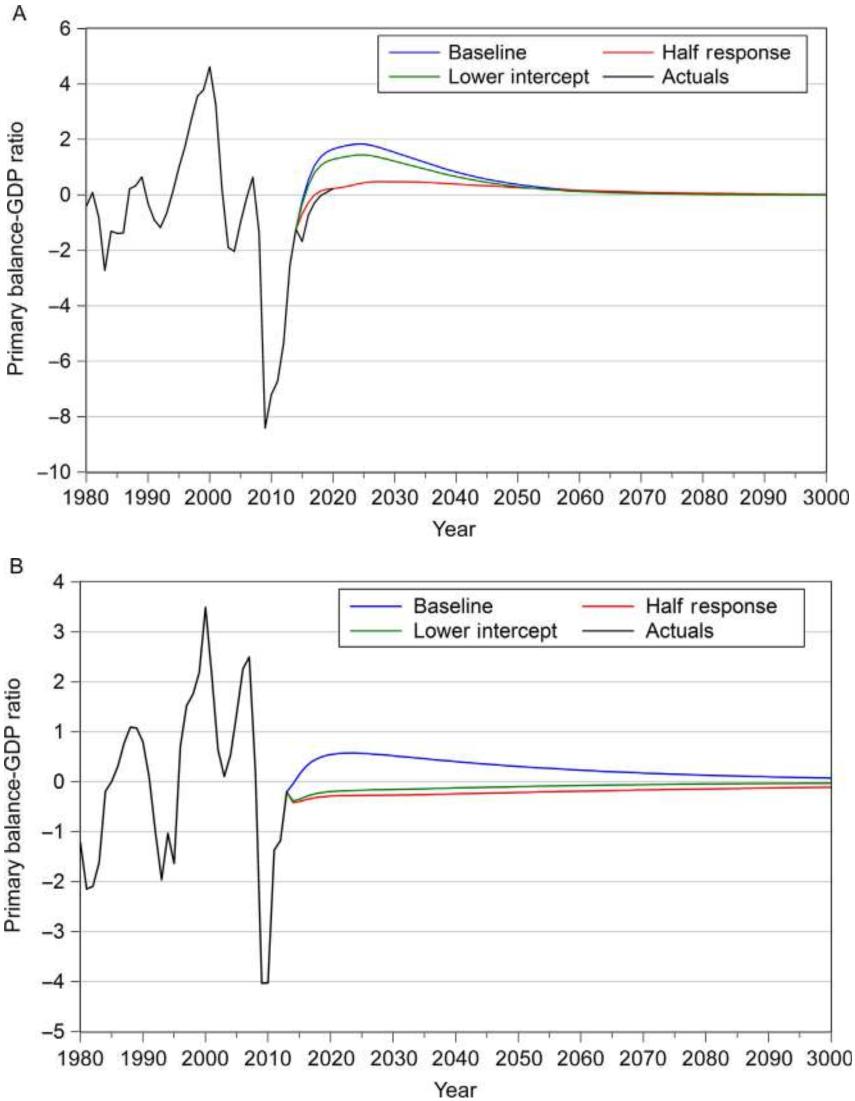

Fig. 7 Primary balance to GDP actuals and simulations since 2014. (A) US primary balance to GDP. (B) Europe primary balance to GDP. *Note*: For details on the construction of this simulations see note on Fig. 6.

declining path for the debt ratio converging back to the average observed in the sample period of the FRF estimates. With lower ρ or lower intercept, the initial surpluses can be significantly smaller or even turned into deficits, but the long-run mean debt ratio would increase significantly. In the case of the United Sates, for example, the long-run average of the debt ratio would rise from 29% in the baseline case to around 57% in the scenario with lower ρ.

All the debt and primary balance paths shown in Figs. 6 and 7 satisfy the same IGBC, and therefore make the same initial debt ratio sustainable, but clearly their macroeconomic implications cannot be the same. Unfortunately, at this point the FRF approach reaches its limits. To evaluate the positive and normative implications of alternative paths of fiscal adjustment, we need a structural framework that can be used to quantify the implications of particular revenue and expenditure policies for equilibrium allocations and prices and for social welfare.

3. STRUCTURAL APPROACH

This section presents a two-country dynamic general equilibrium framework of fiscal adjustment, and uses it to quantify the positive and normative effects of alternative fiscal policy strategies to restore fiscal solvency (ie, maintain debt sustainability) in the United States and Europe after the recent surge in public debt ratios. The structure of the model is similar to the Neoclassical models widely studied in the large quantitative literature on optimal taxation, the effects of tax reforms, and international tax competition (see, for example, Lucas, 1990, Chari et al., 1994, Cooley and Hansen, 1992, Mendoza and Tesar, 1998, 2005, Prescott, 2004, Trabandt and Uhlig, 2011, etc.). In particular, we use the two-country model proposed by Mendoza et al. (2014), which introduces modifications to the Neoclassical model that allow it to match empirical estimates of the elasticity of tax bases to change in tax rates. This is done by introducing endogenous capacity utilization and by limiting the tax allowance for depreciation of physical capital to approximate the allowance reflected in the data.[q]

3.1 Dynamic Equilibrium Model

Consider a world economy that consists of two countries or regions: home (H) and foreign (F). Each country is inhabited by an infinitely-lived representative household, and has a representative firm that produces a single tradable good using as inputs labor, l, and units of utilized capital, $\widetilde{k} = mk$ (where k is installed physical capital and m is the utilization rate). Capital and labor are immobile across countries, but the countries are perfectly integrated in goods and asset markets. Trade in assets is limited to one-period discount bonds denoted by b and sold at a price q. Assuming this simple asset-market structure is without loss of generality, because the model is deterministic.

Following King et al. (1988), growth is exogenous and driven by labor-augmenting technological change that occurs at a rate γ. Accordingly, stationarity of all variables (except labor and leisure) is induced by dividing them by the level

[q] Dynamic models of taxation that consider endogenous capacity utilization include the theoretical analysis of optimal capital income taxes by Ferraro (2010) and the quantitative analysis of the effects of taxes in an RBC model by Greenwood and Huffman (1991).

of this technological factor.[r] The stationarity-inducing transformation of the model also requires discounting utility flows at the rate $\widetilde{\beta} = \beta(1+\gamma)^{1-\sigma}$, where β is the standard subjective discount factor and σ is the coefficient of relative risk aversion of CRRA preferences, and adjusting the laws of motion of k and b so that the date $t+1$ stocks grow by the balanced-growth factor $1+\gamma$.

We describe below the structure of preferences, technology and the government sector of the home country. The same structure applies to the foreign country, and when needed foreign country variables are identified by an asterisk.

3.1.1 Households, Firms, and Government

3.1.1.1 Households

The preferences of the representative home household are standard:

$$\sum_{t=0}^{\infty} \widetilde{\beta}^{t} \frac{\left(c_t(1-l_t)^a\right)^{1-\sigma}}{1-\sigma}, \sigma > 1, a > 0, \text{ and } 0 < \widetilde{\beta} < 1. \tag{5}$$

The period utility function is CRRA in terms of a CES composite good made of consumption, c_t, and leisure, $1 - l_t$ (assuming a unit time endowment). $\frac{1}{\sigma}$ is the intertemporal elasticity of substitution in consumption, and a governs both the Frisch and intertemporal elasticities of labor supply for a given value of σ.[s]

The household takes as given proportional tax rates on consumption, labor income and capital income, denoted τ_C, τ_L, and τ_K, respectively, lump-sum government transfers or entitlement payments, denoted by e_t, the rental rates of labor w_t and capital services r_t, and the prices of domestic government bonds and international-traded bonds, q_t^g and q_t.[t]

The household rents $\widetilde{k}$ and l to firms, and makes the investment and capacity utilization decisions. As is common in models with endogenous utilization, the rate of depreciation of the capital stock increases with the utilization rate, according to a convex function $\delta(m) = \chi_0 m^{\chi_1}/\chi_1$, with $\chi_1 > 1$and $\chi_0 > 0$ so that $0 \leq \delta(m) \leq 1$.

Investment incurs quadratic adjustment costs:

$$\phi(k_{t+1}, k_t, m_t) = \frac{\eta}{2}\left(\frac{(1+\gamma)k_{t+1} - (1-\delta(m_t))k_t}{k_t} - z\right)^2 k_t,$$

[r] The assumption that growth is exogenous implies that tax policies do not affect long-run growth, in line with the empirical findings of Mendoza et al. (1997).

[s] We are using the standard functional form of the utility function from the canonical exogenous balanced growth model as in King et al. (1988) and many RBC applications. This function implies a constant Frisch elasticity for $\sigma = 1$. See Trabandt and Uhlig (2011) for a generalized formulation of the utility function that maintains the constant Frisch elasticity when $\sigma > 1$, and a discussion of the role of the Frisch elasticity in the use of Neoclassical models to quantify the macroeconomic effects of tax changes.

[t] The gross yields in these bonds are simply the reciprocal of these prices.

where the coefficient η determines the speed of adjustment of the capital stock, while z is a constant set equal to the long-run investment-capital ratio, so that at steady state the capital adjustment cost is zero.

The household chooses intertemporal sequences of consumption, leisure, investment inclusive of adjustment costs x, international bonds, domestic government bonds d, and utilization to maximize (5) subject to a sequence of period budget constraints given by:

$$\begin{aligned}(1+\tau_c)c_t + x_t + (1+\gamma)(q_t b_{t+1} + q_t^g d_{t+1}) =& (1-\tau_L)w_t l_t + (1-\tau_K)r_t m_t k_t \\ &+\theta\tau_K\overline{\delta}k_t + b_t + d_t + e_t,\end{aligned} \tag{6}$$

and the following law of motion for the capital stock:

$$x_t = (1+\gamma)k_{t+1} - (1-\delta(m_t))k_t + \phi(k_{t+1}, k_t, m_t),$$

for $t = 0, \ldots, \infty$, given the initial conditions $k_0 > 0$, b_0, and d_0.

The left-hand-side of equation (6) includes all the uses of household income, and the right-hand-side includes all the sources of income net of income taxes. We impose a standard no-Ponzi-game condition on households, and hence the present value of total household expenditures equals the present value of after-tax income plus initial asset holdings.

Notice that in calculating post-tax income in the above budget constraints, we consider a capital tax allowance $\theta\tau_K\overline{\delta}k_t$ for a fraction θ of depreciation costs. This formulation of the depreciation allowance reflects two assumptions about how the allowance works in actual tax codes: First, depreciation allowances are usually set in terms of fixed depreciation rates applied to the book or tax value of capital, instead of the true physical depreciation rate that varies with utilization. Hence, we set the depreciation rate for the capital tax allowance at a constant rate $\overline{\delta}$ that differs from the actual physical depreciation rate $\delta(m)$. The second assumption is that the depreciation allowance only applies to a fraction θ of the capital stock, because in practice it generally applies only to the capital income of businesses and self-employed, and not to residential capital.[u]

We assume that capital income is taxed according to the residence principle, in line with features of the tax systems in the United States and Europe, but countries are allowed to tax capital income at different rates.[v] This also implies, however, that in order

[u] Using the standard 100% depreciation allowance also has two unrealistic implications. First, it renders m independent of τ_K in the long-run. Second, in the short-run τ_K affects the utilization decision margin only to the extent that it reduces the marginal benefit of utilization when traded off against the marginal cost due to changes in the marginal cost of investment.

[v] In principle, the choice of residence vs source based taxation can be viewed as part of the choices made along with the values of tax rates. Indeed, Huizinga (1995) shows that generally optimal taxation would call for a mix of source- and residence-based taxation. In practice, however, most tax systems are effectively residence-based, because widespread bilateral tax treaties provide for source-based-determined tax payments of residents of one country to claim credits for taxes paid to foreign governments.

to support a competitive equilibrium with different capital taxes across countries we must assume that physical capital is owned entirely by domestic residents. Without this assumption, cross-country arbitrage of returns across capital and bonds at common world prices implies equalization of pre- and post-tax returns on capital, which therefore requires identical capital income taxes across countries. For the same reason, we must assume that international bond payments are taxed at a common world rate, which we set to zero for simplicity. For more details, see Mendoza and Tesar (1998). Other forms of financial-market segmentation, such as trading costs or short-selling constraints, could be introduced for the same purpose, but make the model less tractable.

3.1.1.2 Firms

Firms hire labor and effective capital services to maximize profits, given by $y_t - w_t l_t - r_t \tilde{k}_t$, taking factor rental rates as given. The production function is assumed to be Cobb–Douglas:

$$y_t = F(\tilde{k}_t, l_t) = \tilde{k}_t^{1-\alpha} l_t^{\alpha}$$

where α is labor's share of income and $0 < \alpha < 1$. Firms behave competitively and thus choose $\tilde{k}_t$ and l_t according to standard conditions:

$$(1-\alpha)\tilde{k}_t^{-\alpha} l_t^{\alpha} = r_t,$$

$$\alpha \tilde{k}_t l_t^{\alpha-1} = w_t.$$

Because of the linear homogeneity of the production technology, these factor demand conditions imply that at equilibrium $y_t = w_t l_t + r_t \tilde{k}_t$.

3.1.1.3 Government

Fiscal policy has three components. First, government outlays, which include predetermined sequences of government purchases of goods, g_t, and transfer/entitlement payments, e_t, for $t = 0, \ldots, \infty$. In our baseline results, we assume that $g_t = \bar{g}$ and $e_t = \bar{e}$ where $\bar{g}$ and $\bar{e}$ are the steady state levels of government purchases and transfers before the post-2008 surge in public debt. Because entitlements are lump-sum transfer payments, they are always nondistortionary in this representative agent setup, but still a calibrated value of $\bar{e}$ creates the need for the government to raise distortionary tax revenue, since we do not allow for lump-sum taxation. Government purchases do not enter in household utility or the production function, and hence it would follow trivially that a strategy to restore fiscal solvency after an increase in debt should include setting $g_t = 0$. We rule out this possibility because it is unrealistic, and also because if the model is modified to allow government purchases to provide utility or production benefits, cuts in these purchases would be distortionary in a way analogous to raising taxes.

The second component of fiscal policy is the tax structure. This includes time invariant tax rates on consumption τ_C, labor income τ_L, capital income τ_K, and the depreciation allowance limited to a fraction θ of depreciation expenses.

The third component is government debt, d_t. We assume the government is committed to repay its debt, and thus it must satisfy the following sequence of budget constraints for $t=0,\ldots,\infty$:

$$d_t-(1+\gamma)q_t^g d_{t+1}=\tau_C c_t+\tau_L w_t l_t+\tau_K(r_t m_t-\theta\overline{\delta})k_t-(g_t+e_t).$$

The right-hand-side of this equation is the primary fiscal balance, which is financed with the change in debt net of debt service in the left-hand-side of the constraint.

Public debt is sustainable in this setup in the same sense as we defined it in Section 2. The IGBC must hold (or equivalently, the government must also satisfy a no-Ponzi-game condition): The present value of the primary fiscal balance equals the initial public debt d_0. Since we calibrate the model using shares of GDP, it is useful to rewrite the IGBC also in shares of GDP. Defining the primary balance as $pb_t\equiv\tau_C c_t+\tau_L w_t l_t+\tau_K(r_t m_t-\theta{-}\delta)k_t-(g_t+e_t)$, the IGBC in shares of GDP is:

$$\frac{d_0}{y_{-1}}=\psi_0\left[\frac{pb_0}{y_0}+\sum_{t=1}^{\infty}\left(\left[\prod_{i=0}^{t-1}v_i\right]\frac{pb_t}{y_t}\right)\right], \tag{7}$$

where $v_i\equiv(1+\gamma)\psi_i q_i^g$ and $\psi_i\equiv y_{i+1}/y_i$. In this expression, primary balances are discounted to account for long-run growth at rate γ, transitional growth ψ_i as the economy converges to the long-run, and the equilibrium price of public debt q_i^g. Since y_0 is endogenous (ie, it responds to increases in d_0 and the fiscal policy adjustments needed to offset them), we write the debt ratio in the left-hand-side as a share of pre-debt-shock output y_{-1}, which is predetermined.

Combining the budget constraints of the household and the government, and the firm's zero-profit condition, we obtain the home resource constraint:

$$F(m_t k_t,l_t)-c_t-g_t-x_t=(1+\gamma)q_t b_{t+1}-b_t.$$

3.1.2 Equilibrium, Tax Distortions, and International Externalities

A competitive equilibrium for the model is a sequence of prices $\{r_t,\ r_t^*,\ q_t,\ q_t^g,\ q_t^{g*},\ w_t,\ w_t^*\}$ and allocations $\{k_{t+1},\ k_{t+1}^*,\ m_{t+1},\ m_{t+1}^*,\ b_{t+1},\ b_{t+1}^*,\ x_t,\ x_t^*,\ l_t,\ l_t^*,\ c_t,\ c_t^*,\ d_{t+1},\ d_{t+1}^*\}$ for $t=0,\ldots,\infty$ such that: (a) households in each region maximize utility subject to their corresponding budget constraints and no-Ponzi game constraints, taking as given all fiscal policy variables, pretax prices, and factor rental rates; (b) firms maximize profits subject to the Cobb–Douglas technology taking as given pretax factor rental rates; (c) the government budget constraints hold for given tax rates and exogenous sequences of government purchases and entitlements; and (d) the following market-clearing conditions hold in the global markets of goods and bonds:

$$\omega(y_t - c_t - x_t - g_t) + (1-\omega)\left(y_t^* - c_t^* - x_t^* - g_t^*\right) = 0,$$

$$\omega b_t + (1-\omega) b_t^* = 0,$$

where ω denotes the initial relative size of the two regions.

The model's optimality conditions are useful for characterizing the model's tax distortions and their international externalities. Consider first the Euler equations for capital (excluding adjustment costs for simplicity), international bonds and domestic government bonds. These equations yield the following arbitrage conditions:

$$\frac{(1+\gamma)u_1(c_t, 1-l_t)}{\tilde{\beta}\, u_1(c_{t+1}, 1-l_{t+1})} = (1-\tau_K)F_1(m_{t+1}k_{t+1}, l_{t+1})m_{t+1} + 1 - \delta(m_{t+1}) + \tau_K\theta\overline{\delta} = \frac{1}{q_t} = \frac{1}{q_t^g},$$
$$\frac{(1+\gamma)u_1(c_t^*, 1-l_t^*)}{\tilde{\beta}\, u_1(c_{t+1}^*, 1-l_{t+1}^*)} = (1-\tau_K^*)F_1(m_{t+1}^*k_{t+1}^*, l_{t+1}^*)m_{t+1}^* + 1 - \delta(m_{t+1}^*) + \tau_K^*\theta\overline{\delta} = \frac{1}{q_t} = \frac{1}{q_t^{g*}}. \tag{8}$$

Fully integrated financial markets imply that intertemporal marginal rates of substitution in consumption are equalized across regions, and are also equal to the rate of return on international bonds. Since physical capital is immobile across countries, and capital income taxes are residence-based, households in each region face their own region's tax on capital income. Arbitrage equalizes the after-tax returns on capital across regions, but pre-tax returns differ, and hence differences in tax rates are reflected in differences in capital stocks and output across regions. Arbitrage in asset markets also implies that bond prices are equalized. Hence, at equilibrium: $q_t = q_t^g = q_t^{g*}$.

As shown in Mendoza and Tesar (1998), unilateral changes in the capital income tax result in a permanent reallocation of physical capital, and ultimately a permanent shift in wealth, from a high-tax to a low-tax region. Thus, even though physical capital is immobile across countries, perfect mobility of financial capital and arbitrage of asset returns induces movements akin to international mobility of physical capital. In the stationary state with balanced growth, however, the global interest rate R (the inverse of the bond price, $R \equiv 1/q$) is a function of β, γ and σ:

$$R = \frac{(1+\gamma)^\sigma}{\beta},$$

and thus is independent of tax rates. The interest rate does change along the transition path and alters the paths of consumption, output and international asset holdings. In particular, as is standard in the international tax competition literature, each country would have an incentive to behave strategically by tilting the path of the world interest rate in its favor to attract more capital. When both countries attempt this, the outcome is lower capital taxes but also lower welfare for both (which is the well-known race-to-the-bottom result of the tax competition literature).

Consider next the optimality condition for labor:

$$\frac{u_2(c_t, 1-l_t)}{u_1(c_t, 1-l_t)} = \frac{1-\tau_L}{1+\tau_C} F_2(k_t, l_t).$$

Labor and consumption taxes drive the standard wedge $(1 - \tau_W) \equiv (1 - \tau_L)/(1 + \tau_C)$ between the leisure-consumption marginal rate of substitution and the pre-tax real wage (which is equal to the marginal product of labor). Since government outlays are kept constant and the consumption tax is constant, consumption taxation does not distort saving plans, and hence any $(\tau_C,\ \tau_L)$ pair consistent with the same τ_W yields identical allocations, prices, and welfare.

Many Neoclassical and Neokeynesian dynamic equilibrium models feature tax distortions like the ones discussed above, but they also tend to underestimate the elasticity of the capital tax base to changes in capital taxes, because k is predetermined at the beginning of each period, and changes gradually as it converges to steady state. In the model we described, the elasticity of the capital tax base can be adjusted to match the data because capital income taxes have an additional distortion absent from the other models: They distort capacity utilization decisions. In particular, the optimality condition for the choice of m_t is:

$$F_1(m_t k_t, l_t) = \frac{1+\Phi_t}{1-\tau_K} \delta'(m_t), \tag{9}$$

where $\Phi_t = \eta\left(\frac{(1+\gamma)k_{t+1} - (1-\delta(m_t))k_t}{k_t} - z\right)$ is the marginal adjustment cost of investment. The capital tax creates a wedge between the marginal benefit of utilization on the left-hand-side of this condition and the marginal cost of utilization on the right-hand-side. An increase in τ_K, everything else constant, reduces the utilization rate.[w] Intuitively, a higher capital tax reduces the after-tax marginal benefit of utilization, and thus reduces the rate of utilization. Note also that the magnitude of this distortion depends on where the capital stock is relative to its steady state, because the sign of Φ_t depends on Tobin's Q, which is given by $Q_t = 1 + \Phi_t$. If $Q_t > 1$ ($\Phi_t > 0$), the desired investment rate is higher than the steady-state investment rate. In this case, $Q_t > 1$ increases the marginal cost of utilization (because higher utilization means faster depreciation, which makes it harder to attain the higher target capital stock). The opposite happens if $Q_t < 1$ ($\Phi_t < 0$). In this case, the faster depreciation at higher utilization rates makes it easier to

[w] This follows from the concavity of the production function and the fact that $\delta(m_t)$ is increasing and convex.

run down the capital stock to reach its lower target level. Thus, an increase in τ_K induces a larger decline in the utilization rate when the desired investment rate is higher than its long-run target (ie, $\Phi_t > 0$).

The interaction of endogenous utilization and the limited depreciation allowance plays an important role in this setup. Endogenous utilization means that the government cannot treat the existing (predetermined) k as an inelastic source of taxation, because effective capital services decline with the capital tax rate even when the capital stock is already installed. This weakens the revenue-generating capacity of capital taxation, and it also makes capital taxes more distorting, since it gives agents an additional margin of adjustment in response to capital tax hikes (ie, capital taxes increase the post-tax marginal cost of utilization, as shown in eq. 9). The limited depreciation allowance widens the base of the capital tax, but it also strengthens the distortionary effect of τ_K by reducing the post-tax marginal return on capital (see eq. 8). As we show in the quantitative results, the two mechanisms result in a dynamic Laffer curve with a standard bell shape and consistent with empirical estimates of the capital tax base elasticity, while removing them results in a Laffer curve that is nearly-linearly increasing for a wide range of capital taxes.

The cross-country externalities from tax changes work through three distinct transmission channels that result from the tax distortions discussed in the previous paragraphs. First, relative prices, because national tax changes alter the prices of financial assets (including internationally traded assets and public debt instruments) as well as the rental prices of effective capital units and labor. Second, the distribution of wealth across the regions, because efficiency effects of tax changes by one region affect the allocations of capital and net foreign assets across regions (even when physical capital is not directly mobile). Third, the erosion of tax revenues, because via the first two channels the tax policies of one region affect the ability of the other region to raise tax revenue. When one region responds to a debt shock by altering its tax rates, it generates external effects on the other region via these three channels. Given the high degree of financial and trade integration in the world economy today, abstracting from these considerations in quantitative estimates of the effects of fiscal policy is a significant shortcoming.

3.2 Calibration to Europe and the United States

We use data from the United States and the 15 largest European countries to calibrate the model at a quarterly frequency.[x] We calibrate the home region (US) to the United States, and the foreign region (EU15) to the aggregate of the 15 European countries. The EU15 aggregates are GDP-weighted averages. Table 5 presents key macroeconomic statistics and fiscal variables for the all the countries and the two region aggregates in 2008.

[x] The European countries include Austria, Belgium, Denmark, Finland, Greece, France, Germany, Ireland, Italy, the Netherlands, Poland, Portugal, Spain, Sweden, and the United Kingdom. These countries account for over 94% of the European Union's GDP.

Source: OECD Revenue Statistics, OECD National income Accounts, and EuroStat. Tax rates are author’s calculations based on Mendoza, E.G., Razin, A., Tesar, L.L. 1994. Effective tax rates in macroeconomics: cross-country estimates of tax rates on factor incomes and consumption. J. Monet. Econ. 34 (3), 297323. “Total Exp” is total noninterest government outlays.

The first three rows of Table 5 show estimates of effective tax rates on consumption, labor, and capital calculated from revenue and national income accounts statistics using the methodology originally introduced by Mendoza et al. (1994) (MRT). The United States and EU15 have significantly different tax structures. Consumption and labor tax rates are much higher in EU15 than in the United States (0.17 vs 0.04 for τ_C and 0.41 vs 0.27 for τ_L), while capital taxes are higher in the United States (0.37 vs 0.32). The labor and consumption tax rates imply a consumption-leisure tax wedge τ_W of 0.298 for the United States vs 0.496 in EU15. Thus, EU15 has much higher effective tax distortion on labor supply. Notice also that inside of EU15 there is also some tax heterogeneity, particularly with respect to Great Britain, which has higher capital tax and lower labor tax than most of the other EU15 countries.

With regard to aggregate expenditure–GDP ratios, the United States has a much higher consumption share than EU15, by 11 percentage points. EU15 has a larger government expenditure share (current purchases of goods and services, excluding transfers) than the United States by 5 percentage points. Their investment shares are about the same, at 0.21. For net exports, the United States has a deficit of 5% while EU15 has a balanced trade (with the caveat that the latter includes all trade the individual EU15 countries conduct with each other and with the rest of the world). In light of this, we set the trade balance to zero in both countries for simplicity. In terms of fiscal flows, both total tax revenues and government outlays (including expenditures and transfer payments) as shares of GDP are higher in EU15 than in the United States, by 13 and 8 percentage points, respectively. Thus, the two regions differ sharply in all three fiscal instruments (taxes, current government expenditures, and transfer payments).

The bottom panel of Table 5 reports government debt to GDP ratios and their change between end–2007 (beginning of 2008) and end–2011. These changes are our estimate of the increases in debt (or “debt shocks”) that each country and region experienced, and hence they are the key exogenous impulse used in the quantitative experiments. These debt ratios correspond to general government net financial liabilities as a share of GDP as reported in *Eurostat*. As the table shows, debt ratios between end–2007 and 2011 rose sharply for all countries except Sweden, where the general government actually has a net asset position (ie, negative net liabilities) that changed very little. The size of the debt shocks differs substantially across the two regions. The United States entered the Great Recession with a higher government debt to output ratio than EU15 (0.43 vs 0.38) and experienced a larger increase in the debt ratio (0.31 vs 0.20).

Table 6 lists the calibrated parameter values and the main source for each value. The calibration is set so as to represent the balanced-growth steady state that prevailed before the debt shocks occurred using 2008 empirical observations for the corresponding allocations. The value of ω is set at 0.46 so as to match the observation that the United States accounts for about 46% of the combined GDP of the United States and EU15 in 2008. Tax rates, government expenditure shares and debt ratios are calibrated to the values in the United States and EU15 columns of Table 5, respectively. The limit on the

τ_L	Labor income tax	0.27	0.41	MRT modified
τ_K	Capital income tax	0.37	0.32	MRT modified
θ	Depreciation allowance limitation	0.20		$(REV_K^{corp}/REV_K)(K^{NR}/K)$, OECD Revenue Statistics and EU KLEMS

Note: The implied growth adjusted discount factor $\tilde{\beta}$ is 0.995, and the implied precrisis annual interest rate is 3.8%. REV_K^{corp}/REV_K is the ratio of corporate tax revenue to total capital tax revenue. K^{NR}/K is the ratio of nonresidential fixed capital to total fixed capital.

depreciation allowance, θ, is set to capture the facts that tax allowances for depreciation costs apply only to capital income taxation levied on businesses and self-employed, and do not apply to residential capital (which *is* included in k). Hence, the value of θ is set as $\theta=(REV_K^{corp}/REV_K)(K^{NR}/K)$, where (REV_K^{corp}/REV_K) is the ratio of revenue from corporate capital income taxes to total capital income tax revenue, and (K^{NR}/K) is the ratio of nonresidential fixed capital to total fixed capital. Using 2007 data from OECD *Revenue Statistics* for revenues, and from the European Union's *EU KLEMS* database for capital stocks for the ten countries with sufficient data coverage,[y] these ratios range from 0.32% to 0.5% for (REV_K^{corp}/REV_K) and from 27% to 52% for (K^{NR}/K). Weighting by

[y] These countries are Austria, Denmark, Finland, Germany, Italy, Netherlands, Spain, Sweden, the United Kingdom, and the United States.

GDP, the aggregate value of θ is 0.20. Also the value for the United States is close to the weighted value for the European countries.

The technology and preference parameters are set the same across the United States and EU15, except the parameters χ_0 and χ_1 in the depreciation function. The common parameters are calibrated to target the weighted average statistics for all sample countries. The labor share of income, α, is set to 0.61, following Trabandt and Uhlig (2011). The quarterly rate of labor-augmenting technological change, γ, is 0.0038, which corresponds to the 1.51% weighted average annual growth rate in real GDP per capita of all the countries in our sample between 1995 and 2011, based on Eurostat data. We normalize the long-run capacity utilization rate to $\bar{m}=1$. Given γ at 0.0038, x/γ at 0.19 and k/γ at 2.62 from the data, we solve for the long-run depreciation rate from the steady-state law of motion of the capital stock, $x/\gamma=(\gamma+\delta(\bar{m}))k/\gamma$.[z] This yields $\delta(\bar{m})=0.0163$ per quarter. The constant depreciation rate for claiming the depreciation tax allowance, $\overline{\delta}$, is set equal to the steady state depreciation rate of 0.0163.

The value of χ_0 follows then from the optimality condition for utilization at steady state, which yields $\chi_0=\delta(\bar{m})+\dfrac{1+\gamma-\beta}{\beta}-\tau_K\overline{\delta}$. Given this, the value of χ_1 follows from evaluating the depreciation rate function at steady state, which implies $\chi_0\bar{m}^{\chi_1}/\chi_1=\delta(\bar{m})$. Given the different capital tax rates in the United States and EU15, the implied values for χ_0 and χ_1 are slightly different across countries: χ_0 is 0.0233 in the United States and 0.0235 in EU15, and χ_1 is 1.435 in the United States and 1.445 in EU15.

The preference parameter, σ, is set at a commonly used value of 2. The exponent of leisure in utility is set at $a=2.675$, which is taken from Mendoza and Tesar (1998). This value supports a labor allocation of 18.2 h, which is in the range of the 1993–96 averages of hours worked per person aged 15–64 reported by Prescott (2004). The value of β follows from the steady-state Euler equation for capital accumulation, using the values set above for the other parameters that appear in this equation:

$$\frac{\gamma}{\tilde{\beta}}=1+(1-\tau_K)(1-\alpha)\frac{\gamma}{k}-\delta(\bar{m})+\tau_K\theta\overline{\delta}.$$

This yields $\tilde{\beta}=0.995$, and then since $\tilde{\beta}=\beta(1+\gamma)^{1-\sigma}$ it follows that $\beta=0.998$. The values of β, γ and σ pin down the steady-state gross real interest rate, $R=\beta^{-1}(1+\gamma)^{\sigma}=1.0093$. This is equivalent to a net annual real interest rate of about 3.8%.

Once R is determined, the steady-state ratio of net foreign assets to GDP is pinned down by the net exports-GDP ratio. Since we set $tb/\gamma=0$, $b/\gamma=(tb/\gamma)/\left[(1+\gamma)R^{-1}-1\right]=0$. In addition, the steady-state government budget constraint yields

[z] Investment rates are from the OECD National Income Accounts and capital-output ratios are from the AMECO database of the European Commission.

an implied ratio of government entitlement payments to GDP $e/y = Rev/y - g/y - (d/y)\left[1-(1+\gamma)R^{-1}\right] = 0.196$. Under this calibration approach, both b/y and e/y are obtained as residuals, given that the values of all the terms in the right-hand-side of the equations that determine them have already been set. Hence, they generally will not match their empirical counterparts. In particular, for entitlement payments the model underestimates the 2008 observed ratio of entitlement payments to GDP (0.196 in the model vs 0.26 in the data for All EU). Notice, however, that when the model is used to evaluate tax policies to restore fiscal solvency, the fact that entitlement payments are lower than in the data strengthens our results, because lower entitlements means a lower required amount of revenue than what would be needed to support observed transfer payments, thus making it easier to restore solvency. We show below that restoring fiscal solvency is difficult and implies nontrivial tax adjustments with sizable welfare costs and cross-country spillovers, all of which would be larger with higher government revenue requirements due to higher entitlement payments.

The value of the investment-adjustment-cost parameter, η, cannot be set using steady-state conditions, because adjustment costs wash out at steady state. Hence, we set the value of η so that the model is consistent with the mid-point of the empirical estimates of the short-run elasticity of the capital tax base to changes in capital tax rates. The range of empirical estimates is 0.1–0.5, so the target midpoint is 0.3.[aa] Under the baseline symmetric calibration, the model matches this short-run elasticity with $\eta = 2.0$. This is also in line with estimates in House and Shapiro (2008) of the response of investment in long-lived capital goods to relatively temporary changes in the cost of capital goods.[ab]

Table 7 reports the 2008 GDP ratios of key macro-aggregates in the data and the model's corresponding steady-state allocations for the US–EU15 calibration. As noted earlier, this calibration captures the observed differences in the size of the regions, their fiscal policy parameters, and their public debt-GDP ratios. Notice in particular that the consumption-output ratios and the fiscal revenue-output ratios from the data were not directly targeted in the calibration, but the two are closely matched by the model. Hence, the model's initial stationary equilibrium before the increases in public debt is a reasonably good match to the observed initial conditions in the data.

[aa] The main estimate of the elasticity of the *corporate* tax base relative to corporate taxes in the United States obtained by Gruber and Rauh (2007) is 0.2. Dwenger and Steiner (2012) obtained around 0.5 for Germany. Grubler and Rauh also reviewed the large literature estimating the elasticity of *individual* tax bases (which include both labor and capital income taxes collected from individuals) to individual tax rates and noted this: "The broad consensus…is that the elasticity of taxable income with respect to the tax rate is roughly 0.4. Moreover, the elasticity of actual income generation through labor supply/savings, as opposed to reported income, is much lower. And most of the response of taxable income to taxation appears to arise from higher income groups."

[ab] They estimated an elasticity of substitution between capital and consumption goods in the 6–14 range. In the variant of our model without utilization choice, this elasticity is equal to $1/(\eta\delta)$. Hence, for $\delta(\bar{m}) = 0.0164$, elasticities in that range imply values of η in the 1–2.5 range.

3.3 Quantitative Results

The goal of the quantitative experiments is to use the numerical solutions of the model to study whether alternative fiscal policies can restore fiscal solvency, which requires increasing the present discounted value of the primary balance in the right-hand-side of (7) by as much as the observed increases in debt.[ac] Notice that the change in this present value reflects changes in the endogenous equilibrium dynamics of the primary balance-GDP ratio in response to the changes in fiscal policy variables. In turn, the changes in primary balance dynamics reflect the effects of these policy changes on equilibrium allocations and prices that determine tax bases, and the computation of the present value reflects also the response of the equilibrium interest rates (ie, debt prices).

We conduct a set of experiments in which we assume that the United States or EU15 implement unilateral increases in either capital or labor tax rates, so we can quantify the effects on equilibrium allocations and prices, sustainable debt (ie, primary balance dynamics), and social welfare in both regions. We also compare these results with those obtained if the same tax changes are implemented assuming the countries are closed economies, so we can highlight the cross-country externalities of unilateral tax changes.

The model is solved numerically using a modified version of the algorithm developed by Mendoza and Tesar (1998, 2005), which is based on a first-order approximation to the equilibrium conditions around the steady state. Standard perturbation methods cannot be applied directly, because trade in bonds implies that, when the model's pre-debt-crisis steady state is perturbed, the equilibrium transition paths of allocations and prices, and the new steady-state equilibrium need to be solved for simultaneously.[ad] This is because

[ac] The observed increases in debt between end-2007 (beginning of 2008) and end-2011 can be viewed as exogenous increases in d_0/y_{-1} in the left-hand-side of the IGBC (7). As reported in Table 5, the US debt ratio rose by 31 percentage points from 41%, and that of the EU15 rose by 20 percentage points from 38%.

[ad] Alternative solution methods that make the interest rate or the discount factor ad-hoc functions of net foreign assets (NFA), or that assume that holding these assets is costly, are also not useful, because they impose calibrated NFA positions that cannot be affected by tax changes, whereas the "true" model without these modifications can yield substantial world redistribution of wealth as a result of tax policy changes.

in models of this class stationary equilibria depend on initial conditions, and thus cannot be determined separately from the models' dynamics. Mendoza and Tesar dealt with this problem by developing a solution method that nests a perturbation routine for solving transitional dynamics within a shooting algorithm. This method iterates on candidate values of the new long-run net foreign asset positions to which the model converges after being perturbed by debt and tax changes, until the candidate values match the positions the model converges to when simulated forward to its new steady state starting from the calibrated pre-debt-crisis initial conditions.

