when they manage the physical capital. The households' return differs from that of experts, (4), only in the dividend yield that they earn.

We generalize the model in several other ways. (i) We enable experts to issue some (outside) equity, even though they cannot be 100% equity financed. Specifically, we suppose that experts must retain at least a fraction $\underline{\chi} \in (0,1]$ of equity. (ii) We generalize the model by including a force that prevents experts from "saving their way out" away from the constraints. In particular, we assume that experts could have a higher discount rate ρ than that of households, $\underline{\rho}$. (iii) Equipped with the results derived in Section 3.1 we generalize experts' and households' utility functions from log to CRRA with risk aversion coefficient γ.[f]

To summarize, experts and households maximize, respectively,

$$E\left[\int_0^\infty e^{-\rho t} u(c_t)\right] dt \quad \text{and} \quad E\left[\int_0^\infty e^{-\underline{\rho} t} u(\underline{c}_t)\right] dt.$$

We denote the fraction of capital allocated to experts by $\psi_t \leq 1$ and the fraction of equity retained by experts by $\chi_t \geq \underline{\chi}$.

We want to characterize how any history of shocks $\{Z_s, s \leq t\}$ maps to equilibrium prices q_t and r_t, asset allocations ψ_t and χ_t, and consumption so that (1) all agents maximize utility through optimal consumption and portfolio choices and (2) markets clear. Agents optimize portfolios subject to constraints (no short-selling of capital and a bound on equity issuance by experts). For example, households can invest in capital, the risk-free asset, and experts' equity, and optimize over portfolio weights on these three assets (with a nonnegative weight on capital). Thus, the solution is based on a classic problem in asset pricing. Note also that because the required returns are different between households and experts, the experts' inside equity will generally earn a different return from the equity held by households—experts will earn "management fees" that households do not earn.[g]

[f] Brunnermeier and Sannikov (2014) explicitly consider the case of risk-neutral experts and households. Experts are constrained to consume nonnegative quantities, but households can consume both positive and negative amounts. This assumption leads to the simplification that the risk-free rate in the economy r_t always equals the households' discount rate $\underline{\rho}$.

[g] This is not a universal assumption in the literature. For example, He and Krishnamurthy (2013) assume that returns are equally split between experts and households, so that rationing is required to prevent households from demanding more expert equity than the total supply of expert equity.

3.3 The 4-Step Approach

We can solve for the equilibrium in four steps. First, postulate processes for prices and stochastic discount factor. Second, write down the consumption–portfolio optimization and market-clearing conditions. These conditions imply a stochastic law of motion of the price q_t, the required risk premia for experts and households ς_t and $\underline{\varsigma}_t$, together with variables ψ_t and χ_t. Third, focusing on the experts' balance sheets we write down the law of motion of expert's wealth share

$$\eta_t = \frac{N_t}{q_t K_t},$$

as a percentage of the whole wealth in the economy. As before, K_t is the total amount of capital in the economy. Fourth, we look for a Markov equilibrium, and characterize equations for q_t, ψ_t, etc., as functions of η_t. We solve these equations numerically either as a system of ordinary differential equations (using the shooting method) or as a system of partial differential equations in time, via a procedure analogous to value function iteration in discrete time.

Step 1: Postulating Equilibrium Processes. As before, we postulate the equilibrium prices process for physical capital.

$$\frac{dq_t}{q_t} = \mu_t^q dt + \sigma_t^q dZ_t.$$

Furthermore, as experts and households have different investment opportunities, we postulate two stochastic discount factor (SDF) processes, one for experts and one for households.

$$\frac{d\xi_t}{\xi_t} = -r_t dt - \varsigma_t dZ_t, \quad \text{and} \quad \frac{d\underline{\xi}_t}{\underline{\xi}_t} = -\underline{r}_t dt - \underline{\varsigma}_t dZ_t,$$

respectively.

Step 2: Equilibrium Conditions. Note that since both experts and households can trade the risk-free asset the drift of both SDF processes has to be the same, ie, $\underline{r}_t = r_t$. Moreover, (13) implies the following asset-pricing relationship for capital held by experts:

$$\frac{\frac{a-\iota_t}{q_t} + \Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q - r_t}{\sigma + \sigma_t^q} = \chi_t \varsigma_t + (1-\chi_t)\underline{\varsigma}_t, \tag{21}$$

where χ_t is the inside equity share, ie, the fraction of risk held by experts. The required return on capital held by experts depends on the equilibrium capital structure that experts use. If experts require a higher risk premium than households, then $\chi_t = \underline{\chi}$, ie, experts will issue the maximum equity they can. Thus, we have[h]

$$\chi_t = \underline{\chi} \;\text{ if }\; \varsigma_t > \underline{\varsigma}_t, \quad \text{otherwise} \quad \varsigma_t = \underline{\varsigma}_t.$$

Under this condition, we can replace χ_t with $\underline{\chi}$ in (21).

An asset-pricing relationship for capital held by households is

$$\frac{\frac{a - \iota_t}{q_t} + \Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q - r_t}{\sigma + \sigma_t^q} \leq \underline{\varsigma}_t, \tag{22}$$

with equality if $\psi_t < 1$, ie, households hold capital in positive amounts. Note that households may choose not to hold any capital, and if so, then the Sharpe ratio they would earn from capital could fall below that required by the asset-pricing relationship.

It is useful to combine (21) and (22), eliminating μ_t^q and r_t, to obtain

$$\frac{(a - \underline{a})/q_t}{\sigma + \sigma_t^q} \geq \underline{\chi}(\varsigma_t - \underline{\varsigma}_t), \tag{23}$$

with equality if $\psi_t < 1$.

The required risk premia can be tied to the agents' consumption processes via (35) in the CRRA case and to the agents' net worth processes in the special logarithmic case. Under the baseline risk-neutrality assumptions of Brunnermeier and Sannikov (2014), $\underline{\varsigma} = 0$ when households are risk-neutral and financially unconstrained—ie, they can consume negatively.

We will use these conditions to characterize q_t, ψ_t, χ_t, etc., as functions of η_t. Before we do that, though, we must derive an equation for the law of motion of $\eta_t = N_t/(q_t K_t)$.

Step 3: The Law of Motion of η_t. It is convenient to express the laws of motion of the numerator and denominator of η_t by focusing on risks and risk premia. Specifically, the experts' net worth follows

$$\frac{dN_t}{N_t} = r_t\,dt + \underbrace{\frac{\chi_t \psi_t}{\eta_t}(\sigma + \sigma_t^q)}_{\text{risk}} \big(\underbrace{\varsigma_t}_{\text{risk premium}} dt + dZ_t \big) - \frac{C_t}{N_t}dt.$$

To derive the evolution of $q_t K_t$, note that the capital gains rate is the same for both type of agents. Thus, we can just aggregate the individual laws of motion to an aggregate law of motion. After replacing the term $\Phi(\iota_t) - \delta + \mu_t^q - \sigma\sigma_t^q - r_t$ using (21), we obtain

[h] We can rule out the case that $\varsigma_t < \underline{\varsigma}_t$ and $\chi_t = 1$: experts cannot face lower risk premia than households if households hold zero risk.

$$\frac{d(q_tK_t)}{q_tK_t} = r_t dt + (\sigma + \sigma_t^q)\Big((\underline{\chi}\varsigma_t + (1-\underline{\chi})\underline{\varsigma}_t)dt + dZ_t\Big) - \frac{a-\iota_t}{q_t}dt.$$

This is the total return on capital (eg, that held by experts) minus the dividend yield.

Using the already familiar formula (10) for a ratio of two stochastic processes, we have

$$\frac{d\eta_t}{\eta_t} = \mu_t^\eta dt + \sigma_t^\eta dt \ = \left(\frac{a-\iota_t}{q_t} - \frac{C_t}{N_t}\right)dt + \frac{\chi_t\psi_t - \eta_t}{\eta_t}(\sigma + \sigma_t^q)\big((\varsigma_t - \sigma - \sigma_t^q)dt + dZ_t\big) + \\ (\sigma + \sigma_t^q)(1-\underline{\chi})(\varsigma_t - \underline{\varsigma}_t)dt. \tag{24}$$

Step 4: Converting the Equilibrium Conditions and Laws of Motion (24) into Equations for $q(\eta)$, $\theta(\eta)$, $\psi(\eta)$, $\chi(\eta)$, etc. The procedure to convert the equilibrium conditions and the law of motion of η_t into numerically solvable equations for $q(\eta)$, $\psi(\eta)$, etc., depends on the underlying assumptions on the agents' preferences. (The log-utility case is the easiest to solve.) In each case, we have to use Ito's Lemma, which allows us to replace terms such as $\sigma_t^q, \sigma_t^\theta$, μ_t^q, etc., with expressions containing the derivatives of q and θ, in order to arrive at solvable differential equations for these functions in the end.

For example, using Ito's Lemma we can tie the volatility of q_t with the first derivative of $q(\eta)$ as follows

$$\sigma_t^q q(\eta) = q'(\eta)\underbrace{(\chi_t\psi_t - \eta_t)(\sigma + \sigma_t^q)}_{\eta\sigma_t^\eta}. \tag{25}$$

Rewriting Eq. (25) yields a closed form solution for the amplification mechanism.

Amplification

$$\sigma_t^\eta = \frac{\frac{\chi_t\psi_t}{\eta_t} - 1}{1 - \left[\frac{\chi_t\psi_t}{\eta_t} - 1\right]\frac{q'(\eta_t)}{q(\eta_t)/\eta_t}}\sigma \tag{26}$$

The numerator $\frac{\chi_t\psi_t}{\eta_t} - 1$ captures the leverage ratio of the expert sector. The amplification increases with the leverage ratio, the leverage effect. The denominator captures the "loss spiral." Mathematically, it reflects an infinite geometric series. The impact of the loss spiral increases with the product of the leverage ratio and price elasticity, $\frac{q'}{q/\eta}$. The latter measures "market illiquidity," the percentage price impact due to a percentage decline in η_t. Market illiquidity arises from the technological specialization of capital, measured here by the difference $a - \underline{a}$ between the experts' and households' productivity parameters. Market illiquidity interacts with technological illiquidity, captured by the curvature of $\Phi(\cdot)$.

There are various methods to solve the equilibrium equations. Below, we discuss two methods that have been used in practice. One method involves ordinary differential equations (ODE)—we refer to it as the "shooting method" and illustrate it using the risk-neutral preferences of Brunnermeier and Sannikov (2014). The second method involves partial differential equations, and is reminiscent of value function iteration in discrete time. A third method has been used in the literature by Drechsler et al. (2016) and Moreira and Savov (2016), namely Chebyshev collocation which is a special type of projection method, see Judd (1998), chapter 11 for details. We do not present this method here, because a global polynomial approximation is less suitable for our model whose solutions may have kinks.

3.4 Method 1: The Shooting Method

This method involves converting the equations above into a system of ODEs. Before we dive into this, in order to understand how this can be done, we review a very simple and well-known model to illustrate the gist of what we have to do. The model illustrates the pricing of a perpetual American put.

Example of Perputual American Put a la Leland (1994)

Consider the problem of pricing a perpetual option to abandon an asset for an amount K. Given a risk-free rate of r and volatility σ, if the asset pays no dividends, its value follows a geometric Brownian motion

$$\frac{dV_t}{V_t} = r\,dt + \sigma\,dZ_t \tag{27}$$

under the risk-neutral measure.

Under the risk-neutral measure, the expected return of any security must be r. Thus, if the put value P_t follows $dP_t = \mu_t^P P_t\,dt + \sigma_t^P P_t\,dZ_t$, then we must have

$$r = \mu_t^P. \tag{28}$$

Suppose we would like to calculate how the put value P_t depends on the value of the assets V_t. Then we face a problem that is completely analogous to the model with financial frictions we described in this section. We have a law of motion of the state variable V_t and a relationship (28) that the stochastic evolution of P_t has to satisfy, and we would like to characterize P_t as a function of V_t.

How can we do this? Easy. Using Ito's Lemma

$$\mu_t^P P_t = rV_t P'(V_t) + \frac{1}{2}\sigma^2 V_t^2 P''(V_t),$$

and so (28) becomes

$$r = \frac{rVP'(V) + \frac{1}{2}\sigma^2 V^2 P''(V)}{P(V)}. \tag{29}$$

If function $P(V)$ satisfies this equation, then the process $P_t = P(V_t)$ will satisfy (28). We are able to go from an equation like (28) to a differential Eq. (29) by assuming that the value of the put is a *function* of the value of the asset.

We can solve the second-order ordinary differential equation (ODE) (29) if we have two boundary conditions. We have $P(V) \to 0$ as $V \to \infty$ since the put becomes worthless if it is never exercised. We also have $P(V) - (K - V) \geq 0$, since $P(V)$ must equal the intrinsic value at the point where the put is exercised.

Our problem is similar: we have an equation for the stochastic law of motion of the state variable (24), as well as the equilibrium conditions that processes $q(\eta_t)$, $\psi(\eta_t)$, etc., must satisfy. Certainly, the equations are more complicated than those of the put-pricing problem, and the law of motion of η_t is endogenous. However, the mechanics of solving these equations is the same—we have to use Ito's Lemma.

Here, we illustrate the derivation of an appropriate set of ordinary differential equations, as well as the "shooting" method for solving them, using the risk-neutral model of Brunnermeier and Sannikov (2014). Assume that experts and households are risk neutral, and while experts must consume nonnegatively, households can have both positive and negative consumption. Then the required risk premium of households is $\underline{\varsigma}_t = 0$. The required risk premium of experts is $-\sigma_t^\theta$, where θ_t is the marginal utility of the experts' wealth that follows

$$\frac{d\theta_t}{\theta_t} = \mu_t^\theta dt + \sigma_t^\theta dZ_t.$$

We would like to construct differential equations to solve for the functions $q(\eta)$, $\theta(\eta)$ and $\psi(\eta)$. The equations will be of second order in $q(\eta)$ and $\theta(\eta)$, ie, we will design a procedure to compute $q''(\eta)$ and $\theta''(\eta)$, as well as $\psi(\eta)$, from η, $q(\eta)$, $q'(\eta)$ and $\theta(\eta)$, $\theta'(\eta)$. Note also that, since households demand no risk premium, ie, $\underline{\varsigma}_t = 0$, experts will issue the maximum allowed fraction of equity to households, so $\chi_t = \underline{\chi}$ at all times.

In this case $q(\eta)$ is an increasing function that satisfies the boundary condition

$$q(0) = \max_{\iota} \frac{\underline{a} - \iota}{r - \Phi(\iota) + \delta},$$

the Gordon growth formula for the value of capital when it is permanently managed by households. Any expert can get infinite utility if he can buy capital at the price of $q(0)$, so

$$\lim_{\eta \to 0} \theta(\eta) = \infty. \tag{30}$$

Function $\theta(\eta)$ is decreasing: the marginal value of the experts' net worth is declining as η rises, and investment opportunities become less valuable. Experts refrain from consumption whenever $\theta(\eta) > 1,$ and consume only at point η^* where $\theta(\eta^*) = 1$, ie, the marginal value of the experts' net worth is exactly 1. That point becomes the reflecting boundary of the system. That is, the system does not go beyond the reflecting boundary and is rather thrown back. In addition, at the reflecting boundary η^* functions $q(\eta)$ and $\theta(\eta)$ must satisfy

$$q'(\eta^*) = \theta'(\eta^*) = 0.$$

Now to the differential equations. Eq. (25) implies that

$$\sigma + \sigma_t^q = \frac{\sigma}{1 - \frac{q'(\eta)}{q(\eta)}(\underline{\chi}\psi_t - \eta_t)}, \tag{31}$$

and by Ito's Lemma,

$$\sigma_t^\theta = \frac{\theta'(\eta)}{\theta(\eta)} \frac{(\underline{\chi}\psi_t - \eta_t)\sigma}{1 - \frac{q'(\eta)}{q(\eta)}(\underline{\chi}\psi_t - \eta_t)}. \tag{32}$$

Therefore, plugging these expressions into the asset-pricing Eq. (23), we obtain

$$\frac{a - \underline{a}}{q(\eta)} \geq -\underline{\chi}\frac{\theta'(\eta)}{\theta(\eta)} \frac{(\underline{\chi}\psi - \eta)\sigma^2}{\left(1 - \frac{q'(\eta)}{q(\eta)}(\underline{\chi}\psi - \eta)\right)^2}. \tag{33}$$

Assuming that $q'(\eta) > 0$ and $\theta'(\eta) < 0$, the right-hand side is increasing from 0 to ∞ as $\underline{\chi}\psi - \eta$ rises from 0 to $q(\eta)/q'(\eta)$. Thus, we have to set $\psi = 1$ whenever it is possible to do so (ie, $\underline{\chi} - \eta < q(\eta)/q'(\eta)$) and this is consistent with inequality (33). Otherwise we determine ψ by solving the quadratic Eq. (33), in which we replace the $\geq$ sign with equality.

After that, we can find σ_t^q from (31), σ_t^θ from (32), μ_t^η and σ_t^η from (24) (where we set $C_t = 0$ since experts consume only at the boundary η^*), μ_t^q from the asset-pricing condition

$$\frac{a - \iota_t}{q_t} + \Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q - r = \underline{\chi}(\sigma + \sigma_t^q)(-\sigma_t^\theta),$$

μ_t^θ from the pricing condition for the risk-free asset

$$\mu_t^\theta = \rho - r,$$

and $q''(\eta)$ as well as $\theta''(\eta)$ from Ito's formula,

$$\mu_t^q q(\eta) = \mu_t^\eta \eta q'(\eta) + \frac{1}{2}(\sigma_t^\eta)^2 \eta^2 q''(\eta) \quad \text{and} \quad \mu_t^\theta \theta(\eta) = \mu_t^\eta \eta \theta'(\eta) + \frac{1}{2}(\sigma_t^\eta)^2 \eta^2 \theta''(\eta).$$

3.4.1 Solving the System of ODEs Numerically

We can use an ODE solver in Matlab, such as ode45, to solve the system of equations. We need to perform a search, since our boundary conditions are defined at two endpoints of $[0, \eta^*]$, and we also need to deal with a singularity at $\eta = 0$. The following algorithm performs an appropriate search and deals with the singularity issue, effectively, by solving the system of equations with the boundary condition $\theta(0) = M$, for a large constant M, instead of (30):[i]

Algorithm Set

$$q(0) = \max_{\iota} \frac{\underline{a} - \iota}{r - \Phi(\iota) + \underline{\delta}}, \quad \theta(0) = 1 \quad \text{and} \quad \theta'(0) = -10^{10}.$$

Perform the following procedure to find an appropriate boundary condition $q'(0)$. Set $q_L = 0$ and $q_H = 10^{15}$. Repeat the following loop 50 ×. Guess $q'(0) = (q_L + q_H)/2$. Use Matlab function ode45 to solve for $q(\eta)$ and $\theta(\eta)$ on the interval [0, ?) until one of the following events is triggered, either (1) $q(\eta)$ reaches the upper bound

$$q\mathrm{max} = \max_{\iota} \frac{a - \iota}{r - \Phi(\iota) + \delta},$$

(2) the slope $\theta'(\eta)$ reaches 0 or (3) the slope $q'(\eta)$ reaches 0. If integration has terminated for reason (3), we need to increase the initial guess of $q'(0)$ by setting $q_L = q'(0)$. Otherwise, we decrease the initial guess of $q'(0)$, by setting $q_H = q'(0)$.