3.3.1 Dynamic Laffer Curves

We start the analysis of the quantitative results by constructing "Dynamic Laffer Curves" (DLC) that show how unilateral changes in capital or labor taxes in one region affect that region's sustainable public debt. These curves map values of τ_K or τ_L into the equilibrium present discounted value of the primary fiscal balance. For each value that a given tax rate in the horizontal axis takes, we solve the model to compute the intertemporal sequence of total tax revenue, which varies as equilibrium allocations and prices vary, while government purchases and entitlement payments are kept constant. Then we compute the present value of the primary balance, which therefore captures the effect of changes in the equilibrium sequence of interest rates. We take the ratio of this present value to the initial output y_{-1} (ie, GDP in the steady state calibrated to pre-2008 data) so that it corresponds to the term in the right-hand-side of the IGBC (7), and plot the result as a *change* relative to the 2007 public debt ratio. Hence, the values along the vertical axis of the DLCs show the change in d_0/y_{-1} that particular values of τ_K or τ_L can support as sustainable debt at equilibrium (ie, debt that satisfies the IGBC with equality). By construction, the curves cross the zero line at the calibrated tax rates of the initial stationary equilibrium, because those tax rates yield exactly the same present discounted value of the primary balance as the initial calibration. To make the observed debt increases sustainable, there needs to be a value of the tax rate in the horizontal axis such that the DLC returns a value in the vertical axis that matches the observed change in debt.

Since the "passive" region whose taxes are not being changed unilaterally is affected by spillovers of the other region's tax changes, there needs be an adjustment in the passive region so that its IGBC is unchanged (ie, it maintains the same present discounted value of primary fiscal balances). We refer to this adjustment as maintaining "revenue neutrality" in the passive region. In principle this can be done by changing transfers, taxes or government purchases. However, since we have assumed already that government purchases are kept constant in both regions, reducing distortionary tax rates in response to favorable tax spillovers would be more desirable than increasing transfer payments, which are nondistortionary. Hence, we maintain revenue neutrality in the passive region by adjusting the labor tax rate.

3.3.1.1 Dynamic Laffer Curves for Capital Taxes

The DLCs for capital taxes are plotted in Fig. 8. The panel (A) is for the US region, and the panel (B) is for EU15. The solid lines show the open-economy curves and the dotted lines are for when the countries are in autarky. As explained above, the DLCs intersect the zero line at the initial tax rates of $\tau_K = 0.37$ and $\tau_K^* = 0.32$ by construction. We also show in the plots the increases in debt observed in each region, as shown in Table 5: The

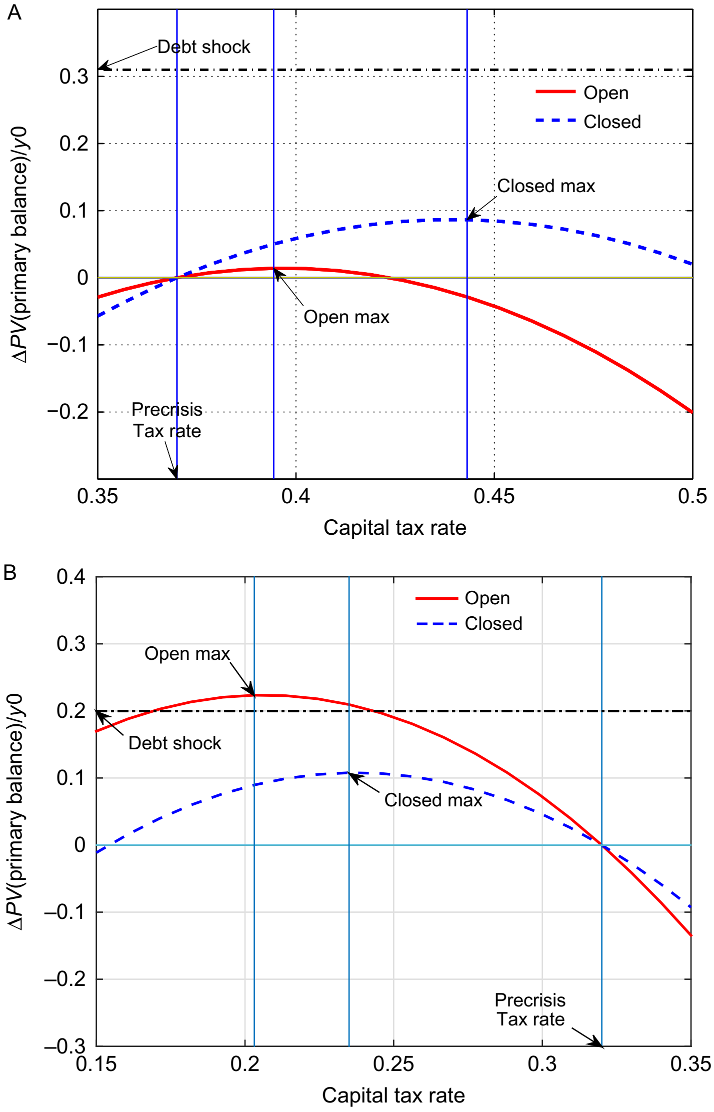

Fig. 8 Dynamic Laffer curves of capital tax rates. (A) United States. (B) EU15.

US net public debt ratio rose 31 percentage points and that of EU15 rose 20 percentage points. These increases are marked with the "Debt Shock" line in Fig. 8.

Fig. 8 shows that the DLCs of the United States and EU15 are very different, with those for EU15 seating higher, shifted to the left, and showing more curvature than those for the United States. Hence, unilateral changes in capital tax rates show a capacity to sustain larger debt increases in EU15 than in the United States, and can do so at lower tax rates. These marked differences are the result of the heterogeneity in fiscal policies present in the data and captured in the calibration, and in the open-economy scenario they are also partly explained by the international externalities of the unilateral tax changes assumed in constructing the DLCs. EU15 has higher revenue-generating capacity because of higher labor and consumption taxes at identical labor income shares and similar consumption shares, although in terms of primary balance the higher revenue is partly offset by higher government purchases. On the other hand, the United States has a lower capital tax rate and by enough to make a significant difference in the inefficiencies created by capital taxes across the two regions, as we illustrate in more detail below. Moreover, the magnitude of heterogeneity in the capital tax DLCs that results from a given magnitude of heterogeneity in fiscal variables depends on the model's modifications made to match the observed elasticity of the capital base. We illustrate below that DLCs are very different if we remove capacity utilization and the limited depreciation allowance.

Beyond the difference in position and shape of the capital tax DLCs across the United States and EU15, these DLCs deliver three striking results: First, unilateral changes in the US capital tax cannot restore fiscal solvency and make the observed increase in debt unsustainable (the peaks of the DLCs of the US region either as a closed or an open economy are significantly below the debt shock line). The maximum point of the open-economy DLC is attained at $\tau_K = 0.402$, which produces an increase in the present value of the primary balance of only 2 percentage points of GDP, far short of the required 31. In contrast, the maximum point of the open-economy DLC for EU15 is attained around $\tau_K^* = 0.21$, which rises the present value of the primary balance by 22 percentage points of GDP, slightly more than the required 20. Under autarky, however, the EU15 DLC also peaks below the required level, and hence capital taxes also cannot restore fiscal solvency for EU15 as a closed economy. This result also reflects the strong cross-country externalities that we discuss in more detail below (ie, unilateral capital tax *cuts* yield significantly more sustainable debt for EU15 as an open economy than under autarky).

Second, capital income taxes in EU15 are highly inefficient. The current capital tax rate is on the increasing segment of the DLC for the United States but on the decreasing segment for EU15. This has two important implications. One is that EU15 could have sustained the calibrated initial debt ratio of 38% at capital taxes below 15%, instead of the 32% tax rate obtained from the data. The second is that to make the observed 20 percentage points increase in debt sustainable, EU15 can *reduce* its capital tax almost in half to about 17% in the open-economy DLC. In both cases, the sharply lower capital taxes would be much less distortionary and thus would increase efficiency significantly.

Third, cross-country externalities of capital income taxes are very strong, and under our baseline calibration, they hurt (favor) the capacity to sustain debt of the United States (EU15). For the United States, the DLC under autarky is steeper than in the open-economy case, and it peaks at a higher tax rate of 43% and with a higher increase in the present value of the primary balance of about 10 percentage points. Thus, the United States can always sustain more debt, or support higher debt increases relative to the calibrated baseline, for a given increase in τ_K under autarky than as an open economy. This occurs because by increasing its capital tax *unilaterally* as an open economy the United States not only suffers the efficiency losses in capital accumulation and utilization, but it also triggers reallocation of physical capital from the United States to EU15, which results in reductions (increases) in the United States (EU15) factor payments and consumption, and thus lower (higher) tax bases in the United States (EU15). The same mechanism explains why reducing the capital tax in EU15 unilaterally generates much less revenue under autarky than in the open-economy case. In the latter, cutting the EU15 capital tax unilaterally triggers the same forces as a unilateral increase in the US capital tax.

This quantitative evidence of strong externalities of capital taxes across financially integrated economies demonstrates that evaluating “fiscal space,” or the capacity to sustain debt, using closed-economy models leads to seriously flawed estimates of the effectiveness of capital taxes as a tool to restore debt sustainability. The results also suggest that incentives for strategic interaction leading to capital income tax competition are strong, and get stronger as higher debts need to be reconciled with fiscal solvency (as evidenced by the history of corporate tax competition inside the EU since the 1980s). Mendoza et al. (2014) study this issue using a calibration that splits the European Union into two regions, one including the countries most affected by the European debt crisis (Greece, Ireland, Italy, Portugal, and Spain) and the second including the rest of the Eurozone members.

3.3.1.2 Dynamic Laffer Curves of Labor Tax Rates

Fig. 9 shows the DLCs for the labor tax rate. Notice that the open-economy and autarky DLCs are similar within each region (although more similar for EU15 than for the United States), which indicates that international externalities are much weaker in this case. This is natural, because labor is an immobile factor, and although it can still trigger cross-country spillovers via general-equilibrium effects, these are much weaker than the first-order effects created by unilateral changes of capital taxes via the condition that arbitrages after-tax returns on all assets across countries.

The main result of the DLCs for labor taxes is that the DLCs for the United States are much higher than those for EU15. Since the international externalities are weak for the

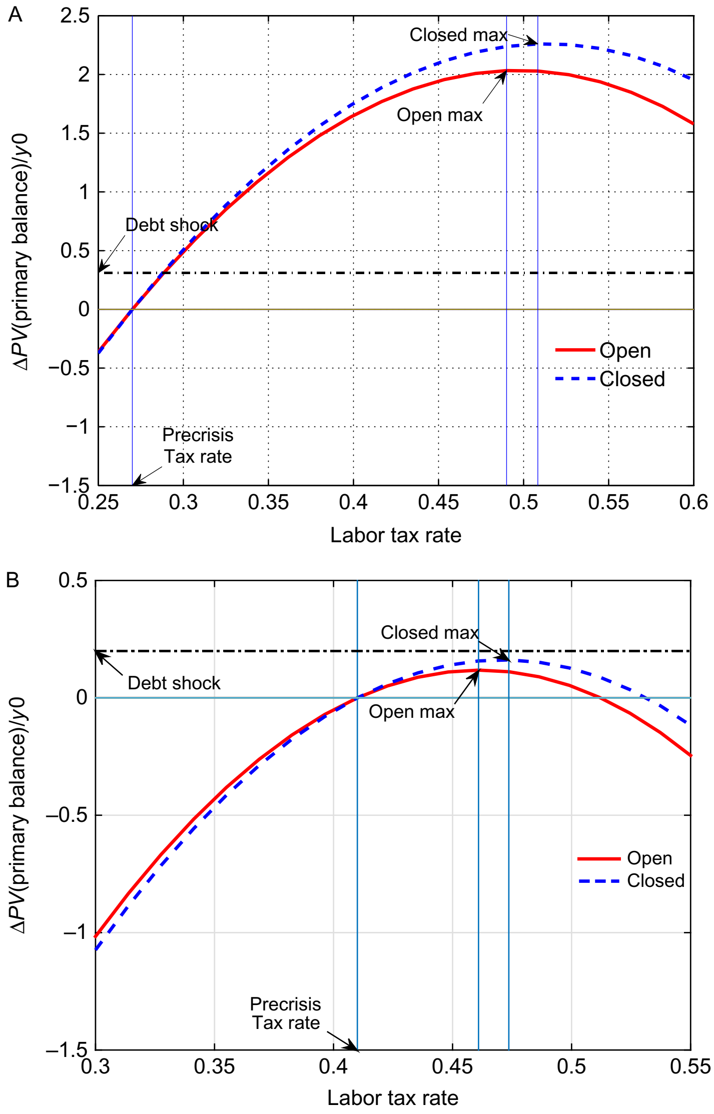

Fig. 9 Dynamic Laffer curves of labor tax rates. (A) United States. (B) EU15.

labor tax, this result is only due to the different initial conditions resulting from the fiscal heterogeneity captured in our calibration, and in particular to the large differences in initial labor and consumption taxes (41 vs 27% for labor and 17 vs 4% for consumption in EU15 vs the United States, respectively). Increasing the calibrated τ_L for the US region to the EU15 rate of 41%, keeping all other US parameters unchanged, shifts down its labor tax DLC almost uniformly by about 200 percentage points in the 0.25–0.55 interval of labor tax rates. This happens because, for an increase in the labor tax of a given size, the difference in initial conditions implies that the US region generates a larger increase in the present value of total tax revenue than EU15, and since the present value of government outlays is nearly unchanged in both, the larger present value of revenue is amplified into a significantly larger increase in the present value of the primary balance.[ae]

The US open-economy DLC for τ_L is considerably steeper than for τ_K, and it peaks at a tax rate of 0.48, which would make sustainable an initial debt ratio larger than in the initial baseline by 200 percentage points of GDP, much more than the 31 percentage points required by the data. The labor tax rate that the United States as an open or closed economy needs to make the observed debt increase sustainable is about 29%, which is just a two-percentage-point increase relative to the initial tax rate. Hence, these results show that, from the perspective of macroeconomic efficiency that representative-agent models of financially integrated economies like the one we are using emphasize, labor taxes are a significantly more effective tool for restoring fiscal solvency in the United States than capital taxes.

The DLC of EU15 yields much less positive results. Since the initial consumption-labor wedge is already much higher in this region than in the United States, the fiscal space of the labor tax rate is very limited. In either the closed- or open-economy cases, the DLC peaks at a labor tax rate of 46% and yields an increase of only about 10 percentage points in the present value of the primary balance, which is half of the 20-percentage-points increase EU15 needs make the observed debt increase sustainable.

It is interesting to note that the debt increase in the United States was about 10 percentage points larger than in Europe, yet the model predicts that given the initial conditions in tax rates and government outlays before the increases in debt, unilateral tax adjustments in Europe cannot generate a sufficient increase in the present value of the primary balance to make their higher debt sustainable. The exception is the capital tax in the open-economy scenario, in which this is possible only because EU15 would benefit significantly from a negative externality on the US region. In contrast, the results show that a modest increase in labor taxes (or consumption taxes since they are equivalent in this model) can restore fiscal solvency in the United States.

It is useful to compare the results we reported here with those of similar exercises in other existing studies based on Neoclassical models, particularly those by Trabandt and

[ae] The percent change in the present value of the primary balance after a tax change of a given magnitude relative to before (assuming that the present value of government outlays does not change) can be expressed as $z[1 + PDV(g + e)/PDV(pb)]$, where $z$is the percent change in the present value of tax revenues after the tax change relative to before, and $PDV(g + e)$ and $PDV(pb)$ are the pretax-change present values of total government outlays and the primary balance, respectively. Hence, for $z > 0$ and since total outlays are much larger than the primary balance $[PDV(g + e)/PDV(pb)] >> 1$, a given difference in z across the United States and EU15 translates into a much larger percent difference in the present value of the primary balance.

Uhlig (2011, 2012) and Auray et al. (2013). Trabandt and Uhlig (2011, 2012) used a closed-economy model without endogenous capacity utilization and focused mainly on steady-state Laffer curves (ie, Laffer curves that map tax rates into steady state tax revenues), while the DLCs studied here are for present values taking into account both transitional dynamics and steady-state changes caused by tax changes relative to the calibrated tax rates. Qualitatively, the results in Trabandt and Uhlig (2011) are similar to the ones in this chapter because they find that capital tax hikes generate much smaller increases in revenue than labor taxes. They find that the maximum increases in steady-state tax revenue obtained with capital (labor) taxes are 6 (30)% for the United States and 1 (8)% for Europe. Quantitatively; however, the results reported here differ not only because both transitional dynamics and steady-states are included, but also because the two-country model with capacity utilization captures the cross-country externalities of tax policy and the observed elasticity of the capital tax base, and these two features undermine the revenue-generating capacity of tax hikes.

Trabandt and Uhlig (2012) extend their analysis to gauge the sustainability of observed debt levels in response to hypothetical permanent increases in interest rates. Keeping government transfers, total outlays and debt constant at observed levels, they calculate the maximum real interest rate at which the revenue generated at the peak of steady-state Laffer curves would satisfy the steady-state government budget constraint. That is, effectively they compute the interest rate at which the Blanchard ratio of the previous section holds with debt and spending set at observed levels and tax revenue set at the maxima of steady-state Laffer curves. They find that the maximum real interest rate for the United States is larger than for European countries if labor taxes are moved to the peak of the Laffer curves. These calculations, however, inherit the limitations of the Blanchard ratios as measures of sustainable debt discussed in the previous section, and imply unusually large primary fiscal surpluses. For instance, depending on the debt measure used, Trabandt and Uhlig estimate the maximum interest rate for the United States in the 12–15.5% range. With a 92% debt ratio, a 1.5% annualized output growth rate and the 12% interest rate, the US economy requires a 9.6% steady-state primary surplus. The largest primary surplus observed in US history using Bohn's historical dataset starting in 1790 was 6.3%, and the average was just 0.4%. Moreover, moving the labor tax to the peak of the Laffer curve reduces steady-state output by 27%, which suggests that the welfare cost of the tax hike is quite large.

Auray et al. (2013) use a Neoclassical model of a small open economy to conduct a quantitative comparison of tax policies aimed at lowering European debt ratios. They introduce a FRF in the class of the ones examined in the previous section: Increases of the debt ratio at date t above its date-t target induce increases in the date-t primary surplus above its date-t target. The primary balance adjustment is obtained by adjusting one of the tax rates as needed to satisfy the FRF. In this environment, lowering the debt ratio requires higher tax rates in the short term in exchange for lower rates in the long term as steady-state debt service falls. They find that a cut of 10 percentage points in the debt ratio can be attained with an increase in welfare using the capital income tax, roughly no change in welfare using the consumption tax, and a welfare loss using the labor income tax. Qualitatively, the model studied here would produce similar results if applied to a similar debt-reduction experiment. Since the capital income tax is highly distorting, using the benefit of the lower debt service burden to cut the capital income tax would be best for welfare and efficiency. Their setup, however, is not calibrated to match the capital tax base elasticity and abstracts from cross-country externalities because of the small-open-economy assumption.

3.3.2 Macroeconomic Effects of Tax Rate Changes

We analyze next the macroeconomic effects of unilateral changes in capital and labor tax rates. In the first experiment, the United States increases its capital tax rate from the initial value of 0.37 to 0.402, which is the maximum point of the open-economy DLC for the United States. Table 8 shows the effects of this change on both regions in the open-economy model and on the US region as a closed economy. EU15 reduces its labor tax rate from 0.41 to 0.40 to maintain revenue neutrality, which is the result of favorable externalities from the tax hike in the United States.

The capital tax hike in the United States as an open economy leads to an overall welfare cost of 2.19% vs 2.22% as a closed economy, while EU15 obtains a welfare gain of 0.74%.[af] Comparing the US outcomes as an open economy relative to the closed economy under the same 40.2% capital tax rate, we find that the sustainable debt (ie, the present value of the primary balance) rises by a factor of 4.5 (from 1.37% to 6.16%). The welfare loss is nearly the same (2.2%), but normalizing by the amount of revenue generated, the United States is much better off in autarky. Thus, seen from this perspective, the United States would have strong incentives for either engaging in strategic interaction (ie, tax competition) or for considering measures to limit international capital mobility.

The 0.74% welfare gain that EU15 obtains from the US unilateral capital tax hike is a measure of the normative effect of the cross-country externalities of capital tax changes. The United States can raise more revenue by increasing τ_K along the upward-sloping region of its DLC, but its ability to do so is significantly hampered by the adverse externality it faces due to the erosion of its tax bases. In EU15, the same externality indirectly improves government finances, or reduces the distortions associated with tax collection, and provides it with an unintended welfare gain.

[af] Welfare effects are computed as in Lucas (1987), in terms of a percent change in consumption constant across all periods that equates lifetime utility under a given tax rate change with that attained in the initial steady state. The overall effect includes transitional dynamics across the pre- and post-tax-change steady states, as well as changes across steady states. The steady-state effect only includes the latter.

The impact and long-run effects on key macro-aggregates in both regions are shown in the bottom half of Table 8. The corresponding transition paths of macroeconomic variables as the economies move from the precrisis steady state to the new steady state are illustrated in Fig. 10. The increase in τ_K causes US capital to fall over time to a level 7.6% below the precrisis level, while EU15's capital rises to a level 1.25% above the pre-tax-change level. Capacity utilization falls at home in both the short run and the long run, which is a key component of the model capturing the reduced revenue-generating capacity of capital tax hikes when the endogeneity of capacity utilization is considered. We show later in this section that this mechanism indeed drives the elasticity of the capital tax base in the model, which matches that of the data and is higher than what standard representative-agent models of taxation show.

On impact when the United States increases its capital tax, labor increases in the United States and falls slightly in EU15, but this pattern reverses during the transition

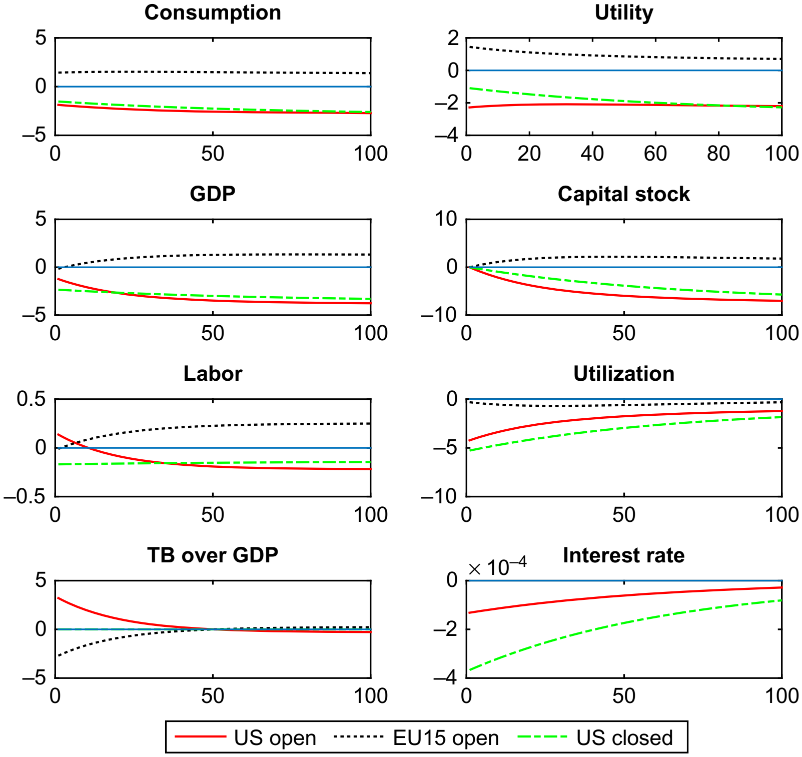

Fig. 10 Responses of macro variables to a US capital tax rate increase.

to steady state because of the lower (higher) capital stock in US (EU15) region in the new steady state. Consequently, US output contracts by almost 4% in the long-run, underscoring efficiency losses due to the capital tax increase and the costs of the fiscal adjustment. The United States increases its net foreign asset position (NFA) by running trade surpluses (tb/y) in the early stages of transition, while EU15 decreases its NFA position by running trade deficits. The US trade surpluses reflect saving to smooth out the cost of the efficiency losses, as output follows a monotonically decreasing path. Still, utility levels are lower than when the United States implements the same capital tax under autarky, because of the negative cross-country spillovers.

We next look at the responses of fiscal variables when the United States increases its capital tax, plotted in Fig. 11. In the United States, tax revenue from capital income increases almost immediately to a higher constant level when τ_K rises, while the revenues from labor and consumption taxes decline both on impact and in the long run. Labor and consumption tax rates are not changing, but both tax bases fall on impact and then decline monotonically to their new, lower steady states. The primary fiscal balance and total revenue both rise initially but then converge to about the same levels as in the precrisis stationary equilibrium. For the primary balance, this pattern is implied by the pattern of the

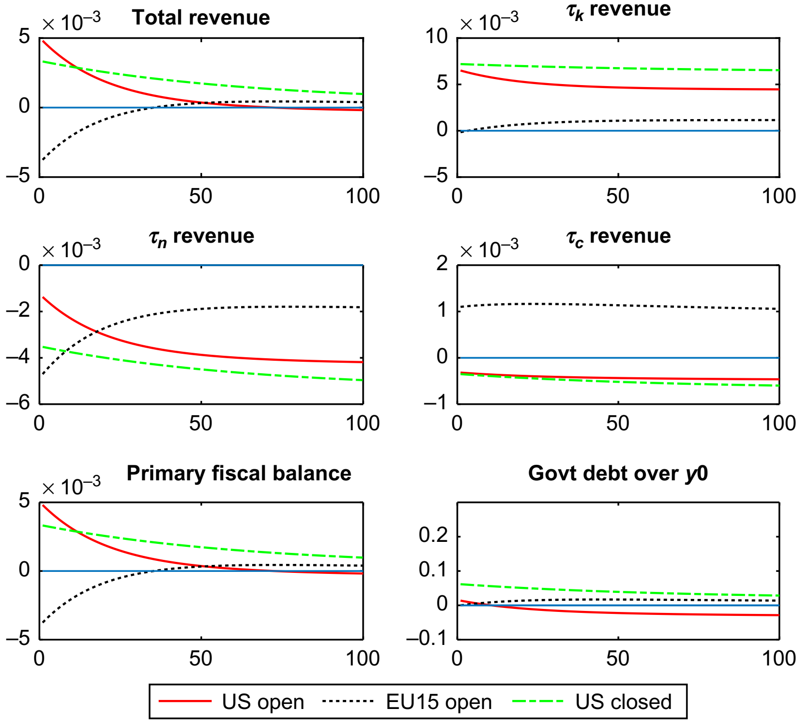

Fig. 11 Responses of fiscal variables to a US capital tax rate increase.

total revenue, since government expenditures and entitlements are held constant. For total revenue, the transitional increase indicates that the rise in capital tax revenue more than offsets the decline in the revenue from the other taxes in the transition, while in the long-run they almost offset each other exactly. This is possible because the change in τ_K to 0.4 is on the increasing side of the Laffer curve, and in fact it is the maximum point of the curve. Hence, this capital tax hike does not reduce capital tax revenues.

The public debt dynamics in the bottom-right panel of Fig. 11 shows that on impact, government debt in the United States responds to the 40% tax rate by increasing 5 percentage points, reflecting the extra initial debt that can be supported at the higher capital tax rate. Since the primary fiscal balance rises on impact and then declines monotonically, the debt ratio also falls monotonically during the transition, and converges to a ratio that is actually about 4 percentage points below the precrisis level. Hence, the initial debt increase allowed by the capital tax hike is followed by a protracted decline in debt converging to a debt ratio even lower that in the precrisis steady state. If the United States implements the same tax hike under autarky, it generates significantly larger revenues and primary balances, and hence the debt ratio increases more initially and converges to a higher steady state of 1 percentage points above the precrisis level. This is again a reflection of the cross-country externalities faced by the United States as an open economy, since equally sized tax hikes produce significantly higher revenues under autarky.

The cross-country externalities are also reflected in the fiscal dynamics of EU15 shown in Fig. 11. Maintaining revenue neutrality (in present value) still allows both its revenue and primary balance to fall initially, while in the long run both converge to very similar levels as in the precrisis steady state. Removing the labor tax adjustment in EU15 that maintains revenue neutrality, the present value of its primary balance as a share of GDP would increase by 10.1 percentage points relative to the precrisis ratio, and both its revenue and primary balances would be higher than in the plots shown in Fig. 11. The welfare gain, however, would be negligible instead of 0.74% in lifetime consumption.

The next experiment examines the effects of lowering the EU15 capital tax rate so as to move it out of the decreasing segment of the DLC. To make this change analogous to the one in the previous experiment, we change the EU15 capital tax to the value at the maximum point of the DLC for EU15, which is about 21%. Table 9 summarizes the results. The cut in the EU15 capital tax rate generates an increase of about 22 percentage points in sustainable debt (just a notch above what is required to make the observed debt increase sustainable), and a large welfare gain of 6.9% for this region. Its capital stock rises over time to a level 26% higher than in the pre-tax-change steady state. Output, consumption, labor supply, and utilization all rise in both the short-run and the long-run in EU15, while the trade balance moves initially into a large trade deficit and then converges to a small surplus. The same tax cut in EU15 as a closed economy yields a much smaller rise in sustainable debt, of just under 10 percentage points, though the welfare gain is about the same as in the open economy. This result indicates that in this case the welfare gain largely reflects the reduction of the large inefficiencies due to the initial capital tax being in the decreasing side of the DLC. In the US region, the tax cut in EU15 causes a welfare loss of 0.2%, with capital declining 1.5 percent from the pre-tax-change level.

The next two experiments focus on changes in labor tax rates. The DLCs for the labor tax rate (Fig. 9) show that the US region has substantial capacity to raise tax revenues and sustain higher debt ratios by raising labor taxes. We examine in particular an increase of the labor tax rate that completely offsets the observed debt increase, which as we noted earlier is only about 2 percentage points higher than in the initial calibration (ie, the labor tax in the United States rises from 27% to 29%). The results are reported in Table 10. The declines in US output, consumption, capital, and welfare are much smaller than with the capital tax hike. Since the international spillovers are small, this tax change produces a welfare gain of just 0.18% in EU15. For the same reason, comparing the United States results as a closed vs open economy, the change in the present value of the primary balance is almost the same, in contrast with the large difference obtained for the capital tax. Also, keep in mind that the capital tax hike, even though it was set at the maximum point of the capital tax DLC of the United States as open economy, cannot generate enough revenue to offset the observed debt increase, whereas the labor tax hike does.

Now consider the case of increasing the EU15 labor tax. As explained earlier in discussing the labor DLCs, the EU15 initial consumption/labor wedge is already high, so the capacity for raising tax revenues using labor taxes is limited. In this experiment, we increase the labor tax in EU15 to the rate at the maximum point of the labor tax DLC of EU15 as an open economy, which implies a labor tax rate of 0.465. The results are summarized in Table 11. The higher EU15 labor tax increases the present value of the primary balance-GDP ratio by only 0.118, falling well short of the observed debt increase of 0.2. The welfare loss is large, at nearly 5%, with output, consumption, capital, and labor falling. EU15 can produce a higher present value of the primary balance (0.16) in the closed economy at a similar welfare loss. Again the international spillover for the labor tax rate is small, so the US region makes a negligible welfare gain.

Taken together these findings are consistent with two familiar results from tax analysis in representative-agent models, which emphasize the efficiency costs of tax distortions. First, the capital tax rate is the most distorting tax. Second, in open-economy models,

taxation of a mobile factor (ie, capital) yields less revenue at greater welfare loss than taxation of the immobile factor (ie, labor). This is in line with our results showing that the cross-country tax externalities are strong for capital taxes but weak for labor taxes.

The sharp differences we found between the United States and EU15 also have important policy implications in terms of debates about debt-sustainability and the effects of fiscal adjustment via capital and labor taxes in Europe and the United States. With capital taxes, the model suggests that the United States is on the increasing side of the Laffer curve, though it cannot restore fiscal solvency for the observed debt shock of 31 percentage points (neither as an open economy nor as a closed economy). In contrast, the model suggests that Europe is on the decreasing side of the Laffer curve, and can make its observed debt increase of 20 percentage point sustainable by reducing its capital taxes and moving away from the decreasing side of the Laffer curve, and in the process make a substantial welfare gain. This is only possible, however, because the United States is assumed to maintain its capital tax rate unchanged as Europe's drops, which results in

large externalities that benefit Europe at the expense of the United States. Capital tax hikes under autarky cannot restore fiscal solvency for Europe either.

With labor taxes, although the model indicates that both the United States and Europe are on the increasing side of their DLCs, the US pre-2008 started with a much smaller consumption/labor distortion than Europe. As a result, the United States has substantial fiscal space to easily offset the debt increase with a small labor tax hike and a small welfare cost of 0.9%. In contrast, the model suggests that Europe cannot restore fiscal solvency after the observed increase in debt using labor taxes.

3.3.3 Why Are Utilization and Limited Depreciation Allowance Important?

As explained earlier, we borrowed from Mendoza et al. (2014) the idea of using endogenous capacity utilization and a limited tax allowance for depreciation expenses to build into the model a mechanism that produces capital tax base elasticities in line with empirical estimates. In contrast, standard dynamic equilibrium models without these features tend to have unrealistically low responses of the capital base to increases in capital taxes. To illustrate this point, we follow again Mendoza et al. in comparing DLCs for capital taxes in three scenarios (see Fig. 12): (i) a standard Neoclassical model with exogenous utilization and a full depreciation allowance ($\theta = 1$), shown as a dashed-dotted line; (ii) the same model but with a limited depreciation allowance ($\theta = 0.2$), shown as a dotted line; and (iii) the baseline calibration of our model with both endogenous utilization and a limited depreciation allowance (using again $\theta = 0.2$), shown as a solid line. All other

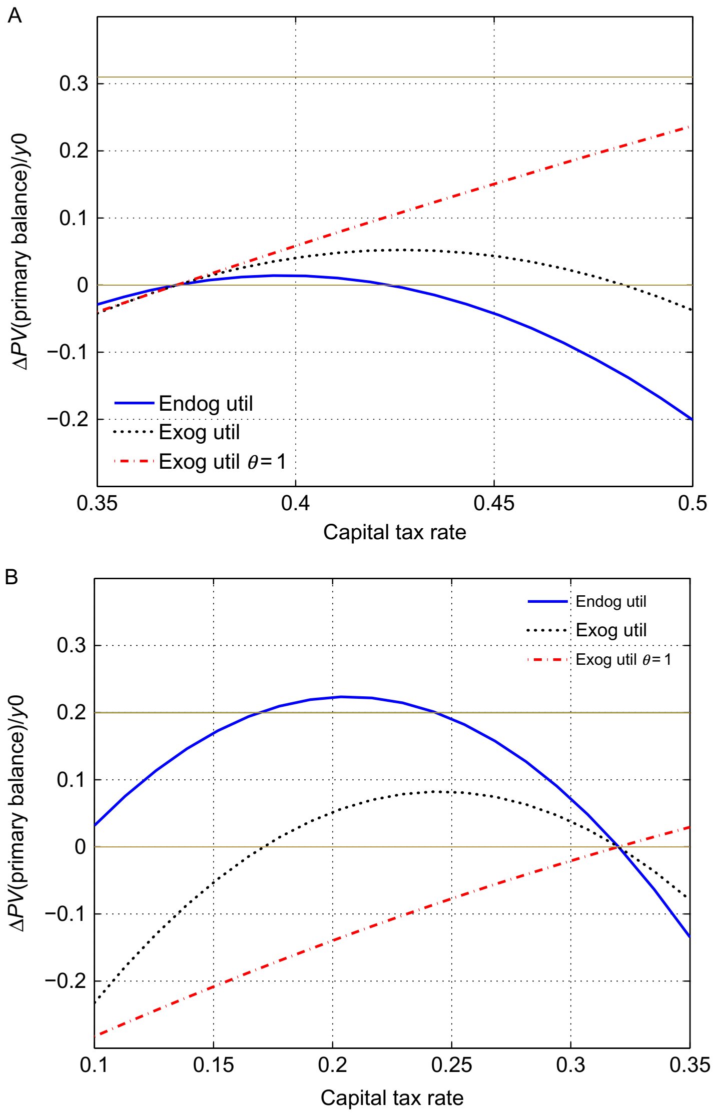

Fig. 12 Comparing dynamic Laffer curves for the capital tax rate. (A) United States. (B) EU15.

parameter values are kept the same. We show the three cases for the United States and EU15 region in panels (A) and (B) of the figure, respectively.

The DLCs for the three cases intersect at the initial calibrated tax rates of 0.37 and 0.32 for the United States and EU15 by construction. To the right of this point, the curves for case (i) are always above the other two, and the ones for case (ii) are always above the ones for case (iii). The opposite occurs to the left of the intersection points.

Consider the US plots. In case (i), the DLC has a positive, approximately linear slope in the 0.35–0.5 domain of capital tax rates. This curve continues to be increasing even when we extend the capital tax rate to 0.9, which is in line with the results obtained by Trabandt and Uhlig (2011).[ag] This behavior of the DLC for the capital tax follows from the fact that at any given date the capital stock is predetermined and has a low short-run elasticity. As a result, the government can raise substantial revenue over the transition period because the capital stock declines only gradually. The increased tax revenue during the transition dominates the fall in the steady-state, resulting in a nondecreasing DLC (recall the DLC is based on present value calculations).

Introducing limited depreciation allowance without endogenizing the utilization choice (case (ii)) has two effects that induce concavity in the DLC. First, it increases the effective rate of taxation on capital income, and thus weakens the incentive to accumulate capital and lowers the steady-state capital-output ratio and tax bases. On the other hand, it has a positive impact on revenue by widening the capital tax base. The first effect dominates the latter when the capital tax rate rises relative to the initial tax of 0.37, resulting in sharply lower DLC curve values than in case (i).

In case (iii) the tax allowance is again limited but now capacity utilization is endogenous. This introduces additional effects that operate via the distortions on efficiency and the ability to raise revenue discussed earlier: On the side of tax distortions, equation (9) implies that endogenous utilization adds to the efficiency costs of capital income taxation by introducing a wedge between the marginal cost and benefits of capital utilization. On the revenue side, endogenous utilization allows agents to make adjustments in effective capital (reducing it when taxes rise and increasing it when it falls), and thus alters the amount of taxable capital income. Hence, when utilization falls in response to increases in capital tax rates, it also weakens the government's ability to raise capital tax revenue. These effects lead to a bell-shaped DLC that has more curvature and is significantly below those in cases (i) and (ii). Thus, endogenous utilization makes capital taxes more distorting and weakens significantly the revenue-generating capacity of capital taxes.[ah]

[ag] They find that present-value Laffer curves of capital tax revenue peak at very high tax rates (discounting with the constant steady state interest rate) or have a positive slope over the full range (discounting with equilibrium interest rates).

[ah] Mendoza et al. also found that removing the limited depreciation allowance from case (iii) still results in a DLC below those of cases (i) and (ii), but it is also flatter and increasing for a wider range of capital taxes than case (iii).

Panel (B) of Fig. 12 shows DLCs for the three cases in the EU15 region. The results are analogous to Panel (A) but emphasizing now the region to the left of the intersection point, which is at the initial tax of 32%. In case (i), again the DLC has an increasing positive slope over a large range of the capital tax rate. Case (ii) shows that limiting the depreciation allowance again induces concavity in the DLC, with the EU15 initial capital tax already in the decreasing segment of the curve. Comparing with case (iii), the exogenous utilization case generates much less revenue. As in the US results, this occurs because with endogenous utilization, reductions in capital taxes lead to higher utilization rates that result in higher levels of capital income and higher wages, thus widening the two income tax bases.

The effects of endogenous utilization and limited depreciation have significant implications for the elasticity of the capital income tax base with respect to the capital tax. In particular, as Mendoza et al. (2014) showed, the model can be calibrated to match a short-run elasticity consistent with empirical estimates because of the combined effects of those two features. As documented earlier, the empirical literature finds estimates of the short-run elasticity of the capital tax base in the 0.1–0.5 range. Table 12 reports the model's comparable elasticity estimates and the effects on output, labor, and utilization 1 year after a 1% increase in the capital tax (relative to the calibrated baseline values), again for cases (i), (ii), and (iii) and in both the United States and EU15 regions.

The United States and EU15 results differ somewhat quantitatively, but qualitatively they make identical points: The neoclassical model with or without limited depreciation allowance (cases (i) and (ii)) yields short-run elasticities with the wrong sign (ie, the capital tax base *rises* in the short run in response to capital tax rate increases). The reason is that capital does not change much, since capital is predetermined in the period of the tax hike and changes little in the first period after because of investment adjustment costs, and

Table 12 Short-run elasticity of US capital tax base

	Elasticity	y_1	l_1	m_1
Empirical estimates	[0.1, 0.5]			
Model implications for the United States				
Exog. utilization and $\theta = 1$	−0.09	0.04%	0.011	
Exog. utilization and $\theta = 0.2$	−0.09	0.08%	0.028	
Endog. utilization and $\theta = 0.2$	0.29	−0.15%	0.010	−0.471
Model implications for the EU15				
Exog. utilization and $\theta = 1$	−0.04	0.01%	0.004	
Exog. utilization and $\theta = 0.2$	−0.02	0.03%	0.008	
Endog. utilization and $\theta = 0.2$	0.32	−0.14%	0.004	−0.393

Note: Elasticity is measured as the percentage decrease of capital tax base in the first year after a 1% increase in the capital tax rate is introduced. For empirical estimates, see Gruber and Rauh (2007) and Dwenger and Steiner (2012). y_1 and m_1 provides the percent deviation from the initial steady state in the impact year. l_1 denotes the percentage points change from the initial steady state.

labor supply rises due to a negative income shock from the tax hike. Since capital does not fall much and labor rises, output rises on impact, and thus taxable labor and capital income both rise, producing an elasticity of the opposite sign than that found in the data. In contrast, the model with endogenous utilization (case (iii)), generates a decline in output on impact due to a substantial drop in the utilization rate, despite the rise in labor supply. With the calibrated values of η, the model generates short-run elasticities of 0.29 and 0.32 for the United States and EU15, respectively, which are both well inside the range of empirical estimates.

It is also worth noting that with exogenous utilization, the model can produce a capital tax base elasticity in line with empirical evidence only if we set η to an unrealistically low value. The short-run elasticity of the capital tax base is negative for any $\eta > 1$, and it becomes positive and higher than 0.1 only for $\eta < 0.1$.[ai] This is significantly below the empirically relevant range of 1–2.5 documented in the calibration section. Moreover, at the value of $\eta = 2$ determined in our baseline calibration, the model without utilization choice yields a capital tax base elasticity of -0.09.

3.3.4 Further Considerations

We close this section with some important considerations and caveats of the structural analysis. In particular, we discuss the predictions of the structural framework for the case of Japan, which is challenging because of its high debt ratio, and the implications of considering the possibility of taxes on wealth or the capital stock.

Japan had a very high public debt to GDP ratio already before the global financial crisis, at about 82% by the end of 2007. By the end of 2011, its debt ratio had increased 46 percentage points to 128%. Hence the level and the change of Japan's debt ratio are both larger than what we saw in the United States and Europe.

What does the structural approach to debt sustainability tell us about the Japanese case? To answer this question, we reset the model so that the foreign region is now a proxy for Japan instead of EU15 and recompute the DLCs. In particular, we calibrate the foreign tax rates to match Japan's precrisis tax structure, using the same Mendoza-Razin-Tesar method we used for the United States and Europe. In 2007, Japan's capital tax rate was 39%, the labor tax rate was 31% and the consumption tax was 6%. This tax structure is similar to that of the United States. In fact, Japan's consumption-leisure tax wedge τ_W is 0.35, which is much closer to the 0.3 estimate for the United States than 0.5 for Europe. We also reset the relative country size to match the fact that Japan's GDP per capita is about 78% that of the United States. The rest of the structural parameters are kept the same as in our baseline analysis. The DLCs for Japan are shown in Fig. 13. The panel (A) is the DLC for the capital tax and the panel (B) is for the labor tax.

[ai] The intuition is simple. As η approaches zero the marginal adjustment cost of investment approaches zero, and hence the capital stock 1 year after the tax hike can respond with large declines.

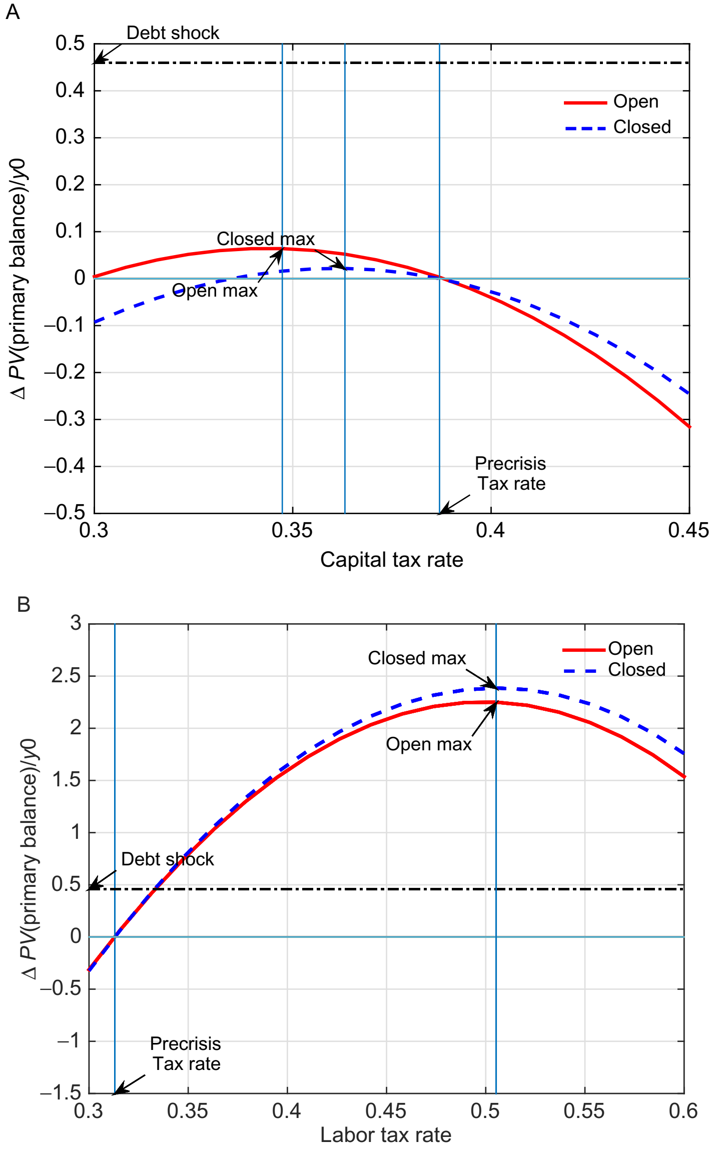

Fig. 13 Dynamic Laffer curves for Japan. (A) Capital tax. (B) Labor tax.

In general, the DLC results for Japan are a more extreme version of those for the United States: The capital tax cannot restore fiscal solvency because Japan's DLC for this tax peaks well below the required increase, while there is a lot of room for labor (or consumption) taxes to do it. One important difference is that the precrisis high capital tax rate in Japan is inefficient (ie, in the decreasing segment of the DLC). Because of this, the tax externalities work in the opposite direction to those observed for the US DLC, and so cutting the capital tax in Japan relative to the precrisis rate as a closed economy yields a smaller increase in the present value of the primary balance than as an open economy. One important caveat to the above results is that Japan has been stuck with slow growth and deflation for about two decades. Although raising consumption and labor taxes helps balance government budgets, higher taxes still cause efficiency and welfare losses. Japan did increase its consumption tax from 5% to 8% in April 2014, but after that the economy tipped back into recession and a further hike of the consumption tax to 10% was postponed. Moreover, if we reduce the long-run growth rate in the model to the 0.8% per-capita GDP growth rate observed on average in Japan between 2001 and 2014, the two DLCs shift downward sharply. The capital tax becomes effectively useless as it yields negligible amounts of extra revenue. The labor tax needed to make the debt sustainable is significantly higher, and thus the associated efficiency and welfare losses are larger as well.

Another caveat is that our analysis abstracts from Japan's aging demographics, rising pressures on government finance from public pensions and medical expenses, etc. These considerations place heavy burdens on the sustainability of public debt. Imrohoroglu and Sudo (2011) and Hansen and Imrohoroglu (2013) use a Neoclassical growth model to quantify the implications of the projected low population growth rate and permanent increase in total government outlays on fiscal sustainability. Imrohoroglu and Sudo find that even an increase in the consumption tax to 15% and an annual GDP growth of 3% over the next 20 years is not sufficient to restore fiscal balance unless expenditures are also contained. Hansen and Imrohoroglu find that fiscal sustainability requires the consumption tax rate be set to unprecedentedly high levels of 40–60%. Moreover, Imrohoroglu et al. (2016) and Braun and Joines (2015) use overlapping generation models and also find that current fiscal policies are not sustainable and large fiscal adjustments are needed.[aj]

Another important consideration in assessing the results of the structural analysis is that we abstracted from the possibility of taxing wealth, in particular taxing the initial capital stock. The optimal taxation literature has made the well-known argument that from an efficiency standpoint taxing the initial, predetermined capital stock is optimal. However, the argument hinges on the assumption of government commitment, which sets aside key issues of time consistency and the implications of lack of commitment.

In our model, a wealth tax would be equivalent to confiscation of a fraction of k_0 unexpectedly. Since utilization is endogenous, this tax would also affect utilization as of date 0: The marginal product of utilization declines with lower capital, utilization falls, and thus capital income and capital income tax revenue fall. But more importantly, three arguments raise serious questions about the possibility of taxing wealth in this way.

[aj] In the next section we discuss the implications of unfunded pension and entitlement liabilities for debt sustainability when the government is not committed to repay and responds to distributional incentives to default.

First, the government would have to sell confiscated capital to raise revenue (in the realistic scenario in which confiscated capital and government outlays involve different goods and services), which would lower the price at which capital goods can be sold. Second, the expectation of future confiscation of capital would not be zero, and to the extent that is positive it would act as a tax on future capital accumulation and capital income. Third, as an implication of the first two arguments, the wealth tax actually looks more like a government default that would seem to necessitate modeling government behavior without commitment (in fact, in a setup without utilization and capital as the only productive factor, the government confiscating some of k_0 is equivalent to defaulting on a fraction of the date-0 debt repayment).

Perhaps because of the above arguments, the history of wealth taxes has not been a happy one. Wealth taxes were discarded by Austria, Denmark, and Germany in 1997, by Finland, Iceland, and Luxembourg in 2006 and by Sweden in 2007. Interestingly, these countries claimed to ditch the wealth tax in efforts to get more revenue, not less. Moreover, implementing wealth taxation faces serious hurdles, particularly for the valuation of assets and for preventing tax evasion. Global financial integration also makes taxing wealth more difficult, because the expectation of potential future confiscation via wealth taxes mentioned above discourages investment and encourages capital flight (see the discussion in Eichengreen, 1989 and the recent experience with "tax inversions" in the United States).

To summarize where the chapter is at this point, we first explored the question of public debt sustainability from the viewpoint of an empirical approach based on the estimation and analysis of fiscal reaction functions. We found that the sufficiency condition for public debt to be sustainable (ie, for IGBC to hold), reflected in a positive conditional response of the primary balance to public debt, cannot be rejected by the data. At the same time, however, there is clear evidence that the fiscal dynamics observed in the aftermath of the recent surge in debt in advanced economies represent a significant structural break in the reaction functions. In plain terms, primary deficits have been too large, and are projected to remain too large, to be in line with the path projected by the reaction functions, and also relative to the fiscal adjustment process observed in previous episodes of large surges in debt.

The main limitation of the empirical approach is that it cannot say much about the macroeconomic effects of multiple fiscal adjustment paths that can restore debt sustainability. To address this issue, this section explored a structural approach that takes a variation of the workhorse two-country Neoclassical dynamic equilibrium model with an explicit fiscal sector. Capacity utilization and a limited tax allowance for depreciation expenses were used to match the observed elasticity of the capital tax base to capital tax changes. Then we calibrated this model to the United States and European data and used it to quantify the effects of unilateral changes in capital and labor taxes aimed at altering the ability of countries to sustain debt. The results suggest striking differences across Europe and the United States. For the United States, the results suggest that changes in capital taxes cannot make the observed increase in debt sustainable, while small increases in labor taxes could. For Europe, the model predicts that the ability of the tax system to make higher debt ratios sustainable is nearly fully exhausted. Capital taxation is highly inefficient and in the decreasing segment of DLCs, so cuts in capital taxes would be needed to restore fiscal solvency. Labor taxes are near the peak of the DLC, and even if increased to the maximum point they fail to increase the present value of the primary balance to make the observed surge in debt sustainable. Moreover, international externalities of capital income taxes are quantitatively large, suggesting that incentives for strategic interaction, and the classic race-to-the-bottom in capital income taxation are nontrivial.

In short, the results from the empirical and the structural approaches to evaluate debt sustainability cast doubt on the presumption that the high debt ratios reached by many advanced economies in the years since 2008 will be fully repaid. To examine debt sustainability allowing for the possibility of nonrepayment, however, we must consider a third approach that relaxes the assumption that the government is committed to repay domestic debt, which is central to the two approaches we have covered. In the next section of this chapter we turn our attention to this issue.

4. DOMESTIC DEFAULT APPROACH

We now examine debt sustainability from the perspective of a framework that abandons the assumption of a government committed to repay domestic debt. The emphasis is on the risk of de-jure, or outright, default on domestic public debt, not the far more studied issues of external sovereign default, which is the subject of another chapter in this Handbook, or de-facto default on domestic debt via inflation. Interest on domestic sovereign default is motivated by the seminal empirical study of Reinhart and Rogoff (2011), which documents episodes of outright default on domestic public debt in a cross-country historical dataset going back to 1750.[ak] Hall and Sargent (2014) describe in detail a similar episode in the process by which the US government handled the management of its debt in the aftermath of the Revolutionary War.

Reinhart and Rogoff noted that the literature has paid little attention to domestic sovereign default, and thus chose to title their paper *The Forgotten History of Domestic Debt*. As we document below, the situation has changed somewhat recently, but relatively speaking the study of domestic government defaults remains largely uncharted territory.

[ak] Reinhart and Rogoff identified 68 outright domestic default episodes, which occurred via mechanisms such as forcible conversions, lower coupon rates, unilateral reductions of principal, and suspensions of payments.

The ongoing European debt crisis also highlights the importance of studying domestic sovereign default, because four features of the crisis (thinking of Europe as a whole) make it resemble more a domestic default than an external default. First, countries in the Eurozone are highly integrated, with the majority of their public debt denominated in their common currency and held by European residents. Hence, a default means, to a large extent, a suspension of payments to "domestic" (ie, European) agents instead of external creditors. Second, domestic public-debt-GDP ratios are high in the Eurozone in general, and very large in the countries at the epicenter of the crisis (Greece, Ireland, Italy, Spain, and Portugal). Third, the Eurozones common currency and common central bank rule out the possibility of individual governments resorting to inflation as a means to lighten their debt burden without an outright default. Fourth, and perhaps most important from the standpoint of the theory proposed in this section, European-wide institutions such as the European Central Bank (ECB) and the European Commission are weighting the interests of both creditors and debtors in assessing the pros and cons of sovereign defaults by individual countries, and creditors and debtors are aware of these institutions concern and of their key role in influencing expectations and default risk.

Table 13 shows that the Eurozone's fiscal crisis has been characterized by rapid increases in public debt ratios and sovereign spreads that coincided with rising government expenditure ratios. The table also shows that debt ownership, as proxied by Gini coefficients of wealth distributions, is unevenly distributed in the seven countries listed, with mean and median Gini coefficients of around two-thirds. The degree of concentration in the ownership of public debt plays a key role in the framework of optimal

Table 13 Euro area: Key fiscal statistics and wealth inequality

	Gov. debt		Gov. exp.		Spreads

Note: Author's calculations are based on OECD Statistics, Eurostat, ECSB, and Davies et al. (2009). "Gov. debt" refers to total general government net financial liabilities (avg 1990–2007); "Gov. Exp." corresponds to government purchases in national accounts (avg 2000–07); "Sov spreads" correspond to the difference between interest rates of the given country and Germany for bonds of similar maturity (avg 2000–07). For a given country i, they are computed as $(1 + r^i)/(1 + r^{Ger}) - 1$. "Crisis Peak" refers to the maximum value observed during 2008–12 using data from Eurostat. "Gini wealth" are Gini wealth coefficients for 2000 from Davies, J., Sandstr´om, S., Shorrocks, A., Wolff, E. 2009. The level and distribution of global household wealth. NBER Working Paper 15508, appendix V.

domestic default examined in this section. The framework also predicts that spreads and the probability of default at higher when government outlays are higher.

The model on which this section is based follows the work of D'Erasmo and Mendoza (2013) and D'Erasmo and Mendoza (2014). The goal is to analyze the optimal default and borrowing decisions of a government unable to commit to repay debt placed with domestic creditors in an environment with incomplete markets. The key difference with standard external default models is in that the payoff of the government includes the utility of agents who are government bondholders, as well as nonbondholders. As a result, the main incentive to default is to redistribute resources across these two groups of agents.[al] Default is assumed to be nondiscriminatory (ie, the government cannot discriminate across any of its creditors when it defaults). There is explicit aggregate risk in the form of shocks to government outlays, and also implicit in the form of default risk.

Government bondholders and nonbondholders are modeled with identical CRRA preferences. Default is useful as a vehicle for redistribution across the two, but it also has costs. We explore the case in which there is an exogenous cost in terms of disposable income, similar to the exogenous income costs typical of the external default literature. But there can also be endogenous costs related to the reduced ability to smooth taxation and provide liquidity, and, in long-horizon environments, to the loss of access to government bonds as the asset used for self-insurance.

In this framework, public debt is sustainable when it is supported as part of the equilibrium without commitment. This implies that a particular price and stock of defaultable government bonds are sustainable only if they are consistent with the optimal debt-issuance and default plans of the government, the optimal savings plans of private agents, and the bond market-clearing condition. Sustainable debt thus factors in the risk of default, which implies paying positive risk premia on current debt issuance when future default is possible. Debt becomes unsustainable when default becomes the optimal choice ex post, or is unsustainable ex ante for debt levels that cannot be issued at a positive price (ie, when a given debt issued at t entails a 100% probability of default at t+1).

This model is not necessarily limited to a situation in which private agents hold directly government debt. It is also applicable to situations in which pension funds hold government bonds and retirement accounts are structured as individual accounts, or where the financial sector holds domestic sovereign debt and households hold claims

[al] The model should not be viewed as focusing necessarily on redistribution across the poor and rich, but across agents that hold public debt and those who do not. The two are correlated but need not be the same. For instance, Hall and Sargent (2014) describe how the domestic default after the US Revolutionary War implied redistribution from bondholders in the South to nonbondholders in the North, with both groups generally wealthy. Similarly, in the European debt crisis, a Greek default can be viewed as redistributing from German tax payers to Greek households and not according to their overall wealth.

on the financial sector. Moreover, the general principle that domestic default is driven by government's distributional incentives traded off against exogenous or endogenous default costs applies to more complex environments that include implicit (or contingent) government liabilities due, for example, to expected funding shortfalls in entitlement programs. Default in these cases can take the form of reforms like increasing retirement eligibility ages or imposing income ceilings in eligibility for programs like medicare. For simplicity, however, the quantitative analysis conducted later in this section is calibrated to data that includes only explicit government debt (total general government net financial liabilities as defined in Eurostat).

We develop the argument using the two-period model proposed by D'Erasmo and Mendoza (2013), which highlights the importance of the distributional incentives of default at the expense of setting aside endogenous default costs due to the loss of access to self-insurance assets. D'Erasmo and Mendoza (2014) and Dovis et al. (2014) study the role of distributional incentives to default on domestic debt, and the use of public debt in infinite horizon models with domestic agent heterogeneity. The two differ in that Dovis et al. (2014) assume complete domestic asset markets, which removes the role of public debt as providing social insurance for domestic agents. In addition, they focus on the solution to the Ramsey problem, in which default is not observed along the equilibrium path. D'Erasmo and Mendoza study an economy with incomplete markets, which turns the loss of the vehicle for self-insurance, and the severity of the associated liquidity constraints, into an endogenous cost of default that plays a central role in their results. They also solve for Markov-perfect equilibria in which default is possible as an equilibrium outcome.

The model discussed here is also related to the literature that analyzes the role of public debt as a self-insurance mechanism and a tool for altering consumption dispersion in heterogeneous-agents models without default (eg, Aiyagari and McGrattan (1998), Golosov and Sargent (2012), Azzimonti et al. (2014), Floden (2001) , Heathcote (2005), and Aiyagari et al. (2002)). A recent article by Pouzo and Presno (2014) introduces the possibility of default into models in this class. They study optimal taxation and public debt dynamics in a representative-agent setup similar to Aiyagari et al. (2002) but allowing for default and renegotiation.

The recent interest in domestic sovereign default also includes a strand of literature focusing on the consequences of default on domestic agents, its relation with secondary markets, discriminatory vs nondiscriminatory default, and the role of domestic debt in providing liquidity to the corporate sector (see Guembel and Sussman, 2009, Broner et al., 2010, Broner and Ventura, 2011, Gennaioli et al., 2014, Basu, 2009, Brutti, 2011, Mengus, 2014, and Di Casola and Sichlimiris, 2014). There are also some recent studies motivated by the 2008 financial crisis that focus on the interaction between sovereign debt and domestic financial institutions such as Sosa-Padilla (2012), Bocola (2014), Boz et al. (2014), and Perez (2015).

4.1 Model Structure

Consider a two-period economy $t=0, 1$ inhabited by a continuum of agents with aggregate unit measure. All agents have the same preferences, which are given by:

$$u(c_0)+\beta E[u(c_1)],\ u(c)=\frac{c^{1-\sigma}}{1-\sigma}$$

where $\beta \in (0, 1)$ is the discount factor and c_t for $t=0, 1$ is individual consumption. The utility function $u(\cdot)$ takes the standard CRRA form.

All agents receive a nonstochastic endowment y each period and pay lump-sum taxes τ_t, which are uniform across agents. Taxes and newly issued government debt are used to pay for government consumption g_t and repayment of outstanding government debt. The (exogenous) initial supply of outstanding government bonds at $t = 0$ is denoted B_0. Agents differ in their initial wealth position, which is characterized by their holdings of government debt at the beginning of the first period.[am] Given B_0, the initial wealth distribution is defined by a fraction γ of households who are the L-type individuals with initial bond holdings b_0^L, and a fraction $(1-\gamma)$ who are the H-types and hold b_0^H, where $b_0^H=\frac{B_0-\gamma b_0^L}{1-\gamma}\geq b_0^L\geq 0$. This value of b_0^H is the amount consistent with market-clearing in the government bond market at $t=0$, since we are assuming that the debt is entirely held by domestic agents. The initial distribution of wealth is exogenous, but the distribution at the beginning of the second period is endogenously determined by the agents' savings choices of the first period.

The budget constraints of the two types of households in the first period are given by:

$$c_0^i+q_0 b_1^i=y+b_0^i-\tau_0 \quad \text{for } i=L,H. \tag{10}$$

Agents collect the payout on their initial holdings of government debt (b_0^i), receive endowment income y, and pay lump-sum taxes τ_0. These net-of-tax resources are used to pay for consumption and purchases of new government bonds b_1^i. Agents are not allowed to take short positions in government bonds, which is equivalent to assuming that bond purchases must satisfy the familiar no-borrowing condition often used in heterogeneous-agents models: $b_1^i\geq 0$.

The budget constraints in the second period differ depending on whether the government defaults or not. If the government repays, the budget constraints take the standard form:

$$c_1^i=y+b_1^i-\tau_1 \quad \text{for } i=L,H. \tag{11}$$

[am] Andreasen et al. (2011), Ferriere (2014), and Jeon and Kabukcuoglu (2014) study environments in which domestic income heterogeneity plays a central role in the determination of external defaults.

If the government defaults, there is no repayment on the outstanding debt, and the agents' budget constraints are:

$$c_1^i = (1-\phi(g_1))y - \tau_1 \quad \text{for } i = L, H. \tag{12}$$

As is standard in the external sovereign default literature, we allow for default to impose an exogenous cost that reduces income by a fraction ϕ. This cost is often modeled as a function of the realization of a stochastic endowment income, but since income is constant in this setup, we model it as a function of the realization of government expenditures in the second period g_1. In particular, the cost is a nonincreasing, step-wise function: $\phi(g_1) \geq 0$, with $\phi'(g_1) \leq 0$ for $g_1 \leq \bar{g}_1$, $\phi'(g_1) = 0$ otherwise, and $\phi''(g_1) = 0$. Hence, $\bar{g}_1$ is a threshold high value of g_1 above which the marginal cost of default is zero. This formulation is analogous to the step-wise default cost as a function of income proposed by Arellano (2008) and now widely used in the external default literature, and it also captures the idea of asymmetric costs of tax collection (see Barro, 1979 and Calvo, 1988). Note, however, that for the model to support equilibria with debt under a utilitarian government all we need is $\phi(g_1) > 0$. The additional structure is useful for the quantitative analysis and for making it easier to compare the model with the standard external default models.[an]

At the beginning of $t = 0$, the government has outstanding debt B_0 and can issue one-period, nonstate contingent discount bonds $B_1 \in \mathcal{B} \equiv [0, \infty)$ at the price $q_0 \geq 0$. Each period it collects lump-sum revenues τ_t and pays for outlays g_t. Since g_0 is known at the beginning of the first period, the relevant uncertainty with respect to government expenditures is for g_1, which follows a log-normal distribution $N((1-\rho_g)\mu_g + \rho_g \ln(g_0), \frac{\sigma_g^2}{(1-\rho_g^2)})$.[ao] We do not restrict the sign of τ_t, so $\tau_t < 0$ represents lump-sum transfers.[ap]

[an] In external default models, the nonlinear cost makes default more costly in "good" states, which alters default incentives to make default more frequent in "bad" states, and it also contributes to support higher debt levels.

[ao] This is similar to an AR(1) process and allows us to control the correlation between g_0 and g_1 via ρ_g, the mean of the shock via μ_g and the variance of the unpredicted portion via σ_g^2. Note that if $\ln(g_0) = \mu_g$, $g_1 \sim N(\mu_g, \frac{\sigma_g^2}{(1-\rho_g^2)})$.

[ap] Some studies in the sovereign debt literature have examined models that include tax and expenditure policies, as well as settings with foreign and domestic lenders, but always maintaining the representative agent assumption (eg, Cuadra et al., 2010; Vasishtha, 2010). More recently Dias et al. (2012) examined the benefits of debt relief from the perspective of a *global* social planner with utilitarian preferences. Also in this literature, Aguiar and Amador (2013) analyze the interaction between public debt, taxes and default risk and Lorenzoni and Werning (2013) study the dynamics of debt and interest rates in a model where default is driven by insolvency and debt issuance driven by a fiscal reaction function.

At equilibrium, the price of debt issued in the first period must be such that the government bond market clears:

$$B_t = \gamma b_t^L + (1-\gamma) b_t^H \quad \text{for } t = 0, 1. \tag{13}$$

This condition is satisfied by construction in period 0. In period 1, however, the price moves endogenously to clear the market.

The government has the option to default at $t = 1$. The default decision is denoted by $d_1 \in \{0, 1\}$ where $d_1 = 0$ implies repayment. The government evaluates the values of repayment and default using welfare weight ω for $L-$type agents and $1-\omega$ for $H-$type agents. This specification encompasses cases in which, for political reasons for example, the welfare weights are biased toward a particular type so $\omega \neq \gamma$ or the case in which the government acts as a utilitarian social planner in which $\omega = \gamma$.[aq] At the moment of default, the government evaluates welfare using the following function:

$$\omega u(c_1^L) + (1-\omega) u(c_1^H).$$

At $t = 0$, the government budget constraint is

$$\tau_0 = g_0 + B_0 - q_0 B_1. \tag{14}$$

The level of taxes in period 1 is determined after the default decision. If the government repays, taxes are set to satisfy the following government budget constraint:

$$\tau_1^{d_1=0} = g_1 + B_1. \tag{15}$$

Notice that, since this is a two-period model, equilibrium requires that there are no outstanding assets at the end of period 1 (ie, $b_2^i = B_2 = 0$ and $q_1 = 0$). If the government defaults, taxes are simply set to pay for government purchases:

$$\tau_1^{d_1=1} = g_1. \tag{16}$$

The analysis of the model's equilibrium proceeds in three stages. First, characterize the households' optimal savings problem and determine their payoff (or value) functions, taking as given the government debt, taxes and default decision. Second, study how optimal government taxes and the default decision are determined. Third, examine the optimal choice of debt issuance that internalizes the outcomes of the first two stages. We characterize these problems as functions of B_1, g_1, γ and ω, keeping the initial conditions (g_0, B_0, b_0^L) as exogenous parameters. Hence, for given γ and ω, we can index the value

[aq] This relates to the literature on political economy and sovereign default, which largely focuses on external default (eg, Amador, 2003, Dixit and Londregan, 2000, D'Erasmo, 2011, Guembel and Sussman, 2009, Hatchondo et al., 2009, and Tabellini, 1991), but includes studies like those of Alesina and Tabellini (1990) and Aghion and Bolton (1990) that focus on political economy aspects of government debt in a closed economy, and the work of Aguiar et al. (2013) on optimal policy in a monetary union subject to self-fulfilling debt crises.

of a household as of $t = 0$, before g_1 is realized, as a function of $\{B_1\}$. Given this, the level of taxes τ_0 is determined by the government budget constraint once the equilibrium bond price q_0 is set. Bond prices are forward looking and depend on the default decision of the government in period 1, which will be given by the decision rule $d(B_1, g_1, \gamma, \omega)$.

4.2 Optimization Problems and Equilibrium

Given B_1, γ, and ω a household with initial debt holdings b_0^i for $i = L, H$ chooses b_1^i by solving this maximization problem:

$$v^i(B_1,\gamma,\omega) = \max_{b_1^i} \left\{ u(\gamma + b_0^i - q_0 b_1^i - \tau_0) + \beta E_{g_1}\left[(1-d_1)u(\gamma + b_1^i - \tau_1^{d_1=0}) \right.\right. \\ \left.\left. + d_1 u(\gamma(1-\phi(g_1)) - \tau_1^{d_1=1})\right]\right\}, \tag{17}$$

subject to $b_1^i \geq 0$. The term $E_{g_1}[.]$ represents the expected payoff across the repayment and default states in period 1. Notice in particular that the payoff in case of default does not depend on the level of individual debt holdings (b_1^i), reflecting the fact that the government cannot discriminate across households when it defaults.

A key feature of the above problem is that agents take into account the possibility of default in choosing their optimal bond holdings. The first-order condition, evaluated at the equilibrium level of taxes, yields this Euler equation:

$$u'(c_0^i) \geq \beta(1/q_0)E_{g_1}\left[u'(\gamma - g_1 + b_1^i - B_1)(1 - d_1(B_1,g_1,\gamma))\right], = \text{ if } b_1^i > 0 \tag{18}$$

In states in which, given (B_1, γ, ω), the value of g_1 is such that the government chooses to default $(d_1(B_1, g_1, \gamma, \omega) = 1)$, the marginal benefit of an extra unit of debt is zero.[ar] Thus, conditional on B_1, a larger default set (ie, a larger set of values of g_1 such that the government defaults), implies that the expected marginal benefit of an extra unit of savings decreases. As a result, everything else equal, a higher default probability results in a lower demand for government bonds, a lower equilibrium bond price, and higher taxes. This has important redistributive implications, because when choosing the optimal debt issuance, the government will internalize how, by altering the bond supply, it affects the expected probability of default and the equilibrium bond prices. Note also that from the agents' perspective, the default choice $d_1(B_1, g_1, \gamma, \omega)$ is independent of b_1^i.

The above Euler equation is useful for highlighting some important properties of the equilibrium pricing function of bonds:

1. The premium over a world risk-free rate (defined as q_0/β, where $1/\beta$ can be viewed as a hypothetical opportunity cost of funds for an investor, analogous to the role played by the world interest rate in the standard external default model) generally differs from the default probability for two reasons: (a) agents are risk averse, and (b) in the repayment state, agents face higher taxes, whereas in the standard model investors are not

[ar] Utility in the case of default equals $u(\gamma(1 - \phi(g_1)) - g_1)$, which is independent of b_1^i.

taxed to repay the debt. For agents with positive bond holdings, the above optimality condition implies that the premium over the risk-free rate is $E_{g_1}\left[u'(y-g_1+b_1^i-B_1)(1-d_1)/u'(c_0^i)\right]$.

2. If the Euler equation for H −type agents holds with equality (ie, $b_1^H>0$) and L −type agents are *credit constrained* (ie, $b_1^L=0$), the H −type agents are the marginal investor and their Euler equation can be used to derive the equilibrium price.
3. For sufficiently high values of B_1, γ or $1-\omega$ the government chooses $d_1(B_1,g_1,\gamma,\omega)=1$ for all g_1. In these cases, the expected marginal benefit of purchasing government bonds vanishes from the agents' Euler equation, and hence the equilibrium for that B_1 does not exist, since agents would not be willing to buy debt at any finite price.[as] These values of B_1 are therefore unsustainable ex ante (ie, these debt levels cannot be sold at a positive price).

The equilibrium bond pricing functions $q_0(B_1,\ \gamma,\ \omega)$, which returns bond prices for which, as long as consumption for all agents is nonnegative and the default probability of the government is less than 1, the following market-clearing condition holds:

$$B_1=\gamma b_1^L(B_1,\ \gamma,\ \omega)+(1-\gamma)b_1^H(B_1,\ \gamma,\ \omega), \tag{19}$$

where B_1 in the left-hand-side of this expression represents the public bonds supply, and the right-hand-side is the aggregate government bond demand.

As explained earlier, we analyze the government's problem following a backward induction strategy by studying first the default decision problem in the final period $t=1$, followed by the optimal debt issuance choice at $t=0$.

4.2.1 Government Default Decision at t = 1

At $t=1$, the government chooses to default or not by solving this optimization problem:

$$\max_{d\in\{0,1\}}\left\{W_1^{d=0}(B_1,\ g_1,\ \gamma,\ \omega),\ W_1^{d=1}(g_1,\ \gamma,\ \omega)\right\}, \tag{20}$$

where $W_1^{d=0}(B_1,\ g_1,\ \gamma,\ \omega)$ and $W_1^{d=1}(B_1,\ g_1,\ \gamma,\ \omega)$ denote the values of the social welfare function at the beginning of period 1 in the case of repayment and default, respectively. Using the government budget constraint to substitute for $\tau_1^{d=0}$ and $\tau_1^{d=1}$, the government's payoffs can be expressed as:

$$W_1^{d=0}(B_1,\ g_1,\gamma,\omega)=\omega u(y-g_1+b_1^L-B_1)+(1-\omega)u(y-g_1+b_1^H-B_1) \tag{21}$$

and

$$W_1^{d=1}(g_1,\gamma,\omega)=u(y(1-\phi(g_1))-g_1). \tag{22}$$

[as] This result is similar to the result in standard models of external default showing that rationing emerges at t for debt levels so high that the government would choose default at all possible income realizations in $t+1$.