At the end, $\theta'(0)$ and $q'(0)$ reach 0 at about the same point, which we denote by η^*. Divide the entire function θ by $\theta(\eta^*)$.[j] Then plot the solutions.

3.4.2 Properties of the Solution

Let us interpret the solution of the risk-neutral model. Point η^* plays the role of the steady state of our system. The drift of η_t is positive everywhere on the interval $[0, \eta^*)$, because the expert sector, which is more productive than the household sector, is growing in expectation. Thus, the system is pushed toward η^* by the drift.

It turns out that the steady state is relatively stable, because volatility is low near η^*. To see this, recall that the amount of endogenous risk in asset prices, from (25), is given by

$$\sigma_t^q = \frac{q'(\eta)}{q(\eta)} \frac{(\underline{\chi}\psi_t - \eta_t)}{1 - \dfrac{q'(\eta)}{q(\eta)}(\underline{\chi}\psi_t - \eta_t)} \sigma.$$

From the boundary conditions, $q'(\eta^*) = 0$, so there is no endogenous risk near η^*.

[i] Footnote j explains why it actually does not to matter what exact value one sets for $\theta(0)$.

[j] We can do this because whenever functions θ and q satisfy our system of equation, so do functions $\Theta\theta$ and q for any constant Θ. Because of that, also, it is immaterial what we set $\theta(0)$ to 1.

However, below η^*, endogenous risk increases as $q'(\eta)$ becomes larger. As prices react to shocks, fundamental risk becomes amplified. As we see from the expression for σ_t^q, this amplification effect is nonlinear, since $q'(\eta)$ enters not only the numerator, but also the denominator. This happens due to the feedback effect: an initial shock causes η_t to drop, which leads to a drop in q_t, which hurts experts who are holding capital and leads to a further decrease in η_t, and so on.

Of course, far in the depressed region the volatility of η_t, $\sigma_t^\eta \eta_t$, becomes low again in this model. This leads to a bimodal stationary distribution of η_t in equilibrium.[k]

Volatility paradox refers to the phenomenon that systemic risk can build up in quiet environments. We can illustrate this phenomenon through comparative statics on σ or the degree of the experts' equity constraint $\underline{\chi}$. One may guess that the system becomes much more stable as σ or $\underline{\chi}$ decline.

This is not the case, as illustrated in Fig. 3 for parameters $\rho = 6\%$, $r = 5\%$, $a = 11\%$, $\underline{a} = 5\%$, $\delta = 3\%$, and an investment function of the form $\Phi(\iota) = \frac{1}{\kappa}(\sqrt{1+2\kappa\iota} - 1)$, $\kappa = 10$,

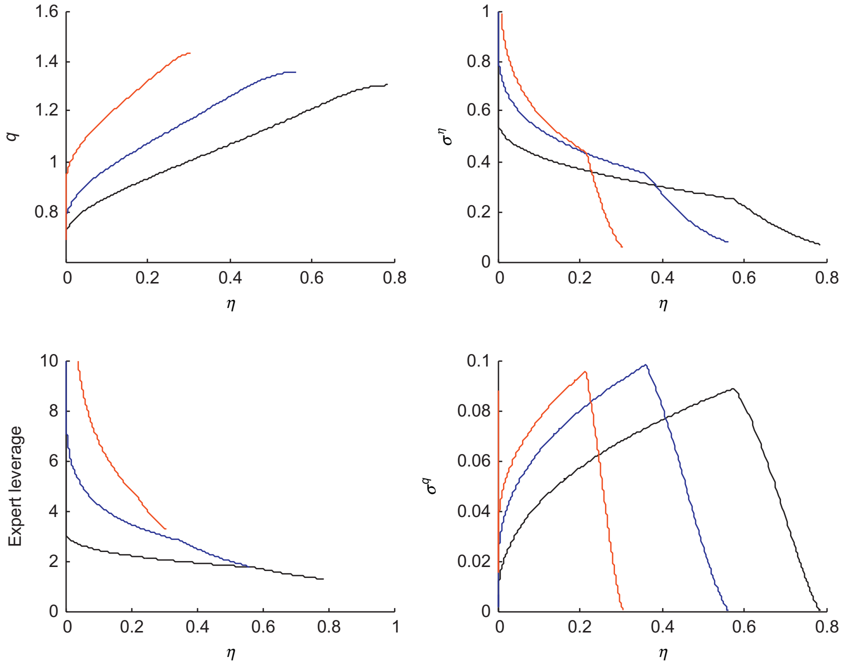

Fig. 3 Equilibrium with $\sigma = 2.5\%$ (red), 10% (blue), and 25% (black). (In the printed version red is grey and blue is dark grey.)

[k] One can prove that the stationary distribution is bimodal analytically by analyzing the asymptotic properties of the solutions near $\eta = 0$ and using the Kolmogorov forward equations that characterize the stationary density—see Brunnermeier and Sannikov (2014) for details.

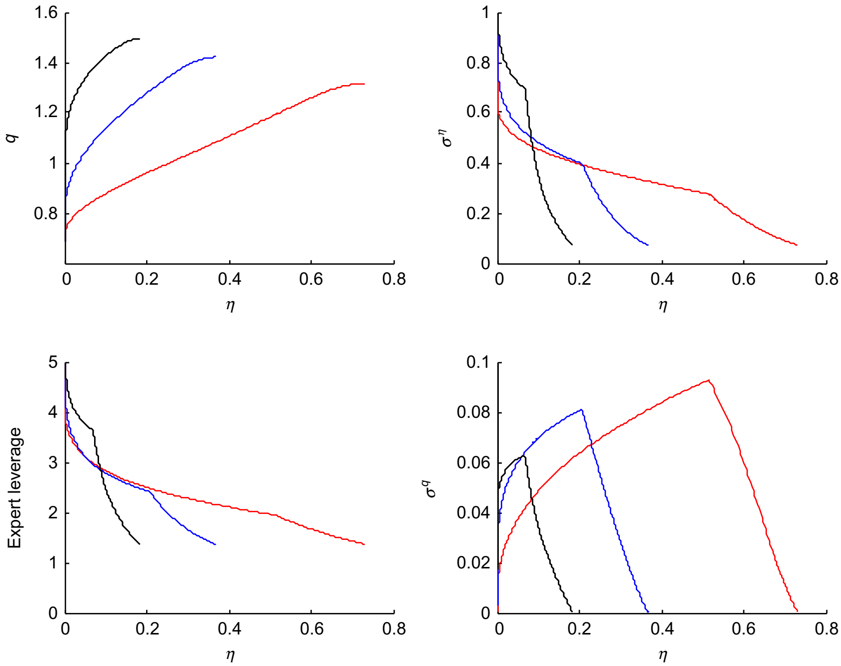

Fig. 4 Equilibrium with $\underline{\chi} = 0.25$ (black), 0.5 (blue) and 1 (red). (In the printed version blue is gray and red light gray.)

$\underline{\chi} = 1$, and various values of σ. (The investment technology in this example has quadratic adjustment costs: an investment of $\Phi + \kappa\Phi^2/2$ generates new capital at rate Φ.)

The volatility paradox shows itself in a number of metrics. As exogenous risk declines,

- maximal endogenous risk σ_t^q may increase (as σ drops from 25% to 10% in Fig. 3)
- the volatility σ_t^η near $\eta = 0$ rises (and this result can be proved analytically)
- from the steady state η^* it takes less time for volatility $\sigma + \sigma_t^q$ to double
- from the steady state, it may take less time to reach the peak of the crisis η^ψ, where experts start selling capital to households.[1]

Fig. 4 takes the same parameters and $\sigma = 20\%$, but varies $\underline{\chi}$. As $\underline{\chi}$ falls, expert net worth at the steady state η^* drops significantly, and the volatility σ_t^η in the crisis regime rises.

3.5 Method 2: The Iterative Method

Here, we describe the iterative method of finding the equilibrium, by solving a system of partial differential equations back in time away from a terminal condition. Specifically, imagine an economy that lasts for a finite time horizon $[0, T]$. Given a set of terminal conditions at time T, we would like to compute the equilibrium over the time horizon

[1] As σ declines, the system spends less time in the crisis region, so some measures of stability improve, but the amount of time spent in crisis does not converge to 0 as $\sigma \rightarrow 0$.

$[0, T]$. The iterative method is based on the premise that as we let $T \to \infty$, behavior at time 0 should converge to the equilibrium of the infinite-horizon economy. Computation uses the equilibrium conditions that express the drifts of various processes, and uses those drifts to obtain time derivatives for the corresponding functions of the state space. The iterative method is analogous to value function iteration in discrete time.

We illustrate the method here based on a model with CRRA utility

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma}.$$

Equilibrium conditions (21) and (19) provide two equations that express the drift of the price q_t, as well as the drifts of aggregate consumption of experts C_t and households $\underline{C}_t$. We also have another asset-pricing condition (23), which does not contain any drift terms. In the end we have three functions but only two drift conditions. As a result, the time dimension of our computation involves only two functions—the value functions of experts and households—and the third function, the price, is found for each time point through a separate procedure.[m]

Our procedure is literally the analogue of value function iteration (but with multiple agents affecting the evolving stochastic state). It is convenient to derive directly the equations that value functions must satisfy. The value functions of experts and households can be presented in the form

$$v_t \frac{K_t^{1-\gamma}}{1-\gamma} = \frac{v_t}{(\eta_t q_t)^{1-\gamma}} \frac{N_t^{1-\gamma}}{1-\gamma} \quad \text{and} \quad \underline{v}_t \frac{K_t^{1-\gamma}}{1-\gamma}.$$

Since the marginal utilities of consumption and wealth must be the same, we have

$$C_t^{-\gamma} = \frac{v_t}{(\eta_t q_t)^{1-\gamma}} N_t^{-\gamma} = \frac{v_t}{\eta_t q_t} K_t^{-\gamma} \quad \Rightarrow \quad C_t = N_t \frac{(\eta_t q_t)^{1/\gamma - 1}}{v_t^{1/\gamma}} = K_t \frac{(\eta_t q_t)^{1/\gamma}}{v_t^{1/\gamma}}. \tag{34}$$

Hence, the risk premia of households and experts are given by

$$\varsigma_t = \gamma \sigma_t^C = -\sigma_t^v + \sigma_t^\eta + \sigma_t^q + \gamma\sigma \quad \text{and} \quad \underline{\varsigma}_t = \gamma \sigma_t^{\underline{C}} = -\sigma_t^{\underline{v}} - \frac{\eta \sigma_t^\eta}{1-\eta} + \sigma_t^q + \gamma\sigma. \tag{35}$$

Since

$$\underbrace{\int_0^t e^{-\rho s} \frac{C_s^{1-\gamma}}{1-\gamma} ds}_{\text{utility flow}} + e^{-\rho t} \underbrace{v_t \frac{K_t^{1-\gamma}}{1-\gamma}}_{\text{continuation utility}}$$

[m] If we used the shooting method to find the equilibrium with CRRA utilities, we would have a system of second-order differential equations for the value functions, and a first-order differential equation for the price.

is by standard dynamic programming arguments a martingale and

$$\frac{d(K_t^{1-\gamma})}{K_t^{1-\gamma}} = \left((1-\gamma)(\Phi(\iota_t)-\delta) - \frac{\gamma(1-\gamma)}{2}\sigma^2\right)dt + (1-\gamma)\sigma dZ_t,$$

we have

$$\frac{C_t^{1-\gamma}}{1-\gamma} - \rho v_t \frac{K_t^{1-\gamma}}{1-\gamma} + v_t \frac{K_t^{1-\gamma}}{1-\gamma}\left(\mu_t^v + (1-\gamma)(\Phi(\iota_t)-\delta) - \frac{\gamma(1-\gamma)}{2}\sigma^2 + \sigma_t^v(1-\gamma)\sigma\right) = 0.$$

Using (34), we obtain

$$\mu_t^v = \rho - \frac{(\eta_t q_t)^{1/\gamma-1}}{v_t^{1/\gamma}} - (1-\gamma)(\Phi(\iota_t)-\delta) + \frac{\gamma(1-\gamma)}{2}\sigma^2 - \sigma_t^v(1-\gamma)\sigma. \tag{36}$$

Likewise,

$$\mu_t^{\underline{v}} = \underline{\rho} - \frac{((1-\eta_t)q_t)^{1/\gamma-1}}{\underline{v}_t^{1/\gamma}} - (1-\gamma)(\Phi(\iota_t)-\delta) + \frac{\gamma(1-\gamma)}{2}\sigma^2 - \sigma_t^{\underline{v}}(1-\gamma)\sigma. \tag{37}$$

Given μ_t^v and $\mu_t^{\underline{v}}$, we obtain partial differential equations for the functions $v(\eta, t)$ and $\underline{v}(\eta, t)$ using Ito's Lemma, and they are as follows:

$$\mu_t^v v(\eta,t) = \mu_t^\eta \eta v_\eta(\eta,t) + \frac{(\sigma_t^\eta \eta)^2}{2} v_{\eta\eta}(\eta,t) + v_t(\eta,t) \quad \text{and} \tag{38}$$

$$\mu_t^{\underline{v}} \underline{v}(\eta,t) = \mu_t^\eta \eta \underline{v}_\eta(\eta,t) + \frac{(\sigma_t^\eta \eta)^2}{2} \underline{v}_{\eta\eta}(\eta,t) + \underline{v}_t(\eta,t). \tag{39}$$

3.5.1 Description of the Procedure

Below we outline the procedure of how we solve for the equilibrium using Eqs. (38) and (39).[n] There are three parts.

- The terminal conditions $v(\eta, T)$ and $\underline{v}(\eta, T)$
- The static step: finding capital price $q(\eta)$, allocations $\psi(\eta)$ and $\chi(\eta)$, volatilities and drifts at a given time point t given the value functions $v(\eta, t)$ and $\underline{v}(\eta, t)$, and
- The time step: finding $v(\eta, t - \Delta t)$ and $\underline{v}(\eta, t - \Delta t)$ from prices, allocations, volatilities and drifts at time t.

[n] For more details on the finite difference method for dynamic programming problems we refer to Candler (1999). Oberman (2006) provides sufficient conditions for a numerical scheme to converge to the solution of a general class of non-linear parabolic Partial Differential Equations.

3.5.1.1 The Terminal Conditions

Our terminal conditions specify the utilities of the representative expert and household, as functions of the experts' wealth share η_t. We have not performed a detailed theoretical study of acceptable terminal conditions, but in practice any reasonable guess works well for a wide range of parameters.

For example, if we set $q_T = 1$ and $C_T/K_T = a\eta_T$, then (34) implies that

$$v_T = \eta_T (a\eta_T)^{-\gamma} \quad \text{and} \quad \underline{v}_T = (1-\eta_T)(a(1-\eta_T))^{-\gamma}. \tag{40}$$

3.5.1.2 The Static Step

Suppose we know value functions through $v(\eta, t)$ and $\underline{v}(\eta, t)$. Let us describe how we can compute the price q_t and characterize equilibrium dynamics at time t.

There are three regions. When η is close enough to 0, then the experts' risk premia are so much higher than those of households that $\psi_t < 1$, ie, households hold capital, and Eq. (23) holds. In this region experts issue the maximal allowed equity share to households, so $\chi_t = \underline{\chi}$, since the households' risk premia are lower. In the middle region, $\psi_t = 1$, ie, only experts hold capital, but the experts' risk premia are still higher than those of households so $\chi_t = \underline{\chi}$. Finally, when $\eta \geq \underline{\chi}$, the capital is allocated efficiently to experts (ie, $\psi_t = 1$) and risk can be shared perfectly between households and experts by setting $\chi_t = \eta_t$. In the last region, (26) implies that $\sigma^\eta = 0$, so there is no endogenous risk, and risk premia of experts and households are both equal to $\varsigma_t = \underline{\varsigma}_t = \gamma\sigma$ by (35).

In the region where $\psi_t < 1$ we solve for $q(\eta)$, $\psi(\eta)$ and $\sigma + \sigma_t^q$ from a system of the following three equations, which ultimately gives us a first-order ODE in $q(\eta)$. We obtain the first by combining (23) and (35) together with evolution of η Eq. (24), we have

$$\frac{a - \underline{a}}{q_t} = \underline{\chi} \underbrace{\left(\frac{\underline{v}'(\eta)}{\underline{v}(\eta)} - \frac{v'(\eta)}{v(\eta)} + \frac{1}{\eta(1-\eta)}\right)(\underline{\chi}\psi_t - \eta)(\sigma + \sigma_t^q)^2}_{\left(\sigma_t^{\underline{v}} - \sigma_t^v + \frac{\sigma_t^\eta}{1-\eta}\right)(\sigma + \sigma_t^q)}. \tag{41}$$

The second we obtain from (25) and Ito's Lemma,

$$(\sigma + \sigma^q)\left(1 - (\underline{\chi}\psi - \eta)\frac{q'(\eta)}{q(\eta)}\right) = \sigma. \tag{42}$$

Finally, from (34) and an analogous condition for households, the market-clearing condition for output is

$$\underbrace{\frac{(\eta_t q_t)^{1/\gamma}}{v_t^{1/\gamma}} + \frac{((1-\eta_t)q_t)^{1/\gamma}}{\underline{v}_t^{1/\gamma}}}_{(C_t + \underline{C}_t)/K_t} = a\psi + \underline{a}(1-\psi) - \iota(q(\eta)). \tag{43}$$

Once ψ_t reaches 1, condition (41) is no longer relevant. From then on, we set $\psi_t = 1$, find $q(\eta)$ from (43) and $\sigma + \sigma_t^q$ from (42). Once η_t reaches $\underline{\chi}$, we enter the last region. There we set $\psi_t = 1, \chi_t = \eta_t,$ compute $q(\eta)$ from (43) and set $\sigma_t^q = 0$.