Combining these payoff functions, if follows that the government defaults if this condition holds:

$$\begin{aligned} &\omega\left[u(y-g_1+\overbrace{(b_1^L-B_1)}^{\leq 0})-u(y(1-\phi(g_1))-g_1)\right] \\ &+(1-\omega)\left[u(y-g_1+\overbrace{(b_1^H-B_1)}^{\geq 0})-u(y(1-\phi(g_1))-g_1)\right]\leq 0 \end{aligned} \tag{23}$$

Notice that all agents forego g_1 of their income to government absorption regardless of the default choice. Moreover, debt repayment reduces consumption and welfare of L types and rises them for H types, whereas default implies the same consumption and utility for both types of agents.

The distributional effects of a default are implicit in condition (23). Given that debt repayment affects the cash-in-hand for consumption of L and H types according to $(b_1^L-B_1)\leq 0$ and $(b_1^H-B_1)\geq 0$, respectively, it follows that, for a given B_1, the payoff under repayment allocates (weakly) lower welfare to L agents and higher to H agents, and that the gap between the two is larger the larger is B_1. Moreover, since the default payoffs are the same for both types of agents, this is also true of the *difference* in welfare under repayment vs default: It is higher for H agents than for L agents and it gets larger as B_1 rises. To induce default, however, it is necessary not only that L agents have a smaller difference in the payoffs of repayment vs default, but that the difference is negative (ie, they must attain lower welfare under repayment than under default), which requires $B_1 > b_1^L + y\phi(g_1)$. This also implies that taxes under repayment need to be necessarily larger than under default, since $\tau_1^{d=0}-\tau_1^{d=1}=B_1$.

We can illustrate the distributional mechanism driving the default decision by comparing the utility levels associated with the consumption allocations of the default and repayment states with those that would be socially efficient. To this end, it is helpful to express the values of hypothetical optimal private debt holdings in period 1 as $b_1^L=B_1-\epsilon$ and $b_1^H(\gamma)=B_1+\dfrac{\gamma}{1-\gamma}\epsilon$, for some $\epsilon\in[0,\ B_1]$. That is, ϵ represents a given hypothetical decentralized allocation of debt holdings across agents.[at] Consumption allocations under repayment would therefore be $c_1^L(\epsilon)=y-g_1-\epsilon$ and $c_1^H(\gamma,\epsilon)=y-g_1+\dfrac{\gamma}{1-\gamma}\epsilon$, so ϵ also determines the decentralized consumption dispersion.

[at] We take ϵ as given at this point because it helps us explain the intuition behind the distributional default incentives of the government, but ϵ is an equilibrium outcome solved for later on. Also, ϵ must be nonnegative, otherwise H types would be the nonbondholders.

The government payoff under repayment can be rewritten as:

$$W^{d=0}(\epsilon, g_1, \gamma, \omega) = \omega u(y - g_1 + \epsilon) + (1 - \omega)u\left(y - g_1 + \frac{\gamma}{1-\gamma}\epsilon\right).$$

The efficient dispersion of consumption that the social planner would choose is characterized by the value of ϵ^{SP} that maximizes social welfare under repayment. In the particular case of $\omega = \gamma$ (ie, when the government is utilitarian and uses welfare weights that match the wealth distribution), ϵ^{SP} satisfies this first-order condition:

$$u'\left(y - g_1 + \frac{\gamma}{1-\gamma}\epsilon^{SP}\right) = u'\left(y - g_1 - \epsilon^{SP}\right). \tag{24}$$

Hence, the efficient allocations are characterized by zero consumption dispersion, because equal marginal utilities imply $c^{L,SP} = c^{H,SP} = y - g_1$, which is attained with $\epsilon^{SP} = 0$.

Continuing under the utilitarian government assumption ($\omega = \gamma$), consider now the government's default decision when default is costless ($\phi(g_1) = 0$). Given that the only policy instruments the government can use, other than the default decision, are nonstate contingent debt and lump-sum taxes, it is straightforward to show that default will always be optimal. This is because default supports the socially efficient allocations in the decentralized equilibrium (ie, it yields zero consumption dispersion with consumption levels $c^L = c^H = y - g_1$). This outcome is invariant to the values of B_1, g_1, γ and ϵ (over their relevant ranges). This result also implies, however, that in this model a utilitarian government without default costs can never sustain debt.

The above scenario is depicted in Fig. 14, which plots the social welfare function under repayment as a function of ϵ as the bell-shaped curve, and the social welfare under default (which is independent of ϵ), as the black dashed line. Clearly, the maximum welfare under repayment is attained when $\epsilon = 0$ which is also the efficient amount of consumption dispersion ϵ^{SP}. Moreover, since the relevant range of consumption dispersion is $\epsilon > 0$, welfare under repayment is decreasing in ϵ over the relevant range.

These results can be summarized as follows:

Result 1. *If $\phi(g_1) = 0$ for all g_1 and $\omega = \gamma$, then for any $\gamma \in (0, 1)$ and any (B_1, g_1), the social value of repayment $W^{d=0}(B_1, g_1, \gamma)$ is decreasing in ϵ and attains its maximum at the socially efficient point $\epsilon^{SP} = 0$ (ie, when welfare equals $u(y - g_1)$). Hence, default is always optimal for any given decentralized consumption dispersion $\epsilon > 0$.*

The outcome is very different when default is costly. With $\phi(g_1) > 0$, default still yields zero consumption dispersion, but at lower levels of consumption and therefore utility,

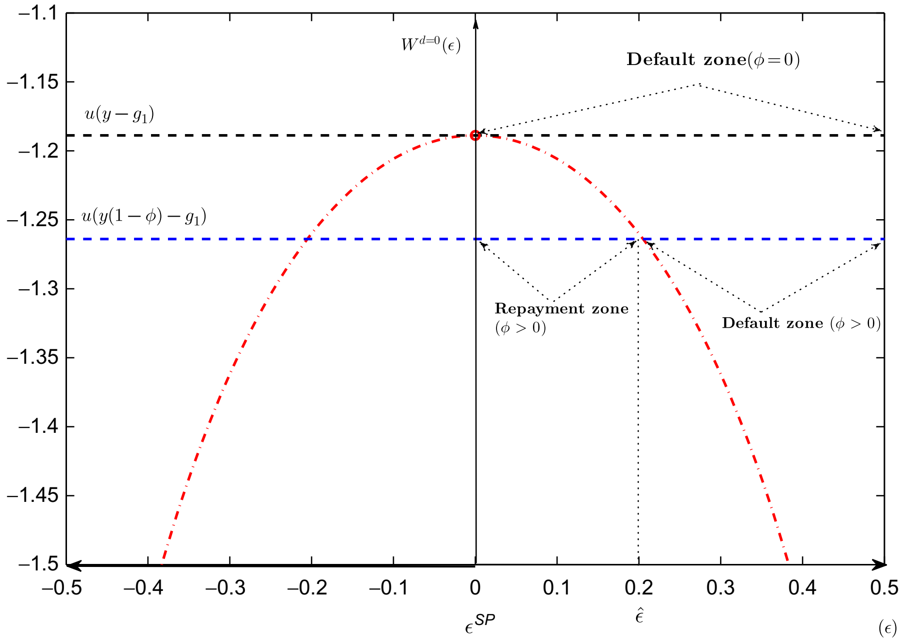

Fig. 14 Default decision and consumption dispersion.

since consumption allocations under default are $c^L = c^H = (1 - \phi(g_1))y - g_1$. This does not alter the result that the social optimum is $\epsilon^{SP} = 0$, but what changes is that default can no longer support the socially efficient consumption allocations. Instead, there is now a threshold amount of consumption dispersion in the decentralized equilibrium, $\hat{\epsilon}(\gamma)$, which varies with γ and such that for $\epsilon \geq \hat{\epsilon}(\gamma)$ default is again optimal, but for lower ϵ repayment is now optimal. This is because when ϵ is below the threshold, repayment produces a level of social welfare higher than under default.

Fig. 14 also illustrates this scenario. The default cost lowers the common level of utility of both types of agents, and hence of social welfare, in the default state (shown in the figure as the blue dashed line), and $\hat{\epsilon}(\gamma)$ is determined where social welfare under repayment and under default intersect. If the decentralized consumption dispersion with the debt market functioning (ϵ) is between 0 and less than $\hat{\epsilon}(\gamma)$ then it is optimal for the government to repay. Intuitively, if consumption dispersion is not too large, the government prefers to repay because the income cost imposed on agents to remove consumption dispersion under default is too large. Moreover, as γ rises the domain of $W_1^{d=0}$ narrows, and thus $\hat{\epsilon}(\gamma)$ falls and the interval of decentralized consumption dispersions that supports repayment narrows. This is natural because a higher γ causes the planner to weight more L-types in the social welfare function, which are agents with weakly lower utility in the repayment state.

These results can be summarized as follows:

Result 2. *If $\phi(g_1) > 0$, then for any $\gamma \in (0, 1)$ and any (B_1, g_1), there is a threshold value of consumption dispersion $\hat{\epsilon}(\gamma)$ such that the payoffs of repayment and default are equal: $W^{d=0}(B_1, g_1, \gamma) = u(y(1-\phi(g_1)) - g_1)$. The government repays if $\epsilon < \hat{\epsilon}(\gamma)$ and defaults otherwise. Moreover, $\hat{\epsilon}(\gamma)$ is decreasing in γ.*

Introducing a bias in the welfare function of the government (relative to utilitarian social welfare) can result in repayment being optimal even without default costs, which provides for an alternative way to sustain debt subject to default risk. Assuming $\phi(g_1) = 0$, there are two possible scenarios depending on the relative size of γ and ω. First, if $\omega > \gamma$, the planner again always chooses default as in the setup with $\omega = \gamma$. This is because for any $\epsilon > 0$, the decentralized consumption allocations feature $c^H > c^L$, while the planner's optimal consumption dispersion requires $c^H \leq c^L$, and hence ϵ^{SP} cannot be implemented. Default brings the planner the closest it can get to the payoff associated with ϵ^{SP} and hence it is always chosen.

In the second scenario $\omega < \gamma$, which means that the government's bias assigns more (less) weight to H (L) types than the fraction of each type of agents that actually exists. In this case, the model can support equilibria with debt even without default costs. In particular, there is a threshold consumption dispersion $\hat{\epsilon}$ such that default is optimal for $\epsilon \geq \hat{\epsilon}$, where $\hat{\epsilon}$ is the value of ϵ at which $W_1^{d=0}(\epsilon, g_1, \gamma, \omega)$ and $W_1^{d=1}(g_1)$ intersect. For $\epsilon < \hat{\epsilon}$, repayment is preferable because $W_1^{d=0}(\epsilon, g_1, \gamma, \omega) > W_1^{d=0}(g_1)$. Thus, without default costs, equilibria for which repayment is optimal require two conditions: (a) that the government's bias favors bond holders ($\omega < \gamma$), *and* (b) that the debt holdings chosen by private agents do not produce consumption dispersion in excess of $\hat{\epsilon}$.

Fig. 15 illustrates the outcomes just described. This figure plots $W_1^{d=0}(\epsilon, g_1, \gamma, \omega)$ for $\omega \gtreqless \gamma$. The planner's default payoff and the values of ϵ^{SP} for $\omega \gtreqless \gamma$ are also identified in the plot. The vertical intercept of $W_1^{d=0}(\epsilon, g_1, \gamma, \omega)$ is always $W^{d=1}(g_1)$ for any values of ω and γ, because when $\epsilon = 0$ there is zero consumption dispersion and that is also the outcome under default. In addition, the bell-shaped form of $W_1^{d=0}(\epsilon, g_1, \gamma, \omega)$ follows from $u'(.) > 0, u''(.) < 0$.[au]

Take first the case with $\omega > \gamma$. In this case, the planner's payoff under repayment is the dotted bell curve. Here, $\epsilon^{SP} < 0$, because the optimality condition implies that the planner's optimal choice features $c^L > c^H$. Since default is the only instrument available to the government, however, these consumption allocations are not feasible, and by choosing

[au] Note in particular that $\frac{\partial W_1^{d=0}(\epsilon, g_1, \gamma, \omega)}{\partial \epsilon} \gtreqless 0 \iff \frac{u'(c^H(\epsilon))}{u'(c^L(\epsilon)}) \gtreqless \left(\frac{\omega}{\gamma}\right)\left(\frac{1-\gamma}{1-\omega}\right)$. Hence, the planner's payoff is increasing (decreasing) at values of ϵ that support sufficiently low (high) consumption dispersion so that $\frac{u'(c^H(\epsilon))}{u'(c^L(\epsilon))}$ is above (below) $\left(\frac{\omega}{\gamma}\right)\left(\frac{1-\gamma}{1-\omega}\right)$.

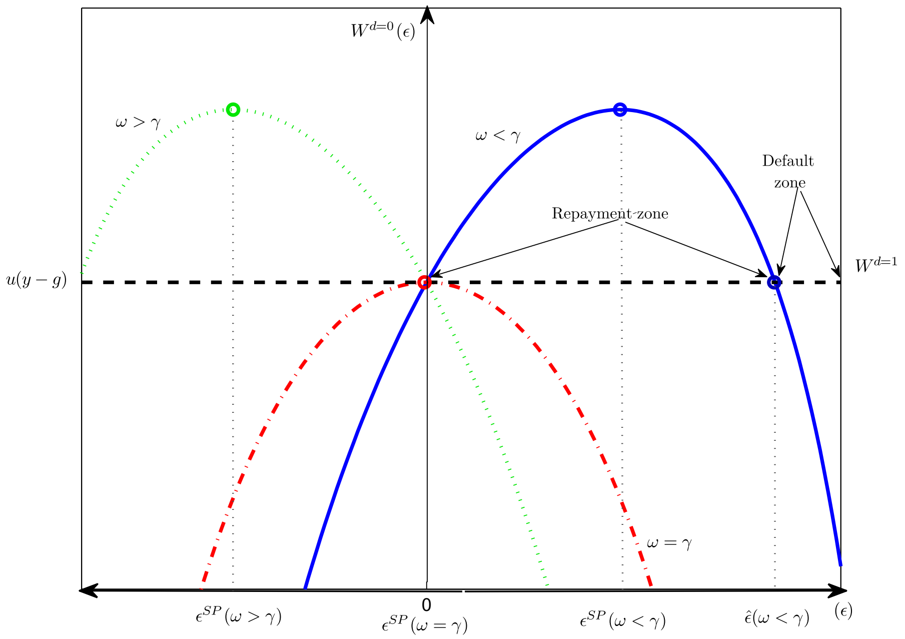

Fig. 15 Default decision with nonutilitarian planner ($\phi = 0$).

default the government attains $W^{d=1}$, which is the highest feasible government payoff for any $\epsilon \geq 0$. In contrast, in the case with $\omega = \gamma$, for which the planner's payoff function is the dashed bell curve, the planner chooses $\epsilon^{SP} = 0$, and default attains exactly the same payoff, so default is chosen. In short, if $\omega \geq \gamma$, the government always defaults for any decentralized distribution of debt holdings represented by $\epsilon > 0$, and thus equilibria with debt cannot be supported.

When $\omega < \gamma$, the planner's payoff is the continuous curve. The intersection of the downward-sloping segment of $W_1^{d=0}(\epsilon, g_1, \gamma, \omega)$ with $W^{d=1}$ determines the default threshold $\hat{\epsilon}$ such that default is optimal only in the *default zone* where $\epsilon \geq \hat{\epsilon}$. Default is still a second-best policy for the planner, because with it the planner cannot attain $W^{d=0}(\epsilon^{SP})$, it just gets the closest it can get. In contrast, the choice of repayment is preferable in the *repayment zone* where $\epsilon < \hat{\epsilon}$,, because in this zone $W_1^{d=0}(\epsilon, g_1, \gamma, \omega) > W^{d=1}(g_1)$.

Adding default costs to this political bias setup ($\phi(g_1) > 0$) makes it possible to support repayment equilibria even when $\omega \geq \gamma$. As Fig. 16 shows, with default costs there are threshold values of consumption dispersion, $\hat{\epsilon}$, separating repayment from default zones for $\omega \lesseqgtr \gamma$.

It is also evident in Fig. 16 that the range of values of ϵ for which repayment is chosen widens asγ rises relative to ω. Thus, when default is costly, equilibria with repayment require only the condition that the debt holdings chosen by private agents, which are implicit in ϵ, do not produce consumption dispersion larger than the value of$\hat{\epsilon}$ associated

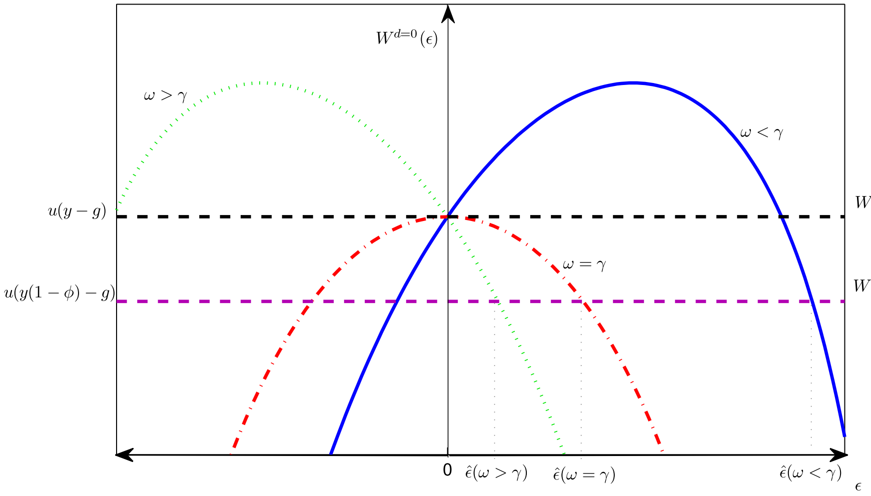

Fig. 16 Default decision with nonutilitarian planner when $\phi(g_1) > 0$.

with a given (ω, γ) pair. Intuitively, the consumption of H-type agents must not exceed that of L-type agents by more than what $\hat{\epsilon}$ allows, because otherwise default is optimal.

The fact that a government biased in favor of bond holders can find it optimally to repay may seem unsurprising. As we argue later, however, in fact governments with this bias can be an endogenous outcome of majority voting if the fraction of agents that are nonbondholders is sufficiently large. This occurs when these agents are liquidity constrained (ie, hitting the no-borrowing constraint), because in this case they prefer that the government favors bondholders so that it can sustain higher debt levels because public debt provides them with liquidity.

4.2.2 Government Debt Issuance Decision at $t = 0$

We are now in a position to study how the government chooses the optimal amount of debt to issue in the initial period. These are the model's predicted sustainable debt levels ex ante, some of which will be optimally defaulted on ex post, depending on the realization of $g_1$in the second period. Both the government and the private sector are aware of this, so the debt levels that can be issued at equilibrium in the first period are traded at prices that can carry a default risk premium, which will be the case if for a given debt stock there are some values of g_1 for which default is the optimal choice in the second period.

The government's optimization problem is easier to understand if we first illustrate how public debt serves as a tool for altering consumption dispersion across agents both within a period and across periods. In particular, consumption dispersion in each period and repayment state is given by these conditions:

$$c_0^H - c_0^L = \frac{1}{1-\gamma}[B_0 - q_0(B_1,\gamma,\omega)B_1],$$

$$c_1^{H,d=0} - c_1^{L,d=0} = \frac{1}{1-\gamma}B_1,$$

$$c_1^{H,d=1} - c_1^{L,d=1} = 0.$$

These expressions make it clear that, given B_0, issuing at least some debt ($B_1 > 0$) reduces consumption dispersion at $t=0$ compared with no debt ($B_1 = 0$), but increases it at $t=1$ if the government repays (ie, $d=0$). Moreover, the use of debt as tool for redistribution of consumption at $t=0$ is hampered by a Laffer curve relationship just like the distortionary taxes of the previous section. In this case, it takes the form of the debt Laffer curve familiar from the external default literature, which is defined by the mapping from an amount of debt issued B_1 to the resources the government acquires with that amount of borrowing, $q_0(B_1, \gamma, \omega)B_1$. This mapping behaves like a Laffer curve because higher debt issuance carries a higher default risk, which reduces the price of the debt. Near zero debt the default risk is also zero so higher debt increases resources for the government, at very high debt near the region at which debt is unsustainable ex ante, higher debt reduces resources because the price falls proportionally much more than the debt rises, and in between we obtain the bell-shaped Laffer curve relationship. It follows then from this Laffer curve that, starting from $B_1 = 0$, consumption dispersion at $t = 0$ first falls as B_1 increases, but there is a critical positive value of B_1 beyond which it becomes an increasing function of debt.

At $t=0$, the government chooses its debt policy internalizing the above consumption dispersion effects, including the debt Laffer curve affecting date-0 dispersion, and their implications for social welfare. Formally, the government chooses B_1 so as to maximize the "indirect" social welfare function:

$$W_0(\gamma,\omega) = \max_{B_1}\left\{\omega v^L(B_1,\gamma,\omega) + (1-\omega)v^H(B_1,\gamma,\omega)\right\}. \tag{25}$$

where v^L and v^H are the private agents' value functions obtained from solving the problems defined in the Bellman equation (17) taking into account the government budget constraints and the equilibrium pricing function of bonds.

Focusing on the case with utilitarian government ($\omega = \gamma$), we can gain some intuition about the solution of this maximization problem from its first-order condition (assuming that the relevant functions are differentiable):

$$u'(c_0^H) = u'(c_0^L) + \frac{\eta}{q_0(B_1,\gamma,\omega)\gamma}\left\{\beta E_{g_1}[\Delta d \Delta W_1] + \gamma\mu^L\right\}$$

where

$$\eta \equiv q_0(B_1, \gamma, \omega)/\left(q_0'(B_1, \gamma, \omega)B_1\right) < 0,$$
$$\Delta d \equiv d(B_1 + \delta, g_1, \gamma) - d(B_1, g_1, \gamma) \geq 0, \quad \text{for } \delta > 0 \text{ small},$$
$$\Delta W_1 \equiv W_1^{d=1}(g_1, \gamma) - W_1^{d=0}(B_1, g_1, \gamma) \geq 0,$$
$$\mu^L \equiv q_0(B_1, \gamma, \omega)u'(c_0^L) - \beta E_{g_1}\left[(1-d^1)u'(c_1^L)\right] > 0.$$

In these expressions, η is the price elasticity of the demand for government bonds, $\Delta d \Delta W_1$ represents the marginal distributional benefit of a default, and μ^L is the shadow value of the borrowing constraint when it binds for L-type agents.

If both types of agents could be unconstrained in their savings decisions, so that $\mu_L = 0$, and if there is no change in the risk of default (or assuming commitment to remove default risk entirely), so that $E_{g_1}[\Delta d \Delta W_1] = 0$, then the optimality condition simplifies to:

$$u'(c_0^H) = u'(c_0^L).$$

Hence, in this case the social planner would want to issue debt so as to equalize marginal utilities of consumption across agents at date 0, which requires simply setting B_1 to satisfy $q_0(B_1, \gamma, \omega)B_1 = B_0$. If it is the case that L-types are constrained (ie, $\mu_L > 0$), and still assuming no change in default risk or a government committed to repay, the optimality condition becomes:

$$u'(c_0^H) = u'(c_0^L) + \frac{\eta\mu^L}{q_0(B_1, \gamma, \omega)}.$$

Since $\eta < 0$, this result implies $c_0^L < c_0^H$, because $u'(c_0^L) > u'(c_0^H)$. Thus, even with unchanged default risk or no default risk at all, the government's debt choice sets B_1 as needed to maintain an optimal, positive level of consumption dispersion, which is the one that supports an excess in marginal utility of L-type agents relative to H-type agents equal to $\frac{\eta\mu^L}{q_0(B_1, \gamma, \omega)}$. Moreover, since optimal consumption dispersion is positive, we can also ascertain that $B_0 > q_0(B_1, \gamma, \omega)B_1$, which using the government budget constraint implies that the government runs a primary surplus at $t = 0$. The government borrows resources, but less than it would need in order to eliminate all consumption dispersion (which requires zero primary balance).

The intuition for the optimality of issuing debt can be presented in terms of tax smoothing and savings: Date-0 consumption dispersion without debt issuance would be $B_0/(1 - \gamma)$, but this is more dispersion than what the government finds optimal, because by choosing $B_1 > 0$ the government provides tax smoothing (ie, reduces date-0 taxes) for everyone, which in particular eases the L-type agents credit constraint, and provides also a desired vehicle of savings for H types. Thus, positive debt increases consumption of L types (since $c_0^L = \gamma - g_0 - B_0 + q_0(B_1, \gamma, \omega)B_1$), and reduces consumption of H types (since $c_0^H = \gamma - g_0 + \left(\frac{\gamma}{1-\gamma}\right)(B_0 - q_0(B_1, \gamma, \omega)B_1)$). But issuing debt (assuming repayment) also increases consumption dispersion a $t = 1$, since debt is then paid with higher taxes on all agents, while H agents collect also the debt repayment. Thus, the debt is being chosen optimally to trade off the social costs and benefits of reducing (increasing) date-0 consumption and increasing (reducing) date-1 consumption for agents who are bondholders (nonbondholders). In doing so, the government internalizes the debt Laffer curve and the fact that additional debt lowers the price of bonds and helps reduce μ^L, which in turn reduces the government's optimal consumption dispersion.[av]

In the presence of default risk and if default risk changes near the optimal debt choice, the term $E_{g_1}[\Delta d \Delta W_1]$ enters in the government's optimality condition with a positive sign, which means the optimal gap in the date-0 marginal utilities across agents widens even more. Hence, the government's optimal choice of consumption dispersion for $t = 0$ is greater than without default risk, and the expected dispersion for $t = 1$ is lower, because in some states of the world the government will choose to default and consumption dispersion would then drop to zero. This also suggests that the government chooses a lower value of B_1 than in the absence of default risk, since date-0 consumptions are further apart. Moreover, the debt Laffer curve now plays a central role in the government's weakened incentives to borrow, because as default risk rises the price of bonds drops to zero faster and the resources available to reduce date-0 consumption dispersion peak at lower debt levels. In short, default risk reduces the government's ability to use nonstate-contingent debt in order to reduce consumption dispersion.

In summary, the more constrained the L −types agents are (higher μ^L) or the higher the expected distributional benefit of a default (higher $E_{g_1}[\Delta d \Delta W_1]$), the larger the level of debt the government finds optimal to issue. Both of these mechanisms operate as pecuniary externalities: They matter only because the government debt choice can alter the equilibrium price of bonds which is taken as given by private agents.

For given values of γ and ω, a *Competitive Equilibrium with Optimal Debt and Default Policies* is a pair of value functions $v^i(B_1, \gamma, \omega)$ and decision rules $b^i(B_1, \gamma, \omega)$ for $i = L, H$, a government bond pricing function $q_0(B_1, \gamma, \omega)$ and a set of government policy functions $\tau_0(B_1, \gamma, \omega)$, $\tau_1^{d\in\{0,1\}}(B_1, g_1, \gamma, \omega)$, $d(B_1, g_1, \gamma, \omega)$, $B_1(\gamma, \omega)$ such that:

1. Given the pricing function and government policy functions, $v^i(B_1, \gamma, \omega)$ and $b_1^i(B_1, \gamma, \omega)$ solve the households' problem.
2. $q_0(B_1, \gamma, \omega)$ satisfies the market-clearing condition of the bond market (equation (19)).
3. The government default decision $d(B_1, g_1, \gamma, \omega)$ solves problem (20).

[av] Note, however, that without default risk the Laffer curve has less curvature than with default risk, because $q_0^{ND}(B_1, \gamma) \geqq q_0(B_1, \gamma)$.

4. Taxes $\tau_0(B_1, \gamma, \omega)$ and $\tau_1^d(B_1, g_1, \gamma, \omega)$ are consistent with the government budget constraints.
5. The government debt policy $B_1(\gamma, \omega)$ solves problem (25).

4.3 Quantitative Analysis

We study the quantitative predictions of the model using a calibration based on European data. Since the model is simple, the goal is not to match closely the observed dynamics of debt and risk premia in Europe, but to show that a reasonable set of parameter values can support an equilibrium in which sustainable debt subject to default risk exists.[aw] We also use this numerical analysis to study show the dispersion of initial wealth and the bias in government welfare affect sustainable debt.

4.3.1 Calibration

The model is calibrated to annual frequency, and most of the parameter values are set to match moments computed using European data. The parameter values that need to be set are the subjective discount factor β, the coefficient of relative risk aversion σ, the moments of the stochastic process of government expenditures $\{\mu_g, \rho_g, \sigma_g\}$, the initial levels of government debt and expenditures (B_0, g_0), the level of income y, the initial wealth of $L-$type agents b_0^L and the default cost function $\phi(g_1)$. The calibrated parameter values are summarized in Table 14. We evaluate equilibrium outcomes for values of γ and ω in the [0,1] interval. Data for the United States and Europe documented in D'Erasmo and Mendoza (2013) suggest that the empirically relevant range for γ is [0.55,0.85]. Hence, when taking a stance on a particular value of γ is useful we use $\gamma = 0.7$, which is the mid point of the plausible range.

The preference parameters are set to standard values: $\beta = 0.96$, $\sigma = 1$. We also assume for simplicity that $L-$types start with zero wealth, $b_0^L = 0$.[ax] This and the other calibration parameters result in savings plans such that L-type agents are credit constrained, and hence $b_1^L = 0$.

We estimate an AR(1) process for government expenditures-GDP ratio (in logs) for France, Germany, Greece, Ireland, Italy, Spain and Portugal and set $\{\mu_g, \rho_g, \sigma_g\}$ to the cross-country averages of the corresponding estimates. This results in the following

[aw] We solve the model following a backward-recursive strategy analogous to the one used in the theoretical analysis. First, for each pair $\{\gamma, \omega\}$ and taking as given B_1, we solve for the equilibrium price and default functions by iterating on $\{d_1, q_0, b_1^i\}$. Then, in the second stage we complete the solution of the equilibrium by finding the optimal choice of B_1 that solves the government's date-0 optimization problem (25). As explained earlier, for given values of B_1, γ and ω an equilibrium with debt will not exist if either the government finds it optimal to default on B_1 for all realizations of g_1 or if at the given B_1 the consumption of L types is nonpositive.

[ax] $\sigma = 1$ and $b_0^L = 0$ are also useful because under these assumptions we can obtain closed-form solutions and establish some results analytically.

Table 14 Model parameters

Parameter		Value
Discount factor	β	0.96
Risk aversion	σ	1.00
Avg. Income	y	0.79
Low household wealth	b_0^L	0.00
Avg. gov. consumption	μ_g	0.18
Autocorrel. G	ρ_g	0.88
Std. dev. error	σ_g	0.017
Initial gov. debt	B_0	0.79
Output cost default	ϕ_0	0.02

Note: Government expenditures, income, and debt values are derived using Eurostat data for France, Germany, Greece, Ireland, Italy, Spain, and Portugal.

values $\mu_g = 0.1812$, $\rho_g = 0.8802$ and $\sigma_e = 0.017$. We set $g_0 = \mu_g$ and use the quadrature method proposed by Tauchen (1986) with 45 nodes in $G_1 \equiv \{\underline{g}_1, \ldots, \bar{g}_1\}$ to generate the realizations and transition probabilities of g_1.

Average income y is calibrated such that the model's aggregate resource constraint is consistent with the data when GDP is normalized to one. This implies that the value of the agents' aggregate endowment must equal GDP net of fixed capital investment and net exports, since the latter two are not modeled. The average for the period 1970–2012 for the same set of countries used to estimate the g_1 process implies $y = 0.7883$.[ay]

We set the initial debt level $B_0 = 0.79$ so that at the maximum observed level of inequality in the data, $\gamma = 0.85$, there is at least one feasible level of B_1 when $\omega = \gamma$. We assume that the default cost takes the following form: $\phi(g_1) = \phi_0 + (\bar{g} - g_1)/y$, where $\bar{g}$ is calibrated to represent an "unusually large" realization of g_1 set equal to the largest realization in the Markov process of government expenditures, which is in turn set equal to 3 standard deviations from the mean (in logs).[az]

We calibrate ϕ_0 to match an estimate of the observed frequency of *domestic* defaults. According to Reinhart and Rogoff (2011), historically, domestic defaults are about 1/4 as frequent as external defaults (68 domestic vs 250 external in their data since 1750). Since the probability of an external default has been estimated in the range of 3–5% (see, for example, Arellano, 2008), the probability of a domestic default is about 1%. The model is close to this default frequency on average when solved over the empirically relevant

[ay] Note also that under this calibration of y and the Markov process of g_1, the gap $y - g_1$ is always positive, even for $g_1 = \bar{g}_1$, which in turn guarantees $c_1^H > 0$ in all repayment states.

[az] This cost function shares a key feature of the default cost functions widely used in the external default literature to align default incentives so as to support higher debt ratios and trigger default during recessions (see Arellano, 2008 and Mendoza and Yue, 2012): The default cost is an *increasing* function of disposable income $(y - g_1)$. In addition, this formulation ensures that the agents' consumption during a default never goes above a given threshold.

range of γ's ($\gamma \in [0.55, 0.85]$) if we set $\phi_0 = 0.02$. Note, however, that the calibration of ϕ_0 and B_0 to match their corresponding targets needs to be done jointly by repeatedly solving the model until both targets are well approximated.

4.3.2 Utilitarian Government ($\omega = \gamma$)

We study first a set of results obtained under the assumption $\omega = \gamma$, because the utilitarian government is a natural benchmark. Since the default decision of the government derives from the agents' utility under the repayment and default alternatives at $t = 1$, it is useful to map the ordinal utility measures into cardinal measures by computing "individual welfare gains of default," which are standard consumption-equivalent values that equalize utility under default and repayment. Given the CRRA functional form, the individual welfare gains of default reduce simply to the percent changes in consumption across the default and no-default states of each agent at $t = 1$:

$$\alpha^i(B_1, g_1, \gamma) = \frac{c_1^{i,d=1}(B_1, g_1, \gamma)}{c_1^{i,d=0}(B_1, g_1, \gamma)} - 1 = \frac{(1 - \phi(g_1))\gamma - g_1}{\gamma - g_1 + b_1^i - B_1} - 1$$

A positive (negative) value of $\alpha^i(B_1, g_1, \gamma)$ implies that agent i prefers government default (repayment) by an amount equivalent to an increase (cut) of $\alpha^i(\cdot)$ percent in consumption. The individual welfare gains of default are aggregated using γ to obtain the utilitarian representation of the social welfare gain of default:

$$\overline{\alpha}(B_1, g_1, \gamma) = \gamma\alpha^L(B_1, g_1, \gamma) + (1 - \gamma)\alpha^H(B_1, g_1, \gamma).$$

A positive value indicates that default induces a social welfare gain and a negative value a loss.

Fig. 17 shows two intensity plots of the social welfare gain of default for the ranges of values of B_1 and γ in the vertical and horizontal axes, respectively. Panel (A) is for a low value of government purchases, $\underline{g}_1$, set 3 standard deviations below μ_g, and panel (B) is for a high value $\bar{g}_1$ set 3 standard deviations above μ_g. "No Equilibrium Zone", represent values of (B_1, γ) for which the debt market collapses and no equilibrium exists.[ba]

The area in which the social welfare gains of default are well defined in these intensity plots illustrates two of the key mechanisms driving the government's distributional incentives to default: First, fixing γ, the welfare gain of default is higher at higher levels of debt, or conversely the gain of repayment is lower. Second, keeping B_1 constant, the welfare gain of default is also increasing in γ (ie, higher wealth concentration increases

[ba] Note that to determine if $c_0^L \leq 0$ at some (B_1, γ) we also need $q_0(B_1, \gamma)$, since combining the budget constraints of the L types and the government yields $c_0^L = \gamma - g_0 - B_0 + q_0 B_1$. Hence, to evaluate this condition we take the given B_1 and use the H-types Euler equation and the market clearing condition to solve for $q_0(B_1, \gamma, \omega)$, and then determine if $\gamma - g_0 - B_0 + q_0 B_1 \leq 0$, if this is true, then (B_1, γ) is in the lower no-equilibrium zone.

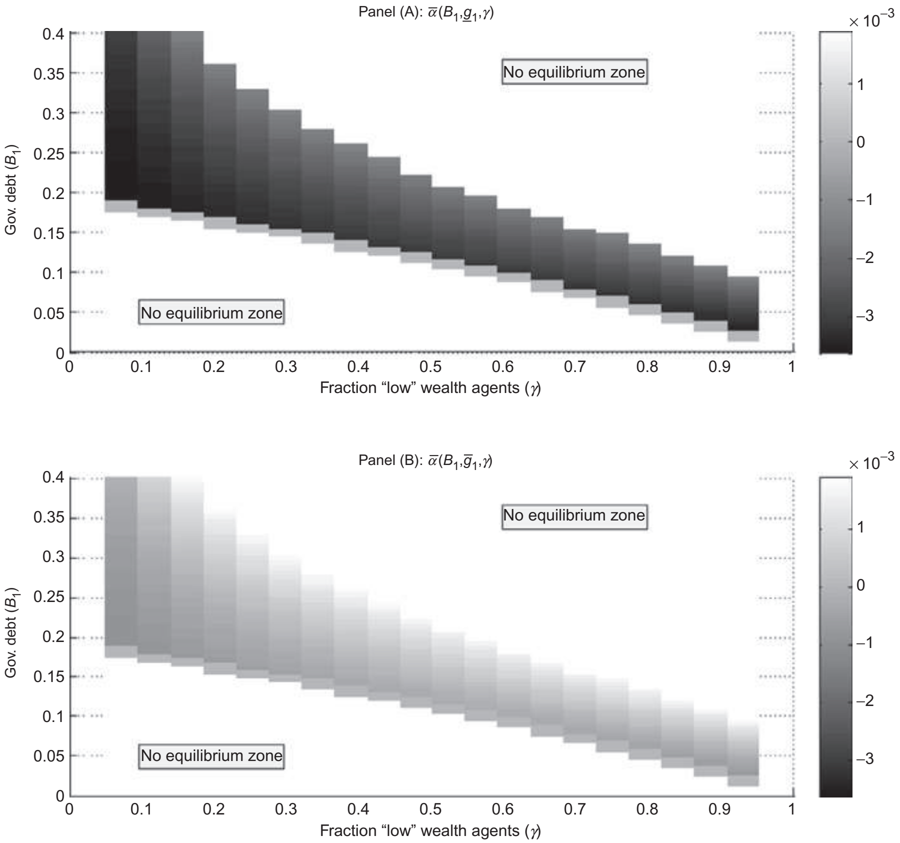

Fig. 17 Social welfare gains of default $\overline{\alpha}(B_1, g_1, \gamma)$. *Note:* The intensity of the color or shading in these plots indicates the magnitude of the welfare gain according to the legend shown to the right of the plots. The regions shown in white and marked as "no equilibrium zone," represent values of (B_1, γ) for which the debt market collapses and no equilibrium exists.

the welfare gain of default). This implies that lower levels of wealth dispersion are sufficient to trigger default at higher levels of debt.[bb] For example, for a debt ratio of 20% of GDP ($B_1 = 0.20$) and $g_1 = \bar{g}_1$, social welfare is higher under repayment if $0 \leq \gamma \leq 0.25$ but it becomes higher under default if $0.25 < \gamma \leq 0.6$, and for higher γ there is no equilibrium because the government prefers default not only for $g_1 = \bar{g}_1$ but for all possible g_1. If instead the debt is 40% of GDP, then social welfare is higher under default for all the values of γ for which an equilibrium exists.

[bb] Note that the cross-sectional variance of initial debt holdings is given by $Var(b) = B^2 \dfrac{\gamma}{1-\gamma}$ when $b_0^L = 0$. This implies that the cross-sectional coefficient of variation is equal to $CV(b) = \dfrac{\gamma}{1-\gamma}$, which is increasing in γ for $\gamma \leq 1/2$.

The two panels in Fig. 17 differ in that panel (B) displays a well-defined transition from a region in which repayment is socially optimal ($\overline{\alpha}(B_1,g_1,\gamma)<0$) to one where default is optimal ($\overline{\alpha}(B_1,g_1,\gamma)>0$) but in panel (A) the social welfare gain of default is never positive, so repayment is always optimal. This reflects the fact that higher g_1 also weakens the incentives to repay. In the "No Equilibrium Zone" in the upper right, there is no equilibrium because at the given γ the government chooses to default on the given B_1 for all values of g_1. In the "No Equilibrium Zone" in the lower left, there is no equilibrium because the given (B_1, γ) would yield $c_0^L \leq 0$, and so the government would not supply that particular B_1.

Consider next the government's default decision choice, which is driven by the sign of the social welfare gains of default. It is evident from Fig. 17 that the government defaults the higher g_1 for given B_1 and γ, the higher B_1 for a given γ and g_1, or at higher γ at given B_1 and g_1. It follows then that we can compute a threshold value of γ such that the government is indifferent between defaulting and repaying in period $t=1$ for a given (B_1,g_1). These indifference thresholds ($\hat{\gamma}(B_1,g_1)$) are plotted in Fig. 18 against debt levels ranging from 0 to 0.4 for three values of government expenditures $\{\underline{g}_1, \mu_g, \overline{g}_1\}$. For any given ($B_1$, g_1), the government chooses to default if $\gamma \geq \hat{\gamma}$.

Fig. 18 shows that the default threshold is decreasing in B_1. Hence, the government tolerates higher debt ratios without defaulting only if wealth concentration is sufficiently low. Also, default thresholds are decreasing in g_1, because the government has stronger

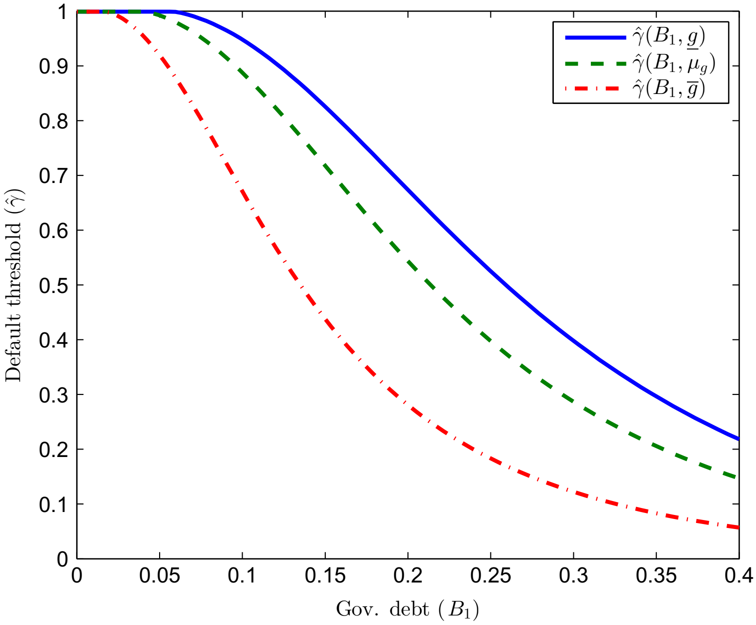

Fig. 18 Default threshold $\hat{\gamma}(B_1,g_1)$.

incentives to default when government expenditures are higher (ie, the threshold curves shift inward).[bc] This last feature of $\hat{\gamma}$ is very important to determine equilibria with sustainable debt subject to default risk. If, for a given value of B_1, γ is higher than the curve representing $\hat{\gamma}$ for the lowest realization in the Markov process of g_1 (which is also the value of $\underline{g_1}$), the government defaults for sure and, as explained earlier, there is no sustainable debt at equilibrium. Alternatively, if for a given value of B_1, γ is lower than the curve representing $\hat{\gamma}$ for the highest realization of g_1 (which is the value of $\overline{g}_1$), the government repays for sure and debt would be issued effectively without default risk. Thus, for the model to support equilibria with sustainable debt subject to default risk, the optimal debt chosen by the government in the first period for a given γ must lie between these two extreme threshold curves. We show below that this is the case in this quantitative experiment.

Before showing those results, it is important to highlight three key properties of the bond pricing function. The quantitative results for this function, the details of which we omit to save space, reflect the properties discussed in the model analysis:

1. *The equilibrium price is decreasing in $B_1$for given γ* (the pricing functions shift downward as B_1 rises). This follows from a standard demand-and-supply argument: For a given γ, as the government borrows more, the price at which the H types are willing to demand the additional debt falls and the interest rate rises.
2. *Default risk reduces the price of bonds below the risk-free price and thus induces a risk premium.* Intuitively, when there is no default risk (ie, for combinations of B_1 and γ such that the probability of default is zero) both prices are identical. However, as the probability of default rises, agents demand a premium in order to clear the bond market.
3. *Bond prices are a nonmonotonic function of wealth dispersion*: When default risk is sufficiently low, bond prices are increasing in γ, but eventually they become a steep decreasing function of γ. Higher γ implies a more dispersed wealth distribution, so that H-type agents become a smaller fraction of the population, and hence they must demand a larger amount of debt per capita in order to clear the bond market (ie, b_1^H increases with γ), which pushes bond prices up. While default risk is low this "demand composition effect" dominates and thus bond prices rise with γ, but as γ increases and default risk rises (since higher wealth dispersion strengthens default incentives), the growing risk premium becomes the dominating force (at about $\gamma > 0.5$) and produces bond prices that fall sharply as γ increases.

Finally we examine the numerical solutions of the model's full equilibrium with optimal debt and default policies. The key element of the solution is the sustainable debt, which is also the government's optimal choice of debt issuance in the first period at the equilibrium price (ie, the optimal B_1 that solves problem (25)). We show this sustainable debt as an equilibrium manifold (ie, as a plot of the sustainable debt obtained by

[bc] $\hat{\gamma}$ approaches zero for B_1 sufficiently large, but in Fig. 18 B_1 reaches 0.40 only for exposition purposes.

solving the model's equilibrium over a range of values of γ). Given this sustainable debt, we can then use the functions that describe optimal debt demand plans of private agents in both periods, the government's default choice in period 1, bond prices, and default risk for *any* value of B_1 to determine the corresponding *equilibrium* manifold values of all of the model's endogenous variables.

Fig. 19 shows the four main components of the equilibrium manifolds: Panel (A) plots the manifold of sustainable first-period debt issuance of the model with default risk, $B_1^*(\gamma)$, and also, for comparison, the debt in the case when the government is committed to repay so that debt is risk free, $B_1^{RF}(\gamma)$. Panel (B) shows equilibrium debt prices that correspond to the sustainable debt of the same two economies. Panel (C) shows the default spread (the difference in the inverses of the bond prices). Panel (D) shows the probability of default. Since in principle the government that has the option to default can still choose a debt level for which it could prefer to repay in all realizations of g_1,

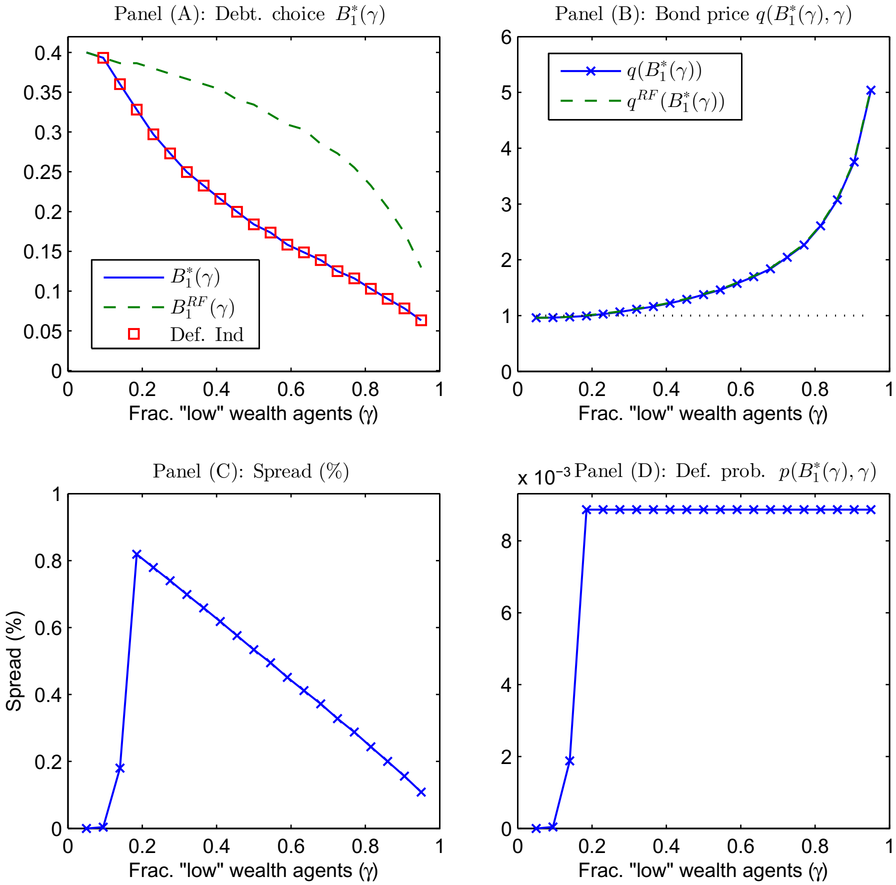

Fig. 19 Equilibrium manifolds.

we identify with a square in Panel (A) the equilibria in which $B_1^*(\gamma)$ has a positive default probability. This is the case for all but the smallest value of gamma considered ($\gamma = 0.05$), in which the government sets $B_1^*(\gamma)$ at 40% of GDP with zero default probability.

Panel (A) shows that sustainable debt falls as γ increases in both the economy with default risk and the economy with a government committed to repay. This occurs because in both cases the government seeks to reallocate consumption across agents and across periods by altering the product $q(B_1)B_1$ optimally, and in doing this it internalizes the response of bond prices to its debt choice. As γ rises, this response is influenced by stronger default incentives and a stronger demand composition effect. The latter dominates in this quantitative experiment, because panel (B) shows that the equilibrium bond prices always rise with γ. Hence, the government internalizes that as γ rises the demand composition effect strengthens demand for bonds, pushing bond prices higher, and as a result it can actually attain a higher $q(B_1)B_1$ by choosing lower B_1. This is a standard Laffer curve argument: In the upward slopping segment of this curve, increasing debt increases the amount of resources the government acquires by borrowing in the first period.

In the range of empirically relevant values of γ, sustainable debt ratios range from 20% to 32% of GDP without default risk and from 8% to 15% with default risk. Since the median in the European data is 35%, these ratios are relatively low, but still they are notable given the simplicity of the two-period setup. In particular, the model lacks the stronger income- and tax-smoothing effects and the self-insurance incentives of a longer life horizon (see Aiyagari and McGrattan, 1998), and it has an upper bound on the optimal debt choice for $\gamma = [0,1]$ lower than $B_0/(1+\beta)$ (which is the upper bound as $\gamma \rightarrow 0$ in the absence of default risk).

Panel (B) shows that bond prices of sustainable debt range from very low to very high as γ rises, including prices sharply above 1 that imply large negative real interest rates on public debt. In fact, as D'Erasmo and Mendoza (2013) explain, equilibrium bond prices are similar and increasing in γ with or without default risk, because at equilibrium the government chooses debt positions for which default risk is low (see panel (D)), and thus the demand composition effect that strengthens as γ rises dominates and yields bond prices increasing in γ and similar with or without default risk.[bd]

[bd] Everything else equal, our model predicts that higher income dispersion (either due to less progressive tax systems or underlying households' income or bond positions) results in higher spreads. In D'Erasmo and Mendoza (2013), we show that an economy with more progressive tax system results in lower spreads. The intuition is simple. The more the government can redistribute via means of taxation the lower the incentives to redistribute through a domestic default on the debt. The results in that paper show that incentives to default do not disappear but spreads decrease considerably. Also in D'Erasmo and Mendoza (2013), we present evidence of the nonlinear relationship between debt to income ratios and wealth inequality. Data limitations prevents us from extending this analysis to the relationship between spreads and income dispersion or the progressivity of the tax system.

Panels (C) and (D) show that, in contrast with standard models of external default, in this model the default spread is neither similar to the probability of default nor does it have a monotonic relationship with it.[be] Both the spread and the default probability start at zero for $\gamma = 0.05$ because $B_1^*(0.05)$ has zero default probability. As γ increases up to 0.2, both the spread and the default probability of the sustainable debt are similar in magnitude and increase together, but for $\gamma > 0.2$ the spread falls with γ while the default probability remains unchanged around 0.9%. For $\gamma = 0.95$ the probability of default is 9 times larger than the spread (0.9 vs 0.1%).

The role of the government's incentives to reallocate consumption across agents and across periods internalizing the response of bond prices when choosing debt can be illustrated further by examining the debt Laffer curve. Fig. 20 shows debt Laffer curves for five values of γ in the [0.05,0.95] range.

In all but one case, the sustainable debt $B_1^*(\gamma)$ (ie, the equilibrium debt chosen optimally by the government at the equilibrium price) is located at the maximum of the corresponding Laffer curve. In these cases, setting debt higher than at the maximum is

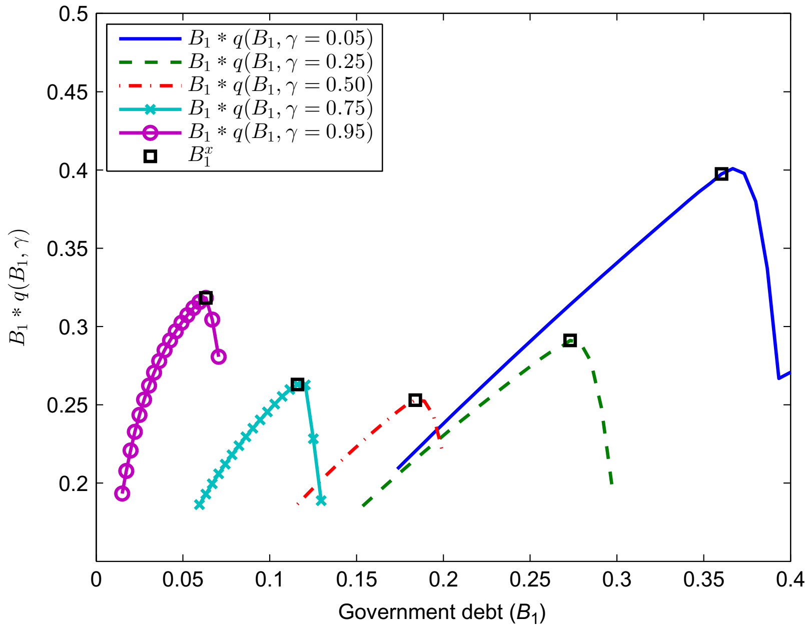

Fig. 20 Debt Laffer curve. *Note*: Each curve is truncated at values of B_1 in the horizontal axis that are either low enough for $c_0^L \leq 0$ or high enough for default to be chosen for all realizations of g_1, because as noted before in these cases there is no equilibrium.

[be] In the standard models, the two are similar and a monotonic function of each other because of the arbitrage condition of a representative risk-neutral investor.

suboptimal because default risk reduces bond prices sharply, moving the government to the downward-sloping segment of the Laffer curve. Setting debt lower than the maximum is also suboptimal, because then default risk is low and extra borrowing generates more resources since bond prices change little, leaving the government in the upward-sloping segment region of the Laffer curve. Thus, if the optimal debt has a nontrivial probability of default, the government's debt choice exhausts its ability to raise resources by borrowing. The exception is the case with $\gamma = 0.05$, in which $B_1^*(\gamma)$ has zero default probability. In this case, the government's optimal debt is to the left of the maximum of the Laffer curve, and thus the debt choice does not exhaust the government's ability to raise resources by borrowing. This also happens when the default probability is positive but negligible. For example, when $\gamma = 0.15$ the default probability is close to zero and the optimal debt choice is again slightly to the left of the maximum of the corresponding Laffer curve.

4.3.3 Biased Welfare Weights ($\omega \neq \gamma$)

The final experiment we conduct examines how the results change if we allow the weights of the government's payoff function to display a bias in favor of bondholders. Fig. 21 shows how the planner's welfare gain of default varies with ω and γ for two different levels of government debt ($B_{1,L} = 0.143$ and $B_{1,H} = 0.185$). The no-equilibrium region, which exists for the same reasons as before, is shown in white.

In line with the previous discussion, within the region where the equilibrium is well-defined, the planner's value of default increases monotonically as ω increases, keeping γ constant, and falls as actual wealth concentration (γ) rises, keeping ω constant. Because of this, the north-west and south-east corners in each of the panels present cases that are at very different positions on the preference-for-default spectrum. When ω is low, even for very high values of γ, the government prefers to repay (north-west corner), because the government puts relatively small weight on L-type agents. On the contrary, when ω is high, even for low levels of γ, a default is preferred. It is also interesting to note that as we move from Panel (A) to Panel (B), so that government debt raises, the set of γ's and ω's such that the equilibrium exists or repayment is preferred (ie, a negative $\overline{\alpha}(B_1, g_1, \gamma, \omega)$) expands. This is because as we increase the level of debt B_1, as long as the government does not choose to default for all g_1, the higher level of debt allows L-type agents to attain positive levels of consumption (since initial taxes are lower).

Panels (A)–(D) in Fig. 22 display the model's equilibrium outcomes for the sustainable debt chosen by the government in the first period and the associated equilibrium bond prices, spreads and default probabilities under three possible values of ω, all plotted as functions of γ. It is important to note that along the blue curve of the utilitarian case both ω and γ effectively vary together because they are always equal to each other, while in the other two plots ω is fixed and γ varies. For this reason, the line corresponding to the ω_L

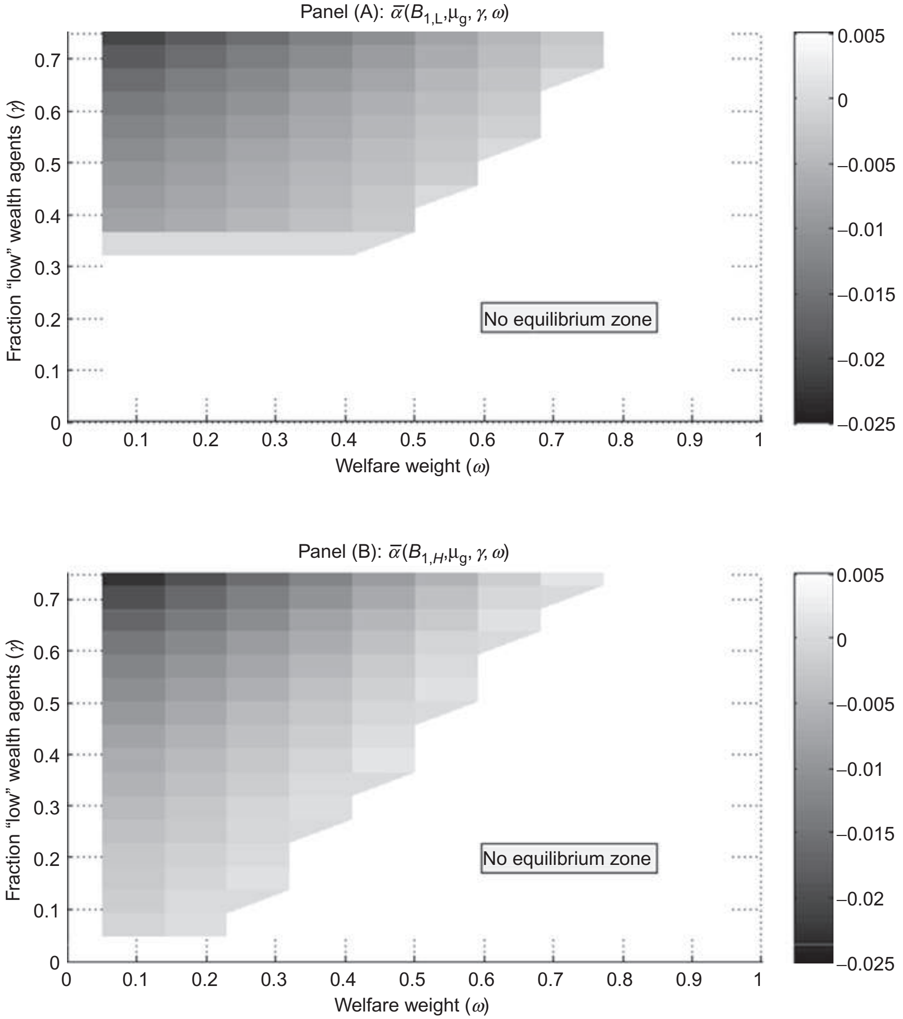

Fig. 21 Planner's welfare gain of default $\bar{\alpha}(B_1, g_1, \gamma, \omega)$.

case intersects the benchmark solution when $\gamma = 0.32$, and the one for ω_H intersects the benchmark when $\gamma = 0.50$.

Fig. 22 shows that the optimal debt level is increasing in γ. This is because the incentives to default grow weaker and the repayment zone widens as γ increases for a fixed value of ω. It is also interesting to note that in the ω_L and ω_H cases the equilibrium exists only for a small range of values of γ that are lower than ω. Without default costs each curve would be truncated exactly where γ equals either ω_H or ω_H, but since these simulations retain the default costs used in the utilitarian case, there can still be equilibria with debt for some lower values of γ (as explained earlier).

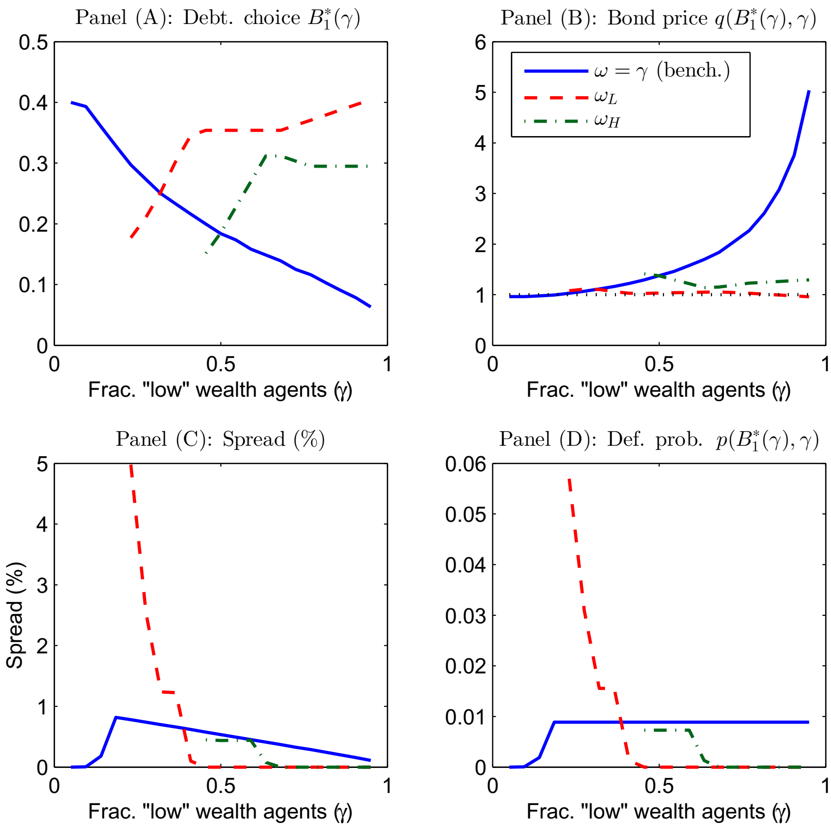

Fig. 22 Equilibrium manifolds with government bias at different values of ω.

With the bias in favor of bondholders, the government is still aiming to optimize debt by focusing on the resources it can reallocate across periods and agents, which are still determined by the debt Laffer curve $q_0(.)B_1$, and internalizing the response of bond prices to debt choices.[bf] This relationship, however, behaves very differently than in the benchmark model, because now *higher* sustainable debt is carried at increasing equilibrium bond prices, which leads the planner internalizing the price response to choose higher debt, whereas in the benchmark model *lower* debt was sustained at increasing equilibrium bond prices, which led the planner internalizing the price response to choose lower debt.[bg]

[bf] When choosing B_1, the government takes into account that higher debt increases disposable income for L-type agents in the initial period but it also implies higher taxes in the second period (as long as default is not optimal). Thus, the government is willing to take on more debt when ω is lower.

[bg] Fig. 22 makes clear that with the government bias, the level of sustainable debt changes with the preferences of the government. Even though we do not model how these preferences arise, it is evident that two countries with the same fundamentals (ie, distribution of wealth and income) could end up with very different levels of sustainable debt depending on how household preferences are aggregated by the government in power.

The behavior of equilibrium bond prices (panel (B)) with either $\omega_L = 0.32$ or $\omega_H = 0.50$ differs markedly from the utilitarian case. In particular, the prices no longer display an increasing, convex shape, instead they are a relatively flat and nonmonotonic function of γ. This occurs because the higher supply of bonds that the government finds optimal to provide offsets the demand composition effect that increases individual demand for bonds as γ rises.

The domestic default approach to study sustainable debt adds important insights to those obtained from the empirical and structural approaches, both of which assumed repayment commitment. In particular, panel (A) of Fig. 19 shows that sustainable debt falls sharply once risk of default is present, even when it is very small, and that (if the government is utilitarian) sustainable debt falls sharply with the concentration of bond ownership, because of the strengthened incentive to use default as a tool for redistribution. Hence, estimates of sustainable debt based on models in which the government is assumed to be committed to repay are likely to be too optimistic. Intuitively, one can infer that in the structural model, a given increase in the initial debt would be harder to offset with higher primary balances if the interest rate at which those primary balances are discounted rises with higher debt because of default risk. Moreover, the representative-agent assumption is also likely to lead to optimistic estimates of sustainable debt, because representative-agents models abstract from the strong incentives to use debt default as a tool for redistribution across heterogeneous agents. These incentives are likely to be weaker than in the model in practice, because tax and transfer policies that we did not include in the model can be used for redistribution as well. But when these other instruments have been exhausted, and if inequality in bond holdings is sufficiently concentrated, the incentives to default as vehicle for redistribution are likely to be very strong.

A second important insight from this analysis is that sustainable debt is higher if the government's payoff function is biased in favor of bondholders, and can even exceed debt that is sustainable without default risk when the government has a utilitarian social welfare function. Furthermore, D'Erasmo and Mendoza (2013) show that nonbondholders may prefer equilibria where the government favors bondholders, instead of being utilitarian, because higher sustainable debt help relax their liquidity constraints. Hence, at sufficiently high levels of concentration of bond ownership, a biased government can sustain high debt and the biased government can be elected as a majority government.

The main caveat of this analysis is that, because it was based on a two-period model, it misses important endogenous costs of default that would be added to the model by introducing a longer life horizon. In this case, default costs due to the reduced ability to smooth taxation and consumption when the debt market closes, and due to the loss of access to the self-insurance vehicle and the associated tightening of liquidity constraints, can take up the role of the exogenous default costs and/or government bias for bondholders, enabling the model to improve its ability to account for key features of the data and sustain higher debt levels at nontrivial default premia. D'Erasmo and Mendoza (2014) examine a model with these features and study its quantitative implications.

5. CRITICAL ASSESSMENT AND OUTLOOK

We started this chapter by noting that the question of what is a sustainable public debt has always been paramount in the macroeconomics of fiscal policy. The question will remain paramount for years to come, as the precarious public debt and deficit positions of many advanced and emerging economies today will make it a central focus of both policy analysis and academic research. This chapter aimed to demonstrate the flaws that affect the classic, but still widely used, approach to analyze public debt sustainability, and to show how three approaches based on recent research can provide powerful alternative ways to tackle the question. Two of these approaches, the empirical approach and the structural approach, assume that the government is committed to repay its debt, and the third approach, the domestic default approach, assumes that the government cannot commit to repay. In this section, we reflect further on the limitations of each of these approaches and suggest directions for further research.

The empirical approach has been widely studied and is by now very well established. Its strengths are in that it can easily determine whether debt has been consistent with fiscal solvency in available time-series data via straightforward estimation of a fiscal reaction function, and in that analyzing the characteristics of this FRF it can shed light on the dynamics of adjustment of debt and the primary balance. Unfortunately, as we explained earlier, it is not helpful for comparing alternative fiscal policy strategies to maintain debt sustainability and/or cope with public debt crises in the future.

The structural approach showed how an explicit dynamic general equilibrium model can be used to compare alternative fiscal policy strategies aimed at maintaining fiscals solvency at different levels of observed outstanding debt. We used a variation of the workhorse two-country Neoclassical framework with exogenous, balanced growth in which endogenous capacity utilization and a limited tax allowance for capital depreciation allow the model to match a key feature of the data for fiscal sustainability analysis: The observed elasticity of the capital tax revenue. Yet, the model is also very limited inasmuch as it abstracts from other important features of the data. In particular, the model is purely "real," and hence abstracts from the fact that public debt is largely nominal debt denominated in domestic currencies, and also abstracts from linkages between potentially important nominal rigidities, relative prices, and the evolution of government revenues and outlays.

The model used in the structural approach also has the drawbacks that it abstracts from heterogeneity in households and firms and assumes that agents are infinitely lived. Hence, while it takes into account important efficiency effects resulting from alternative fiscal policies, it cannot capture their distributional implications across agents and/or generations. The fiscal policy research on heterogeneous-agents and overlapping-generations models has shown that these distributional effects can be quite significant, and hence it is important to develop models of debt sustainability that incorporate them. For instance, Aiyagari (1995) showed that reductions in capital taxes have adverse distributional consequences that can offset the efficiency gains emphasized in representative agent models. Aiyagari and McGrattan (1998) showed that public debt has social value because it acts as vehicle to provide liquidity (ie, relax borrowing constraints) of the agents at the low end of the wealth distribution, and Birkeland and Prescott (2006) provide a setup in which using debt to save for retirement dominates a tax-and-transfer system. Imrohoroglu et al. (2016) and Braun and Joines (2015) also show how sophisticated overlapping-generations models can be applied to study debt-sustainability issues, with a particular focus on the implications of the adverse demographics dynamics facing Japan.

Of the approaches to debt sustainability analysis reviewed here, the domestic default approach is the one that has been studied the least. We provided a very simple canonical model in which default on domestic debt can emerge as an optimal outcome for a government with incentives to redistribute across debt holders and nonholders, but clearly significant further research in this area is needed (in addition to the recent work by D'Erasmo and Mendoza (2014) and Dovis et al. (2014) that we cited).

There are also two other directions in which research on debt sustainability should go. First, to model the role of public debt in financial intermediation in general and in financial stabilization policies in particular. In terms of the former, domestic banking systems are often large holders of domestic public debt, so a domestic default of the kind the third approach we examined seeks to explain tends to materialize in terms of a redistribution that hurts the balance sheets of banks. A deeper question in a similar vein is why public debt is such a high-demand asset, or liquidity vehicle, in modern financial systems. Macro/finance research is looking into this questions, but introducing these considerations into debt sustainability analysis is still a pending task. Regarding crisis-management policies, the aftermath of the global financial crisis has been characterized by strong demand for public debt instruments driven by quantitative easing policies and by the new regulatory environment. This may account for the apparent paradox between the pessimistic fiscal prospects that the analysis of this chapter presents and the observation that we currently observe near-zero and even negative yields on the public debt of some advanced economies (ie, demand for public debt remains very strong despite the highly questionable capacity of governments to repay it through standard improvements of the primary fiscal balance). But to be certain we need a richer model of debt sustainability that incorporates both the long-term forces that drive the government's capacity to repay and short-term debt dynamics around a financial crisis in which demand for risk-free asset surges.

The second direction in which debt sustainability analysis needs to branch out is to develop tools to incorporate considerations of potential multiplicity of equilibria in public debt markets. The seminal work of Calvo (1988) showed how debt can move between two equilibria supported by self-fulfilling expectations. In one the debt is repaid because agents expect that the government will be able to access the debt market, and thus maintain the efficiency losses of taxation small enough to indeed generate enough revenue to repay. In the other, the government defaults because agents expect that it will not be able to access the debt market and will be forced into highly distorting levels of taxation that indeed result in revenues that are insufficient to repay. The external default literature has explored models with this kind of equilibrium multiplicity extensively, as documented in the corresponding chapter of this handbook, and theoretical work applying these ideas to domestic debt crises is also available, but research to incorporate this mechanism into quantitative models of domestic debt sustainability is still needed.

6. CONCLUSIONS

What is a sustainable public debt? Assuming that the government is committed to repay, the answer is a debt that satisfies the intertemporal government budget constraint (ie, a debt that is equal to the present discounted value of the primary fiscal balance). In this chapter we showed that the traditional approach to debt sustainability analysis is flawed. This approach uses the steady-state government budget constraint to define sustainable debt as the annuity value of the primary balance, but it cannot establish if current or projected debt and primary balance dynamics are consistent with that debt level. We then discussed two approaches to study public debt sustainability under commitment to repay: First, an empirical approach, based on a linear fiscal reaction function, according to which a positive, conditional response of the primary balance to debt is sufficient to establish debt sustainability. Second, a structural approach based on a two-country variant of the workhorse Neoclassical dynamic general equilibrium model with an explicit fiscal sector. The model differs from the standard Neoclassical setup in that it introduces endogenous capacity utilization and a limited tax allowance for depreciation expenses in order to match the observed elasticity of the capital tax base to changes in capital taxes. In this setup, the initial debt that is sustainable is the one determined by the present value of primary balances evaluated using equilibrium allocations and prices.

Applications of these first two approaches to cross-country data produced key insights. With the empirical approach, we found in tests based on historical US data and cross-country panels that the sufficiency condition for public debt to be sustainable (the positive, conditional response of the primary balance to debt), cannot be rejected. We also found, however, clear evidence showing that the fiscal dynamics observed in the aftermath of the recent surge in debt in advanced economies represent a significant structural break in the estimated reaction functions. Primary deficits have been too large, and are projected to remain too large, relative to what the fiscal reaction functions predict, and they are also large compared with those observed in the aftermath previous episodes of large surges in debt.

The structural approach differs from the empirical approach in that it can be used to evaluate the positive and normative effects of alternative paths of fiscal adjustment to attain debt sustainability, whereas the empirical approach is silent about these effects. We calibrated the model to the United States and European data and used it to quantify the effects of unilateral changes in capital and labor taxes, particularly their effects on sustainable debt. The results suggest key differences across Europe and the United States. For the United States, the results suggest that changes in capital taxes cannot make the observed increase in debt sustainable, while small increases in labor taxes could. For Europe, the model predicts that the capacity to use taxes to make higher debt ratios sustainable is nearly fully exhausted. Capital taxation is highly inefficient (in the decreasing segment of dynamic Laffer curves), so cuts in capital taxes would be needed to restore fiscal solvency. Labor taxes are near the peak of the dynamic Laffer curve, and even if increased to the maximum point they do not generate enough revenue to make the present value of the primary balance match the observed surge in debt. In addition, international externalities of capital income taxes were quantitatively large, which suggest that incentives for strategic interaction are nontrivial and could lead to a classic race-to-the-bottom in capital income taxation.

The results of the applications of the empirical and structural approaches paint a bleak picture of the prospects for fiscal adjustment in advanced economies to restore fiscal solvency and make the post-2008 surge in public debt ratios sustainable. In light of these findings, and with the ongoing turbulence in European sovereign debt markets and recurrent debt ceiling debates in the United States, we examined a third approach to debt sustainability that relaxes the assumption of a government committed to repay and allows for the risk of default on domestic public debt. In this environment, debt is sustainable when it is part of the equilibrium that includes the optimal debt issuance and default choices of the government. The government has incentives to default as a vehicle for redistribution across agents who are heterogeneous in wealth. Public debt is not sustainable in the absence of default costs or a political bias to weigh the welfare of bond holders by more than their share of the wealth distribution. This is the case because without these assumptions default is always the optimal choice that maximizes the social welfare function of a government who values the utility of all agents, and this is the case regardless of the present value of primary balances used to characterize sustainable debt under the other two approaches.