Once we know function $q(\eta)$ in all three regions, we can find the volatility of η_t from (24) and the volatilities of v_t and $\underline{v}_t$ from Ito's Lemma, ie,

$$\sigma_t^\eta = \frac{\chi_t \psi_t - \eta_t}{\eta_t}(\sigma + \sigma_t^q), \quad \sigma_t^v = \frac{v'(\eta)}{v(\eta)}\sigma_t^\eta \eta, \quad \text{and} \quad \sigma_t^{\underline{v}} = \frac{\underline{v}'(\eta)}{\underline{v}(\eta)}\sigma_t^\eta \eta. \tag{44}$$

We find the required risk premia ς_t and $\underline{\varsigma}_t$ from (35) and the drift of η_t from (24), ie,

$$\mu_t^\eta = \left(\frac{a - \iota_t}{q_t} - \frac{(\eta_t q_t)^{1/\gamma - 1}}{v_t^{1/\gamma}}\right) + \sigma_t^\eta(\varsigma_t - \sigma - \sigma_t^q) + (\sigma + \sigma_t^q)(1 - \underline{\chi})\left(\varsigma_t - \underline{\varsigma}_t\right).$$

Finally, we solve for the drifts of v_t and $\underline{v}_t$ from (36).

3.5.1.3 The Time Step

Once we have all characteristics of the equilibrium at a given time point t, we can solve for the value functions at an earlier time step $t - \Delta t$ from Eqs. (38) and (39). These are parabolic equations, which can be solved using either explicit or implicit methods.

3.5.1.4 Summary

Set terminal conditions for value functions $v(\eta, T)$ and $\underline{v}(\eta, T)$ according to (40) on a grid over η. Divide the interval $[0, T]$ into small subintervals. Going backwards in time, for each subinterval $[t - \Delta t, t]$ perform the static step and then the time step. That is, from value functions $v(\eta, t)$ and $\underline{v}(\eta, t)$ find the drift and volatility of η as well as the drifts of v and $\underline{v}$ using the following procedure (static step). Start from an initial condition near $(\eta = 0, \psi = 0)$ (perturb the condition to avoid division by 0). Solve (41), (42), and (43) (as a first-order ordinary differential equation for $q(\eta)$) until ψ reaches 1. Then set $\psi = 1$ and use (43) to find $q(\eta)$ and (42) to find σ^q. Throughout, use $\chi_t = \max(\underline{\chi}, \eta)$. With functions (of η) q, σ^q, ψ and χ obtained in this way, compute volatilities from (44), ς_t and $\underline{\varsigma}_t$ from (35), μ_t^η from (24), and the drifts of v_t and $\underline{v}_t$ from (36). Then (this is the time step) solve the partial differential Eqs. (38) and (39) for v and $\underline{v}$ backward in time over the interval $[t - \Delta t, t]$, using fixed functions $\mu_t^v, \mu_t^{\underline{v}}, \mu_t^\eta$ and σ_t^η of η computed by the static step. Continue until time 0. We get convergence when T is sufficiently large.

Remark The static step alone is sufficient to solve for the equilibrium prices, allocations and dynamics in a model with logarithmic utility (ie, $\gamma = 1$), since in this case we know that $(C_t + \underline{C}_t)/(q_t K_t) = \rho\eta + \underline{\rho}(1 - \eta)$ and expert and household risk premia are $\varsigma_t = \sigma_t^N = \chi_t \psi_t / \eta_t (\sigma + \sigma_t^q)$ and $\underline{\varsigma}_t = (1 - \chi_t \psi_t)/(1 - \eta_t)(\sigma + \sigma_t^q)$. Hence, Eqs. (41) and (43) become

$$\frac{a-\underline{a}}{q_t}=\chi\frac{\underline{\chi}\Psi_t-\eta}{\underline{\ }\eta(1-\eta)}(\sigma+\sigma_t^q)^2 \quad \text{and} \quad (\rho\eta+\underline{\rho}(1-\eta))q_t=a\psi+\underline{a}(1-\psi)-\iota(q(\eta)). \qquad (45)$$

Eq. (42) remains the same.

For logarithmic utility, however, we do not immediately obtain the agents' value functions. Those can be found using an extra step.

3.6 Examples of Solutions: CRRA Utility

In this section, we illustrate solutions generated by our code, using the iterative method, and what we learn from them. We use baseline parameters $\rho = 6\%$, $r = 5\%$, $a = 11\%$, $\underline{a}=3\%$, $\delta = 5\%$, $\sigma = 10\%$, $\underline{\chi}=0.5$, $\gamma = 2$ and an investment function of the form $\Phi(\iota)=\log(\kappa\iota+1)/\kappa$ with $\kappa = 10$. We then study how several parameters, specifically $\underline{a}$, σ, $\underline{\chi}$ and γ affect the equilibrium.

Fig. 5 illustrates the equilibrium for the baseline set of parameters. Notice that capital price q_t has a kink—the kink separates the crisis region near $\eta=0$ where $\psi_t<1$, ie, households hold some capital, and the normal region where experts hold all capital in the economy.

Here, point η^* where the drift of η_t becomes 0 plays the role of a steady state of the system. In the absence of shocks, the system stays still at the steady state and in response to small shocks, drift pushes the system back to the steady state. Moving away from the crisis regime, at η^* risk premia decline sufficiently so that the experts' earnings are exactly offset by their slightly higher consumption rates.

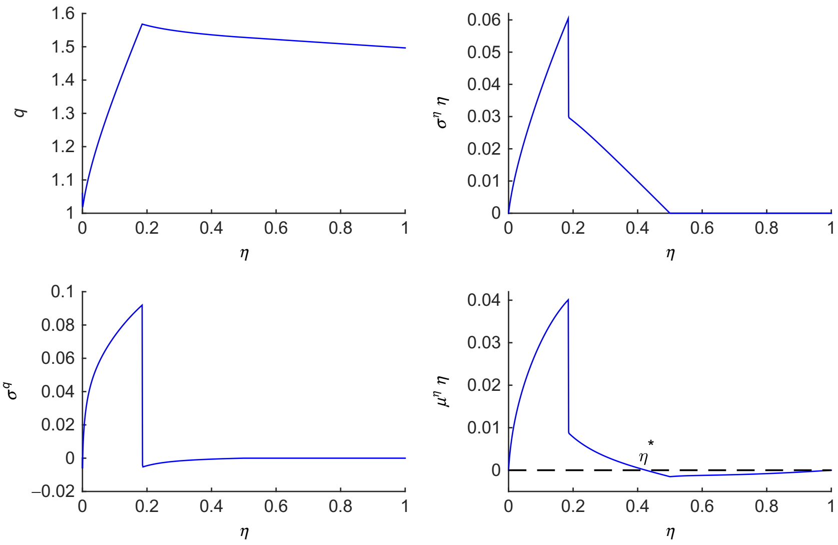

Fig. 5 Equilibrium for the baseline set of parameters.

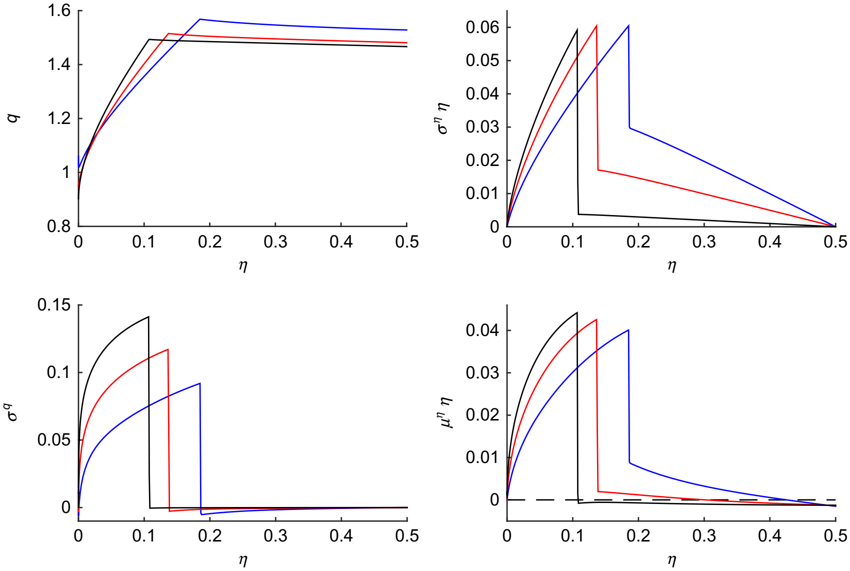

Fig. 6 Equilibrium for $\sigma = 0.01$ (black), 0.05 (red), 0.1 (blue). (In the printed version red is gray and blue is dark gray.)

Above $\eta = \underline{\chi} = 0.5$ is the region of perfect risk sharing, where the volatility of η is zero. Since the drift in that region is negative, the system never ends up there (and if the initial condition is $\eta_0 > \underline{\chi}$, then η_t drifts deterministically down to $\underline{\chi}$).

Fig. 6 shows the effect of σ on the equilibrium dynamics. We bound the horizontal axis at $\eta = \underline{\chi} = 0.5$, since the system never enters the region $\eta > \underline{\chi}$. The steady state η^* declines as σ falls, as risk premia decline in the normal regime, until η^* coincides with the boundary of the crisis region for low σ (this happens for $\sigma = 0.01$ in Fig. 6). We also observe the volatility paradox: as σ declines, endogenous risk σ_t^q does not have to fall, and may even rise.

But what happens as $\sigma \to 0$? Does endogenous risk disappear altogether, and does the solution converge to first best? The answer turns out to be no: in the limit as $\sigma \to 0$, the boundary of the crisis region η^ψ converges not to 0 but to a finite number.

Likewise, what happens if financial frictions become relaxed, and experts are able to hold capital while retaining a smaller portion of risk? It is tempting to conjecture that as financial frictions become relaxed, the system becomes more stable. Yet, as the bottom left panel of Fig. 7 demonstrates, endogenous risk σ_t^q rises sharply as $\underline{\chi}$ declines.[o]

It turns out that a crucial parameter that affects system stability is the household productivity parameter $\underline{a}$. The level of endogenous risk in crises depends strongly on the

[o] Of course, there is a discontinuity at both $\sigma = 0$ and $\underline{\chi} = 0$. As financial frictions disappear altogether, the crisis region disappears.

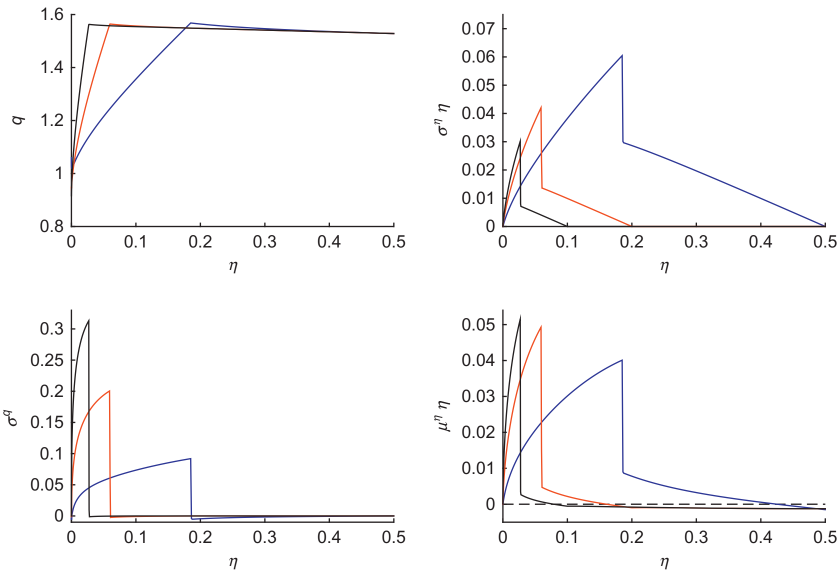

Fig. 7 Equilibrium for $\underline{\chi} = 0.1$ (black), 0.2 (red), and 0.5 (blue). (In the printed version red is gray and blue dark gray.)

market illiquidity of capital—the difference between parameter a and $\underline{a}$ that determines how much less households value capital, in the event that they have to buy it, relative to experts. Fig. 8 illustrates the equilibrium for several values of $\underline{a}$. Note that endogenous risk in crises rises sharply as $\underline{a}$ drops. However, the dynamics in the normal regime and the level of η^* have extremely low sensitivity to $\underline{a}$—only dynamics in the crisis regime are extremely sensitive. This is a surprise. While expert leverage responds endogenously to fundamental risk σ in the normal regime it does not respond strongly to endogenous tail risk. In fact, for logarithmic utility it is possible to prove analytically that the dynamics in the normal regime do not depend on $\underline{a}$ at all (but here we illustrate the dynamics for $\gamma = 2$).

Finally, let us consider risk aversion γ in Fig. 9. There are several effects. Lower risk aversion leads to a smaller crisis region (but with greater endogenous risk), and lower steady state η^* as the risk premia become lower. In this example, higher risk aversion leads to a higher price of capital, as risk creates a precautionary savings demand.

4. A SIMPLE MONETARY MODEL

So far we focused on a real model with a single risky asset, physical capital, and a risk-free asset. Now, building on Brunnermeier and Sannikov's (2015a) "I Theory of Money" we introduce instead of the (real) risk-free asset, another asset, money. In general, money has three roles: it is a unit of account, it facilitates transactions, and it serves as a store of value (safe asset). Here, we focus on its role as a store of value, which arises in our setting due to

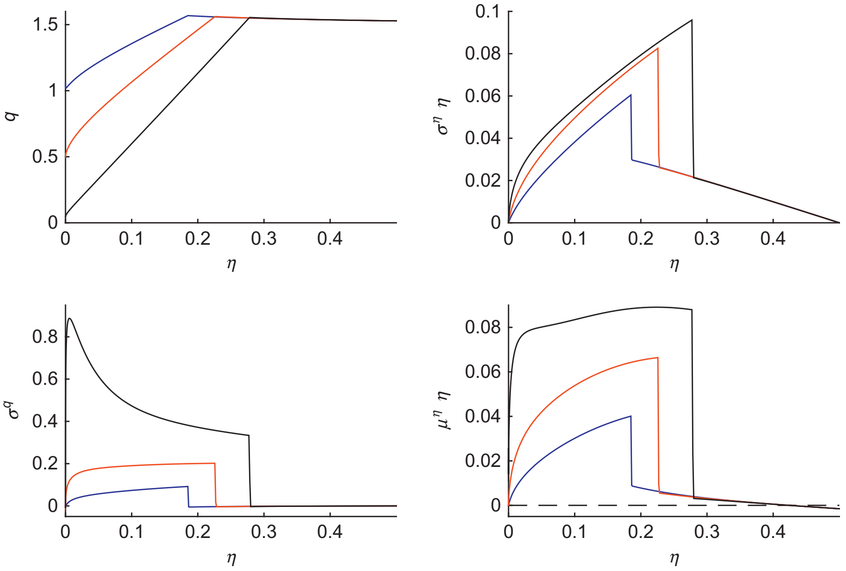

Fig. 8 Equilibrium for $\underline{a} = 0.03$ (blue), -0.03 (red), and -0.09 (black). (In the printed version blue is dark grey and red is gray.)

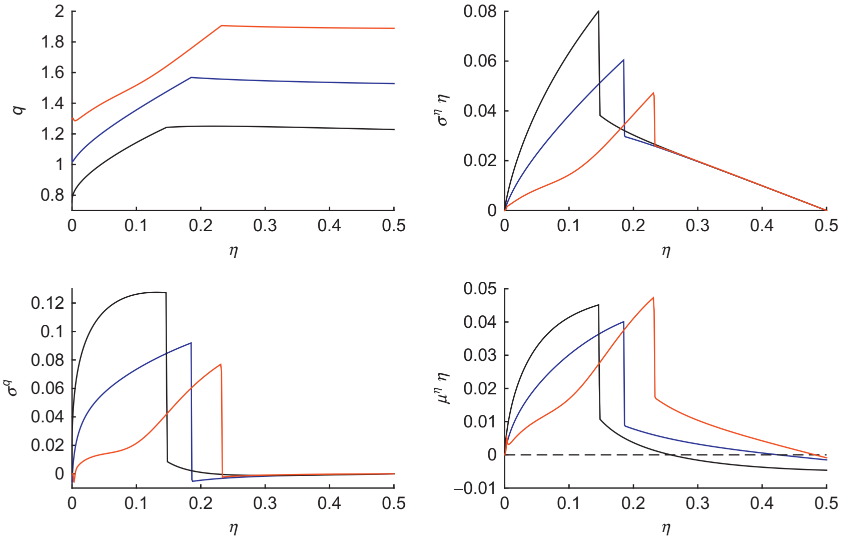

Fig. 9 Equilibrium for $\gamma = 0.5$ (black), 2 (blue), and 5 (red). (In the printed version blue is dark gray and red is gray.)

incomplete markets frictions. Unlike in New Keynesian models, which focus on the role of money as a unit of account and rely on price and wage rigidities as the key frictions, prices are fully flexible in our model.

This section focuses on the following:

1. Money can have positive value despite the fact that it never pays any dividend. That is, money is a bubble.
2. Money helps agents to share risks in an economy that is plagued by financial frictions. Hence, having a nominal store of value instead of a real short-term risk-free bond alters the equilibrium risk dynamics.
3. The "*paradox of prudence*" coined in Brunnermeier and Sannikov (2015a) arises. Experts hold money to self-insure against idiosyncratic shocks, an action which is micro-prudent but macro-*im*prudent. By selling capital to achieve a greater portfolio weight on money, experts depress aggregate investment and growth, leading to lower returns on all assets (including money). The paradox of prudence is in the risk space what Keynes' Paradox of Thrift is for the consumption-savings decision. The Paradox of Thrift describes how each person's attempt to save more paradoxically lowers overall aggregate savings.

4.1 Model with Idiosyncratic Capital Risk and Money

Let us return to the Basak–Cuoco model of Section 2 with experts holding physical capital and households who cannot, ie, $\underline{a} = -\infty$. We introduce the following two modifications: (i) Capital has in addition to aggregate risk also idiosyncratic risk. (ii) There is no risk-free asset, but there is money in fixed supply. Agents can long and short it and want to hold it to self-insure against idiosyncratic risk.

More formally, we assume as before that each expert operates a linear production technology, ak_t, with productivity a, but now they also face idiosyncratic risk $\tilde{\sigma}\, d\tilde{Z}_t$ in addition to aggregate risk σdZ_t. That is a single expert's capital k_t evolves according to

$$dk_t/k_t = (\Phi(\iota_t) - \delta)dt + \sigma dZ_t + \tilde{\sigma}\, d\tilde{Z}_t.$$

The shock dZ_t is the same for the whole economy, while the shock $d\tilde{Z}_t$ is expert-specific and orthogonal to dZ_t. Idiosyncratic shocks cancel out in the aggregate.