Quantitatively, this domestic default approach adds valuable insights to those obtained from the empirical and structural approaches without default risk. In particular, sustainable debt falls sharply once risk of default is present, even when it is very small, and it also falls sharply with wealth inequality, because of the strengthened incentive to use default as a tool for redistribution. Hence, estimates of sustainable debt based on models in which the government is assumed to be committed to repay are too optimistic. Moreover, the representative-agent assumption is also likely to lead to optimistic estimates of sustainable debt, because models in this class abstract from the strong incentives to use debt default as a tool for redistribution across heterogeneous agents. A second important insight from the domestic default approach is that sustainable debt is higher if the government's payoff function weighs the welfare of bond holders more heavily than their share of the wealth distribution. In addition, it is possible that low-wealth agents may also prefer that the government weights high-wealth agents more heavily, instead of acting as a utilitarian government, because higher debt stocks help relax their liquidity constraints.

The three approaches reviewed in this chapter provide useful tools for conducting debt sustainability analysis. When applied to the current fiscal situation of advanced economies, all three suggest that substantial fiscal adjustment is still needed, is likely to entail substantial welfare costs, and is likely to continue to be challenged by potential default risk in domestic sovereign debt markets.

APPENDIX: DETAILS ON MEASUREMENT OF EFFECTIVE TAX RATES

Effective tax rates have been widely used in a number of studies including Carey and Tchilinguirian (2000), Sorensen (2001), and recently by Trabandt and Uhlig (2011, 2012). The MRT methodology uses the wedge between reported pretax and post-tax macro estimates of consumption, labor income and capital income to estimate the effective tax rate levied on each of the three tax bases. This methodology has two main advantages. First, it provides a fairly simple approach to estimating effective tax rates at the macro level using readily available data, despite the complexity of the various credits and deductions of national tax codes. Second, these tax rates correspond directly to the tax rates in a wide class of representative-agent models with taxes on consumption and factor incomes, including the model proposed here. The main drawback of the MRT tax rates is that they are average, not marginal, tax rates, but because they are intended for use in representative-agent models, this disadvantage is less severe than it would be in a model with heterogeneous agents. Moreover Mendoza et al. (1994) show that existing estimates of aggregate marginal tax rates have a high time-series correlation with the MRT effective tax rates, and that both have similar cross-country rankings.

Following Trabandt and Uhlig (2011), we modify the MRT estimates of labor and capital taxes by adding supplemental wages (ie, employers' contributions to social security and private pension plans) to the tax base for personal income taxes. These data were not available at the time of the MRT 1994 calculations and, because this adjustment affects the calculation of the personal income tax rate, which is an initial step for the calculation of labor and capital income tax rates, it alters the estimates of both. In general, this adjustment makes the labor tax base bigger and therefore the labor tax rate smaller than the MRT original estimates. [bh]

[bh] Trabandt and Uhlig make a further adjustment to the MRT formulae by attributing some of the operating surplus of corporations and nonincorporated private enterprises to labor, with the argument that this represents a return to entrepreneurs rather than to capital. We do not make this modification because the data do not provide enough information to determine what fraction of the operating surplus should be allocated to labor.

ACKNOWLEDGMENTS

We are grateful to Juan Hernandez, Christian Probsting and Valentina Piamiotti for their valuable research assistance. Abstract

This chapter critically reviews the literature which explains why and under which circumstances governments accumulate more debt than it would be consistent with optimal fiscal policy. We also discuss numerical rules or institutional designs which might lead to a moderation of these distortions.

Keywords

Political economy, Optimal taxation, Budget rules, Government debt

1. INTRODUCTION

Fiscal policy is deeply intertwined with politics since it is mostly about redistribution across individuals, regions, and generations: the core of political conflict. The redistributive role of governments has been increasing over time starting with the welfare programs introduced during the Great Depression and then with the additional jumps in the sixties and seventies of last century. But even recently the size of social spending (as defined by the OECD[a]) in 18 OECD countries jumped from 18% of GDP in 1980 to 26% in 2014.[b] In addition, the provision of public goods, which is therefore not classified as directly redistributive, has a redistributive component to the extent that public goods are used more or less intensively by individuals in different income brackets. The structure of taxation, such as the progressivity of the income tax brackets, also implies redistributions.[c] Politics matter for other macro policy areas, such as monetary policy and financial regulation. The recent financial crisis, for example, has reopened issues regarding the desirable conduct of monetary policy and the connection between

[a] OECD defines Social Expenditure as the provision by public (and private) institutions of benefits to, and financial contributions targeted at, households and individuals in order to provide support during circumstances which adversely affect their welfare, provided that the provision of the benefits and financial contributions constitutes neither a direct payment for a particular good or service nor an individual contract or transfer. Such benefits can be cash transfers, or can be the direct (in-kind) provision of goods and services.

[b] OECD (2014). The list of countries is: Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Ireland, Italy, Japan, Netherlands, Norway, Portugal, Spain, Sweden, United Kingdom, United States.

[c] Alesina and Giuliano (2012) review the vast literature which has investigated the political and social determinants for the demand of redistribution.

monetary and fiscal policy. The ECB is at the center stage of the political discussion about institutional building in the Euro area. In the present chapter we focus exclusively on fiscal policy.[d]

The politics of fiscal policy could cover issues as diverse as the level of centralization vs decentralization, the structure of taxation, pension systems, the design of insurance programs like health care and unemployment subsidies, the optimal taxation of capital, international coordination of tax systems, just to name a few topics. In this chapter we focus on debt. Many countries have been struggling with large debt over GDP ratios even before the financial crisis: countries which faced the Great Recession starting with large debt risked (or experienced) debt crises, like Greece, Italy, and Portugal putting at risk even the survival of the Monetary Union. Japan has a public debt held by the private sector of at least 140% of GDP.[e] The political debate on how and at what speed to reduce the public debt after the Great Recession is at the center stage of the political debate.[f] When adding expected future liabilities of entitlements and pensions the public budget of most OECD countries, including the Unites States, look bleak. Debt problems in developing countries, especially in Latin America have been common. Any attempt to explain all of these phenomena leaving politics out is completely pointless.

In particular we ask two broad questions. First, is there a tendency in democracies to pursue suboptimal fiscal policies which lead to the accumulation of excessive debt, where "excessive" is in reference of what a benevolent social planner would do? In other words, how far are the observed pattern of debt accumulation and fluctuations in line with normative prescription of the literature on debt management like, in particular, Barro (1979), Lucas and Stokey (1983), and Aiyagari et al. (2002)? What explains substantial departure from optimality?[g] Second, are fiscal rules (and which ones) a possible solution to limit the extent of the problem of excessive deficits? The balanced budget rule is the most famous one, but may other have been proposed, especially in the Euro area. Two are the key issues in this debate. The trade off between the rigidity of a rule and the lack of flexibility which these rules create. More flexible rules may be superior but harder to enforce because they have too many escape clauses. Finally, assuming that a rule would work, would a country adopt it? Or would political distortions prevent it?[h]

We shall begin with a brief sketch of the prescriptions of the optimal debt management in order to identify the normative implication against which to confront actual

[d] Alesina and Stella (2010) address old and new issues regarding the politics of monetary policy.

[e] The gross figure is well above 200% but it includes debt held by various public institutions.

[f] Reinhart and Rogoff (2010) and Rogoff (1990) have emphasized the cost of debt burden for long run growth.

[g] For a review of an early literature on this point see Alesina and Perotti (1995). For more recent surveys see Persson and Tabellini (2000) and Drazen (2000).

[h] An issue which we do not consider in this chapter is the question of procyclicality of budget deficits and the political distortions which may lead to this problem. See Gavin and Perotti (1997) and Alesina et al. (2008).

policies. The goal of this chapter is not to review in detail the optimal debt literature. We will exclusively focus on models with distortionary taxation and we will not enter the discussion of the Ricardian equivalence. We will not discuss issues regarding governments' defaults on their liabilities, a topic which would deserve an entire chapter on its own. After having described which are the implications of the optimal taxation theory regarding debt management, we show that even a cursory look at the empirical evidence suggest substantial deviations from these prescriptions even amongst OECD countries. In fact, in terms of empirical evidence we will focus almost exclusively on OECD economies. Then, we discuss several different approaches which have tried to explain these deviations from optimality, by introducing political variables in debt management models. Finally, we return to a normative question. Given the presence of all of the potential political distortions examined above, which rules, institutions, procedures or a combination of them is more likely to bring actual fiscal policy closer to the social planner ideal policy? In addition, are these rule and procedures likely to be chosen? Have they worked in the past?.

This chapter is organized as follows. In Section 2, we briefly review the theories of optimal deficit management and the related empirical evidence. In Section 3 to 7, we address the first question, namely whether or not there is a deficit bias in modern economies, and what explains it. In Sections 7 to 10, we cover the question of fiscal rules and of which institutional arrangement would be more suitable to limit suboptimal conduct of fiscal policy. The last section discusses open issues for future research.

2. OPTIMAL DEBT POLICIES: A BRIEF REVIEW

2.1 Tax Smoothing

The theory of tax smoothing is due to Barro (1979) in a model where debt is not contingent and risk free, spending needs are exogenously given and known, taxes have convex costs. The public debt takes the form of one-period, single-coupon bond and the rate of return on public and private debt is constant over time. The government raises in each period tax revenues τ_t. Government spending is indicated with G_t and debt with b_t and the interest rate on debt with r. Thus the government budget constraint in each period is given by:

$$G_t + rb_{t-1} = \tau_t + (b_t - b_{t-1}) \tag{1}$$

The lifetime government budget constraint is given by:

$$\sum_{t=1}^{\infty}\left[\frac{G_t}{(1+r)^t}\right] + b_0 = \sum_{t=1}^{\infty}\left[\frac{\tau_t}{(1+r)^t}\right] \tag{2}$$

Raising taxes generates some extra costs which can be interpreted as collection costs, or more in general deadweight losses or excess burden of taxes and the timing in which taxes are collected. Let Z_t be this cost which depends on the taxes of that period τ_t and negatively on the pool of taxable income/resources Y_t. In particular, let Z_t be defined as:

$$Z_t = F(\tau_t, Y_t) = \tau_t f(\frac{\tau_t}{Y_t}) \tag{3}$$

with $f'(\cdot) > 0$ and $f''(\cdot) > 0$. The present discounted value of these costs is:

$$Z = \sum_{t=1}^{\infty} \tau_t \frac{f(\frac{\tau_t}{Y_t})}{(1+r)^t} \tag{4}$$

The social planner chooses τ_t in order to minimize (4) subject to the budget constraint (2). From the first order conditions, one can find that the tax–income ratio $\frac{\tau}{Y}$ is equal in all periods. Given that, the level of taxes in each period is determined from the values of income $(Y_1, Y_2, \ldots)$, government expenditure $(G_1, G_2, \ldots)$, interest rate r and the initial debt stock b_0. The properties of the solution are considered under different assumptions about the time paths of income Y and government expenditure G. With constant income and government expenditure (ie, $Y_t = Y_{t+1} = \ldots = Y$ and $G_t = G_{t+1} = \ldots = G$) since the tax–income ratio is constant, this implies that τ is also constant and the government budget is always balanced. With transitory income and government expenditure (eg, transitory expenditure during wartime or during recessions) deficits are larger the longer and the larger is the transitory shock. The debt–income ratio would be expected to be constant on average, but would rise in periods of abnormally high government spending or abnormally low aggregate income.

2.2 Keynesian Stabilization

This is not the place to discuss the potential benefits of discretionary countercyclical fiscal policy actions, namely increases in discretionary spending during recessions and reductions during booms. According to Keynesian theories, higher government spending or lower taxes during a recession may help economic recovery. The reason is that under high unemployment and low capacity utilization, higher government spending, and lower tax rates may increase aggregate demand. Note that Keynesian models would prescribe that deficits should be countercyclical (ie, increase in recessions), but should not lead to a secular increase in debt over GDP. The reason being that spending increases during recessions should be compensated by discretionary spending cuts during booms.

We only note that the "long and variable lags" argument raised by Milton Friedman regarding monetary stabilization policy applies even more to fiscal policy where the lags are even longer and less predictable than for monetary policy. Friedman's original argument was applied to monetary policy. He argued that the lags in between the uncovering of the need of, say, a stimulus, the discussion of it, the implementation and the realization of its effects were "long and variable." Therefore, by the time the expansionary policy came into action it was too late and it was counterproductive. This argument applies even more strongly to fiscal policy since the latter requires also an explicit political process, debate, and approval in parliaments. The recent Great Recession and the lower bound issue for monetary policy has made popular the view that in this scenario, aggressive discretionary fiscal policies are necessary since automatic stabilizers are not enough. We do not enter in the zero lower bound debate in the present chapter.

2.3 Contingent Debt

Lucas and Stokey (1983) build on Ramsey (1927) and show that Barro's intuition does not generally apply. The main difference with Barro (1979) is in the set of instruments available to the government to smooth the distortionary cost of taxation. While Barro (1979) focuses in only one instrument, namely noncontingent one-period bonds, Lucas and Stokey (1983) consider a model with complete markets, no capital, exogenous Markov government expenditures, state-contingent taxes, and government debt. In this, environment optimal tax rates and government debt are not random walks, and the serial correlations of optimal taxes are tied closely to those for government expenditures. Moreover, they find that taxes should be smooth, not by being random walks, but in having a smaller variance than a balanced budget would imply. Thus, to some extent, the idea of tax smoothing holds but not in the extreme version as in Barro (1979).[i]

2.4 Accumulation of Government Assets

Aiyagari et al. (2002) reconsider the optimal taxation problem in an incomplete markets setting. They begin with the same economy as in Lucas and Stokey (1983), but allow only risk-free government debt. Under some restrictions on preferences and the quantities of risk-free claims that the government can issue and own, it is possible to obtain back Barro's random walk characterization of optimal taxation. However, by dropping the restriction on government asset holdings (or modifying preferences) generates different results.

More specifically, under the special case of utility linear in consumption and concave in leisure, the authors show that as long as the government can use lump-sum transfers and spending shocks are bounded, then distortionary labor taxes converge to zero in the long run. The optimal solution prescribes reducing debt in good times, so that eventually the government has accumulated enough assets to finance the highest possible

[i] Interestingly, Klein et al. (2008) address the same issue raised in Lucas and Stokey (1983) but find different and strikingly results. In particular, they find that the time series of debt in the economy without commitment is extremely similar to that with commitment. Welfare is very similar as well. This result is surprising: under commitment, there is always an incentive for a once-and-for-all tax cut/debt hike, thus suggesting ever-increasing debt under lack of commitment. However, they show that the incentives that naturally arise in the dynamic game between successive governments actually help limit the time-consistency problem: they lead to very limited debt accumulation, and long-run debt levels can even be lower than under commitment. This incentive mechanism is a result of forward looking and strategic use of debt.

expenditure shock with the interest earned on its stock of assets. This is the so-called "war chest of the government." Instead, if one set a binding upper bound on the government asset level (Ad Hoc Asset Limit) the Ramsey solution for taxes and government debt will resemble the results stated in Barro (1979).[j]

2.5 Evidence on Optimal Policy

The very basic principles of optimal debt policies, namely the debt–income ratio would be expected to be constant on average, but would rise in periods of abnormally high government spending or abnormally low aggregate income, are generally not satisfied by the data.

Government debts do go up during wars and major recessions, but beyond that, deviations from optimal policy are widespread. Figs. 1 and 2 clearly show that government debts do go up in wars and recessions in the United Kingdom and United States.

The major role played by wars is evident in these graphs. However, even the United States shows anomalous features, like the accumulation of debt in the eighties, which is a

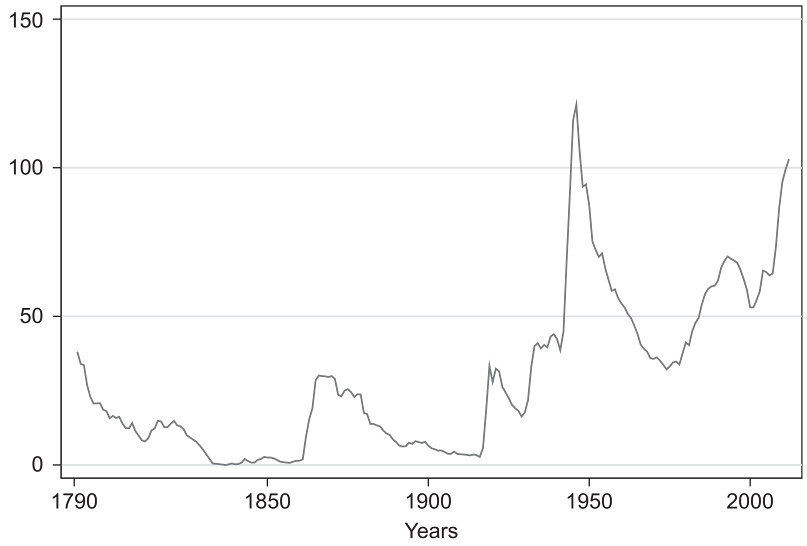

Fig. 1 Ratio of public debt to trend real GDP, the United States, 1790–2012. *Source: Abbas, S.A., Belhocine, N., Elganainy, A., Horton, M. 2010. A historical public debt database. Working Papers 245, International Monetary Fund.*

[j] By imposing a time invariant ad hoc limit on debt, the distribution of government debt will have a nontrivial distribution with randomness that does not disappear even in the limit. In particular, rather than converging surely to a unique distribution, it may continue to fluctuate randomly if randomness on government expenditures persists sufficiently.

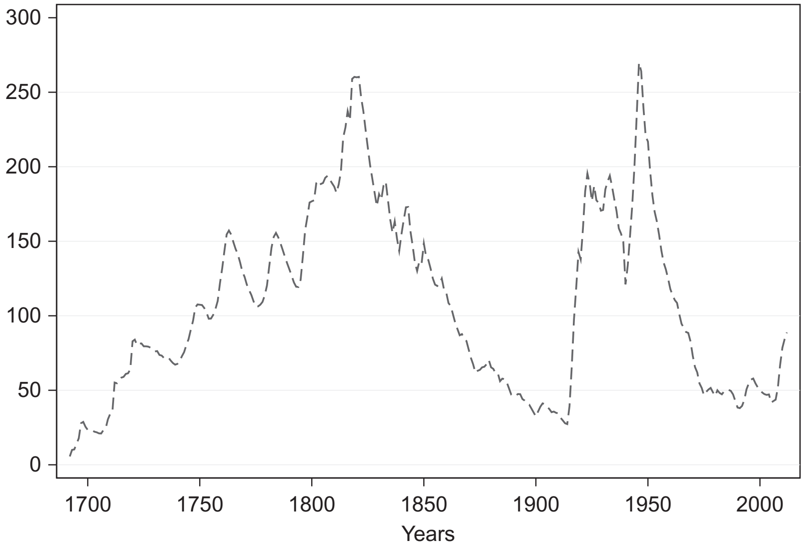

Fig. 2 Ratio of public debt to trend real GDP, United Kingdom, 1692–2012. *Source: Abbas, S.A., Belhocine, N., Elganainy, A., Horton, M. 2010. A historical public debt database. Working Papers 245, International Monetary Fund.*

period of peace. This episode (the so-called "Reagan deficits") in fact inspired a few papers reviewed later and, at the time, generated a major policy debate about the political forces which led to these deficits. Other OECD countries show remarkable deviation from optimality.

We show in Figs. 3 and 4 two graphs for a group of relatively high and low debt countries.

Several observations are in order. First, the decline in the debt ratios after the Second World War in both groups of countries stopped in the seventies. In both groups of countries it increased for several decades in peace time, obviously much more in the high debt group. For instance, in Italy and Greece the debt to GDP ratio skyrocketed in the eighties and nineties in a period of relatively rapid growth for these countries. Belgium and Ireland as well entered the nineties with debt level normally typical of postwar periods well above 100% of GDP. Second, several countries (ie, Ireland, Belgium, Denmark) had massive variations up and down of their debt ratios in peace time. Third, very few countries when they adopted the Euro satisfied the requirement of a less than 60% debt over GDP ratio. In addition, in the first decade of the Euro, up to the financial crisis, there was not much of an effort to converge to the prescribed target of 60%. Fourth, no country comes even close to a policy as prescribed by Aiyagari et al. (2002) which would imply the accumulation of assets to build a "war chest." Fifth, the Great Recession has led to very large accumulation of government debts and this is, at least in large part, consistent

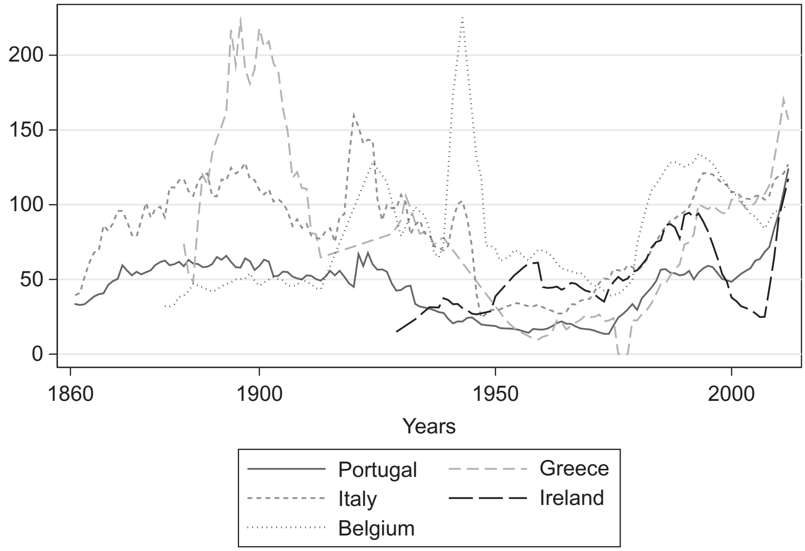

Fig. 3 High debt countries, ratio of public debt to trend real GDP. *Source: Abbas, S.A., Belhocine, N., Elganainy, A., Horton, M. 2010. A historical public debt database. Working Papers 245, International Monetary Fund.*

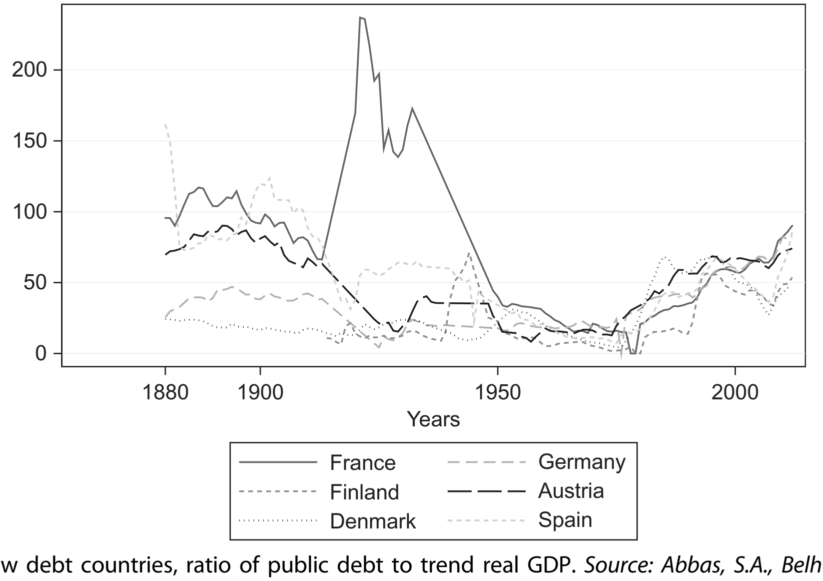

Fig. 4 Low debt countries, ratio of public debt to trend real GDP. *Source: Abbas, S.A., Belhocine, N., Elganainy, A., Horton, M. 2010. A historical public debt database. Working Papers 245, International Monetary Fund.*

with the tax smoothing hypothesis. However, countries which had already accumulated large debts for no obvious reasons before the crisis were constrained in how much they could accumulate more. Some additional accumulation created market panics; Greece had a partial default; Italy in 2011 was on the brink of a major crisis. Fifth, a few countries like Ireland and Spain entered the Great Recession with relatively low debt/GDP ratio but their fiscal position looked better than they really were due to extraordinarily and temporary tax revenues, namely the housing boom. When this became apparent these countries also faced debt panics. In fact, public debt problem in Europe almost degenerated to the point of a collapse of the Euro.

Table 1 shows that out of 20 OECD countries only 4 had a deficit for less than 50% of the time since 1960, and 11 countries had a deficit for more than 80% of the years. Italy and Portugal achieved a "perfect" 100%! These data do not distinguish between primary and total deficit, do not account for the cycle but nevertheless raise a significant flag about government profligacy. After the first oil shock of 1973–74, surpluses close to disappear. Easterly (1993) suggests that at that time (early seventies) many countries did not internalize a secular downturn of their growth process which would have required a reduction in the growth of government spending to keep the size of government constant. This lead to an accumulation of debt. Whether this misperception was an "honest mistake" or it was due to political distortions is a topic of discussion. In fact, it is pretty common for governments to justify large spending programs with very optimistic growth forecasts.

When considering the future liabilities of government, the picture regarding debt levels, appears substantially worse. The aging of the population (and the retirement of the baby boomers) will induce substantial strains over the social security budgets.

(Eds.), Fiscal Policy After the Financial Crisis, Volume Fiscal Rules: Theoretical Issues and Historical Experiences. University of Chicago Press and National Bureau of Economic Research, pages 495–529.

In different degrees, in various countries health expenses (also related to the aging of the population) are rising at phenomenal rates. The US Congressional budget office (CBO (2014)) predicts that with unchanged legislature, the debt over GDP ratio in the United States will never fall in the most optimistic scenarios in the next couple of decades. With "middle range" assumptions, the (net) debt over GDP ratio may be well above 100%. The forecasts of the social security administration have been called into question for being too optimistic and not transparent (Kashin et al., 2015). Similar considerations apply to Japan and European countries. There is a large difference between United States vs European countries, and also within European countries. Specifically, in the United States these entitlement programs are about 18.5% of the GDP, while in the European countries between 20% and 30% of GDP. Within the European countries, Norway is the leading country which spent about 30% of the GDP in Entitlement programs. Regarding the type of entitlement programs, pension expenditures account for more than half of the entitlements in Italy and Greece, while they are less than 20% in Ireland and Denmark.[k] In countries like Italy, we are reaching paradoxes in which youngsters do not find jobs because of high labor taxes and high labor cost for firms to collect tax revenues needed to pay pensions for the parents who then support the unemployed children.

The intergenerational accounting procedure for evaluating liabilities of the government offers an alternative measure to federal budget deficit to gauge intergenerational policy. It was developed by Auerbach et al. (1991) and it computes the net amount in present value that current and future generations are projected to pay to the government now and in the future. If one thinks that the government has an intertemporal budget constraint, then this constraint would require that the sum of generational accounts of all current and future generations plus existing government net wealth be sufficient to finance the present value of current and future government consumption. The generational accounts can be viewed simply as a tabulation of the net effect of future taxes paid and transfers received by various generations, assuming that current policy remains unchanged into the indefinite future. Auerbach et al. (1991) compute the "lifetime net tax rate," which measures the burden of taxes minus transfer payment on a generation over its lifetime. The Generational accounting criteria presumes that fiscal policies should be generational balanced. This would imply that the net tax rate for current and future generations should be the same. If the net tax rate for future generations exceeds the net tax rate for newborns, then according to this criteria, fiscal policy is not in generational balance. Haveman (1994) provides an excellent discussions of the pros and cons of generational accounting methods.

[k] Specifically, in 2011 pensions account for 51.9% of total Entitlement programs in Italy, 51.1% in Greece, 19.6% in Denmark, and 16.8% in Ireland. *Source*: OECD (2015).

3. DEFICITS AND ELECTIONS

3.1 Fiscal Illusion

The idea of "fiscal illusion" is due to the public choice school (see in particular Buchanan and Wagner, 1977). According to this argument voters do not understand the notion of intertemporal budget constraint for the government, therefore when (especially close to elections) voters see pending hikes or tax cuts (the public choice schools was especially concerned with the former) they reward the incumbent, and remain unaware of the consequences of such policies on public debt and the future costs of taxation needed to service it. The problem, according to the Public Choice school, is aggravated by the "Keynesian" policy stand. Politicians are eager to follow the Keynesian rule of increasing discretionary spending during recessions, but then they do not counterbalance it with cuts during booms. Thus, the result of keynesianism and fiscal illusion leads to persistent deficits and explosive debt levels.

In general, the view that the best way to please the voters is to spend more and tax less is so pervasive that it is assumed to be an obvious fact. As we show later, the evidence is much more nuanced than it would appear. In addition, given the extensive discussion of the deficits, the pros and cons of austerity policies in the United States and Europe, it is hard to believe that today's voters are unaware of the potential cost of deficits because of fiscal illusion, even though there may be disagreement on what policies to follow to respond to deficits. The fiscal illusion argument is overly simplistic although it does raise important warning bells on the conduct of fiscal policies in democracies.

3.2 Political Budget Cycles: Theory

The traditional fiscal illusion argument rely on some form of irrationality or ignorance on the part of the voters. However, political budget cycles can be derived also in models where voters are fully rational but imperfectly informed as in Rogoff (1990) and Rogoff and Sibert (1988). What leads to these cycles is a combination of delays in the acquisition of information on the part of the voters regarding the realization of certain policy variables and different degrees of "competence" of policymakers.[1]

In Rogoff and Sibert (1988) more competent governments can tax less to provide public goods, because they introduce less wastage in the fiscal process. However, the full combination of income taxes, spending, seigniorage, and government wastage (ie, negative competence) is learned with one period delay by the voters. A higher level of competence implies that the government can provide public goods with lower taxes (or seigniorage). Suppose that before an election voters see a tax cut. They cannot distinguish whether the cut is due to a high realization of competence (which is unobservable by them immediately) or transitory deficit which they do not fully observe.

[1] For a review of political business cycles in general see Alesina et al. (1993) and Drazen (2000).

After the election, a less competent government would have to increase seigniorage generating also an inflation cycle. With a finite time horizon the only equilibrium that exists is a separating equilibrium, ie, the one in which voters are able to infer exactly the incumbent's level of competency from the tax she selects in order to signal her competence. The competent policymaker cut taxes before election to a level that cannot be matched by the less competent one. A somewhat unpleasant feature of these models is that the more competent policymakers engages in budget cycles by cutting taxes before elections to signal their competence and distinguish themselves from the less competent ones who cannot afford such a large tax cut. Rogoff (1990) adds a distinction between two types of public goods, those that are clearly visible before an election, say fixing the holes in the street, and those less immediately visible, like increasing the quality of the training of teachers. In this model politicians have an interest in overspending in more visible but not necessarily the most productive public goods close to election time.

While, in principle, the implication of rationally based modern theories of political business cycles may be similar to the traditional one, they differ in two ways. First, the rationality of voters output a limit on the extent of these policies. Second, and this will be revealed by the empirical evidence, the more the voters are informed and understand the incentive of policymakers, the less they reward them for their behavior; thus for instance more freedom of the press in established democracies would be a constraint on this behavior.[m]

Drazen and Eslava (2010b) present models of political budget cycles in which the incumbent favors with certain spending projects specific and critical to constituencies and/or localities. By varying the composition of government spending the incumbent can target swing voters before elections. Incidentally, this imply that a political budget cycles may imply distribution of spending from one district to another, holding constant the total amount of government spending.[n]

3.3 Political Budget Cycles: Evidence

Are political budget cycles common? Persson and Tabellini (2000) argue that the answer depends upon the nature of the political institutions of the country. In particular, they argue that political budget cycles are less likely to occur in majoritarian systems rather than proportional representation systems. Brender and Drazen (2005), however, challenge these results. They find that the existence of political budget cycles do not depend on voting rules. Political budget cycles exist only in "new democracies," where fiscal

[m] For instance, Besley and Prat (2006) develop a model in which more press freedom reduces the space for policymakers to extract rents. For a review of the political economy of mass media refer to Prat and Stromberg (2013).

[n] Hassler et al. (2005) show an interesting result, namely that the introduction of political distortions would reduce, instead of exacerbate, oscillations in tax rates. This is contrast with the predictions of the literature on political business cycles.

manipulation may work because voters are inexperienced with electoral politics or may simply lack information, which may be one of the main factors generating the political budget cycle, as implied by the models reviewed earlier.

The role of information is tested by Brender (2003) for local elections in Israel. Peltzman (1992) and Drazen and Eslava (2010a) perform an analogous analysis in the United States and Colombia, respectively.[o] Gonzalez (2002) and Shi and Svensson (2006) test the importance of transparency, which ultimately means the probability that voters at no costs learn the incumbent's characteristics. They find that the higher the degree of transparency, the smaller the political budget cycle. Moreover, while the proportion of uninformed voters may be initially large, it is likely to decrease over time, thus decreasing the magnitude of the budget cycle. Akhmedov and Zhuravskaya (2003) find that measures of the freedom of the regional media and the transparency of the regional governments are important predictors of the magnitude of the cycle. Alt and Lassen (2006) find that, in the sample of OECD countries, higher fiscal transparency eliminates the electoral cycle.[p]

The other important aspect is whether or not governments which generated political budget cycles are more easily reelected. Brender and Drazen (2008) consider the effect of deficits on the probability of reelection and show that voters are (weakly) likely to punish rather than reward budget deficits over the leader's term in office. Their results are robust by considering different subsamples: (i) developed countries and less developed countries; (ii) new and old democracies; (iii) countries with presidential or parliamentary government systems; (iv) countries with proportional or majoritarian electoral systems; (v) countries with different levels of democracy.

A related literature directly tests the political consequences of large fiscal adjustments, ie, whether large reductions of budget deficit have important negative political consequences. Alesina et al. (1998) consider a sample of OECD countries and they find that fiscal austerity has a weakly positive, rather than negative, electoral effect. However, they focus on cabinet changes and opinion pools, rather than on election results. Alesina et al. (2012) fill this gap, by looking directly at the election results. They find no evidence of a negative effect on the election results due to a fiscal adjustment. Buti et al. (2010) find that the probability of reelection for the incumbent politicians are not affected by their efforts in implementing pro-market reforms. This literature, however, suffers from a potential sort of reverse causality problem, namely governments which are especially popular for whatever reasons, manage to get reelected despite their deficit reduction policies, not

[o] Schuknecht (2000) presents evidence of cycles in 35 developing countries and Buti and Van Den Noord (2004) some evidence on European Union countries.

[p] Alesina and Paradisi (2014) show evidence of political budget cycles in Italian cities. Foremny et al. (2015) provide evidence on political budget cycles using data on two German regions. Arvate et al. (2009) find evidence on localities in Brazil.

because of them. While the authors are aware of this issues and try to asses it, measuring the "popularity" of a government is not always straightforward.

The bottom line is that political budget cycles may explain relative small departures from optimal policy around election times, especially in new democracies. However, they cannot be the main explanation for large and long lasting accumulation of public debt, as we documented earlier. Also, the cross country empirical evidence seems to have been exhausted. Perhaps natural experiments at the local level might be interesting.

4. SOCIAL CONFLICT: WAR OF ATTRITION AND RIOTS

4.1 War of Attrition: Theory

War of attrition models do not explain "why" a deficit occurs, but they explain why deficit reduction policies are postponed. Alesina and Drazen (1991) focus on the case of a country that for whatever reason, due a permanent shock on revenues (or on expenditures), is on a "nonsustainable" path of government debt growth. The debt is held by foreigners and the interest rate is constant and exogenously given and there is no default. The longer the country waits to raise tax rates to stop the growth of debt, the more the interest burden accumulates and the more expensive the stabilization will be. The latter implies a reduction to zero of total deficits.

There are two equally sized groups of equal (exogenous) income which cannot agree on how to share the costs of the stabilization. The social planner would choose an equal division of costs for each group since the groups have the same income and size. In this case, stabilization would occur immediately since delays only create inefficient costs, namely higher interests on the accumulated foreign debt. The critical feature of the model is that without a social planner political polarization leads to an uneven distribution of the costs of the stabilization. In particular, one group has to pay more than 1/2 of the taxes needed for the stabilization and in every period after that. When both groups perceive the possibility of shifting this burden elsewhere, each group attempts to wait the other out. In order for this to happen there has to be some uncertainty about the costs of each group to wait the other out, namely how long a group can bear the costs of delaying the stabilization. These costs are modeled as the economic costs of living in the distorted prestabilization economy (for instance with inflation) or the political cost of "blocking" attempts of the opponent to impose an undesired stabilization plan. This war of attrition ends, and a stabilization is enacted, when a group concedes and allows its political opponents to be the winner. The loser then pays more than half of the costs of the stabilization, allowing the winner to pay less. The condition which determines the concession time is the one which equals the marginal cost living an extra moment in the unstable economy to the probability that in the next moment the opponent group will concede, multiplied by the differences the costs of being the winner rather than the loser. This is why uncertainty about the strength of the groups is critical. If one group knew from the beginning that its cost of living in an unstable economy were larger than those of the other group, it would know that it may end up losing the war of attrition and therefore it would concede immediately; this would be cheaper than postponing the inevitable loss. The passage of time reveals the type of the groups, namely which one is stronger. The more unequal are the divisions of the cost of the stabilization, which can be interpreted as a degree of polarization of a society, the longer the war of attrition and the higher the level of debt accumulated since the relative benefit of winning increase.

The war of attrition implies that individually (group level) rational strategies lead to a suboptimal accumulation of debt. The group which will end up being the loser is the one with the highest cost of prolonging the war of attrition. This is why uncertainty about these cost are critical. If it was common knowledge which was the weaker groups, the latter would capitulate immediately, since waiting adds to the costs and this group would lose anyway. Therefore anything that eliminates this uncertainty ends the war of attrition.

4.2 War of Attrition: Empirical Evidence

The model has several empirical implications. The first one is that the passage of time may lead a country to stabilize even if nothing observable happens, simply because one group has reached the condition of "conceding," namely has learned its relative strength to that of the opponent. Second, an electoral or legislative victory of one of the groups may signal its superior political strength and may lead the opponent to concede. Third, longer delays and higher debt should occur in polarized societies which cannot reach a "fair" and acceptable distribution of costs. In addition, delays are longer when many groups have a "veto power" to block policy decisions which they do not like. Fourth, a worsening of the economic crisis may lead to a resolution of the war of attrition. When the costs of delay increase for one of the groups the latter may concede sooner. Drazen and Grilli (1993) show that in their case a "crisis" can be beneficial, since it worsens the utility level of one of the groups in the short run, but it may be welfare improving for all in the long run since the war of attrition ends sooner. Fourth, for the opposite reason foreign aid can be counterproductive (Casella and Eichengreen, 1996). If foreign aid makes life easier before the stabilization, delays are longer and in the long run welfare is lower. The result, however, depends on how aid is disbursed; for instance foreign aid that implicitly "picks" a winner would end the war of attrition sooner. Finally, an external commitment, say an IMF conditionality agreement, may accelerate the resolution of the war of attrition making it more costly to "fight it." Several authors have suggested empirical observations consistent with the implications of the war of attrition model. Alesina and Drazen (1991) discuss a few historical examples of cases in which the same government first fails to stabilize because it encounters political opposition then it succeeds because the opposition is defeated. The idea that multiple veto players delay the elimination of deficits is consistent with the evidence by Grilli et al. (1991) and Kontopoulos and Perotti (1999).

The former argue that in the eighties, debt accumulated more in parliamentary democracies with multiparty systems. The latter argue that the number of spending ministers is associated with looser fiscal controls, an issue upon which we return later. Volkerink and De Haan (2001) and Elgie and McMenamin (2008) provide evidence on a sample of 22 advanced economies showing that more fragmented governments with smaller majorities in parliaments have larger deficits. Persson and Tabellini (2000) review and add to this line of research with additional evidence. These authors and Milesi-Ferretti et al. (2002) show also that coalition governments spend more on welfare, a point analyzed also by Alesina and Glaeser (2005) in a comparison of United States vs Europe. As we discussed earlier, Easterly (1993) noted that countries accumulated debt because they did not adjust their spending programs to the secular reduction of growth which started in the late seventies. These delays in adjusting to a permanent shock is consistent with the general message of the war of attrition. Various constituencies objected to reducing the growth of their favorite spending programs.

A second line of inquiry has focused on the idea that "crisis generates reforms," as in Drazen and Easterly (2001). Needless to say, the evidence suffers from problems of reverse causality: why would you need a reform if you did not have a problem to begin with?[q] Alesina et al. (2010) combine these institutional hypothesis with the crisis hypothesis, making a step closer toward testing the war of attrition model. In particular, they test whether certain institutions are more likely and rapid to resolve crisis, a result consistent with the model by Spolaore (2004). Alesina et al. (2010) define a country as being in a "crisis" if at time *t* the country is in the "worst" 25% of the countries in the (large) sample in terms of budget deficits.[r] They find support for the view that "stronger governments" stabilize more in time of crisis, ie, when a crisis comes, strong governments adjust more and exit more quickly from the state of "crisis." Strong governments are presidential systems and amongst parliamentary systems those in which the majority has a greater share advantage over the minority. They also find that stabilization (ie, exit from crisis) are more likely to occur at the beginning of a term of office of a new government. These results are consistent with the war of attrition model in the sense that in an unstable situation (ie, a crisis), a stabilization occurs sooner with fewer veto players or with a clear political winner. Results on the effect of IMF programs are inconclusive but, as discussed earlier, causality problems are especially serious in this case.

4.3 War of Attrition: Summing up

The war of attrition model has proven to be successful as an explanation of observed characteristics of run away debts and the timing of stabilization. One issue with this model is that it has been proven difficult to extend it. In particular, the division of costs of the

[q] Similar issues arise on the huge literature on foreign aid, which we can not even begin to survey here.

[r] In their paper these authors also consider inflation crisis, not only deficit crisis.

stabilization is taken as exogenous and not bargained amongst groups. Moving in that direction would lead to bargaining models where institutional details on how the game occurs are critical. Perhaps one may think about connecting this approach with the one discussed later on voting in legislatures. Also the extensions to n rather than 2 groups implies results which are not clear cut and the formation of coalitions amongst n groups are intractable (thus far) problems. Finally, in the model, a stabilization is a zero-one event. Partial or failed attempts are not explicitly modeled even though in reality are quite common.

4.4 Riots

Passarelli and Tabellini (2013) provide a model of political competition which has some connection to the war of attrition although with substantial differences and a "behavioral" bend. In their model several social groups have views about what is a "fair" allocation of resources. The sum of those views about what is fair for each group may be larger than the available resources. In addition groups are willing to engage in costly political actions (riots) when they feel that they have not obtain their fair allocation. When a group perceives that fairness (according to this group's view) has been violated, individuals are willing to engage in costly political actions, like riots, because of this emotional reaction to a perceived unfair behavior. The groups which are more homogeneous are also more likely to be more successful in organizing riots. This feeling of "anger" when perceived fairness has been violated solves the free rider problem of political actions. In a dynamic setting the threats of riots pose constraints to the government. In particular, even a benevolent government may be forced to accumulate excessive debt (above the optimal level) to reduce the threats of riots. Empirically, Woo (2003) shows that public debt accumulation is associated with the occurrence of riots. Ponticelli and Voth (2011) and Passarelli and Tabellini (2013) show how budget cuts are sometimes followed by riots.

It is interesting to compare this evidence on riots and the one reviewed earlier by Brender and Drazen (2008) and Alesina et al. (2012) which suggest that, at least in democracies fiscal adjustments are not associated with consistent electoral losses for the incumbent. Perhaps homogeneous and organized groups organize riots while the less organized median voter is much more prone to accept fiscal retrenchments when necessary. In other words, a government may face strikes and riots organized by specific homogeneous constituencies and those actions may block fiscal adjustment policies and increase public debt. However, the unorganized voters (which may be the majority) may not approve those policies.

It would be interesting to expand Passarelli and Tabellini (2013) framework to incorporate these features in which part of the electorate is organized and has this behavioral bend about fairness, and another part of the electoral is unorganized and does not have self serving feelings of fairness.

5. DEBT AS A STRATEGIC VARIABLE

Government debt is a state variable which "links" several successive governments. Different governments may have different preferences over fiscal policy, say the level and/or composition of public spending. If the current government is not sure of its reappointment, it may want to choose a level of deficit while in office (thus a level of debt) in order to influence the fiscal choices of future governments. In these models, deficits do not affect the probability of reelection since the voters are fully rational, fully informed, and forward looking, but deficits serve the purpose of insuring that future governments follow policies closer to the preference of the current government by constraining future governments' actions. The asymmetry of information that would lead to political business cycles, as we discussed earlier, are assumed away here, and the strategic manipulation of the debt by the current government or majority in office is fully in the interest of those who supported the current government. Another way to put this is the following. Given the inability of current government to control future public spending, it may prefer to take a $1 of tax revenue away from the future government by borrowing because it may not be in power and be able to decide how that $1 is spent in future, but it can decide how it can be spent today. Clearly, this logic applies only if there is political turnover and heterogeneity of preferences over fiscal policy amongst the different potential governments.

In Alesina and Tabellini (1990) two parties, with exogenously given preferences, stochastically alternate in office. They care about the level of income of the representative individual and care about two different public goods, say military spending vs domestic spending (more generally they place different weights on these two public goods). In the model there is a representative voter/citizen in terms of his/her choices of labor and leisure but with a distribution of preferences about the type of public goods that they prefer, so they would vote for different parties depending on the parties' choice of public goods. Private and public goods enter separately in the utility function. If a party is unsure of being reappointed, it will issue debt. By doing so it "forces" the following government (possibly of a different party) to spend less on the public good the current government does not care as much. In other words, the current government chooses to distort the path of income taxation in order to spend more on the public goods that it prefers leaving future governments with the task of reducing the debt since default is ruled out by assumption. The future government will do so, at least in part, by cutting spending on the public good the current government does not care much about.[s] The lower is the probability of reappointment of the current government the higher the level of

[s] When both parties care (with different weights) about the two public goods the result about excessive deficit require a weak condition on the third derivative of the utility function on the public goods.

debt chosen. Only a government sure of reappointment would issue no debt. The social planner would issue no debt since there is no reason to do so and would choose a stable combination of the two public goods in order to satisfy, say, utilitarian social preferences. Tabellini and Alesina (1990) provide analogous results in a model in which fiscal decisions are taken by the median voter. The current median voter is uncertain about the preferences of future median voters, because of shocks to the distribution of preferences. Today's median voter choose to issue debt for the political incentives of creating "facts" for future majorities. Alesina and Tabellini (1989) extend this type of model to a small open economy and show a connection between excessive public debts and private capital flights.

Persson and Svensson (1989) provide a related model which, however, does not imply a deficit bias but nonobvious implications about which government would lead a deficit and which would run a surplus. In their model, there are two parties, one of the left who likes a large amount of public goods even at the cost of high taxes, and a party of the right which, on the contrary dislikes public spending and taxation. The public debts links the two alternating parties in office. When the left is in office it chooses to leave a surplus by taxing more in order to generate an incentive for the right when in office to spend more on public goods. The right, when in office, will cut taxes creating a deficit in order to prevent easy spending when the left comes in to office.[t]

In a similar vein Aghion and Bolton (1990) consider the commitment effect of debt in two ways. First, by limiting future expenditure on public goods. Second, in forcing to raise higher tax revenues to repay the debt. Lizzeri (1999) uses similar insights, linking excessive debt accumulation and redistributive policies. In his model, two candidates, motivated purely by the desire of winning elections, can redistribute to some citizens and cannot make promises on future redistribution. In the first period, by running deficits they can target with "excessive" redistribution of transfer skewed in favor of a majority and against a minority.

6. THE COMMON POOL PROBLEM

In these types of models agents do not fully internalize the tax burden of spending decisions leading to "excessive" spending. The most widely studied "common pool problem" is the one of legislators (like the United States Congress) which would like to approve spending programs for their districts without fully internalizing the cost of taxation; in fact, the latter are spread on all (or many other) districts. As we discuss later, similar political distortions arise in different institutional settings.

[t] Pettersson-Lidbom (2001) presents supporting evidence for this model using Swedish data on localities.

6.1 Bargaining in Legislatures

Weingast et al. (1981) provide a model of excessive spending on pork barrel projects which was later extended to various voting rules and applied to study debt accumulation. These authors show how representatives with a geographically based constituency overestimate the benefits of public projects in their districts relative to their financing costs, which are distributed nationwide. The voters of district i receive benefits equal to B_i for a project, but have to pay $1/N$ of the total costs if taxes are equally distributed among districts. Thus, a geographically based representative does not internalize the effect of his proposals on the tax burden of the nation. The aggregate effect of rational representatives facing these incentives is an oversupply of geographically based public projects. Specifically, the size of the budget is larger with N legislators elected in N districts than with a single legislator elected nationwide, and the budget size is increasing in N, the number of districts.

Baron and Ferejohn (1989) substantially improve upon this model by considering voting on the distribution of taxes rather than assuming that every district pays $1/N$ of the cost of every project. They study decisions with majority rule with various alternative procedural rules. In their model there are n members (they can be interpreted as people, districts, or States) in the legislature. The task of the legislature is to choose the distribution of one unit of benefits among the n districts, with no side payments outside the legislature. A "recognition rule" defines who, at each session is going to be the agenda setter with the task of making a proposal. In each session, member i is chosen with probability p_i. Member i then puts forward a bargaining proposal of the form $x^i = (x_1^i, x_2^i, \ldots, x_n^i)$ such that $\sum_j^n x_j^i \leq 1$. If no proposal is approved, each member of the legislature gets zero benefits, the status quo. Members of the legislature have a common discount factor δ.

These authors distinguish between a "close amendment rule" and an "open amendment rule." In the first case, the proposal on the floor is voted upon against the status quo, with no amendments. If the proposal is approved, then the benefits are distributed and the legislature adjourns. If the proposition is rejected the benefits are not distributed and the legislature moves to the next turn. In this case the process starts over, but the benefits are discounted by the factor δ. With an "open amendment rule," after the member is randomly chosen to make the proposal, another member can be recognized at random and may either offer an amendment (ie, an alternative allocation) or move to vote. If the proposal is seconded, the legislature votes as previously. If the proposal is amended, a runoff election is held to determine which proposal will be on the floor. The process is repeated until a recognized member moves the previous question and a yes vote is reached.

In the case of closed amendment Rule, the subgame perfect equilibrium has the following characteristics: (i) the equilibrium distributions of benefits is majoritarian, ie, only a minimum majority gets something; (ii) the agenda setter can get a strictly greater allocation; and (iii) the legislature completes its task in the first session. In the case of open amendment rule, the agenda-setting power of the first proposer is diminished. Indeed, each member must consider the fact that her proposal may be pitted against an amendment. Thus, she has to take this into account when making the proposal. In particular, the proposing member must make a proposal acceptable for at least m out of $n - 1$ other members in the legislature. By choosing m, the original proposer determines the likelihood of acceptance. The higher is m, the higher the probability that the section rule will choose one of the m legislators and the proposal is accepted, but also the lower the benefits that the agenda setter can keep for himself.

6.2 Bargaining in Legislatures and Government Debt

In Velasco (1999, 2000) several interest groups benefit from a particular kind of government spending. Each group can influence the central fiscal authorities to set net transfers on the group's target item at some desired level. The equilibrium implies a debt level at the maximum feasible level. In fact each group demands transfers large enough to cause fiscal deficits and a sustained increase in government debt. Eventually, the government hits its credit ceiling and is locked forever in a position of paying sufficient taxes to service the associated maximal debt level. The intuition for this result is simple. Property rights are not defined over each group's share of overall revenue or assets. A portion of any government asset, which is not spent by one group, will be spent by the other group. Hence, there are incentives to raise net transfers above the collectively efficient rate. Groups do not fully internalize the costs of public spending, namely each of them uses the whole stock of resources instead of a fraction, as the basis for consumption of spending decisions. Krogstrup and Wyplosz (2010) provide a related common pool model of deficit bias in an open economy.

Battaglini and Coate (2008) adopt the Baron and Ferejohn (1989) framework described earlier and study how such bargaining leads to deviations from the optimal path of debt. They focus on the case in which a social planner would implement the solution by Aiyagari et al. (2002). Battaglini and Coate (2008) link the Baron and Ferejohn (1989) model of bargaining in a legislature with the insight of the literature on strategic debt which we have reviewed earlier, in particular the model by Tabellini and Alesina (1990). Current majorities in the legislature will bargain over spending with uncertainty about the nature of future majorities and the debt becomes, as earlier, a strategic tool to control future fiscal decisions.[u] While in Tabellini and Alesina (1990) the will of the majority is simply represented by the optimal policy of the median voter, Battaglini

[u] In a related work Barseghyan et al. (2013) consider, as a driver of fiscal policy persistent tax revenue shocks, which come from business cycle impacts on the private sector. Battaglini and Coate (2015) consider an economic model with unemployment and the distinction between private and public sector jobs. They explore the relationship between debt, unemployment, and the relative size of the public and private sector.

and Coate (2008) provide a much richer institutional setting to characterize decision making.

Battaglini and Coate (2008) model a continuum of infinitely lived citizens located in n identical districts. A single (nonstorable) consumption good z and a public good g are produced using labor. Citizens maximize their lifetime utility which depend on consumption, labor supply, and a parameter A_t, which is the realization at time t of a random variable, which represents the value of the public good for citizens at time t. If, for instance, the public good is defense spending, we value it a lot higher during a war. The legislature provides the public good g and it can finance targeted-district specific transfers s_i, ie, "pork barrel" spending. To finance its activities, the legislature can either set a proportional tax on labor τ or issue one-period risk free bonds x. The legislature faces three different constraints. A feasibility constraint, which imposes that the government revenues have to be high enough to cover expenditures. The "District Transfer Constraint," which imposes that the district-specific transfers must be nonnegative. This constraint excludes lump negative transfers (lump sum taxes) to finance government spending. Finally, the government has to satisfy the Borrowing Constraint, which implies setting an upper and lower bound on the amount of bonds that can be issued or bought back each period. The lower bound is set without loss of generality. Indeed, the government would never need more than the assets the lower bound implies so the constraint never binds. An upper bound is necessary to avoid the government to issue an amount of debt which is unable to pay back the next period. A lower bound is defined by the level according to which it is possible to finance the optimal level of public good just with the interests on the assets the government has accumulated.[v] The legislature, consisting of a representative from each of the n districts, make decisions with closed rules. The legislature meets at the beginning of each period knowing both b_t and A_t. One representative is randomly selected to make the government policy proposal, which consists of the tax rate on labor r_t, the level of public good g_t, the level of bonds x_t, and the district-specific transfers $(s_1,\ldots,s_n)$. The proposal requires consensus of a minimum winning coalition of $q < n$ legislators to be accepted and implemented. If the proposal is rejected another legislator is randomly chosen to make a new proposal. If, after τ rounds, all the proposals are rejected, then the government implements the "Default Policy," which has to satisfy the feasibility constraint and has to treat all the districts equally, ie, $s_1 = \ldots = s_n$.

In this model a social planner would choose the optimal debt path as in Aiyagari et al. (2002). More specifically, the social planner takes as given (b,A) and chooses a policy $\{r, g, x, s_1, \ldots, s_n\}$ which maximizes the utility of citizens in all district. Given (b,A) there

[v] The optimal level of public good is the one which satisfies the Samuelson Rule, ie, the level at which the sum of marginal benefits is equal to the sum of marginal costs.

are two possible cases, namely with or without transfers to the districts. In the first case, with positive pork barrel transfers, the optimal tax rate on labor is set to zero and the optimal level of public good is set to $g_S(A)$, ie, the level that satisfies the Samuelson's Rule. The reason is straightforward. Suppose that the tax rate is positive. Then, the Social planner finds strictly dominant to reduce the pork barrel transfers and to reduce the (distortionary) tax. If the Social Planner does not make any pork barrel transfer, it must be the case that the tax rate is positive, the level of public good provided is less than $g_S(A)$ and the level of public debt exceeds the one with transfers. Thus, pork barrel transfers depend upon the realization of the value for the public good, A. In particular, for high enough values of A, the optimal policy has no transfers: g is high and no room is left for pork barrel. Instead, if the government has resources left to provide pork barrel transfers, then the level of debt must be the lowest possible, ie, the lower bound $\underline{x}$. (Remember that the lower bound implies accumulation of assets). Intuitively, if the planner is willing to give revenues back to citizens through district transfers $(s_1,\ldots,s_n)$, then it must expect not to be imposing taxes in the next period; otherwise, he would be better off reducing transfers and acquiring more bonds. This suggests that the steady state debt level must be such that future taxes are equal to zero, implying it to be equal to $\underline{x}$.

Consider now bargaining in the legislature. The agenda setter has to find $q-1$ supporters for his proposal to pass. The equilibrium policies are driven by the realization of the value of the public good, A, and the value of the public debt left from the previous period. For high enough values of A and/or b, the marginal value of the public good is so high that the proposer does not find it optimal to make positive pork barrel transfers. Thus, the equilibrium policy consists of the outcome as the proposer maximize the utility of all representatives. In other words, we are back to the Social Planner solution with no transfer. For low levels of b and/or A, there may be resources left that can be transferred to the q districts. This implies there exists a cutoff value A^* which divides the space into two different regimes. For $A > A^*$ the economy is in the "responsible policy making" regime (RPM). In this case, the optimal level of the tax rate, the public good and the debt to issue are defined by the Social Planner's optimal conditions with no pork barrel. For $A < A^*$ the economy is in the "business-as-usual" regime (BAU). In this case the proposer defines $(r^*, g^*(A), x^*)$ by maximizing the utility for the q districts included in the "Minimum Winning Coalition." This equilibrium includes also transfers $(s_1,\ldots,s_q)$ high enough to induce the member of the coalition to accept the proposal.

The same optimal conditions can be defined in terms of the public debt. In particular, the equilibrium debt distribution converges to a unique invariant distribution whose support is a subset $[x^*, -x]$. When the debt level is x^*, then the optimal conditions for the tax rate and the public good are those defined by the BAU, with the proposer who makes pork barrel transfers to the q districts. If instead the debt level exceeds x^*, then the economy is in the RPM regime where the tax rate is higher than the one defined in BAU, the provision of public good is lower, and no districts receive transfers.

In the long run, the economy oscillates between BAU and RPM regimes, depending on the realization of the value of the public good A. For instance, pork barrel would disappear during a war when A is large.[w]

In summary, the political distortions which make the social planner solution differs from the political equilibrium arises for two specific reasons. The first one, which can be related to the "Common Pool problem" discussed in the previous section. The minimum winning coalition does not fully internalize the costs of raising taxes or reducing the public good but it fully enjoys the benefit of receiving the pork barrel transfers. The other distortion comes from the uncertainty suffered by the legislators. They do not know ex-ante whether they are going to be included in the minimum winning coalition next period. Thus, they do not fully internalize costs and benefits across periods. In particular, they compare $\$\frac{1}{q}$ benefit today by belonging to the coalition, vs $\$\frac{1}{n}$ expected costs tomorrow. This intuition is similar to the strategic model of debt of Tabellini and Alesina (1990) reviewed earlier. In conclusion, this section makes two important contributions. First, it merges the results found in Tabellini and Alesina (1990) by using Baron and Ferejohn (1989) type of model. Second, it shows that taxation smoothing "a la Barro" is still an important factor in a political economy model, but distortion smoothing through debt is inefficient, and therefore not only this results in excessive accumulation of debt, but also in excessive volatility of the policies in the steady state. From an empirical standpoint, Baqir (2002) shows results consistent with the common pool problem using data from US cities. He shows that larger city council, where the common pool problems may be larger, are associated with more public spending, holding other determinants of the latter constant.

There is also a potential connection with the war of attrition model discussed earlier. In these bargaining models the passage of time is not considered. With a closed rule agreement is immediate but even with an open rule to the extent that proposals and amendments can be made instantaneously time does not matter. In reality, bargaining in legislatures takes time, and the passage of time is critical in the war of attrition models to allow the game to be resolved. At the same time the passage of time leads to the accumulation of debt. Allowing for a realistic consideration of time in these bargaining model could be an interesting avenue for theoretical and empirical research.

6.3 The Common Pool Problems in Other Institutional Settings

The general idea of the common pool problem with strategic debt is relevant for other institutional settings beyond the US Congress.

[w] Battaglini (2014) illustrates an extension of that model, which includes two-party competition in a legislature modeled as earlier.

In particular, in many democracies the budget is crafted by a government (possibly formed by more than one party), it is presented in the legislature and approved, if the parties of the government have a majority, with or without amendments. In this case, we may have a common pool problem with the spending ministers in the government even before the budget reaches the legislature. Each spending minister would generally like to obtain more spending for its own ministry, often pushed by the bureaucracy of the latter. A winning coalition of spending ministers may lead to the approval of a budget which, like in the BAU regime of Battaglini and Coate lead to a sort of "pork barrel" transfers to a minimum winning coalition of spending ministers. These pork barrel spending may be geographically or functionally defined and the bargaining may get especially complicated when different spending ministers belong to different competing parties. In this institutional setting normally the Treasury Minister has the task of preventing spending ministers to overspend but he or she may be overruled by a minimum winning coalition of spending ministers. In fact, as we shall discuss later, different institutional settings attribute different levels of prerogatives to spending ministers vs the Treasury, making the problem arising in the BAU regime more or less serious. In addition, even in parliamentary democracies, legislatures have the ability of proposing and voting upon amendments on the budget presented by the government.[x]

Often budget deficits at the national levels originate at subnational levels of governments. Some famous examples are both from Latin America (ie, Argentina) and European countries (Italy and Spain, for instance). This is related to suboptimal allocation of spending and taxing prerogatives amongst various level of governments. Suppose that spending is decided by local governments and revenues are collected by the national government and allocated to localities on the basis of their spending decisions. Obviously, in this case localities do not internalize the full cost of taxation of their spending decisions since taxes are levied nationally. Most countries have arrangements which attempt to put a limit on these incentives, such as having some local taxes required to finance some type of spending, or having budget rules on local governments (as we will discuss later). In many cases, however, these arrangements are imperfect and a common pool problem remains. The relationship between local governments and the Central Government may also imply a case of soft budget constraint (see Kornai et al., 2003). Localities expect Central Government to bail them out and overspend. Pettersson-Lidbom (2010) provides a test using Swedish data.

[x] Tornell and Lane (1999) develop a model of a sort of common pool problem applicable more directly to developing countries with poorly developed institutions and large informal sectors. They develop a dynamic model of the economic growth process that contains two common characteristics of those developing countries that have grown slowly in the last decades, namely (i) the absence of strong legal and political institutions and (ii) the presence of multiple powerful groups in society. The focus is on the fiscal process as it is the mechanism through which powerful groups interact with the society (which is characterized by weak legal and political institutions) and where they can enforce discretionary fiscal redistribution—a kind of pork barrel transfer—as a way to appropriate national resources for themselves.

This discussion is of course related to the fundamental issues of fiscal federalism.[y] The trade off is well known. On the one hand, one wants to allow to federal countries some freedom of choice on their localities. On the other hand, such freedom should not imply a deficit bias at the national level.

7. INTERGENERATIONAL REDISTRIBUTION

Current generations, by means of government debt, redistribute from future generations to themselves. The argument is very appealing. However, it needs to take into account the fact that private bequest are positive, thus one needs to account for negative "public" bequest (government debt) and private positive bequests. In this respect Cukierman and Meltzer (1986) consider the standard framework with overlapping generation model, lump sum taxes and intergenerational transfers from parent to child, and no uncertainty. Individuals differ in their abilities, (and therefore in wage earnings) and in their nonhuman wealth. Some of them desire to leave positive bequests, and others would prefer to borrow resources from future generations. Individuals who would choose to leave negative bequests are "bequest-constrained" individuals. These individuals favor any fiscal policy that increases their lifetime income at the expense of future generations. Individuals who are not bequest constrained are indifferent to an intergenerational reallocation of taxes. In fact they can adjust up or down their private bequest when public bequests (government debt or assets) move up or down. By majority rule, if the decisive voter is bequest constrained, he will choose lower current taxes financed by additional debt, which cannot be defaulted. If instead the decisive voter is not bequest constrained, he is indifferent to a reallocation of taxes and social security over time that maintains present value. Thus, in this model by majority rule we will easily have an accumulation of debt. The likelihood to have deficits increases with an extension of the franchise to low wealth individuals who are likely to be bequest constrained. This is a simple but very powerful idea which strikes us as just right.

Tabellini (1991) explores a different argument, that is the redistribution consequences of debt repudiation in an overlapping generation framework implying both intra and intergenerational redistributions. The main idea is that issuing debt creates a constituency in support of repaying it. Thus, issuing debt makes a coalition of voters favorable to repaying it in order to avoid intragenerational redistributive consequences of the debt repudiation. In particular, parents have a first-mover advantage since they can vote on how much debt they want to be issued (ie, how much resources they want to extract from future, yet-unborn generation), without the future generation to have a word. Issuing government debt results in intergenerational redistribution to be tight to intragenerational consequences of choosing how much debt to repay. In particular, debt reputation harms the old, but it harms the wealthy more than the poor.

[y] See Oates (2011) for the classic work.

Young voters (specifically the children of the wealthiest debt holder parents) want to avoid intragenerational redistribution (ie, repudiation would result in redistributing wealth from rich to poor families) and for this reason they are willing to accept to repay some debt (ie, transferring resources to the parents), an action that would have been opposed by them ex-ante.[z] Therefore, there is a coalition that includes both old and young voters (the wealthiest) who vote in favor of debt repayment. The most interesting and valuable aspect of this chapter is the joint consideration of intra and intergenerational redistribution, a topic which is surprisingly understudied both theoretically and empirically. In many countries pension systems redistribute both across and within generations, to the extent that poor citizen get proportionally more than rich ones from pensions. This is an excellent topic for further theoretical and empirical research.

Song et al. (2012) develop a dynamic general equilibrium model of small open economies where voters in each period choose domestic public goods and the financing via taxes and debt. Within each country, old agents support high spending on public goods, high labor taxes and large debt. Instead, the young dislike debt, since it crowds out public good provision when they will be old. Specifically, the model consists of a set of small open economies populated by overlapping generations of two-period-lived agents who work in the first period and live off savings in the second period. In each country j there two types of goods: a private good c and a domestic public good g provided by each economy's government. There are two types of agents, the young and the old, each with a different preference towards the public good, which are represented, respectively, by the parameters θ_j and $\lambda\theta_j$. λ represents a preference weight that old put on the public good. Intuitively, this parameter can take value 0—individuals do not value the public good—or positive values—not necessarily bounded to 1. There are cross-country differences in θ which may reflect cultural diversity or differences in the efficiency and quality of public good provision, related to the technology and organization of the public sector. Capital is perfectly mobile across countries and it fully depreciates after one period. The private good is produced by using both capital and labor as inputs in the production function. The domestic fiscal policy is determined through repeated elections and government debt is traded on worldwide markets. Given an inherited debt b_j, the elected government chooses the labor tax rate τ_j, public expenditure g_j and debt accumulation $b_j^{\prime}$, subject to a standard dynamic government budget constraint. A probabilistic voting model delivers an equilibrium in which fiscal policy maximizes a weighted sum of young and old voters' utility. The weights assigned to each group represent the relative political influence of

[z] This is because, ex-ante issuing debt has only intergenerational, but not intragenerational effect. Given that agents would prefer not to redistribute resources, they would vote against this policy ex-ante. However, ex-post the policy has also intragenerational effect and the young generation would prefer to transfer resources to their parents rather than to the fraction of poor people in the same cohort.

each group. The model yields a trade-off between the marginal costs of taxation, due to the reduction in private consumption *c* suffered by the young, and the marginal benefit of public good provision. Such a trade-off reveals a conflict of interest between young and old voters. The old want higher taxes and current spending on public goods. Thus, the more power held by the old, the greater the reduction in private consumption. The preference for public good provision affects this trade-off: a higher θ or a higher λ reduces private consumption *c*. Moreover, there exists a sort of "disciplining effect" exercised by the young voters. In particular, they anticipate that increasing debt will prompt a fiscal adjustment reducing their future public good consumption. A key result is that the model provides a politico-economic theory of the determination of the debt level. In particular, in spite of the complete lack of intergenerational altruism (assumed through finite lives) debt converges to a finite level, strictly below the natural borrowing constraint. This results from the combination of forward-looking repeated voting and distortionary taxation. Higher debt can be financed by increasing taxes or cutting public good provision. As debt grows larger, the convexity of tax distorsions (a Laffer curve effect) implies that most of the adjustment will be in the form of less future public goods. The concern for avoiding a future situation of private affluence and public poverty makes young voters oppose debt increases. Given the prediction of a determined debt level, the model yields mean-reverting debt dynamics. Suppose that the economy is hit by a one-time fiscal shock (eg, a surprise war) requiring an exogenous spending. The government reacts by increasing taxes and decreasing nonwar expenditure in wartime. After the war, debt, taxes, and expenditure revert slowly to the original steady state. These predictions accord well with the empirical evidence of Bohn (1998), who finds the US debt-to-output ratio to be highly persistent, but mean reverting and Müller et al. (2016) which provide similar evidence for the period 1950–2010 for a panel of OECD countries.

Müller et al. (2016) extend their model by assuming that there are two types of voters, left wing (*l*-type) and right wing (*r*-type), who differ in their trade-off between private consumption and public good consumption: *l*-type voters like government expenditure and public good provision more than do *r*-type voters. Voters choose sequentially a fiscal policy which includes labor taxation, government expenditure on public goods, and debt policy, subject to the government's dynamic budget constraint. The novelty of this model compared to Song et al. (2012) is that, here there are political shocks which can be interpreted as shocks over time to the preference for public goods. In particular, during a left-wing wave the government increases taxation and public expenditure while reducing debt. Instead, during a right-wing wave the opposite occurs. In fact the driver of fiscal discipline of the young is based on their preferences for public good when old—that is how much the young expect that they will appreciate public good provision as they become old. During left-wing governments, the demand for fiscal discipline is stronger because the young left-wing voters—who are more concerned for future public good provision than right-wing voters of the same age—detain more political influence.

This is because *r*-type voters have less appeal to public good and more for private consumption. Thus, when the right-wing party is in power is less concerned to the provision of public good in the future and instead it would push up current debt today in order to use the resources as subsidies for private consumption. Left-wing voters are instead concerned with future public good provision, and would oppose such fiscal policy. The key predictions of the model are that, on the one hand, right-leaning governments are more prone to issue debt in normal times, while on the other hand left-leaning government engage in more proactive countercyclical fiscal policy—including issuing more debt during recessions. In other words, during normal times left-leaning governments do more public savings but use the debt to smooth income shortfalls associated with recessions.[aa] This result is reminiscent of the model by Persson and Svensson (1989) reviewed earlier, in a nonoverlapping generation framework.[ab]

It should be mentioned that all the models discussed earlier imply voting. Mulligan and Sala-i Martin (1999) argue that indeed spending on pensions is high in nondemocracies as well as democracies, namely variables like the aging of population and the relative size of young and old matter in both regimes. In fact the relative "strength" (ie, political influence) of the constituencies of young and old may be relevant in both democracies and nondemocracies even though the nature of the way in which this relative strength manifests itself is of course different. These differences in the intergenerational games in perfect and imperfect democracies and in dictatorships is an excellent topic for additional research.[ac]

8. RENT SEEKING

Acemoglu et al. (2008, 2010, 2011) study the dynamic taxation in a standard neoclassical model under the assumption that taxes and public good provision are decided by a self-interested politician who cannot commit to policies. Citizens can discipline politicians by means of election as in Barro (1973) and Ferejohn (1986) in a dynamic game. The self-interested politician creates distortions, namely he wants to extract rents from being

[aa] They show that these theoretical predictions are consistent with US postwar data on debt, and also with a panel of OECD countries.

[ab] However, the key difference between the two papers is that in Persson and Svensson (1989) a conservative government expecting to be replaced in the future strategically issues more debt. In contrast, the results in Müller et al. (2016) are unrelated to persistence or reelection probabilities. The robust prediction of their theory is that a left-leaning government issues less debt, irrespective of the probability of being replaced.

[ac] Azzimonti et al. (2014) make the case that the secular increase in debt to output ratios can be due to the liberalization of financial markets that took place in the mid eighties. While the political-economy comes from probabilistic voting, the paper provides an alternative theory of debt (to that of tax smoothing) and an explanation of why we could observe inefficiently higher debt to GDP ratios in the recent years. Specifically, they propose a multicountry political economy model with incomplete markets and endogenous government borrowing and show that governments choose higher levels of public debt when financial markets become internationally integrated and inequality increases.

in office. This adds an additional constraint in the economy, the political economy constraint. This constraint implies that politicians in power compare the lifetime utility from extracting rents in each period vs the one-time shot deviation of extracting all the resources available in the economy in one period and being voted out of office. Distortions are generated by the fact that citizens have to provide incentives to politicians to stay in office. These distortions may or may not disappear in the long run. In particular, if politicians are as patient or more patient than citizens, they value more staying in office and thus they set a tax rate equal to zero. If politicians are less patient than citizens, it may be optimal to set positive taxation. The idea is that, starting from a situation with no distortions as before, an increase in taxation has a second-order effect on the welfare of the citizens holding politician rents constant, but reduces the resources available in the economy and, thus, the rents that should be provided to politicians by a first-order amount.[ad] Thus, it is less costly to reduce the potential output in the economy, than to provide a higher rents to politicians to stay in office. These types of models therefore focus on the role of taxation as a tool to govern the interaction between citizens and self-interested politicians. There is no role for government deficit.

Yared (2010) develops a rent seeking model with implications on the accumulation of public debt using a Lucas and Stokey (1983) model. Yared considers a closed economy with no capital, with shocks to the productivity of public spending, and with complete markets. The self-interested politician has a utility function which is increasing in rents (namely tax revenues not used for productive public goods, ie, spending with no social value). A politician cannot commit to policies once in office and citizens cannot commit to keeping the incumbent in power in the future. Thus, in an infinitely repeated game, reputation sustains equilibrium policies. The focus is on "Efficient Sustainable Equilibria" in which a politician who pursues rent seeking extractive policies is voted out of office, and a politician who purses the policies expected by citizens is rewarded with future office.[ae] Therefore, the incumbent politician follows equilibrium policies as long as rents are sufficiently high, since this raises the value of cooperation, and as long as government debt is sufficiently high, since this limits what he can acquire through maximally extractive policies prior to removal from office. There is no default. Citizens reward a

[ad] Specifically, the marginal cost of additional savings for the citizens is higher in equilibrium than in the undistorted allocation, because a greater level of the resources in the economy increases the politician's temptation to deviate and thus necessitates greater rents to the politician to satisfy the political sustainability constraint.

[ae] The equilibrium refinement used is the sustainable equilibrium as in Chari and Kehoe (1993). In particular, individual households are anonymous and nonstrategic in their private market behavior (ie, buying government debt), while the representative citizen is strategic in the replacement decision. The politician in office is strategic in his decision regarding the policies, which have to satisfy the government dynamic budget constraint. The set of sustainable equilibrium are those in which citizens solve their optimal decision with respect to consumption, labor supply and bonds' decision given their individual budget constraints. Within the set of sustainable equilibrium, the focus is on the efficient ones, ie, the ones that maximize citizens' utility.

well-behaved incumbent by not replacing him as long as equilibrium taxes are sufficiently low and productive public spending is sufficiently high. Note that given the fact that citizens are all identical, there is no conflict in the political decision. Efficient sustainable policies thus solve the standard program of the benevolent government subject to incentive compatibility constraints for the politician and the representative citizen.