Since idiosyncratic risk is uninsurable due to markets incompleteness, experts also want to hold money. Money is an infinitely divisible asset in fixed supply, which can be traded without frictions. Since money does not pay off any dividends it has value in equilibrium only because agents want to self-insure against idiosyncratic shocks to their capital holdings. In other words, money is a bubble, like in Samuelson (1958) and Bewley (1980). Unlike in Bewley (1980), our idiosyncratic shocks are not endowment shocks, but investment shocks like in Angeletos (2007). We assume that idiosyncratic risk of the dividend-paying capital is large enough, $\tilde{\sigma} > \sqrt{\rho}$, so that money, which does not pay dividends, still has value in equilibrium. This is unlike Diamond (1965) who introduces physical capital in Samuelson's OLG model and Aiyagari (1994) who introduces capital in Bewley's incomplete markets setting. In those models, the presence of capital crowds out money as a store of value.[p]

Experts can invest in (outside) money and capital, while households like in Section 2 only hold money. We also assume for simplicity that all agents have logarithmic utility with time preference rate ρ.[q]

As before, let us follow our four step approach to solve the model.

4.2 The 4-Step Approach

Step 1: Postulate Price and SDF Processes. In this monetary setting we now have to postulate not only a process for the price of capital, but also for the "real price" of money. We denote (without loss of generality) the value of the total money stock in terms of the numeraire (the consumption good) by $p_t K_t$. We normalize the total value of the money stock by K_t to emphasize that, everything else being equal, the value of money should be proportional to the size of the economy.

$$\frac{dq_t}{q_t} = \mu_t^q dt + \sigma_t^q dZ_t,$$
$$\frac{dp_t}{p_t} = \mu_t^p dt + \sigma_t^p dZ_t,$$

In addition, like in Section 3 we postulate the processes for individual experts' and households' stochastic discount factors:

$$\frac{d\xi_t}{\xi_t} = -r_t dt - \varsigma_t dZ_t - \tilde{\varsigma}_t d\tilde{Z}_t \quad \text{and} \quad \frac{d\underline{\xi}_t}{\underline{\xi}_t} = -\underline{r}_t dt - \underline{\varsigma}_t dZ_t,$$

where r_t and $\underline{r}_t$ are the (real) shadow risk-free interest rates of experts and households, respectively. Note that shadow risk-free rates need not be identical, since no real risk-free asset is traded. Note also that experts require a risk premium not only for the aggregate risk ς_t but also for the idiosyncratic risk they have to bear $\tilde{\varsigma}_t$.

We will show that there exists an equilibrium in which the wealth share η_t evolves deterministically and so do the prices q_t and p_t. Hence, for simplicity we set $\sigma_t^q = \sigma_t^p = 0$. Under this conjecture the return on physical capital accruing to experts is

[p] We assume that money is intrinsically worthless, and so along with the equilibrium in which money has value, there is also an equilibrium in which money has no value. However, in a perturbation of the model, in which agents get small utility from holding money (eg, because money facilitates transactions), only the equilibrium with full value of money survives.

[q] Solving this model with CRRA models using the results on page 1511 in Section 3.1 is a worthwhile exercise.

$$dr_t^k = \frac{a - \iota_t}{q_t} dt + (\Phi(\iota_t) - \delta + \mu_t^q) dt + \sigma dZ_t + \tilde{\sigma}\, d\tilde{Z}_t$$

and world stock of money $p_t K_t$ earns the (real) return of

$$dr_t^M = \left(\Phi(\iota_t) - \delta + \mu_t^p\right) dt + \sigma dZ_t,$$

where ι_t is the investment rate in physical capital.

Step 2: Equilibrium Conditions. First, note that the optimal investment rate is determined by q_t through $\Phi'(\iota_t) = 1/q_t$. Second, the optimal consumption rate of all agents is simply ρ times their net worth, since the utility of all agents is logarithmic with time preference rate ρ. Hence, aggregate demand for the consumption good is $\rho(q_t + p_t)K_t$. Given total supply of consumption goods after investing, we have the following goods market equilibrium condition:

$$\rho(q_t + p_t)K_t = (a - \iota)K_t.$$

Next, we solve the experts' and households' portfolio problems. Notice that, given the returns dr_t^M and dr_t^k on capital and money, the only two assets traded in this economy, all agents have exposure σdZ_t to aggregate risk. At the same time, experts also have exposure $x_t \tilde{\sigma}\, d\tilde{Z}_t$ to their individual idiosyncratic shocks, where x_t is the experts' portfolio weight on capital. Hence, the required risk premia of these log-utility agents are

$$\varsigma_t = \underline{\varsigma}_t = \sigma \quad \text{and} \quad \tilde{\varsigma}_t = x_t \tilde{\sigma}\,.$$

The experts' and households' asset pricing equations for money, respectively, are

$$\frac{E_t[dr_t^M]}{dt} - r_t = \frac{E_t[dr_t^M]}{dt} - \underline{r}_t = \underbrace{\sigma^2}_{=\varsigma_t\sigma=\underline{\varsigma}_t\sigma}\,.$$

Thus, $r_t = \underline{r}_t$: even though there is no risk-free real asset in this economy, both agent types would agree on a single real risk-free real interest rate.

The experts' asset pricing equation for physical capital is

$$\frac{E_t[dr_t^k]}{dt} - r_t = \varsigma_t\sigma + \tilde{\varsigma}_t\,\tilde{\sigma}\,,$$

reflecting the fact that experts are also exposed to idiosyncratic risk for which they earn an extra risk premium. Hence,

$$\frac{E_t[dr_t^k]}{dt} - \frac{E_t[dr_t^M]}{dt} = x_t \tilde{\sigma}^2. \tag{46}$$

Capital market clearing implies that

$$x_t = \frac{q_t K_t}{\eta_t (p_t + q_t) K_t} = \frac{1}{\eta_t} \frac{q_t}{p_t + q_t}, \tag{47}$$

Step 3: Evolution of $\boldsymbol{\eta}$. Experts' aggregate net worth N_t evolves according to

$$\frac{dN_t}{N_t} = r_t + \sigma(\underbrace{\sigma}_{\varsigma_t} dt + dZ_t) + x_t \tilde{\sigma} \tilde{\varsigma}_t dt - \rho dt,$$

given their exposures to aggregate and idiosyncratic risk, and since idiosyncratic risk cancels out in the aggregate. The law of motion of aggregate wealth is

$$\frac{d((q_t + p_t)K_t)}{(q_t + p_t)K_t} = r_t + \sigma(\sigma dt + dZ_t) + \eta_t x_t \tilde{\sigma} \tilde{\varsigma}_t dt - \rho dt,$$

where $\eta_t = \dfrac{N_t}{(q_t + p_t)K_t}$ is the experts' net worth share and $\eta_t x_t = q_t/(p_t + q_t)$ is the exposure to idiosyncratic risk in the world portfolio. Hence,

$$\frac{d\eta_t}{\eta_t} = x_t^2 (1 - \eta_t) \tilde{\sigma}^2 dt = \left(\frac{q_t}{p_t + q_t} \right)^2 \frac{1 - \eta_t}{\eta_t^2} \tilde{\sigma}^2 dt. \tag{48}$$

Step 4: Derive ODEs for the postulated price processes q and p as a function of the state variable η. We omit this step as it is similar to the previous section.

4.3 Observations and Limit Case

The increase in experts' wealth share η_t, or equivalently the decline of households' wealth share, $1 - \eta_t$, results in part from the fact that experts earn a risk premium from taking on idiosyncratic risk. The higher the idiosyncratic risk $\tilde{\sigma}^2$, the faster experts' wealth share rises toward 100%. Interestingly, it is the fact that experts are unable to share idiosyncratic risk which makes them richer over time compared to households.

Money allows for some sharing of idiosyncratic risk, since the experts' exposure to idiosyncratic risk of $x_t \tilde{\sigma}$ is less than what it would have been without money, ie, $\tilde{\sigma} / \eta_t$, as long as $x_t < 1/\eta_t$ or $p_t > 0$.

4.3.1 Comparison with Real Model

It is instructive to contrast the settings of this section with that of Section 2, where households hold the real risk-free asset instead of money. The evolution η follows now (48) instead of (11). Note that in both settings the experts' wealth share drifts towards 100%. However, there are crucial differences. In the setting with nominal money, aggregate risk is shared fully between experts and households. Hence, both groups receive a risk premium and therefore aggregate risk does not impact the wealth share in the model with money. In contrast, in the real model experts hold all the aggregate risk and hence only they earn a risk premium, leading to a positive drift in η. More importantly, aggregate risk sharing with money makes the evolution of experts' wealth share deterministic. In contrast, in the real model that experts' wealth share is necessarily stochastic, as revealed by (11).

4.3.2 The Only Experts Case

Finally, we are able to derive a closed form solution for the absorbing state $\eta = 1$ to which the system drifts. When the state $\eta = 1$ is reached $\mu^q(1) = \mu^p(1) = 0$ and thus experts' asset pricing Eq. (46) and capital market clearing (47) can be combined and simplified as follows

$$\frac{1}{\tilde{\sigma}^2}\frac{a-\iota}{q} = \frac{E[dr^k - dr^M]/dt}{\tilde{\sigma}^2} = x_t = \frac{q}{p+q} \tag{49}$$

Combining Eq. (49) with the goods market clearing condition

$$\rho(p+q)K_t = (a-\iota)K_t \tag{50}$$

and the optimal investment rate

$$\iota = \frac{q-1}{\kappa}, \tag{51}$$

for the functional form $\Phi(\iota) = \frac{1}{\kappa}\log(\kappa\iota + 1)$ one obtains the "money equilibrium," in which money is a bubble with

$$q = \frac{1+\kappa a}{1+\kappa\sqrt{\rho}\,\tilde{\sigma}} \quad \text{and} \quad p = \frac{\tilde{\sigma}-\sqrt{\rho}}{\sqrt{\rho}}q.$$

The "money equilibrium" exists as long as $\tilde{\sigma} > \sqrt{\rho}$.

In addition, there exists a "moneyless equilibrium," obtained by setting $p = 0$ and solving (50) with (51) to obtain

$$q^0 = \frac{1+\kappa a}{1+\kappa\rho} \quad \text{and} \quad p^0 = 0.$$

Eq. (49) is no longer relevant because money is no longer an asset in which agents can put their wealth.

Note that the price of capital for the "moneyless" equilibrium is the same as in the real economy of Section 2. The growth rate of the economy in both equilibria is given by $g = \frac{1}{\kappa}\log q - \delta$. In the money equilibrium, q is lower and so is overall economic growth, but experts have to bear less risk.

4.3.3 Financial Deepening

Financial deepening or innovation that lower the amount of idiosyncratic risk households have to bear also lowers the value of money, p. However, it increases the price of capital q and with it, the investment rate, ι, and the overall economic growth rate g. Surprisingly, $q + p$ declines. That is, financial deepening lowers total wealth in the economy.

4.3.4 The Paradox of Prudence

The paradox of prudence arises when experts try to lower their risk by tilting their portfolio away from real investment and towards safe asset, money. Scaling back risky asset holding can be micro-prudent, but macro-*im*prudent. As experts try to lower their (idiosyncratic) risk exposure, the price of capital falls in Brunnermeier and Sannikov (2015a). This behavior lowers overall economic growth and with it the real return on money holdings. Since each individual expert takes prices and rates of return as given, they do not internalize this pecuniary externality. As shown in Brunnermeier and Sannikov (2015a), money holdings in this model are inefficiently high if $\tilde{\sigma}(1-\kappa\rho) > 2\sqrt{\rho}$. Our paradox of prudence is analogous to Keynes' Paradox of Thrift, but the former is about changes in portfolio choice and risk, while the latter refers to the consumption–savings decision.[r]

5. CRITICAL ASSESSMENT AND OUTLOOK

The economy with two types of agents gives rise to a number of general ideas—we describe these broader ideas in this section. We would like to make the point that continuous time has the capacity to build upon many ideas present in the literature, with fuller and less stylized models, and to drive a deeper understanding of financial frictions in the macroeconomy in new ways. We comment on how the methodology we presented above can be extended, and used fruitfully, in higher-dimensional state spaces. We also comment on the issues of uniqueness of equilibria and the characterization of the full set of equilibrium possibilities when multiple equilibria exist.

One key idea is that the wealth distribution in the economy matters. In the models we solved in Sections 2 and 3, the wealth distribution is characterized by a single state variable, the wealth share of experts η_t. When η_t is low, experts become undercapitalized. More generally, other sectors can become undercapitalized. Mian and Sufi (2009) argue that a big drag on the economy in the recent financial crisis has been the fact that many households are undercapitalized. Caballero et al. (2008) discuss how during Japan's lost

[r] Keynes' Paradox of Thrift states that an increase in the savings propensity can paradoxically lower aggregate savings. An increase in savings propensity lowers consumption demand. If the increased savings are "parked in (bubbly) money" instead of additional real investments, aggregate demand becomes depressed. This lowers aggregate income. Saving a fraction of now lower income can lower overall dollar savings.

decade it was the corporate sector that became undercapitalized. The general message here is that the wealth distribution across sectors matters for the level of economic activity—asset allocation—as well as the rates of earnings and risk exposures of various sectors. These earnings and risk exposures in turn drive the stochastic evolution of the wealth distribution.

The idea that the wealth distribution drives economic cycles is not new in the literature. Kiyotaki and Moore (1997) and Bernanke et al. (1999) consider the fluctuations of the wealth of a class of agents near the steady state. Of course, continuous-time methods facilitate a full solution of this type of a model. He and Krishnamurthy (2013) consider a model similar to the ones we presented here, but without asset misallocation and with a somewhat different assumption of the earnings of the households' holdings of expert equity.[s]

More broadly, several papers introduce the idea of intergenerational wealth distribution. This idea exists already in Bernanke and Gertler (1989), where the wealth of old entrepreneurs affects wages in the labor market, which in turn impact the accumulation of wealth by young entrepreneurs. Myerson (2012) builds a model with T generations of bankers, in which the wealth distribution evolves in cycles, causing cycles in real activities. When the wealth of old bankers is high, risk premia are low, and hence earnings of young bankers are low. Wealth distribution across sectors also matters. Brunnermeier and Sannikov (2015b) develop a rather symmetric model, in which there are two sectors that produce two essential goods, and either one of the sectors can become undercapitalized. Brunnermeier and Sannikov (2012) discuss the idea that multiple sectors can be undercapitalized, and that monetary policy can affect "bottlenecks" through its redistributive consequences. They envision an economy in which multiple assets are traded, and agents within various sectors hold specific portfolios, backed by a specific capital structure. Brunnermeier and Sannikov (2015a) provide formal backing of these ideas using a three-sector model, in which traded assets include capital, money and long-term bonds, and monetary policy can affect the prices of these assets (and hence affect the sectors that hold theses assets) in various ways.

This leads us to the obvious question about the capacity of continuous-time models to develop these complex ideas. Can continuous-time methods successfully handle models with multiple state variables, which describe, eg, the distribution of wealth across sectors together with the composition of productive capital? We believe that yes—we are highly optimistic about the potential of continuous-time models. Certainly, the curse of dimensionality still exists. However, models with as many as four state variables should be solvable through a system of partial differential equations in a matter of minutes, if not faster,

[s] In that model, households earn more than their required return, and therefore there is rationing of experts' shares. Effectively, the alternative assumption gives households some market power, which intermediaries do not have. This leads to a lower intermediary earnings rate and a slower recovery from crisis.

through the use of efficient computational methods. The authors of this chapter have some experience with computation, and on a personal level many possibilities seem feasible now which appeared out of reach 5 years ago. To gauge computational speed, DeMarzo and Sannikov (2016) solve a model with three state variables, using a system of two partial differential equations. In addition the procedure involves an integration step somewhat reminiscent of the "static step" of the procedure in Section 3.5. With 201 × 51 × 51 grid points, the procedure using the explicit(!) method takes only a minute to compute the optimal contract. The implicit method of solving partial differential equations, which we use to compute the examples in Section 3.6 is significantly faster. For example, when solving a partial differential equation of the parabolic type in two dimensions (all equations for computing the value function using the iterative method are parabolic), with N grid points in space, one needs $O(N^2)$ grid points in time to ensure that the computational procedure is stable, when using the explicit method. In contrast, when using the implicit method, stability does not depend on the length of the time step, ie, the time step can be kept constant when greater resolution is required along the space dimension. Hence, we believe that by making a claim that models with four state variables are feasible to solve, we are in fact quite conservative.

We think that the iterative method, based on value function iteration for each type of agent, should prove quite fruitful. This method is based on backward induction starting from a terminal condition on the state space. At each new time interval, we start with value functions computed for the end of the interval. These value functions determine the agents' incentives through their continuation values from various portfolio choices. As a result, we can determine at each time point the allocations of assets and risk consistent of equilibrium—this is the "static step"—and hence we can compute the value function one period earlier. We see this method as fairly general and suitable for multiple dimensions.

In contrast, the shooting method aims at solving for the fixed point—equilibrium value functions and allocations in an infinite-horizon economy—up front. The straightforward extension of this method to multidimensional state spaces may be difficult to implement, as one would have to guess functions that match boundary conditions on the entire periphery of the state space, instead of just two endpoints. Nevertheless, procedures that use variations of policy iteration may lead to an efficient way of solving for a fixed point.

What makes continuous-time models particularly tractable is that transitions are local (when shocks are Brownian)—hence it is possible to determine the agents' optimal decisions and solve for their value functions by evaluating only first and second derivatives. In discrete time, with discrete transitions, the agents' decisions at any point may depend on entire value functions.

What about environments with so many dimensions that the straightforward discretization of the state space makes computation infeasible, due to the curse of dimensionality? Here, we are curious about the idea of describing state variables through certain essential moments—following the suggestions of Krusell and Smith (1998). We have not processed this possibility sufficiently to comment on it in the chapter, but generally we are very eager to know about ways to choose moments that describe the state space in a meaningful way for a given model. We should say, however, that continuous time can be helpful here as well, for describing continuation values and prices as functions of moments.

We finish this section by discussing the question of equilibrium uniqueness in the model we presented and in more complex models we envision. First, consider a finite-horizon economy that we are solving for via an iterative procedure. The procedure has two steps—the time step of value function iteration and the static step that determines prices and allocation. The time step cannot be a source of nonuniqueness—given continuation values, transition probabilities and payoff flows, the value function one period earlier is fully determined. The static step may or may not lead to nonuniqueness. In the model of Section 3 there are multiple nonstationary equilibria. For example, at any time point, the price of capital q_t can jump. If q_t jumps up by 10% then the risk-free asset must have an instantaneous return of 10% as well to ensure that the markets for capital and the risk-free asset clear. Of course, by the market-clearing condition for output (43), the price of capital q_t must correspond to the allocation of capital $\psi_t \in [0, 1]$. The allocation itself must be justified by the local volatility of capital, so that all agents have incentives to hold their portfolios. However, the possibility of jumps opens up room to many possibilities.