Consider now the rent seeking politicians. Given the lack of commitment, there are two set of incentives that have to be satisfied, the politician's and the citizens' incentives. The incumbent politician knows that citizens will remove him from office at the beginning of the following period if he misbehaves. In particular, a politician who is removed after period t receives period t rents and a punishment which is a function of χ^p, ie, an exogenous parameter representing the strength of political institutions, namely the institutional constraints on politicians. The optimal policy for the citizens has to satisfy the constraint that the politician does not want to extract maximal rents and be removed from office. Maximal rents implies getting as much revenues as possible today, take out as much debt as possible today, delivering zero public goods, and repaying current debt. Therefore, the incumbent politician is less likely to deviate from the equilibrium policies if: (i) he is receiving a high level of equilibrium rents today and in the future because in this case the value of cooperation is high; (ii) if government debt is high because there is little space for him to expropriate resources through increasing his rents. Satisfaction of this incentive compatibility constraint implies a lower bound on taxes and an upper bound on public spending which both bind whenever the incentive compatibility constraint binds. This is because there has to be a limit on the size of resources owed to the government in each period. Indeed, if the size of these resources is too large, there is a high incentive for the politician to deviate and appropriate them as rents. This implies that resources going into a given period cannot be too large, and government activity must be financed mostly with current and future taxes, instead of past taxes.

The second set of incentives to take into account are those for the citizens. In this model, citizens may have an incentive to replace an incumbent politician even if he is well behaving. In this sense, citizens cannot commit to a plan where they keep an incumbent in power no matter what. Therefore, the incumbent politician has to set fiscal policies such that they define a sufficiently low level of taxation and/or a sufficiently high level of public expenditure in order to have some chances to stay in office the subsequent period. In this framework, replacing an incumbent politician provides a benefit for the citizens which is a function of the exogenous parameter χ^c. Here, χ^c represents the lack of popularity of the incumbent.[af] These conditions provide upper bounds on revenues and lower bounds on public spending.

[af] Another interpretation may be the gains for the citizens from having a new incumbent, reflected in the policies that are promoted during the electoral campaign. The author interprets it as a general "social benefit of political turnover."

Summing up, satisfying the incentives of politicians requires sufficiently high revenues and sufficiently low levels of public spending. In contrast, satisfying the incentives of citizens requires sufficiently low level of taxes and sufficiently high level of public spending. The best policy is therefore found to be the one that maximizes citizens' lifetime utility subject to the two set of incentive compatible constraints. This political distortion leads to several departures from the social planner policies. In particular, taxes are not constant but *volatile*. This is because the constant revenue policy characterizing the benevolent government is associated with too much rent seeking by politicians. Second, the increase in debt reduces the potential rents that the politician can appropriate and thus make it easier for citizens to provide the incentives to politicians. This approach is elegant, although contingent debt as in Lucas and Stokey (1983) is not issued by real world governments.

9. BUDGET RULES

Given that for so many reasons there are incentives for the government to run excessive deficits, is it feasible to devise rules and institutions that limit or eliminate those problems? By rules we mean numerical targets like a balanced budget rules, or a limit on the level of deficit, perhaps adjusted by the cycles, or excluding certain items such as public investment.[ag]

9.1 Balanced Budget Rule for National Governments

The pros and cons of national balanced budget rules, namely rules which imply zero or negative deficits (surpluses) are clear. A balanced budget rule does not allow to smooth out spending shocks (ie, to run deficits when the need for spending are especially large) or fluctuations of tax revenues over the cycle for given tax rates. However, to the extent that political distortions are so large that governments may be far from the optimal policy, then a balanced budget rule might be a second best solution to massive political distortions.

The political debate on balanced budget rules is extensive, since the pros and cons are, in principle, straightforward but there are strong prior views about which costs or benefits are bigger and those views are not likely to be changed by the available, relatively scant, evidence.[ah] An additional set of issues relates to the enforceability of balanced budget rules, namely whether governments restricted by these rules would engage in "creative accounting" to circumvent them or simply *de facto* ignore them.

[ag] For a review see Fatás and Mihov (2003b).

[ah] See Sabato (2008) for a presentation of the policy debate. Fatás and Mihov (2003a) present evidence on a cross section of countries consistent with the view that the presence of budget rules limits the volatility of fiscal policy.

Azzimonti et al. (2015) present a quantitative evaluation of the net benefits of a balanced budget rule (BBR) for the US economy using the political economy model developed by Battaglini and Coate (2008).[ai] As reviewed earlier, political economy frictions lead to inefficiently high levels of government debt in the long run. A constitutional requirement that imposes that tax revenues must be sufficient to cover spending and the interest on debt (eg, permitting surpluses but not deficits) may improve welfare by restraining policymakers from excessive debt creation. The authors show that the BBR leads to a gradual reduction of debt in equilibrium. Intuitively, the reduction in flexibility to smooth taxes imposed by the rule increases the expected costs of taxation. Therefore, savings become more valuable as a buffer against adverse shocks. By lowering the stock of debt in good times, legislators reduce interest payments, which decreases pressure on the budget in bad times. In the long run, this results in lower taxes and higher spending in equilibrium than in the unconstrained case, "pushing" the model on the direction of optimal fiscal policy. The impact of a BBR on welfare is theoretically ambiguous: in the short run, citizens experience a loss in utility since the government has to cut spending and raise taxes to reduce debt above what might be optimal. In the long run, citizens benefit from lower debt levels but, due to the inability to borrow in bad times, suffer from higher volatility. Because the net effect depends on parameters, the authors calibrate the model to the US economy using data between 1940 and 2013, and show that it can fit the path of US fiscal policy reasonably well. One immediately wonders whether including the Second World War years in this exercise is appropriate given that during a major war probably the balanced budget rule could be easily abandoned. By including a major war period they, in a sense, may set the stage for a framework with high costs for balanced budget rules. The authors find that the short run costs are too large to compensate for the steady state benefits of a lower stock of debt. However, quite apart from the parametrization (which, as always, could be debatable) the model makes an interesting point: the balanced budget rule could be costly in the short run and beneficial in the long run. This result leads to interesting and immediate consequences on the political economy implications on voting upon a balanced budget rule in say, an overlapping generations model.

Halac and Yared (2015) discuss the optimal design of centralized supranational fiscal rules like those for Euro area countries, and how they compare to decentralized (national) fiscal rules in an environment in which there is a trade-off between allowing flexibility while also reducing a government's deficit bias. They consider a two-period model in which a continuum of identical governments choose deficit-financed public spending. At the beginning of the first period, each government suffers an idiosyncratic shock to the social value of spending in that period. Governments are benevolent ex-ante, prior to the realization of the shock, but present-biased ex-post, when it is time to choose

[ai] See also Stockman (2001) for calibrations of balanced budget rules in RBC models.

spending—which can be interpreted as the results of the potential political turnover (ie, the political business cycle). The results of the chapter compare optimal rules—which maximize the social welfare of all countries—when it is set by a central authority or an individual government. The results can be summarized as follows: when governments are not too impatient when choosing public spending, then the optimal centralized fiscal rule is tighter than the decentralized one, and hence interest rates are lower under centralization. The idea is that, in choosing decentralized rules, an individual country does not internalize the fact that by allowing itself more flexibility, a country pushes the global interest rate up, and thus redistributing resources away from governments that borrow more towards governments that borrow less. Instead, committing ex-ante to tighter rules is good as this pushes down the global interest rate and therefore allows countries with higher marginal value of spending to borrow more cheaply. If governments' present bias is large, the optimal centralized fiscal rule is slacker than the decentralized one, and hence interest rates are higher under centralization. The idea is that governments choosing rules independently do not internalize the fact that by reducing their own discretion—ie, by choosing very tight borrowing limits—they lower interest rates, thus increasing governments' desire to borrow more and worsening fiscal discipline for all. Instead, committing ex-ante to more flexibility is socially beneficial: the cost of increasing discretion for over borrowing countries is mitigated by the rising interest rate, which induces everyone to borrow less. The interest rate has a disciplining effect in the sense that it reduces the incentives for over borrowing countries to borrow more.

Aguiar et al. (2015) investigate the conditions under which the imposition of debt ceilings is welfare improving. Specifically, they study the interaction between fiscal and monetary policy in a monetary union with the potential for rollover crises in sovereign debt markets. Each member-country chooses how much to consume and borrow by issuing nominal bonds. A common monetary authority chooses inflation for the union, taking as given the fiscal policy of its member countries. Both types of policies are implemented without commitment. The lack of commitment on fiscal policy is especially critical because it may lead to the possibility of default. They show the existence of a "fiscal externality" in this type of environment. This externality leads countries to over borrow and thus, higher inflation and lower welfare. This gives credit to the imposition of debt ceiling in a monetary union which overcome the problem of lack of commitment on fiscal policy. Aguiar et al. (2015) go further and investigate the impact of the composition of debt in a monetary union, that is the fraction of high-debt vs low-debt members, on the occurrence of self-fulfilling debt crisis. Specifically, they show that a high-debt country may be less vulnerable to crises and have a higher welfare when it belongs to a union with an intermediate mix of high- and low-debt members, than one where all other members are low debt.

One could also think of balanced budget rule with escape clauses. An obvious one, mentioned earlier already would be a major world war. This (fortunately) rare event may be used as a relatively easy contingency to verify, but if the contingencies become too frequent then not only the stringency of the rule but even its enforceability is called into question. For instance, how does one define a "major" war? Clearly the Second World War was major, but would the Iraq war be a major one? Also one might think of cyclically adjusted balanced budget rules to overcome some of the rigidity of the latter, but then debates about how to measure the cyclical adjustment might lead to strategic manipulation of the rule itself. With specific reference to the United States, Primo (2007) discusses the pitfalls of balanced budget rules with complicated escape clauses.

An additional argument against formal budget rules is that financial markets might impose increasing borrowing costs on government which move far away from the optimal policy and accumulate large debts. Increasing borrowing costs would lead to more discipline even without rules. The recent experience of the Euro area and its fiscal crisis, casts doubts on this argument. Until 2008 the interest rate spread on, say German government bonds and even Greek ones was virtually nil. In fact, as a result of this low spreads several countries accumulated large debts in the first decade of the monetary union even when these countries were growing at respectable rates, including Greece whose economy was booming and debt skyrocketing. The reason of this is that probably investors did not believe the no bail out case of European treaties and assumed (largely correctly) that in case of a debt crisis they would be protected. In fact, probably because market discipline was not considered sufficient the funding fathers of the monetary union introduced contingent budget rules, like the stability and growth pact. These rules have been changed repeatedly and generally implied a maximum level of deficit (3% of GDP) with various escape clauses in case of major recessions. The discussion about the optimality of such rules in the Euro area is immense and we do not review it here (see the excellent discussion in Wyplosz, 2014).[aj] However, we want to make three points here. One is that the enforceability of these rules has been questionable. Even as early as 2002 Germany itself broke the rule and then many countries followed this example. The complexity and contingency of these rules did not help. The second is that probably now some European countries are feeling the bite of such rules, binding during a prolonged recession. The third is that especially at the time of the introduction of the Euro much creative accounting was widely used to satisfy "on paper" the 3% rule. These procedures introduced confusion and decreased trust amongst members of the Euro area.[ak]

How can balanced budget rules for a sovereign national government can be enforced? One possibility is to have the law in the constitution so that it would take a Constitutional revision to change it. An alternative would be to require a qualified majority. Such rules need to be stable, namely they should not imply that the rule itself can be changed, as in Barbera and Jackson (2004). For some discussion of this issue, see Primo (2007) which

[aj] For some empirical evidence on the stability and growth pact see von Hagen and Wolff (2006).

[ak] Von Hagen (2006) compare the effectiveness of budget rules in the EU vs Japan.

elaborates over the Baron and Ferejohn (1989) approach with specific reference to the US institutional setting. This is an excellent topic for future research not only within the specific American institutions.

9.2 Balanced Budget Rules for Local Governments

The pros and cons of balanced budget rules discussed earlier for national government apply also to subnational ones. However, there are reasons to believe that balanced budget rules for local governments may be more attractive than for national governments. First, as we discussed earlier, local governments add an additional political distortion: a common pool problem given by the fact that their local spending is at least in part financed by national transfers and therefore local governments do not fully internalize the taxation costs of their spending decisions. Second, some (or most) of the countercyclical fiscal stabilizers may be national not local. In fact, balanced budget rules for local governments should be accompanied by nationally based automatic stabilizers, to avoid procyclical fiscal policy, unless, as were discussed earlier, a balanced budget rule is chosen also for the national government. Third, enforcement of local balanced budget rule may be easier since it may be done by the national governments. Fourth, a balanced budged rule for local governments would avoid accumulation of unsustainable debts with the related uncertainty, disruption and costs associated with bail outs of excessively indebted localities. In summary, balanced budget rules for local government may be a tool of an optimal allocation of fiscal responsibilities between national and local governments.[al]

Indeed, work by Alt and Lowry (1994), Poterba (1995), Bayoumi and Eichengreen (1994), Bohn and Inman (1996), and Alesina and Bayoumi (1996) show that more strength budget rules in the United States, namely tight fiscal controls which impose restrictions on government deficit, have been more effective at creating incentives to states more quickly responding to spending or revenue shocks.[am]

9.3 Other Types of Budget Rules

The policy discussion over balanced budget rules has also dealt with other types of budget restrictions. One is the so-called "golden rule," namely a rule which allows budget deficits only to finance public investments but not current expenditures. Bassetto and Sargent (2006) discuss the optimality of such rules. In principle, this may be a "good" rule especially for developing countries in need of investment in infrastructures. The problem, however, is that this rule may lead to creative accounting, namely simply reporting as spending in infrastructures what is really current spending. For developed countries one may wonder whether the political incentives to spend in physical

[al] See Inman (1997) and Poterba (1996) for a review of this literature.

[am] Canova and Pappa (2006), however, present results suggesting that in some cases US states managed to circumvent the rules.

infrastructures which would be induced by this rule is really necessary. In Western Europe, in particular, the emphasis on physical infrastructures seem overplayed already, relative to other fiscal problems in this continent, and a budget rule of this type may add to this misperception and lead to overinvestment in physical infrastructures.

Another possible budget rule would impose limits on spending. The issue here is that while we have a theory of optimal deficit management, reasonable people can disagree on the optimal size of government spending because of different views about the role of the state and the size of welfare policies, for instance. Thus, while pork barrel inefficient programs (like bridges to nowhere) might be constrained by spending limits, the latter may interfere with programs desired by the majority.

10. BUDGET INSTITUTIONS

10.1 Theory

The definition and approval of a budget in an advanced democracy is often a complex process, possibly kept strategically complex to achieve behind the scene deals or to be able to introduce them in some corner of the budget provisions in a sufficiently obscure manner to escape detection of the voters. One can identify three phases in the budget process: (1) the formulation of a budget proposal within the executive; (2) the presentation and approval of the budget in the legislature; and (3) the implementation of the budget by the bureaucracy. Two issues are crucial: the voting procedures leading to the formulation and approval of the budget, and the degree of transparency of the budget. We begin with the former.

We focus upon a key trade-off between two types of institutions. One type, which we label "hierarchical," limits the democratic accountability of the budget process with a high degree of delegation. The second type, we label "collegial," has the opposite features. Hierarchical institutions are those that, for instance, attribute strong prerogatives to the prime minister (or the Finance or Treasury minister) to overrule spending ministers within intergovernmental negotiations on the formulation of the budget. Hierarchical institutions also limit in a variety of ways the capacity of the legislature to amend the budget proposed by the government. Collegial institutions emphasize the democratic rule in every stage, like the prerogatives of spending ministers within the government, the prerogatives of the legislature vis-a-vis the government, and the rights of the minority opposition in the legislature. There is a trade-off between these two types of institutions: hierarchical institutions are more likely to enforce fiscal restraints, avoid large and persistent deficits, and implement fiscal adjustments more promptly. On the other hand, they are less respectful of the rights of the minority, and more likely to generate budgets heavily tilted in favor of the interests of the majority. Collegial institutions have the opposite features.

Let's begin with the definition of the budget within the government where we have a division of responsibilities between spending ministers and the Treasury minister. The latter has the role of aggregating the spending proposals of other ministers and produce a budget document. Spending ministers prefer a larger fraction of the budget devoted to their department: more money means more favors to constituencies. Thus, more hierarchical institutions are those which attribute stronger prerogatives to the Treasury. In the legislature, as we discussed earlier, different amendment rules may aggravate or reduce the common pool problem. Much of this research is based, directly or indirectly, upon a view of the budget as the result of conflicting interests of representatives with geographically based constituencies. The literature on procedures has addressed three related questions: what procedural rules mitigate or aggravate the problem of oversupply of pork barrel projects? What procedural rules make the choice of projects, given a certain total budget, more or less efficient? How do different procedural rules influence the final allocation of net benefits among districts? Two issues are particularly interesting for our purposes: (a) the sequence of voting on the budget, and (b) the type of admissible amendments on the proposed budget. Intuitively, one may argue that by voting first on the maximum size of the budget (and eventually of the deficit) one would limit the excessive multiplication of budget proposal. Ferejohn and Krehbiel (1987) study theoretically the determination of the size of the budget under the two alternative voting procedures. They assume that the budget can be allocated to two projects and different legislators have different preferences for the relative benefits of these two projects. It is not always the case that the size of the budget is smaller when the legislatures vote first on the size and then on the composition, relative to the case in which the overall budget size is determined as a residual. While the size of the budget is in general not independent on the order of votes, the relative size of the budget with different orders of votes depends on the distribution of legislatures' preferences for budget composition.[an]

In parliamentary democracies, the agenda setter in the budget process is the government. Thus, closed rules attribute more power to the government and less to the floor of the legislature. The result is that closed rules are more hierarchical as we discussed earlier. They give more influence to the government and lead to an immediate approval of the budget than the government poses. Open rules require more time for voting and with those rules the government gets a lower surplus relative to the nongovernmental minority. With a closed rule you achieve quick approval of a proposal, at the cost of implementing "unfair" budgets. Budgets are unfair in the sense that they are tilted in favor of those who make the first proposal, and always distribute benefits to the smallest possible majority. Hierarchical procedures are obviously preferable when the key problem is the control of the size of the budget and the implied deficit.

[an] The same issue has been revisited by Hallerberg and Von Hagen (1999).

Finally, the issue of transparency. The budgets of modern economies are very complex, sometimes unnecessarily so. This complexity, partly unavoidable, partly artificially created, helps in various practices to "hide" the real balance (current and future) of costs and benefits for the taxpayers. Politicians have incentives to hide taxes, overemphasize the benefits of spending, and hide government liabilities (the equivalent of future taxes). At least two theoretical arguments support this claim. The first is the theory of "fiscal illusion" reviewed earlier. By taking advantage of voters' irrational confusion, politicians can engage in strategic fiscal policy choices for reelection. The second argument does not rely on voters' irrationality and confusion. Several papers, although in different contexts (eg, Cukierman and Meltzer, 1986 and Alesina and Cukierman, 1990), highlight the benefit for policymakers of a certain amount of ambiguity even when they face a rational electorate. The idea is that, by creating confusion and, in particular, by making it less clear how policies translate into outcomes, policymakers can retain a strategic advantage vs rational, but not fully informed, voters. This advantage would disappear with "transparent" procedures; therefore, policymakers would often choose to adopt ambiguous procedures. Milesi-Ferretti (2004) shows that politicians who want to run excessive deficits would choose nontransparent procedures, and the latter would help them to achieve their (distorted) goals. As we discussed earlier, Rogoff and Sibert (1988) and Rogoff (1990) make a similar point in the context of political business cycle models. They show that if voters cannot easily observe the composition of the budget (on the spending or on the financing side), then policymakers can follow loose fiscal policies before elections and increase their chances of reappointment. Gavazza and Lizzeri (2009) develop a model in which the lack of voters' information about the complexity of the budget lead to transfers to voters even when taxation is distortionary and voters are homogeneous. Transfers are financed with debt and the latter is higher the less transparent the system is, that is the less likely it is that voters can fully observe fiscal variables.[ao]

How, in reality, do policymakers obfuscate the budget? and what to do about it? In practice, a variety of tricks can serve the purpose of strategically influencing the beliefs and information of taxpayers/voters. For instance: (1) Overestimate the expected growth of the economy, so as to overestimate tax revenues, and underestimate the level of interest rates, so as to underestimate outlays. At the end of the fiscal year, the "unexpected" deficit can be attributed to unforeseen macroeconomic developments, for which the government can claim no responsibility; (2) Project overly optimistic forecasts of the effect on the budget of various policies, so that, for instance, a small new tax is forecast to have major revenue effects, thus postponing to the following budget the problem of a real adjustment; (3) Keep various items off budget; (4) Use budget projections strategically. For example, in all the discussions about future budgets, a key element is the

[ao] The same authors (Gavazza and Lizzeri, 2011) investigate how lack of transparency may lead to the choice of inefficient fiscal tolls for redistribution.

"baseline." By inflating the baseline, politicians can claim to be fiscally conservative without having to create real costs for the constituencies. In this way, they create an illusion: they appear conservative in the eyes of the taxpayers, worried about the size of the budget, but they do not really hurt key constituencies with spending cuts. Clearly, this illusion cannot last forever, since adjustment, rigorous only relative to inflated baseline, in the end will not stop the growth of the debt. However, this procedure creates confusion and, at the very least, delays the electorate's realistic perception of the actual state of public finance; (5) Strategic use of multiyear budgeting. By announcing a, say, 3-year adjustment plan in which all the hard policies occur in years 2 and 3, politicians can look responsible and can buy time; then, they can revise the next 3-year budget policies to further postpone the hard choices.[ap]

We can think of three possibilities for increasing transparency. The first and most commonly followed is a "legalistic" approach. That is, more and more rules and regulations are imposed on how the budget should be prepared, organized, and executed. This approach is unlikely to be successful: complicated rules and regulations provide fertile ground for nontransparent budget procedures. A second alternative is to create legislative bodies in charge of evaluating the transparency, accuracy, and projections of the government budget. This approach is superior to the legalistic one, but it relies heavily on the political independence of this public body. This independence may be problematic, particularly in a parliamentary system where the government parties control a majority in the legislature. A third alternative, the most radical but the most effective, is to delegate to a respected private institution the task of verifying the accuracy and transparency of the budget process. In addition, the government budget should be based on an average of the economic forecasts of and projections derived by international organizations or private institutions.

10.2 Empirical Evidence

The empirical evidence on the relationship between rules and deficit is, generally speaking, supportive of the idea that hierarchical institutions are associated with lower deficits. Hallerberg et al. (2009), in a book which also summarizes and consolidate previous works by the same authors, classify budget institutions for the EU countries in terms of delegation of prerogatives to the Treasury minister versus a contracting approach within ministers, the presence of targets, voting rules in parliament, relationship between central and local governments. They argue that institutions matter and delegations and targets (ie, hierarchical institutions) are effective at containing deficits and debts. Alesina et al. (1998) and Stein et al. (1999) consider Latin America countries and construct an index of their budget institutions based upon surveys of local officials. In doing so they can distinguish up to a point between *de iure* and *de facto* procedures. These authors correlated

[ap] See Alesina et al. (2015) for a detailed study of multiyear fiscal adjustment plans.

positively an index of hierarchical of budget institutions and of transparency to lower levels of debt. Fabrizio and Mody (2006) obtain similar results for Center and Eastern European countries. Dabla-Norris et al. (2010) on a vast sample of developing countries. These results should be taken very cautiously since they are based upon a handful of countries and often the classification of procedures is open to question. For instance, *de iure* and *de facto* procedures may differ substantially. Also comparing along those lines very different countries might be challenging, for instance think of a comparison of United States vs parliamentary democracies budget institutions. Debrun et al. (2008) compile a detailed data set for European Union countries for the period 1990–2005. They consider numerical fiscal rules on any fiscal aggregate, their legal status (normal law, constitutional law, supranational rules, accepted norms) and consider both national and subnational governments. Based upon this vast data set they build an index of stringency of the rules and they find that it strongly correlates with fiscal performance. More stringent rules reduce a deficit bias and improves upon the countercyclical stance of fiscal policy in EU countries. Miano (2015) has shown that national rules have the effect of reducing deficits. A recent work at IMF (Budina et al., 2012) provide extensive data on budget institutions for many countries and examine how the recent financial and fiscal crisis in many countries have led to reforms in budget institutions. These data have not been used yet for extensive empirical analysis.

11. QUESTIONS FOR FUTURE RESEARCH

In this final section, we elaborate on some issues which in our view are left open in this literature.

11.1 Endogenous Institutions

The literature which we have reviewed thus far uses certain political institutions (eg, type of government, electoral rules, presidential vs parliamentary systems) as exogenous or at least predetermined in explaining economic variables. In the present chapter we focus on debt and deficits but a vast literature also considers other related variables like the size of government and the level of redistribution for instance.

The assumption of exogeneity of predetermined institutions as “cause” of deficits can, however, be called into question. The same historical, sociological, cultural variables which may have led to the choice of certain institutions may also be correlated with fiscal policies.[aq] For instance, suppose that a parliamentary proportional system (generating a multiparty system with many veto players) was adopted because it was the only way to guarantee representation to very polarized and divided societies (across income, ideological, religious or ethnic lines). Those same characteristics of society might lead to

[aq] See Alesina and Giuliano (2015) for a discussion of the relationship between culture and institutions.

certain choices of fiscal policies (spending, deficits, debt). Thus, proportional representation and deficits would correlate but causality is called into question. Along those lines, Alesina and Glaeser (2005) review the literature showing that in many European countries proportional representation was introduced after the First or Second World War under pressure from Socialist and Communist parties. The presence of the latter clearly is not exogenous to fiscal policy decisions. Aghion et al. (2004) discuss how certain types of voting rules would be chosen optimally or not (ie, with or without a veil of ignorance) in divided societies.[ar] Empirically, they show how ethnic fractionalization is correlated with various institutional variables. Galor and Klemp (2015) present results along similar lines using different measures of diversity. On the other hand a vast literature on ethnic fractionalization (see the survey by Alesina and La Ferrara, 2005) show how the latter variable is correlated with several economic variables which may be directly or indirectly correlated with deficits and debt. Thus, diversity of populations may "cause" both institutions and fiscal outcomes. The correlation between the latter two does not imply causality, strictly speaking. Persson and Tabellini (2000) in their work on institutional determinants of fiscal policies are aware of this limitation and make some progress in addressing causality, but this remains an open question. The literature on fiscal policy which appeals to institutional variables as causal explanation for deviations from optimality (especially when thinking of long run horizons) needs to make the extra step. At this point, the correlations seem clear, identification of causality is not.

These arguments apply even more strongly when focusing specifically to budget institutions. The latter may work very differently in different countries depending upon their interaction with other features of the country itself. Hallerberg et al. (2009) argue that delegations to the Treasury minister does not work well in countries with sharp differences in the preferences of different parties for fiscal policy, a result which is consistent also with the model of political delegation by Trebbi et al. (2008). With a deep political conflict delegation to one decision maker is hard, undesirable by the minority and possibly counterproductive. Budget institutions are clearly endogenous. Why do countries choose different budget institutions and therefore to what extent the latter can be used as right hand side variables in a regression with debt and deficits on the left hand side? Countries with lower polarization and more homogeneous governments may be more likely to choose more hierarchical fiscal institutions, since delegation is easier, as argued earlier. But then it may be that the lower political conflict leads to more restrained fiscal policies; in this case, institutions are just an "intermediate" variable. In other words, paradoxically countries which needs stringent budget rules the least, since they have a lower tendency to run deficits, may be those which adopt more stringent budget rules. As noted by Hallerberg et al. (2009), some institutional reforms in the direction of making them more hierarchical have followed deep crisis, like the case of Sweden in the nineties. But again,

[ar] See also Trebbi et al. (2008) for an application to US cities.

causality is an issue: perhaps changes in attitudes due to the crisis might have led to a political equilibrium with more fiscal restraints regardless of the institutions. It is virtually impossible to establish causality from budget institutions to fiscal outcomes, although the correlations are interesting. Debrun et al. (2008) are fully aware of this problem and attempt to instrument their index of stringency of rules with some institutional variables but the exclusionary restriction is highly questionable. Miano (2015) shows how the adopting of various budget institutions are endogenous to a host of sociopolitical variables and are affected by the timing of elections. Overall, the argument that budget institutions "cause" fiscal discipline is virtually impossible to make empirically given the endogeneity of these institutions. Countries with a culture of fiscal profligacy will not adopt them (or will not enforce them) while countries with a culture of rigor will adopt and enforce them. The evidence presented earlier is consistent with a weaker argument namely that countries which, for whatever reason, cultural or otherwise, prefer budget discipline will be helped in their goal by choosing certain institutions rather than others. We think that we need more research on this point: to what extent institutions "cause" fiscal policies? Perhaps more natural experiment-based research may help address this question.

A second line of argument relates to the time consistency of institutional rules. To what extent institutional choices would be time consistent and not reversed as a result of various shocks? Halac and Yared (2014) address precisely this issue in a model where a government has an incentive to overspend. The government chooses a fiscal rule to trade off its desire to commit to not overspend against its desire to have the flexibility to react to shocks. These authors show that in the case of persistent shocks the ex-ante optimal rule is not sequentially optimal. The optimal rule in fact is time dependent with large fiscal shocks leading to an erosion of future fiscal discipline. It would be very useful to investigate the choice of budget rules under a Rawlsian veil of ignorance at the constitutional table or in a situation in which the veil of ignorance has holes, as in related work by Trebbi et al. (2008) on voting rules.

11.2 Culture

A rapidly growing literature has recently explored how various cultural traits affect economic decisions in a variety of dimensions including, savings, investment, trade, labor markets and the private or public provisions of safety networks and, more generally, growth and development.[as] Cultural traits like trust, relationship between family members (including intergenerational generosity), individualism, respect of the rules of laws, propensity to save and in which form, have been widely studied and their relevance for economic behavior is well established. Many of these attitudes are relevant for a society's acceptance of government deficits, including their intergenerational redistributive effects. Also the acceptability of policies geared towards reducing excessive deficits

[as] Guiso et al. (2006) and Alesina and Giuliano (2015) provide surveys of this literature.

may be different in different cultural settings. For instance, Guiso et al. (2015) investigate how cultural differences among Euro area countries may have led to the aggravation of conflict over debt policies and delayed resolutions of the latter. Cultural values certainly affect decisions about tax evasion,[at] another variables which clearly determines the accumulation of debt. While a relatively vast literature studies tax evasion, we are not aware of much work linking it to the accumulation of debt.[au]

The connection between institutions and culture is important (Alesina and Giuliano, 2015; Bisin and Verdier, 2015). The adoption of certain budget institutions may be endogenous to certain cultural traits. Countries more prone to thriftiness (say Germany) may be more likely to adopt certain budget rules and institutions, others may do the opposite. In addition, the rigorous application of certain budget rules (say a balanced budget amendments) may be endogenous to certain cultural traits having to do, for instance with the social acceptability towards "bending the rules," which may vary greatly across countries.[av] Both cross-country and within-country evidence would be useful. The latter could hold constant national institutions and examine the effect of difference cultural attitudes within the same national institutions.

The control of politicians is also a "public good" which may be under supplied in certain cultures, as shown by Nannicini et al. (2012) who develop an intuition by Banfield (1958). When "social capital" is low, people do not feel compelled to participate in political activities, control politicians and punish the latter when they misbehave. In fact, with low social capital individuals may expect private favors rather than public goods. Politicians then feel more free to exert less effort, be self-motivated or corrupt. Less control by voters may also allow powerful lobbies to have easier access to politicians. For instance, Campante and Do (2014) show that more isolated capital cities show more levels of corruption and are associated with a greater role for money in state-level elections. In particular, firms and individuals contribute disproportionately more compared to nonisolated capital cities. Thus, lower social capital may be associated with more political distortions and rent seeking of policymakers which may aggravate the deficit bias problem.

11.3 Delegation

In the case of monetary policy, the benefit of delegation to an independent (up to a point) agency is widely accepted. For fiscal policy this kind of delegation is virtually nonexistent. The question is why and whether some delegation in fiscal policy (and how and to whom) might be useful.

[at] See Richardson (2008).

[au] An exception on Italy is Alesina and Maré (1996) on Italy.

[av] On this point see for instance Guiso et al. (2011), Tabellini (2010), and Guiso et al. (2015).

The fundamental reason why delegation of an independent agency in monetary policy is more acceptable than fiscal policy goes back to where we started in this chapter. Fiscal policy is perceived as much more closely linked to redistributions of various type than monetary policy. In the case of the latter, instead a policy based upon some form of Taylor rule is (at least in normal times) considered as beneficial for society as a whole and redistribution issues may eventually be corrected by fiscal policy (say unemployment benefits during a recession). Alesina and Tabellini (2007) and Alesina et al. (2008) discuss issues of delegation and show results consistent with this argument: delegation is much less agreed upon when it involves redistribution while it is easier to achieve for more technical questions (say the conduct of monetary policy) with less direct distributional consequences.[aw] Blinder (1997) argues that even aspects of fiscal policies may benefit from some delegation. He notes that the benefits of Central Bank independence derived from the technical nature of the task, the long term effects of certain decisions, the desire to delegate to bureaucrats through choices when needed (say creating unemployment to fight inflation and diffuse the blame away from politicians) and the tendency of policymakers to inflate too much, possibly close to elections. This author correctly notes how many of these features apply also to certain fiscal policy decisions, especially in the case of tax policy. During the financial crisis, the close connections between monetary and fiscal policy (immortalized by the dramatic joint appearance of Henry Paulson and Ben Bernanke in front of Congress at the outset of the crisis) also made the sharp distinction between independent central banks and totally "political" governments even more striking and possibly artificial.

An intermediate step which does not imply delegation can be to create an independent fiscal council which examines the fiscal policy of the government and expresses an evaluation in terms of its short and long run effects and its technical problems. In the United States, the Congressional Budget Office with a reputation of skills and independence has this role. In Sweden a highly respected fiscal council issues an influential document every year to review the policy of the Swedish government. In the matter of delegation, even to a Council, probably cultural variables examined above play a role. In countries with high level of trust, delegation is easier and the independence of, say, a fiscal council would be (correctly) believed. This might be precisely the case of Sweden. In countries with low levels of trust (say Italy, Spain, or France), the independence of the council would not be believed, and this skepticism might not be unreasonable. Thus, the status of the council would be compromised and it would be viewed as politically influenced and would lose its legitimacy and its potentially useful role. This is another example of the interaction between institutions and culture discussed earlier. What and how to delegate in the area of fiscal policy remains an excellent topic of research.

[aw] Pettersson-Lidbom (2012) discuss evidence on legislature and bureaucratic relationship as a determinant of the size of government using two natural experiments.

11.4 Lobbyist and Bureaucrats

The role of the bureaucracy in the implementation of the budget is hardly studied by economists.[ax] Highly ranked bureaucrats may have an influence which goes well beyond the implementation of executive decisions. Thus, even without any formal delegation (discussed earlier) highly ranked bureaucrats when applying the fiscal provisions of the budget may have sufficient discretion to favor this or that pressure groups. Up to a point this may be a sort of "unwanted" delegation, that is a delegation which *de facto* but not *de iure* has the bureaucracy gains. This may increase the difficulty in implementing reforms because of a status quo preferences of existing bureaucratic bodies.

Finally, virtually all of the models we have considered model the polity by means of voting. A different view about the political process sees voting in legislatures simply as a result of lobbying pressure and therefore modeling lobbies' behavior is the fundamental step. While a rich literature on lobbies exists (see Grossman and Helpman, 2008), especially with regard to trade issues, we are not aware of lobbying models related to optimal debt management. Lobbyist and bureaucrats may be connected because the former may have access to the latter and may obtain favors in the implementation of various fiscal measures. This is especially the case when budget procedures and prescriptions are sufficiently opaque so as to guarantee a *de facto* discretion of bureaucrats. In turn, this lack of transparency may be strategically preserved precisely to allow for such pressures from lobbyist, with the related gains for policymakers. Linking the lobbying literature to government debt is an excellent topic of research.

11.5 Empirical Work

Much of the politico-economic literature reviewed earlier is theoretical. We think that there are high payoff in empirical research. Probably cross-country regressions have exhausted what they can teach us in most (but necessarily all) cases. Other tools are available. One is of course dynamic general equilibrium models where one could introduce political constraints or distortions and quantify their effects. A good example of this type of empirical work is the paper by Azzimonti et al. (2015) on the balanced budget rule reviewed earlier. At the opposite extreme of methodology one can think of historical case studies which would be especially helped by "natural experiment." For instance, imagine natural experiments which imply institutional changes (or other kind of changes) which can be considered relatively exogenous to fiscal policy. These studies may help address the question of endogeneity emphasized earlier. The use of historical evidence with time period spanning over institutional changes can be especially useful.

Within-country studies can also be helpful. Imagine a situation in which different localities within a country display very different policy stance regarding deficits. These

[ax] See Bertrand et al. (2015) and Gratton et al. (2015) for some recent work on the bureaucracy in India and Italy, respectively.

studies may shed some light on determinants of deficits, holding institutions constant. Evidence on localities is useful for two reasons. One because local public finance is important and interesting per se. Second, because, holding constant national institutions, we can investigate variations in other determinants of deficits. Much of this type of research is on US localities. Thus, there is room for work on other countries.

Another dimension in which progresses could be made is in the disaggregation of fiscal variables. Most of the literature refers to government spending, taxes and debt, without distinguishing within these broad categories. This is true (with few exceptions) both for the macro literature on fiscal policy and for the political economy literature. There is much unexplored territory here.

ACKNOWLEDGMENTS

We thank Marina Azzimonti, Marco Battaglini, Stephen Coate, Casey Mulligan, Per Pettersson-Lindbom, Guido Tabellini, Pierre Yared, Fabrizio Zilibotti. and the editors for very useful conversations and comments on earlier drafts.