We compute the Markov equilibrium, in which prices and allocations are functions of η. If so, then the price of capital $q(\eta_t)$ must satisfy the differential equation that follows from (41) and (42). Notice that there are two values of $\sigma + \sigma_t^q$ consistent with the quadratic Eq. (41), positive and negative. We select the positive value, since otherwise amplification is negative, in the sense that a positive fundamental shock would result in a drop in the value of capital. Hence, the equilibrium we compute is the unique Markov equilibrium, in which the return on capital is always positively correlated with fundamental shocks to capital.

In more general models, we envision that some of the same forces are present. We also anticipate that, when there are multiple equilibria, it may be of interest to characterize the whole set of equilibria via an appropriate recursive structure. To answer this question, one may need to construct/compute a correspondence from the state space to the vector of equilibrium payoffs of all agent types. We envision that this correspondence can be found recursively by solving for the boundaries of attainable equilibrium payoff sets backwards in time, but the details of this procedure are certainly work in progress.

Abstract

This chapter surveys the literature on housing in macroeconomics. We first collect facts on house prices and quantities in both the time series and the cross section of households and housing markets. We then present a theoretical model of frictional housing markets with heterogeneous agents that nests or provides background for many studies. Finally, we describe quantitative results obtained during the last 15 years on household behavior, business cycle dynamics, and asset pricing, as well as boom bust episodes.

Keywords

Booms and busts in housing markets, land prices, market segmentation, mortgages, residential investment, expectations, collateral constraints, illiquidity, transaction costs

1. INTRODUCTION

The first volume of the *Handbook of Macroeconomics*, published in 1999, contains essentially no references to housing. This statistic accurately summarizes the state of the field at the time. Of course, housing was not entirely absent from macroeconomic studies, which typically account for all production, consumption and wealth in an economy. The lack of references instead reflected the treatment of housing as simply one component of capital, consumption or household wealth that does not deserve special attention.

At the turn of the millennium, housing was implicitly present in three loosely connected literatures. One is work on aggregate fluctuations that studies the sources of business cycles and the response of the economy to fiscal and monetary policy. In the typical 20th century model, residential structures were part of capital, or sometimes "home capital" (together with consumer durables). Housing services were part of nondurables (or home good) consumption. Models of financial frictions and the role of capital as collateral focused on borrowing by firms. Volatility of house prices played no role—in fact, any volatility of asset prices was largely a sideshow.

Second, housing was implicitly present in the large body of work on asset pricing concerned with differences in average returns and price volatility across assets. Studies in this area used to largely stay away from properties of house prices and returns. At the same time, a common modeling exercise identified a claim to all consumption with equity and tried to explain the volatility of its price with a consumption-based stochastic discount factor. Housing thus played an implicit role as part of payoffs and risk adjustment. Finally, there is work on heterogenous households that seeks to understand the role of frictions and policy for inequality as well as distributional effects of shocks. Here, housing was included as a large implicit component of household wealth as well as a share of consumption.

The first half of the 2000s saw not only the largest housing boom in postwar US history, but also new research that introduced an explicit role for housing in macroeconomics. The new research studies the interaction of house prices and collateralized household borrowing with business cycles and monetary policy. It also explores how the role of housing as a consumption good as well as a collateralizable asset affects savings, portfolio choice, and asset pricing. By the time the US housing boom turned into a spectacular bust in 2007, housing was already a prominent topic in macroeconomics. The Great Recession added important new data points and further underscored the importance and unique properties of housing. As a result, housing now routinely receives special attention in macroeconomic discussions.

While the new literature grew out of the three lines of research described earlier, the focus on housing brought out several distinctive features. First, it naturally pushed researchers toward integration of themes and tools from all three lines of research. It is difficult to describe household behavior while ignoring uncertainty about house prices, or to think about mortgage debt without heterogeneous agents. Many papers surveyed below thus employ tools from financial economics to study exposure to uncertainty, and many quantitative models are analyzed with computational techniques that allow rich heterogeneity within the household sector.

The second feature is familiar from urban economics: "the housing market" is really a collection of many markets that differ by geography as well as other attributes. Disaggregating not only the household sector but also the housing stock provides valuable insights into the transmission of shocks and alters policy conclusions. For example, shocks to financial intermediaries or policies that change the cost of mortgage credit might have stronger effects on prices in markets where the typical buyer is also a borrower. Moreover, those shocks might have larger aggregate effects if their impact cannot be shared across subpopulation of agents. Availability of new large scale micro data sets has made it possible to explicitly study the interactions of many agents in many markets, and derive the aggregate effects of those interactions.

A third, related, feature is that the literature on housing has brought to bear a lot of evidence from the cross section of markets in a single episode to complement time series evidence that is common in macroeconomics. To illustrate, one can learn a lot about the role of technology shocks for residential investment from recurrent time series patterns in postwar history. In contrast, to assess the role of recent financial innovation for house prices, such patterns are less informative. Fortunately, though, we can learn from cross-sectional patterns in financing and prices across submarkets and types of households.

The literature shows how both time series and cross-sectional patterns on housing markets lend themselves to the same style of analysis that is common elsewhere in macroeconomics. Reduced form statistical tools are used to document facts and sometimes to isolate certain properties of equilibrium relationships. Insights on the quantitative importance of different mechanisms as well as policy counterfactuals are derived from multivariate structural models. In many ways, modeling the cross-sectional comovement in a single period of, say, mortgage borrowing and wealth across households and house prices across market segments, is conceptually similar to modeling the time series comovement of, say, residential and business investment, GDP and house prices in postwar history. Both exercises require tracing out the effect of exogenous variation in some features of the environment jointly on many endogenous variables.

This chapter describes work on housing in macroeconomics in three parts. Section 2 collects the new facts that emerge once disaggregation makes housing explicit. We first document business cycle properties of housing consumption, residential investment and mortgage debt. We then look at the dynamics of house prices at the national, regional and within-city level, and compare price volatility and trading volume for housing and securities. Finally, we document the dual role of housing as a consumption good as well as an asset in household portfolios.

Section 3 describes a theoretical framework that nests or provides background for many studies in the literature. It allows for four special features of housing that are motivated by facts from Section 2: *indivisibility*, *nontradability of dividends*, *illiquidity*, and *collateralizability*. Indeed, many homeowners own only their residence, directly consume its dividend in form of housing services and bear its idiosyncratic risk. Moreover houses are relatively costly to trade and easy to pledge as collateral even for individual households. In contrast, securities such as equity and bonds are typically held in diversified portfolios, have tradable payoffs, are traded often at low cost, and are harder to use as collateral, at least for individual investors.

Section 4 summarizes quantitative results derived from versions of the general framework over the last two decades or so. While no study contains all the ingredients introduced in Section 3, each one quantifies one or more of the tradeoffs discussed there. We start by reviewing work on consumption, savings and portfolio choice. We also consider mortgage choice and the role of financial innovation for household decisions. We then move on to general equilibrium analysis of the business cycle, monetary policy and asset prices. Finally, we consider boom–bust episodes, with an emphasis on the 1970s and 2000s US housing cycles.

We interpret results from different types of quantitative exercises in light of the general framework. One approach studies structural relationships with an explicit shock structure. For example, large bodies of work assess the ability of life cycle models of consumption, savings and portfolio choice to explain cross-sectional patterns as well as the ability of DSGE models to match time series patterns. An alternative approach investigates families of Euler equations for different agents and/or markets to reconcile allocations and asset prices. A third approach tries to isolate properties of the decision rules or the equilibrium law of motion with reduced form approaches.

What have we learned so far? We highlight here two key takeaways from the new literature that underlie the quantitative successes reported in detail below. First, *frictions matter*: Quantitative modeling of household behavior now routinely relies on collateral constraints, incomplete markets and transaction costs as key ingredients. Incompleteness of markets means in particular that homeowners bear property-level price risk. A large body of reduced form evidence provides additional support for this approach. Second, *heterogeneity of households matters*: Models with heterogeneous households and frictions introduce powerful new amplification and propagation mechanisms. In particular, they provide more scope for effects of shocks to the financial sector which have become important in accounts of postwar US history, especially the recent boom–bust cycle.

We also conclude that making housing explicit improves our understanding of classic macroeconomic questions, previously studied only with models that provide an implicit role for housing. For thinking about business cycles, the comovement and relative volatility of residential and business investment provide discipline on model structure. For thinking about asset pricing, the role of housing as a consumption good as well as a collateralizable asset generate the type of slow moving state variables for model dynamics that are needed in order to understand observed low frequency changes in the risk return tradeoffs for many assets, including housing itself. Finally, financial frictions in the household sector change the transmission of both aggregate and distributional shocks and policy interventions, especially to consumption.

At the same time, many open questions remain and there is ample opportunity for future research. One issue is the tradeoff between tractability and detail faced by any macroeconomic study. There are three areas in particular where more work is needed to converge on the right level of abstraction—with possibly different outcomes depending on the question. One is aggregation across housing markets: do we gain, for example, from building more models that treat the United States as a collection of small countries identified with, say, states or metropolitan areas? Another area is choosing dimensions of household heterogeneity: since observable demographic characteristics such as age, income, and wealth explain only a small share of cross-sectional variation, how should unobservable heterogeneity be accommodated? Finally, the majority of studies reviewed below capture financial frictions by assuming short term debt and financial shocks as changes to maximum loan-to-value ratios. Given the rich and evolving contractual detail we see in the data, what are the essential elements that should enter macroeconomic models?

A major outstanding puzzle is the volatility of house prices—including but not only over the recent boom–bust episode. Rational expectations models to date cannot account for house price volatility—they inevitably run into "volatility puzzles" for housing much like for other assets. Postulating latent "housing preference shocks" helps understand how models work when prices move a lot, but is ultimately not a satisfactory foundation for policy analysis. Moreover, from model calculations as well as survey evidence, we now know that details of the expectation formation by households—and possibly lenders and developers—play a key role. A promising agenda for research is to develop models of expectation formation that can be matched to data on both market outcomes and survey expectations. A final point is that most progress we report is in making sense of household behavior. The supply side of housing as well as credit to fund housing has received relatively less attention, another interesting direction for future work.

To keep the length of chapter manageable, we have narrowed focus along some dimensions where other recent survey papers already exist. In particular, the *Handbook* *of Urban and Regional Economics* contains chapters on search models of housing (Han and Strange, 2015) as well as US housing policy (Olsen and Zabel, 2015).[a] Since we focus on work that is already published, we have also left out much of the important emerging literature on the housing bust and Great Recession, as well as policy at the zero lower bound for nominal interest rates. Finally, our chapter deals almost exclusively with facts and quantitative studies about the United States. This reflects the focus of the literature, which in turn has been driven in part by availability of data. Another exciting task for future research is to use the tools discussed in this chapter to study the large variation in housing market structure and housing finance across countries, surveyed for example by Badarinza et al. (2016).

2. FACTS

2.1 Quantities

Fig. 1 plots the aggregate expenditure share on housing from the National Income and Product Account (NIPA) tables. The numbers in NIPA table 2.3.5 are based on survey data. The questionnaires in these surveys (for example, the Residential Finance Survey conducted by the Census Bureau) ask renters about their actual monthly rent payments. These payments are imputed to comparable owner-occupied units (Mayerhauser and Reinsdorf, 2007). The sample consists of quarterly data from 1959:Q1 to 2013:Q4.

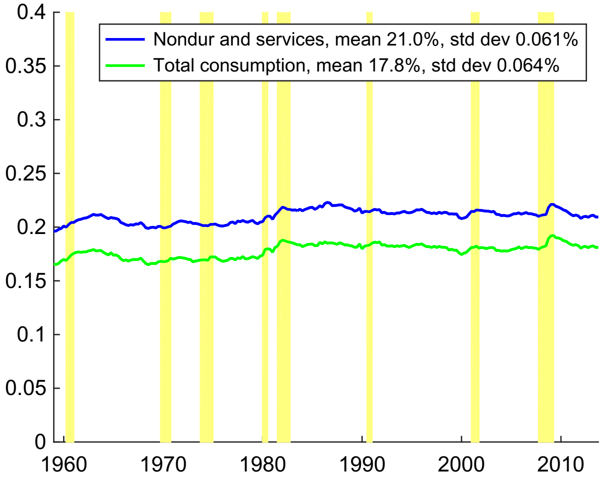

Fig. 1 Aggregate expenditure share on housing, 1959:Q1–2014:Q4.

[a] The same handbook contains a chapter on housing, finance and the macroeconomy (Davis and Van Nieuwerburgh, 2015) that also discusses some of the material covered in the present chapter.

We compute the expenditure share in two ways. The blue line shows housing expenditures as a fraction of expenditures on nondurables and services. This series has a mean of 21% and a standard deviation of 0.061%. The green line shows housing services as a fraction of total consumption (including durables). This series has a slightly lower mean of 17.8% and a bit higher standard deviation of 0.064%. The yellow bars indicate NBER recessions.

The overall impression from Fig. 1 is that the aggregate expenditure share is pretty flat over time. The expenditure share on housing is also similar across households in micro data, as shown by Piazzesi et al. (2007). Their table A.1 shows evidence from the Consumer Expenditure Survey, where the definition of housing expenditures depends on tenure choice. The CEX asks renters about their rent payments, while owner occupiers are asked about their interest payments on mortgages and other lines of credit, property taxes, insurance, ground rents, and expenses for maintenance or repairs. Davis and Ortalo-Magné (2011) use micro data on the expenditure share of renter households alone. The paper shows that individual expenditure shares based on the 1980, 1990, and 2000 Decennial Housing Surveys do not vary much within or across the top 50 US metropolitan statistical areas.

Fig. 2 plots three series: residential investment, nonresidential investment and output. The series are from NIPA table 1.1.3; they are all logged and detrended using the Hodrick–Prescott filter. The figure illustrates that both investment series are more volatile than output. Also, residential investment is twice as volatile as nonresidential investment. The volatility of residential investment is 9.7%, while nonresidential investment

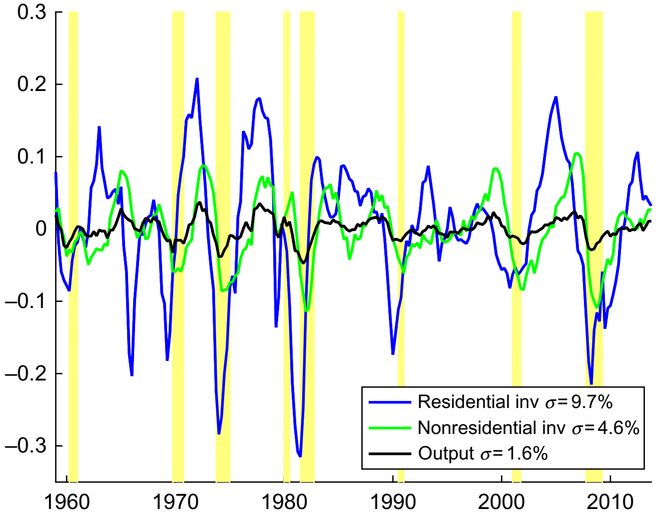

Fig. 2 Aggregate residential investment, nonresidential investment, and output; logged and detrended with Hodrick–Prescott filter.

has a volatility of 4.6% and the volatility of output is 1.6%. The figure also shows that the series for residential investment tends to increase before nonresidential investment and output, and it tends to decrease before the other two series. In other words, residential investment leads the cycle.

Once investment has created housing capital, it stays around for a long time. As reported by Fraumeni (1997), structures depreciate at rates of 1.5–3% per year. The depreciation rates for nonresidential capital are higher, between 10% and 30%. Moreover, housing combines housing capital with land, which is a fixed factor.

2.1.1 Constraints on the Supply of Housing

The degree to which new developments can increase the supply of housing varies across geographic areas. For example, developers in Indianapolis and Omaha find it easier to buy land and construct new homes than developers in San Francisco and Boston. There are two popular indices that carefully measure such housing supply constraints.

The first index is by Saiz (2010) and captures physical constraints. These geographical constraints capture two main features of land topology that make new developments difficult or impossible. The first feature is the presence of water. Saiz measures the area within 50 km from cities that is covered by oceans, lakes, rivers, and other water bodies such as wetlands. The second feature of land topology is steep slopes. Saiz computes the share of the area with a slope above 15% within a 50-km radius around an MSA.

The second measure of supply constraints captures regulatory restrictions. These are measured by the Wharton Residential Urban Land Regulation Index created by Gyourko et al. (2008). This index captures the stringency of residential growth controls in terms of zoning restrictions or project approval practices.

2.2 Prices

Fig. 3 shows the price–dividend ratio for stocks as a green line which measured on the left axis. The figure also shows the price–rent ratio for housing as a blue line with units indicated on the right axis. The figure illustrates the large volatility of the two series. The price–dividend ratio for stocks uses data from the Flow of Funds and represents the overall valuation of companies in the United States. The dividend series includes net repurchases. The price–dividend ratio fluctuates between 20 and 65, as measured on the left axis.

The numerator of the price–rent series for housing is the value of residential housing owned by partnerships, sole proprietors, and nonfinancial corporations, which are landlords for many rental units, as measured by the Flow of Funds. The denominator of the price–rent series is rents from the NIPA table 2.3.5, which includes actual rent payments as well as imputed rents for owner–occupiers (as discussed in the context of Fig. 1). The price–rent ratio fluctuates between 11 and 19, as measured on the right axis.

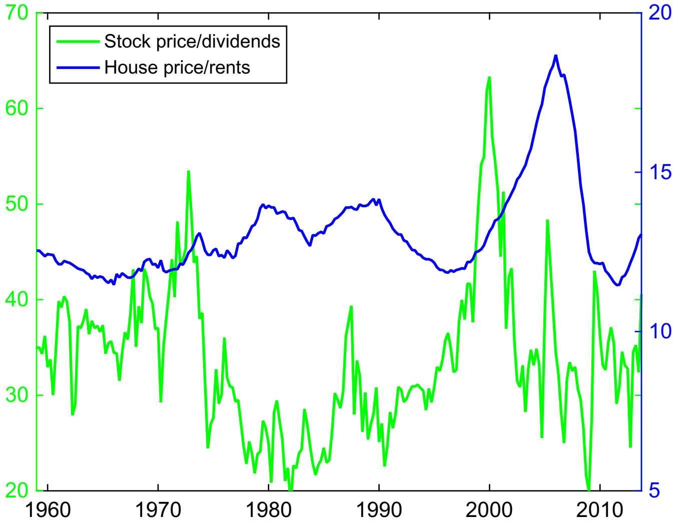

Fig. 3 Aggregate price/dividend ratio for stocks and price/rent ratio for housing.

The two valuation ratios often move inversely. For example, stocks tanked during the housing booms in the 1970s and 2000s. By contrast, stocks appreciated during the 1990s while housing did poorly. The recent boom–bust episode in housing stands out in the postwar experience.

2.2.1 Excess Volatility of Individual House Prices

House prices, like the prices of other assets, are highly volatile. The prices of individual houses are especially volatile. The volatility of various house price indices is smaller, but still a challenge for economic models—this is the excess volatility puzzle.

Most house price indices are constructed from repeat sales—average price changes in houses that sell more than once in the sample. CoreLogic constructs such city-wide indices for many metropolitan areas, various tiers of these markets, as well as the US national index. These indices are published as the S&P/Case–Shiller Home Price Indices by Standard & Poor's. The Federal Housing Finance Agency also constructs such indices from repeat sales or refinancings on the same properties (formerly called the OFHEO index). Zillow also publishes such indices for cities, states or the nation.

Case and Shiller (1989) estimate the standard deviation of annual percentage changes in individual house prices to be close to 15%. The paper concludes that individual house prices are similar to individual stock prices that are also very volatile. City-wide indices are less volatile than individual house prices. Flavin and Yamashita (2002) estimate a 14% volatility for individual house prices in their table 1A. Their table 1B reports a 4% volatility for Atlanta, 6% for Chicago, 5% for Dallas, and 7% for San Francisco. Landvoigt et al. (2015) estimate the volatility of individual house

Table 1 House price volatility

	Individual house	City	State	Aggregate
Volatility	14%	7%	5%	2–3%

Note: This table is from tables B1 and B2 in Piazzesi et al. (2007).

prices in different years. Their table 1 shows estimates that range between 8–11% during the 2000s boom and 14% during the bust.

Compared to stocks, which commove strongly with the aggregate stock market, a larger share of the volatility in individual house prices is idiosyncratic, as documented in Case and Shiller (1989). Their evidence stems from regressions of individual house price change on city-wide price changes. The regressions have low R^2s: 7% for Atlanta, 16% for Chicago, 12% for Dallas, and 27% for San Francisco.

Table 1 summarizes information from tables B1 and B2 from Piazzesi et al. (2007). The table illustrates the rule of thumb that 1/2 of the volatility in individual house prices is city-level variation, while 1/4 of the individual volatility is aggregate house price variation. This volatility decomposition illustrates the importance to understand the variation within narrow locations or individual houses. The high volatility of individual house prices together with high transaction costs lead to low Sharpe ratios (defined as average excess return on an asset, divided by its volatility) on housing. In other words, individual houses are not as attractive as an investment.

Idiosyncratic shocks to house prices are difficult to diversify. The problem with houses is that they are *indivisible*—they are sold in their entirety, not in small pieces. As a consequence, households own 100% of a specific house rather than small portions of many different houses. Moreover, the market for housing indices is not very liquid. In any given month, only a couple of futures contracts on city-wide house price indices trade on the Chicago Mercentile Exchange, if they trade at all.[b]

The ease of diversification distinguishes houses from other assets such as stocks. For example, households can save a small amount of money and invest it in a stock market index (such as the S&P 500) that tracks the value of a large stock portfolio. Alternatively, households can buy a few shares from several companies. The conventional wisdom in finance is that a small number of different stocks—such as five or six companies—are sufficient to achieve a high degree of diversification in a portfolio.

2.2.2 Momentum and Reversal

House prices have more momentum than other assets and also exhibit long-run reversal. The changes in log real prices of houses are more highly serially correlated compared to other assets. Case and Shiller (1989) provide the first evidence of such high serial

[b] The data on volume in these markets is here http://www.cmegroup.com/market-data/volume-open-interest/real-estate-volume.html

correlation. They document that a change in the log real price index in a given year and a given city tends to be followed by a change in the same direction the following year between 25% and 50% as large. Englund and Ioannides (1997) provide cross-country evidence where changes are followed by changes between 23% and 74% the next year. Glaeser et al. (2014) find changes the next year between 60% and 80%.

Cutler et al. (1991) compare the serial correlation in housing markets to that in other asset markets across many countries. For example, stocks, bonds and foreign exchange exhibit weak momentum for horizons less than a year. The monthly autocorrelation in excess stock returns is 10%, for US bonds it is 3%, 24% for foreign bonds, and 7% for foreign exchange. The excess returns on all these assets are essentially uncorrelated from year to year. In contrast, the excess returns on housing in their table 4 has an autocorrelation of 21% from year to year.

Over longer periods, house prices experience reversal. Englund and Ioannides (1997) document that changes in log real prices are followed by changes in the opposite direction after 5 years. Glaeser et al. (2014) also provide evidence of such reversal in their table 4. They estimate the autocorrelation of real house price changes over 5 years to be −0.80.

2.2.3 Predictable Excess Returns on Housing

The excess returns on many assets, including housing, are predictable. Case and Shiller (1989) show that excess returns on the city indices are predictable with excess returns in the previous year in their table 3. Case and Shiller (1990) provide further evidence of predictability for excess returns. Their table 8 runs regressions of city excess returns on rent–price ratios and construction costs divided by price. The coefficient on the rent–price ratio is positive: a high rent–price ratio predicts high excess returns over the next year.

Cochrane (2011) compares the predictability regressions for houses and stocks. Table 2 replicates his table 3. "Houses" in Table 2 refers to the aggregate stock of housing in the United States. "Stocks" refers to a value-weighted index of US stocks. The estimated slope coefficients indicate that high rents relative to prices signal high subsequent returns, not lower subsequent rents. The results for housing in the left panel look remarkably similar to those in the right panel for stocks. The returns are predictable for both, but dividend growth and rent growth are not predictable. The ratio of rents or dividends to prices is highly persistent, but stationary.

Campbell et al. (2009) decompose house price movements with the Campbell–Shiller linearization of the one-period return

$$r_{t+1} \approx \text{const.} + \rho(p_{t+1} - d_{t+1}) - (p_t - d_t) + \Delta d_{t+1},$$

where $r_{t+1} = \log R_{t+1}$ is the log housing return, $p_t = \log(P_t)$ is the log house price, $d_t = \log(D_t)$ is the log rent, $\Delta d_{t+1} = d_{t+1} - d_t$ is rent growth, and $\rho = 0.98$ is a constant in the approximation. This return identity simply says that high returns either come from higher prices (future $p - d$), lower initial prices, or higher dividends.

Table 2 House price and stock price regressions

	Houses			Stocks		
	b	***t***	***R*²**	***b***	***t***	***R*²**
r_{t+1}	0.12	(2.52)	0.15	0.13	(2.61)	0.10
Δd_{t+1}	0.03	(2.22)	0.07	0.04	(0.92)	0.02
dp_{t+1}	0.90	(16.2)	0.90	0.94	(23.8)	0.91

Note: This table is table 3 from Cochrane (2011). It reports results from regressions of the form

$$x_{t+1} = a + b \times dp_t + \varepsilon_{t+1}$$

where dp_t is either the log rent–price ratio in the left panel or the log dividend–price ratio in the right panel. In the left panel, x_{t+1} is either log annual housing returns r_{t+1}, log rent growth Δd_{t+1}, or the log rent–price ratio dp_{t+1} measured with annual data for the aggregate stock of housing in the United States, 1960–2010, from http://www.lincolninst.edu/subcenters/land-values/rent-price-ratio.asp In the right panel, x_{t+1} is either log stock returns r_{t+1}, dividend growth Δd_{t+1} , or the log dividend–price ratio dp_{t+1} measured with annual CRSP value-weighted return data, 1947–2010.

By iterating the return identity forward, we get the present value identity

$$dp_t \approx \text{const.} + \sum_{j=1}^{k} \rho^{j-1} r_{t+j} - \sum_{j=1}^{k} \rho^{j-1} \Delta d_{t+j} + \rho^k dp_{t+k}, \tag{1}$$

where $dp_t = d_t - p_t$ is the log rent–price ratio. The present value identity holds state-by-state as well as in expectation. Any movement in the rent–price ratio on houses therefore has to be associated with a movement in either the conditional expected value of future returns r_{t+j}, expected future rent growth Δd_{t+j} or a bubbly anticipation of future high prices dp_{t+k}.

Campbell et al. estimate a vector-autoregression that includes real interest rates, rent growth and excess returns on housing. The housing data are from various metropolitan regions and US aggregate data. Based on the estimated VAR, the paper evaluates the expected infinite sums of future returns and future rent growth on the right-hand side of Eq. (1) for $k \to \infty$ by imposing the no-bubble condition[c] $\lim_{k\to\infty} \rho^k dp_{t+k} = 0$. It finds that movements in price–rent ratios can be attributed to a large degree to time variation in risk premia and less so to expectations of future rent growth. The time variation in real interest rates does not explain price–rent ratio movements. Their fig. 2 also shows that the 2000s boom is hard to explain through the lense of their estimated VAR which predicts low price–rent ratios throughout the 2000s.

[c] Giglio et al. (2016) provide direct evidence on the no-bubble condition in housing markets by comparing the value of freeholds (infinite maturity ownerships of houses) with the value of leaseholds with maturities over 700 years in the United Kingdom and Singapore.

2.2.4 Value of Land vs Structures

Fig. 4 plots the value of the residential housing stock together with its two components, the value of the residential structures and the value of land. All series are from the Flow of Funds and are reported as multiples of GDP. The figure illustrates that movements in the value of the residential housing stock are mostly due to movements in the value of land. The value of structures fluctuates much less. The figure again highlights the importance of the recent boom–bust episode in the postwar housing experience.

Knoll et al. (2014) collect data on house values in many industrialized countries going back to 1870. The paper documents that real house values in most countries were largely constant from the 19th to the mid 20th century. Over the postwar period, real house prices approximately tripled. The majority of this increase in real house prices is associated with rising land prices, while real construction costs have been roughly constant.

There is also large cross-sectional variation in the share of land in the overall house value. A key component of this variation is what realtors call "location, location, location": each location is unique. There may be attractive locations with unique characteristics in fixed supply such as lake and oceanfronts, locations with strict zoning rules, outstanding amenities such as good schools or opera houses, low crime, etc. For example, table 4 in Davis and Heathcote (2007) reports that houses in San Francisco have a land share of 80.4% while houses in Oklahoma City have a land share of 12.6%. The table shows that areas with higher land shares tend to have higher house prices, higher average house price growth and more volatile house prices.

Another source of cross-sectional variation is differences in the durability and/or attractiveness of the existing structures. For example, the building material for structures in earthquake prone areas like California tends to be wood, which is cheaper and

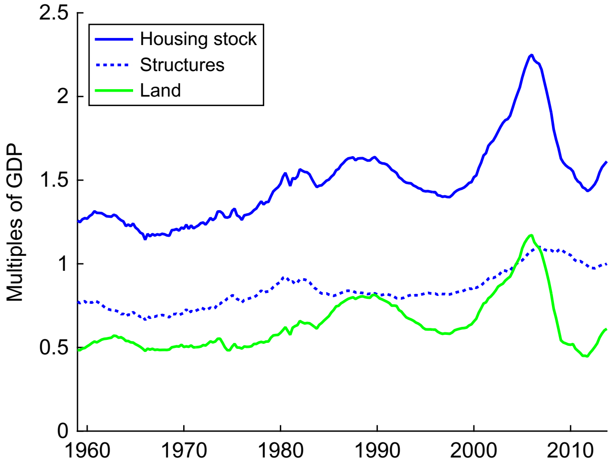

Fig. 4 The value of the residential housing stock together with its individual components, the value of residential structures, and the value of land.

deteriorates faster than brick which is used for most constructions in Pennsylvania. Architectural styles may also matter. For example, Victorian homes are valued at a premium, while 1950s postwar structures come at a discount.

2.2.5 Cross Section of House Prices

There are important cross-sectional patterns in house prices that help understand the variation across and within narrow areas. For example, during the 2000s, cheaper houses experienced a stronger boom–bust than more expensive houses. This pattern is different from previous boom–busts, where cheaper houses have experienced weaker boom–busts (such as in the 1970s.) Gentrification matters for poorer neighborhoods within a city that are in close proximity to more expensive neighborhoods. These low-price neighborhoods experience stronger booms–bust episodes than other low-price neighborhoods as well as high-price neighborhoods. Finally, the recent experience of the sand states challenges the notion that house prices in areas with an elastic housing supply should be less volatile.

Fig. 5 plots median house prices by city and tiers starting in the mid 1990s. The series are defined and constructed by Zillow Research. The top left panel shows that median house prices in the top tier of Los Angeles, California, gained 22% per year during the recent housing boom (1996–2006). The bottom tier gained *additional* 6 percentage points per year. During the housing bust (2006–11), the top tier made 4% capital losses per year, while the bottom tier dropped 5 percentage points more than the top tier.

The main stylized fact—houses in the bottom tier experienced a stronger boom–bust episode during the 2000s than houses in the upper tiers—can also be observed in other cities. In Las Vegas, houses in the bottom tier appreciated by 16% per year, while houses in the top tier only appreciated by 13%. During the bust, bottom-tier house prices fell by 14% while top-tier house prices fell only by 10% per year. In Chicago, capital gains across these tiers were the same on the way up, but there were larger losses in the lower tiers on the way down. In Omaha, the boom was not as pronounced, but still the bottom tier appreciated by 2 percentage points more than the top tier and was the only tier to experience a capital loss during the bust.

Landvoigt et al. (2015) estimate these patterns for the metro area of San Diego based on individual transaction data. The paper documents a roughly 20% difference between capital gains on the cheapest houses and most expensive houses between the years 2000 and 2005. The Zillow tiers group the cross section of houses and thereby reduce these cross-sectional differences. Kuminoff and Pope (2013) show a similar pattern for the land component of house values: cheap land appreciated more than expensive land during the 2000s boom.

Guerrieri et al. (2013) document that gentrification matters for poorer neighborhoods that are geographically close to high-price neighborhoods within a city. Their table 3

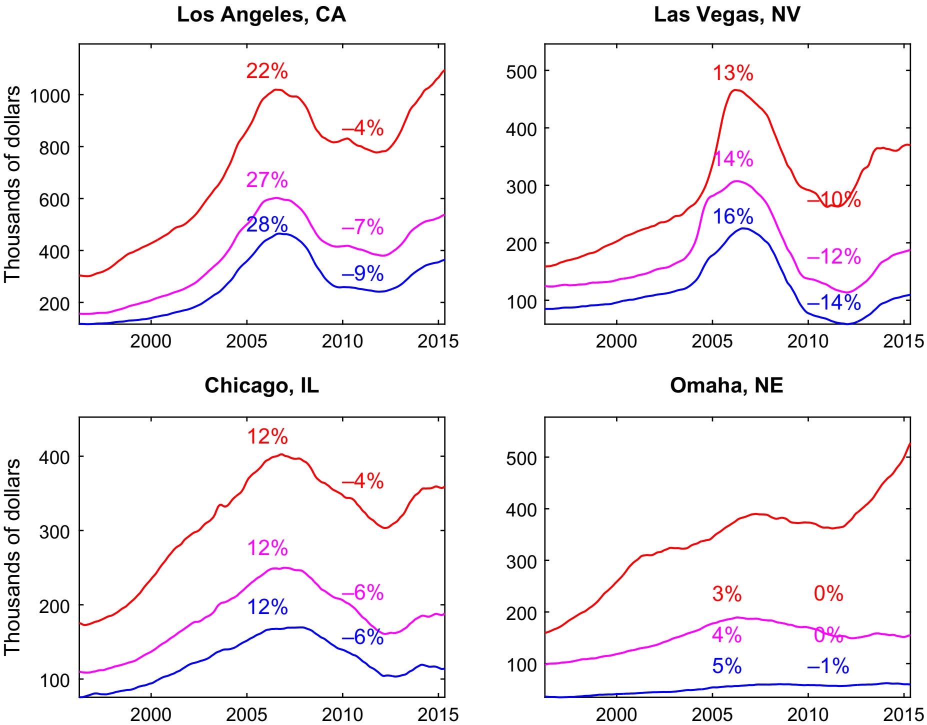

Fig. 5 Median house prices (in thousands of dollars) by city and tier: top tier (red (dark gray in the print version) line), medium tier (magenta (gray in the print version) line), and low tier (blue (black in the print version) line). The colored numbers indicate the tiered capital gains in percent per year during the housing boom (1996–2006) and during the bust (2006–11). *The data are from Zillow Research.*

shows that neighborhoods with an initially low price which were in close proximity to high-price neighborhoods appreciated more than otherwise similar initially low-price neighborhoods. For example, low-priced neighborhoods that were roughly 1 mile away from high-price neighborhoods appreciated by 12.4 percentage points more than low-priced neighborhoods that were roughly 4 miles away.

The recent experience in the "sand states"—Arizona, Florida, Nevada, and inland California—has challenged the notion that supply constraints amplify house price cycles. Fig. 1 in Davidoff (2013) shows that the magnitude of the house price cycle in the early 2000s in the sand states was larger than the cycle in coastal markets. His fig. 2 documents that the increase in the number of housing units was also larger in the sand states. Nathanson and Zwick (2015) argue that some cities, such as Las Vegas, do not have an abundance of land. Instead, these cities face long-run supply constraints in the form of tight virtual urban growth boundaries, formed by encircling federal and state lands.

2.3 Financing

Fig. 6 shows aggregate household debt from the Flow of Funds as multiple of GDP in the United States over the postwar period. The increase in the series happened in three discrete steps: right after World War II, the 1980s, and the 2000s. After the collapse of the housing market in 2006, households have been deleveraging. The red line in Fig. 6 is mortgage debt/GDP, which is roughly 3/5 of overall household debt. Most of household debt is thus collateralized. The plot shows that mortgage debt is chiefly responsible for the three discrete steps in which debt drastically increased. Household debt, especially mortgage debt, has also increased in other countries over the postwar period, as documented by Cardarelli et al. (2008). Jordà et al. (2016a) document this increase for many industrialized countries in a sample that goes back to 1870.

Jordà et al. (2016b) document that asset price boom–bust episodes that are combined with prior run-ups in leverage are associated with larger output costs during their bust. The data sample covers many industrialized countries going back to 1870. Moreover, boom–busts in housing have more severe output costs than those in equity markets.

2.3.1 Mortgage Growth During the 2000s

Mian and Sufi (2009) investigate who borrowed more during the 2000s. Did these borrowers expect higher future income growth? To address this question, Mian and Sufi use IRS data on income and mortgage debt data from the "Home Mortgage Disclosure Act" (HMDA). Their fig. 1 shows that income growth and mortgage growth are positively correlated across metro areas between 2002 and 2005 (in their top right panel). The evidence within metro areas, however, shows a *negative* correlation between income growth

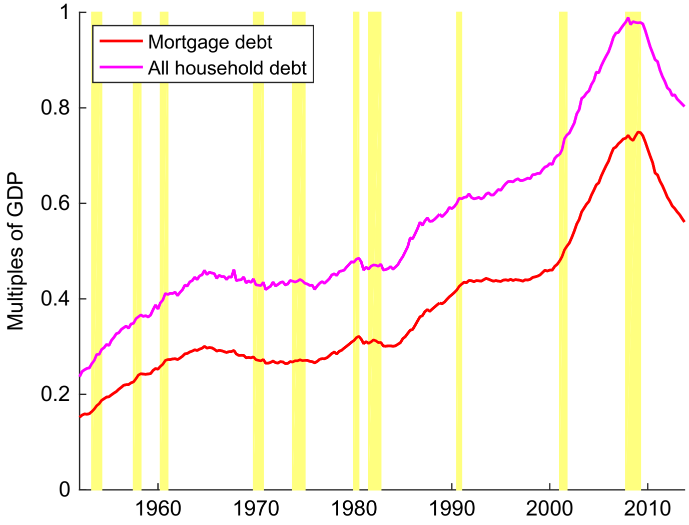

Fig. 6 Aggregate household debt and mortgage debt as fraction of GDP.

and mortgage growth across zip codes (in the lower right panel.) Moreover, they show that this negative correlation at the zip code level is unique to the 2002–05 period. These findings suggest that the 2000s were a unique episode in which mortgage debt increased in zip codes that experienced lower income growth.

Adelino et al. (2015) decompose mortgage growth into the extensive margin—the growth rate in the number of mortgages in a zip code—and the intensive margin—the growth rate in the size of individual mortgages. Their table 2 shows that the extensive margin is responsible for the negative correlation between IRS income growth and mortgage growth across zip codes. In fact, the intensive margin is *positively* correlated with IRS income at the zip code level. Moreover, Adelino et al. show that the growth rate of individual HMDA income—borrowers' income as indicated on their mortgage applications—is *positively* correlated to individual mortgage size across households. The paper argues that the negative correlation between income and mortgage growth documented by Mian and Sufi (2009) may be explained by a change in buyer composition (ie, richer buyers in poorer zip codes).

Mian and Sufi (2015) present evidence that the growth rate of HMDA income is higher than IRS reported income growth at the zip code level. They argue that the difference between the two growth rates represents mortgage fraud. Of course, the comparison of HMDA income and IRS income is tricky, because mover households who purchase a home have different characteristics than stayer households, especially during the 2000s boom. Table 2 in Landvoigt et al. (2015) compares the characteristics of home buyers and homeowners in 2000 Census data and 2005 data from the American Community Survey. They find that the median buyer in 2005 has more income and is richer than in 2000 in real terms.

Another important component of the increase in mortgage debt is existing homeowners who borrowed against the increased value of their house. Mian and Sufi (2011) document that especially homeowners in areas with stronger house price appreciation extracted equity from their houses with home equity lines of credit. Chen et al. (2013) report that a large fraction of refinancing during the 2000s were cash-outs, defined as more than 5% increases in loan amounts.

2.3.2 *Mortgage Contracts*

In the United States, the predominant mortgage contract is a fixed-rate mortgage with long maturity, usually 30 years. The main alternative is an adjustable-rate mortgage. In a basic adjustable-rate mortgage, the initial rate is set as a markup (or margin) on top of a benchmark, such as the 1-year Treasury rate. Adjustable rates are periodically reset to the current benchmark. During the recent housing boom, hybrid adjustable-rate mortgages became more popular. These hybrid contracts have a fixed rate for an initial period up to 10 years and adjusted periodically thereafter.

Campbell and Cocco (2003) report that fixed-rate mortgages accounted for 70% of newly issued mortgages on average during the period 1985–2001, while adjustable-rate mortgages accounted for the remaining 30%. The share of fixed-rate mortgages in new originations fluctuates over time. Fig. 2 in Campbell and Cocco (2003) shows the evolution of the share of fixed-rate mortgages, which is strongly negatively correlated with long-term interest rates.

Cardarelli et al. (2008), Andrews et al. (2011), and Badarinza et al. (2016) provide cross-country evidence on mortgage contracts. Table 4 in Andrews et al. shows that the typical mortgage maturity varies across countries between 10 years in Slovenia and Turkey to 30 years in Denmark and the United States. Table 3 in Badarinza et al. shows wide differences in the use of adjustable-rate mortgages and prepayment penalties. For example, the majority of mortgages in Australia, Finland, Portugal and Spain have an adjustable rate, while Belgium, Denmark, Germany, and the United States have mostly fixed-rate mortgages. Belgium and Germany have prepayment penalties, which make these fixed-rate mortgages highly risky. Table 3.1 in Cardarelli et al. (2008) shows that the countries with the largest fractions of securitized mortgages are the United States, Australia, Ireland, Greece, United Kingdom, and Spain.

2.3.3 Recent Financial Innovation and Lender Incentives

Leading up to the recent housing boom, the banking sector underwent a profound transformation. The traditional role of banks was to originate mortgages and hold them on their books until they are repaid. More and more, modern banks "originate-to-distribute"; banks originate mortgages, pool and tranche them, as resell them via the securitization process. In other words, mortgages are not kept on the balance sheet of the originating bank but are sold to investors. This transformation of the banking sector has changed the incentives of banks to screen mortgages. The resulting decline in lending standards has lead to a large expansion in credit.

Financial innovation also helped create new types of mortgages. Many mortgage contracts were designed to defer amortization, for example, with teaser rates or no interest rate payments during an initial period (such as "2–28 mortgages"). The share of alternative mortgages increased from below 2% until 2003 to above 30% during the peak years of the US housing boom (as documented, for example, in fig. 1 of Amromin et al., 2013). Another aspect of the deterioration of lending aspects were "no doc" loans, which did not require any documentation of income, or NINJA ("no income, no job or assets") loans.

Keys et al. (2010) provide evidence that securitization was associated with laxer screening of mortgages. The idea of the paper is to compare the performance of mortgages that are securitized with those that are not securitized. Since the 1990s, credit scoring has become the key tool to screen borrowers. The guidelines established by the government-sponsored enterprises, Fannie Mae and Freddie Mac, cautioned against lending to risky borrowers with a FICO score below 620. The 620 cutoff is also important for securitization as mortgages above the cutoff are easier to securitize. The paper studies the performance of a million mortgages over the years 2001–06. It finds that mortgages with a FICO score right above 620 performed *worse* than mortgages slightly below the 620 cutoff.

2.4 Market Structure

Housing has *broad ownership*. Roughly two thirds of US households own a house. Over the postwar period, the home ownership rate varied between 62% and 69%. It peaked at 69.2 at the end of 2004, toward the peak of the recent boom. The current ownership rate is down to 63.7%.

More households own a house than stocks. The ownership rate for stocks crucially depends on whether indirect holdings (through mutual funds and pension funds) are included or not. But even if we include indirect holdings, the ownership rate for stocks is below 50%.

Housing markets are *illiquid* relative to other asset markets. Turnover (per year) in housing markets is low relative to the stock market. The average turnover rate in the stock market is 110%, which means that every stock changes hands at least once in any given year. By contrast, the average turnover rate in the housing market is only 7%. This illiquidity is manifested in the fact that time on market—the number of days or months between listing and selling a house—is a key statistic in housing markets, while time on market plays no role in stock markets.

An important aspect of housing is that it is more *difficult to short* than other assets such as stocks. Because houses are unique and indivisible, an investor may not be able to take a short position in a particular house. The low liquidity in house price indices and their derivatives makes it either impossible or costly to take large short positions in the overall market. It is possible to short REITs, which are indexed to the value of commercial real estate. However, REITs are not perfectly correlated with the value of residential real estate. During recent housing booms, investors have used creative strategies to short housing. For example, during the recent housing boom, investors were short in mortgage-backed securities. In the ongoing Chinese boom, investors short the stock of large developers. Many of these investment strategies are costly and require sophistication, and are not perfect shorts for residential real estate.

Bachmann and Cooper (2014) document a secular decline in the turnover rate (the sum of their owner-to-owner and renter-to-owner moves) from the mid 1980s to 2000s in data from the Panel Study of Income Dynamics (PSID). Moreover, the paper documents that the turnover rate (in particular, the rate of owner-to-owner moves) is procyclical. Kathari et al. (2013) document a secular decline in moving rates of both renters and owners since the mid 1980s based on the Current Population Survey.

2.5 Household Portfolios

A sizeable literature uses various household level data sets to document cross-sectional patterns in housing consumption and the role of housing and mortgages in household portfolios. We summarize here key cross-sectional patterns that have been fairly stable over time. In particular, housing choices depend significantly on age and net worth.

It is well known that expenditure on nondurable consumption is hump-shaped over the life cycle (eg, Deaton, 1992). Fernandez-Villaverde and Krueger (2007) document a similar hump-shaped life cycle pattern for expenditure on durables. Their definition of durables includes purchases of consumer durables as well as housing expenditure by renters and owners in the CEX. Their fig. 6 shows that the hump peaks roughly at the age of 50 years, similar to the pattern for nondurables. After the peak, durables expenditure declines substantially with age. For example, durables expenditure at age 50 is twice as large as expenditure at 75.

Yang (2009) distinguishes expenditure on housing from that on other durables. For renters, housing expenditure is from CEX data. For owners, housing expenditure is from the SCF, assuming that expenditure is proportional to house value. Her fig. 4 shows that housing expenditure for owners also increases with age similar to durable expenditures. However, it peaks later in life—at age 65—rather than at age 50. Moreover, housing expenditure flattens out after age 65; unlike durable expenditure, it does not decline with age.

The homeownership rate is also hump-shaped over the life cycle. For example, table 6 in Chambers et al. (2009b) shows the homeownership rate first increases from roughly 40% for young households (aged 20–34 years) to twice that share for older households (aged 65–74 years). The homeownership rate then declines slightly for very old households.

The homeownership rate also increases with income. For example, Gyourko and Linneman (1997) study decennial census data from 1960 until 1990 to show that homeownership rates increase with income even after conditioning on age. There is also evidence that low income and minority households are less able to sustain homeownership than high income and white households. For example, Turner and Smith (2009) examine data from the PSID spanning the years 1970–2005 and document that homeowners in these groups have consistently higher exit rates from ownership.

The portfolio share on housing depends on both age and wealth. It declines monotonically with age. Young households are *house poor*: they choose highly leveraged positions in housing. As they age and accumulate wealth, they lower their portfolio weight on housing and pay down their mortgages. For example, table 2 in Flavin and Yamashita (2002) shows that young homeowners (aged 18–30) have an average portfolio weight of 3.51 on housing and −2.83 on mortgages in the PSID. Middle-aged households (aged 41–40 years) have an average weight of 1.58 on housing and −0.88 on mortgages. Older households (aged 71+) have an average weight of 0.65 on housing and −0.04 on mortgages.

The portfolio share on housing is hump-shaped in wealth. For example, table 1 of Campbell and Cocco (2003) shows that households in the bottom third of the wealth distribution are renters—they do not own a home, so their portfolio share on housing is zero. Wealthier households have a large fraction of their wealth, between 60% and 70%, invested in housing. For rich households (in the top 20% of the wealth distribution), the portfolio share on housing rapidly declines with wealth. These households shift more and more of their portfolio into stocks.

Wealth is also hump-shaped over the life cycle. Fig. 7 in Piazzesi and Schneider (2009a) uses the Survey of Consumer Finances to document the hump in wealth for middle-aged households (aged 53 years). The figure plots wealth of "rich households"—defined as the top 10% of net worth in their cohort—separately from cohort totals. These rich households own more than half of the cohort wealth—indicating a high concentration of wealth.

The hump in wealth over the life cycle multiplied by portfolio shares on housing that decline with age results in a hump-shaped pattern in housing wealth over the life cycle (third left panel in fig. 7 of Piazzesi and Schneider, 2009a). This housing wealth is somewhat concentrated—rich households own roughly a third of the housing wealth in their cohort. However, most of the overall wealth concentration can be attributed to the extremely high concentration of wealth invested in stocks: rich households own almost all of the stock wealth in their cohort.

3. THEORY

This section describes a theoretical framework that nests or provides background for many studies in the literature. At its heart is the intertemporal household decision problem with housing as both an asset and a consumption good. The papers discussed below all share a version of this problem. They differ in what other aspects of housing are included—in particular, the option to rent, collateral constraints or transaction costs—in whether equilibrium is imposed and, if yes, in how the supply side is modeled.

We thus begin with a "plain vanilla" household problem. It assumes that houses of every quality as well as other assets and consumption of the nonhousing good are all traded in competitive markets. The only friction is that consumption of housing services requires ownership of a house. Housing thus differs from other assets because of *indivisibility* and *nontradability of dividends*. Indeed, households hold either zero or one units of the housing asset and the "dividend"—that is, the value of housing services less maintenance cost—cannot be sold in a market to other households.

After introducing the plain vanilla problem, we discuss household optimization, derive asset pricing equations and define an equilibrium with a fixed aggregate supply of housing services. Here, we highlight the distinction between an exogenous distribution of house qualities and a fixed stock of housing that developers can costlessly convert into one of many distributions with the same mean. We also discuss the role of expectation formation. In later sections, we then add further key ingredients one by one: production and land, a rental market, collateral constraints and transaction costs.

3.1 Basic Setup

We work in discrete time. Studies differ in how long the economy lasts and what households' planning horizons are. To explain the basic tradeoffs, these details are not important, so we do not take a stand on them now. Instead, we focus on the period t decisions of a household who expects to also live in period $t+1$. Studies also typically assume a large number of different households who may differ in characteristics such as age, income or beliefs. We do not make such heterogeneity explicit, but instead describe a generic household problem with minimal notation.

To represent uncertainty, we fix a probability space $(\Omega, \mathcal{F}, P^0)$. The set Ω contains states of the world. Events in the σ-field $\mathcal{F}$ correspond to all exogenous events that can occur. For example, each state of the world could imply a different sequence of shocks to a household's income over his lifetime. The probability measure P^0 says how likely it is that each event $F \in \mathcal{F}$ occurs. In other words, it tells us with what probability nature draws a state of the world $\omega \in F$. In general, the "physical" probability P^0 need not coincide with the belief of a household.[d]

3.1.1 Preferences

The evolution of the households' information is summarized by a filtration $\mathcal{F}_t$ on Ω: $F \in \mathcal{F}_t$ means that the household knows in period t whether event F has occurred or not. The household's belief about states of the world is described by a probability P. In what follows, we keep these objects in the background and instead work directly with random variables and conditional moments. Our convention is that random variables dated t are contained in the household's period t information set. For example, c_t is (random) consumption of nonhousing goods and we write $E_t c_{t+1}$ for the household's expected period $t+1$ consumption given period t information.

Households derive utility from housing services s and other consumption c. Utility is state and time separable; in particular, period t utility from the two goods is given by

$$U(g(s_t, c_t)),$$

where $g: \mathbb{R}^2 \rightarrow \mathbb{R}$ is an "aggregator function" that is homogeneous of degree one and $U: \mathbb{R} \rightarrow \mathbb{R}$ is strictly increasing and concave. Decomposing utility in this way helps

[d] The physical probability is what one would use to compute or simulate the distribution of outcomes of the economy. It thus coincides with the belief of an outside observer, for example, an econometrician, who observes a large sample of data generated from the model.

distinguish substitution across goods within a period from substitution of consumption bundles $g(s_t, c_t)$ across periods.

The aggregator g describes households' willingness to substitute housing services for other consumption within a period. A common example is the CES functional form

$$g(s_t, c_t) = \left(c_t^{(\varepsilon-1)/\varepsilon} + \omega s_t^{(\varepsilon-1)/\varepsilon}\right)^{\varepsilon/(\varepsilon-1)}, \tag{2}$$

where ε is the *intra*temporal elasticity of substitution and ω is a constant. Agents are more willing to substitute within the period the higher is ε. As $\varepsilon \to \infty$, the two goods become perfect substitutes and as $\varepsilon \to 0$, they become perfect complements. The limit $\varepsilon \to 1$ represents the Cobb–Douglas case with constant expenditure shares.

The function U captures agent's willingness to substitute consumption *bundles* g over time (as well as states of nature). A common example is the power function $U(g) = g^{1-1/\sigma}/(1-1/\sigma)$ where σ is the *inter*temporal elasticity of substitution among bundles at different points in time. For $\sigma \to 0$, households want to maintain a stable bundle over time whereas for $\sigma \to \infty$ utility becomes linear in bundles. The limit $\sigma \to 1$ corresponds to logarithmic utility. With a CES aggregator, the special case $\sigma = 1/\varepsilon$ results in utility that is separable across the two goods.

While our assumptions on utility are convenient for exposition, several straightforward extensions are also common in the literature. First, some papers replace time separable utility by recursive utility, for example, the tractable functional form introduced by Epstein and Zin (1989). To deal with multiple goods, the usual recursive utility formulation is applied directly to bundles aggregated by g.[e] Second, some papers add preference shocks; in particular, a "housing preference shock" is often introduced via a random weight ω in (2). Finally, labor is often added as a third good in utility.

3.1.2 Technology

Households obtain housing services by living in exactly one house. Houses come in different qualities $h \in \mathcal{H} \subset \mathbb{R}$ where the set $\mathcal{H}$ can be either discrete or continuous. Our convention is that $\mathcal{H}$ may contain zero to accommodate households who do not live in a house. A household who lives in a house of quality h_t from t to $t + 1$ obtains a flow of housing services $s_t = h_t$ that enters period t utility. In quantitative applications, the flows s_t and c_t are typically identified with the household's consumption over a time range

[e] Formally, let $W : \mathbb{R}^2 \to \mathbb{R}$ denote a function that captures substitution over time and let $\nu : \mathbb{R} \to \mathbb{R}$ denote a function that captures aversion to risk about utility gambles. Utility from a consumption process (c_t, g_t) is defined recursively by

$$U_t = W\left(g(c_t, s_t), \nu^{-1}(E_t[\nu(U_{t+1})])\right).$$

Our time separable case obtains if $\nu = U$ and $W(x, y) = U(x) + \beta U(y)$. Epstein and Zin propose a CES aggregator for W and a power function for ν.

that includes date t, and the quality of his residence h_t is an average over that time range. Our timing convention implies that the house quality h_t relevant for period t consumption is chosen based on the period t information set.[f]

The one-dimensional quality index h orders houses from low to high qualities. In general, it captures many characteristics of a house—its location, the size of the land, square footage of lot and structure, its view, amenities, etc. The underlying assumption is that households agree on the ranking of all houses within the housing market that is being studied. At the same time, households may differ in their taste for house quality relative to other consumption and hence be willing to pay different amounts for any given house.

A household who lives in a house of quality h_t from t to $t+1$ must undertake maintenance worth $I(h_t)$ units of the other (nonhousing) good. The quality of the house then evolves over time according to

$$h_{t+1} = H_{t+1}(h_t), \tag{3}$$

where the subscript $t+1$ indicates that the evolution may be random. We highlight two popular special cases. The first assumes that all depreciation is "essential maintenance" without which the house is uninhabitable. As long as essential maintenance is performed, house quality is constant, that is, $I(h_t) = \delta_h h_t$ and $H(h_t) = h_t$. A second special case is that households do not pay for maintenance but average quality deteriorates geometrically, that is, $I(h_t) = 0$ and $H(h_t) = (1-\delta_h)h_t$. In both cases, $\delta_h h_t$ is depreciation of housing. The first approach is convenient when the set of qualities $\mathcal{H}$ is finite.

3.1.3 Housing Markets

Houses are traded in competitive markets. The only friction is that consumption of housing services requires ownership of a house. Housing thus differs from other assets because of *indivisibility* and *nontradability of dividends*. Indeed, it is held in indivisible units and its "dividend"—that is, the value of housing services less maintenance cost—cannot be sold in a market. This assumption is relaxed in Section 3.6 where we introduce a market for rental housing. In line with our timing convention, utility from a house bought at date t is enjoyed at date t itself—date t house prices are thus "cum dividend."

A house of quality h_t trades in period t at the price $p_t(h_t)$, denominated in units of the nonhousing good which serves as numeraire. The price function is increasing in quality. If the set $\mathcal{H}$ consists of a finite number of house types, then house prices can be summarized by a vector. With a continuum of qualities, it often makes sense to assume that the price function is smooth—a small change in quality leads to a small change in price. For example, in some applications the price function is linear, that is, there is a number $\bar{p}_t$ such that $p_t(h) = \bar{p}_t h$ for all quality levels h.

[f] Alternative timing conventions are possible and sometimes used in the literature. For example, we might assume that quality chosen at date t yields housing services only at date $t+1$.

3.1.4 What Is a House?

The setup emphasizes indivisibility and quality differences: housing services are provided by a distribution of housing capital stocks of different qualities, one for each household. In general, pricing is nonlinear: each quality level represents a different good and relative prices depend on relative demand and supply. This approach goes back to Rosen (1974) who studied competitive equilibrium with consumers who choose one "design" of a product that is identified by a vector of characteristics.

Braid (1981, 1984) and Kaneko (1982) studied housing with a one-dimensional quality index in static models with a continuum and a finite set of qualities, respectively. Caplin and Leahy (2014) characterize comparative statics of competitive equilibria in a static setting with a finite number of agents and goods. The dynamic setup here follows the finite quality models in Ortalo-Magné and Rady (1999, 2006) and Ríos-Rull and Sánchez-Marcos (2010) as well as the continuum approach in Landvoigt et al. (2015).

At first sight, allowing for nonlinear pricing may appear unnecessary: why not assume that there is a homogenous housing capital good—akin to physical capital in many macroeconomic models—with households choosing different quantities of that good at a common per-unit price? The latter approach is a special case of the setup that obtains when some market participants can convert houses of different quality with a marginal rate of transformation of one. For example, in Section 3.4, we derive it from the presence of a developer sector who undertakes this activity.

Work on housing has more often gone beyond setups with homogeneous capital and linear pricing than work on, say, business capital. One likely reason is measurement. The difficulties with measuring house prices in national accounts have been discussed frequently. At the same time, new micro data provide evidence on price dynamics at fine levels of disaggregation by geography and type of house. The evidence in Section 2.2 suggests that linear pricing is perhaps too restrictive, since both volatility conditional on quality is high and conditional means vary systematically by quality. We return to this issue below.

While our setup nests essentially all specifications in the macro literature, it is restrictive in at least two ways. First, it may not be possible or desirable to represent the cross section of houses by a one-dimensional index. A more general approach could follow Rosen (1974) and directly model preference over many characteristics. In particular, households may rank houses differently because they disagree about the weighting of characteristics. Second, a more general approach to household capital accumulation might start from an evolution equation

$$h_{t+1} = z_{t+1} H(h_t, I_t),$$

where z_{t+1} is a depreciation shock. In this equation, initial quality h_t and improvements I_t are imperfect substitutes, so that upkeep of the house is an explicit margin for the household. This approach could generate a distribution of houses in different states of disrepair.

3.2 Household Choice

We now consider the household's decision problem when houses as well as other assets and consumption of the nonhousing good are all traded in competitive markets. The household receives an exogenous labor income stream y_t. Securities, such as equity or bonds, trade at date t at prices collected in a $J \times 1$ vector q_t and provide payoffs at date $t+1$ summarized by a $J \times 1$ vector π_{t+1}. For long-lived securities such as equity, the payoff may contain the date $t+1$ price. We make no further assumption on market structure. Markets may be incomplete in the sense that it is not possible for households to assemble a portfolio of securities in period t with payoff equal to any given consumption plan that depends on date $t+1$ information. With incomplete markets, households may not be able to insure against future labor income risk.

3.2.1 Recursive Household Problem

Without trading frictions, past portfolio choice—including housing choice—affects the household at date t only through its effect on wealth. We can thus formulate the problem recursively with a single endogenous state variable *cash on hand w* that comprises housing wealth, other wealth plus income from labor and securities. To start off the recursion, we define a terminal value function $V_T(w_T)$. In a finite horizon life cycle problem, this function captures utility at the end of life, perhaps including bequests. In an infinite horizon setup ($T=\infty$), existence of a value function can be derived from trading restrictions that prevent Ponzi schemes.

For a household who expects to live for an additional period, the Bellman equation is

$$V_t(w_t) = \max_{c_t,\,,\theta_t;h_t \in \mathcal{H}} U(g(c_t,h_t)) + \beta E_t[V_{t+1}(w_{t+1})] \tag{4}$$

$$c_t + p_t(h_t) + I(h_t) + \theta_t^\top q_t = w_t,$$

$$w_{t+1} = \theta_t^\top \pi_{t+1} + p_{t+1}(H_{t+1}(h_t)) + y_{t+1}.$$

The first condition is the current budget constraint that says how cash on hand is split into consumption, asset purchases and maintenance. The second constraint describes the evolution of cash on hand which depends on future security payoffs, house value and labor income.

The same Bellman equation works for problems with random horizon. Indeed, a common approach assumes that households survive with a probability that can depend on age. Those survival probabilities are then used in computing the conditional expectation in the Bellman equation. In the terminal period of life, households learn that this is their last period, sell all assets and either consume the proceeds or transfer wealth to children. Given our timing convention on housing services and the need for ownership, we also assume that households do not consume housing services in the terminal period of life.

3.2.2 Two Stage Solution Approach

We consider household choice in two stages. The household first decides on house quality and thus how much of cash on hand to spend on housing. In a second stage, he allocates the remaining funds to numeraire consumption and securities. The split is helpful because indivisibility and nontradability make the housing choice special. On the one hand, indivisibility means that house quality may be discrete and the pricing of house quality may be nonlinear. On the other hand, nontradability means that housing and securities are imperfect substitutes even if there is no risk—a case when all other securities become perfect substitutes.

We write the second stage problem with returns and portfolio weights, rather than asset prices and quantities. The gross return on the jth security is $R_{t+1,j} = \pi_{t+1,j}/q_{t,j}$. We assume that the Jth security is a risk-free bond and denote the gross risk-free rate by R_t^f. Moreover, the returns on securities $j = 1, \ldots, J-1$ are risky and collected in a vector R_{t+1}. The household selects a portfolio weight $\alpha_{t,j}$ for each of the risky assets j. These weights are collected in a $J-1$ vector α_t, so that $1-\alpha_t^\top \iota$ is invested in risk-free bonds, where ι is a $J-1$ vector of ones. There are no restrictions on the sign of the portfolio position: the households can short a risky asset by choosing $\alpha_{t,j} < 0$ or borrow at the riskless rate by choosing $\alpha_t^\top \iota > 1$. The return on the portfolio is $\widetilde{R}_{t+1}(\alpha_t) = \alpha_t^\top R_{t+1} + (1-\alpha_t^\top \iota)R_t^f$.

The second stage problem is

$$\widetilde{V}_t(\widetilde{w}_t, h_t) = \max_{c_t, \alpha_t} U(g(c_t, h_t)) + \beta E_t[V_{t+1}(w_{t+1})]$$

$$w_{t+1} = (\widetilde{w}_t - c_t)\widetilde{R}_{t+1}(\alpha_t) + p_{t+1}(H_{t+1}(h_t)) + y_{t+1}. \tag{5}$$

The household starts with cash $\widetilde{w}_t = w_t - p_t(h_t) - I(h_t)$ left over after housing expenditure. He then chooses numeraire consumption c_t and invests the remaining funds $\widetilde{w}_t - c_t$ in securities. Cash next period consists of savings in securities multiplied by their average return plus the payoffs from housing and human capital, both of which are nontradable assets in the second stage problem.

Optimal choice depends on risk in house values, labor income and securities returns. To illustrate, we perform a second-order Taylor expansion of the future value function in (5) around expected future wealth to obtain

$$\widetilde{V}_t(\widetilde{w}_t, h_t) \approx U(g(c_t, h_t)) + \beta V_{t+1}(E_t w_{t+1}) + \frac{1}{2}\beta E_t V''_{t+1}(E_t w_{t+1}) var_t(w_{t+1}).$$

Without risk, the last term vanishes and the problem has a solution only if all returns are the same. Securities are then perfect substitutes and portfolio choice is indeterminate. More generally, for a risk-averse household with $V''_{t+1} < 0$, welfare declines with the volatility of future wealth. As a result, securities are imperfect substitutes. Moreover, utility declines with the volatility of future house values as well with the covariance of house values and labor income.

3.2.3 Housing Choice

The first stage problem takes as given the maximized objective $\widetilde{V}_t$ from the second stage. We assume that $\widetilde{V}_t$ is increasing in both its arguments and smooth as a function of $\widetilde{w}_t$; properties usually inherited from g, U and V_T. The first stage problem is then to choose optimal house quality to solve

$$V_t(w_t) = \max_{h_t \in \mathcal{H}} \widetilde{V}_t\left(w_t - p_t(h_t) - I(h_t), h_t\right). \tag{6}$$

The household thus trades off expenditure on a house against its indirect utility value. From (5), the latter comes from two sources: housing not only earns capital gains, but also enters utility as a consumption good—it delivers a nontradable dividend. Nontradability thus implies that housing and other assets can be imperfect substitutes even when there is no risk.

In the typical application, optimal house quality is increasing in wealth, other things equal. Indeed, the objective on the right-hand side of (6) is typically supermodular in (w, h), that is, the benefit from additional cash is increasing in house quality and vice versa. Intuitively, one key force is diminishing marginal utility of numeraire consumption and future wealth: if more is spent on housing then extra cash becomes more valuable. However, we also need that the utility value of house quality does not overturn this effect. This might happen, for example, if housing services are not a normal good in the aggregator g or if the distribution of capital gains R^h becomes much more attractive at higher qualities.

With a discrete set of house qualities, an increasing policy function is a step function in wealth: there are cutoff wealth levels at which households are indifferent between two adjacent quality levels. Households with wealth in between two cutoffs all choose the same quality level which they strictly prefer. Moreover, our setup allows for zero holdings of housing—in general, marginal utility need not increase without bound as consumption of housing services tends to zero. As a result, there can be a wealth cutoff at which households are indifferent between the lowest available house quality and not buying any house. With continuous house quality, we work with a smooth price function and also assume further that the objective $\widetilde{V}_t$ is smooth in h_t. At the optimal quality, a household is then indifferent between his optimal quality and a slightly better or worse house. Optimal choice is characterized by the first order condition

$$p_t'(h_t) + I'(h_t) = \frac{\widetilde{V}_{t,2}(w_t - p_t(h_t) - I(h_t), h_t)}{\widetilde{V}_{t,1}(w_t - p_t(h_t) - I(h_t), h_t)}, \tag{7}$$

where $\widetilde{V}_{t,i}$ are the partial derivatives of $\widetilde{V}_t$.

The marginal rate of substitution of housing for other expenditure is equated to the *slope* of the house price function at quality h. The slope appears because of indivisibility: the quantity of housing is one for all households, and indifference is across nearby quality levels. In contrast to a competitive model with divisible goods, the marginal rates of substitution of different households are not necessarily equated in equilibrium. The only exception is the case of a linear function for prices as well as linear improvements (for example, either one of the two special cases for technology highlighted above $I(h_t) = \delta_h h_t$ and $I(h_t) = 0$.). Indeed, if the slopes on the left-hand side are the same everywhere, then h_t can equivalently be interpreted as the quantity of a divisible housing capital.

3.2.4 Consumption and Savings

Consider now the second-stage problem for given house quality. The first-order conditions with respect to nonhousing consumption c_t as well as portfolio weights α_t on the $J-1$ risky securities can be arranged as

$$\begin{aligned} U'(g(c_t,h_t))g_1(c_t,h_t) &= \beta E_t\left[V'_{t+1}(w_{t+1})\right]R_t^f \\ 0 &= \beta E_t\left[V'_{t+1}(w_{t+1})\left(R_{t+1} - \iota R_t^f\right)\right]. \end{aligned} \tag{8}$$

The first equation says that households are indifferent at the margin between consumption and borrowing or lending at the risk-free rate. The second equation shows the portfolio choice margin: households are indifferent between risk-free investment and investment in any of the risky securities.

The first equation helps understand which households hold leveraged positions in housing. Indeed, suppose there are no risky securities. The first equation then determines optimal consumption, the only variable affecting future cash on hand w_{t+1} in (5) that is not predetermined given h_t, $\widetilde{w}_t$ and y_{t+1}. In particular, if the household has more labor income next period, he consumes more so that his bond position $\widetilde{w}_t - c_t$ declines and may become negative. We would thus expect homeowners with an upward sloping labor income profile and little initial financial wealth to leverage up. This intuition is quite general and continues to hold when labor income or security returns are risky. It allows life cycle models to successfully replicate the age profile of household portfolios in the data.

We emphasize that borrowing (that is, negative $\widetilde{w}_t - c_t$) does not imply negative savings, because savings also include the positive housing position. This feature is important for matching the data where savings are rarely negative. In the model, savings can be positive because the purpose of borrowing is not necessarily to move income from the future to the present—in fact, a borrower household with positive savings moves income from the present to the future. Instead, the purpose of borrowing for such a household is to buy a large enough house to enjoy his desired flow of housing services.

3.2.5 Securities Portfolios

To get intuition on the role of housing in portfolio choice, suppose that the continuation value function V_{t+1} is known as of date t.[g] From the first order conditions for risky

[g] This is literally true only under restrictive conditions, for example, when asset returns are iid and income is deterministic. More generally, V_{t+1} is random conditional on date t because continuation values depend on state variables that forecast future asset returns and income. The optimal portfolio weights then contain an additional term that reflects "intertemporal hedging demand"—agents prefer assets that insure them against bad realizations of the state variables. We simplify here to focus on the new effects introduced by housing.

securities and using the definition of cash on hand, we can then approximate the optimal portfolio weights on risky securities by

$$\alpha_t \approx \frac{E_t w_{t+1}}{\tilde{w}_t - c_t} var_t(R_{t+1})^{-1} \left(\rho_{t+1}^{-1} \left(E_t R_{t+1} - R_t^f \right) - cov_t \left(R_{t+1}, \frac{y_{t+1} + p_{t+1}(H_{t+1}(h_t))}{E_t w_{t+1}} \right) \right), \tag{9}$$

where $\rho_{t+1} = -E_t w_{t+1} V''_{t+1}(E_t w_{t+1}) / V'_{t+1}(E_t w_{t+1})$ reflects curvature in the value function and can be interpreted as a measure of relative risk aversion.

The optimal portfolio equation resembles textbook formulas, but makes important corrections for the presence of nontradable assets, here human capital and housing. To interpret it, consider first the scale factor $E_t w_{t+1} / \left(\tilde{w}_t - c_t \right)$. If there are no nontradable assets, then this factor equals the expected return on the entire securities portfolio and typically has only a small effect on the optimal weights. More generally, it says that the weights should be scaled up if there a lot of nontradable assets. This is because total wealth is not only $\tilde{w}_t - c_t$ but includes the present value of those nontradable assets.

Consider now the big bracket in (9). The first term reflects the desire to exploit premia on securities—expected returns that differ from the risk-free rate. To illustrate, suppose there is a security with payoffs that are orthogonal to any other shock including house prices and labor income. Up to the scale factor, the optimal weight on that security is simply its expected excess return divided by its variance as well as risk aversion. The household thus exploits a nonnegative premium on the security, and more so if there is less risk and he is less risk averse. The sign of the premium determines the direction of trade: the household holds the security if the premium is positive and shorts it otherwise.

The second term reflects hedging of labor income and housing risk. Consider first the role of labor income. If markets are complete, then there exists a portfolio of securities, θ_t^y say, that exactly replicates labor income, that is, $y_{t+1} = \pi_{t+1}^\top \theta_t^y$. Optimal portfolio choice for any risk-averse investor then involves a term that shorts the portfolio θ^y. Intuitively, the household wants to avoid risks that he is already exposed to via his nontradable human capital position. With incomplete markets, it may not be possible to short labor income. Instead, the household trades against labor income "as much as he can" with the existing set of assets. The precise meaning of "as much as he can" is given by the projection of labor income on returns $var_t(R_{t+1})^{-1} cov_t(R_{t+1}, y_{t+1})$.

Housing enters the optimal portfolio formula (9) in much the same way as labor income: it affects the demand for securities through the second "hedging demand" term. The presence of housing thus generally changes the optimal mix of securities. For example, households who work at local companies with payoffs that are correlated with their house price would optimally short the stocks of those companies. This type of interaction effect is present whether or not housing is traded in every period.

An interesting special case arises when labor income is uncorrelated with all risky securities. In this case, labor income enters (9) only because its mean increases the scale factor. The portfolio weights on all risky assets are thus scaled up along with mean labor income, regardless of labor income risk. At the same time the riskless asset position $1-\alpha_t^{\top}\iota$ is decreased. Households again trade away labor income, except that the portfolio best suited to do so now consists entirely of the risk-free security.

3.3 Asset Pricing

The previous section characterized households' optimal decision rules given prices. In particular, we have used household first-order conditions to interpret model implications for savings and portfolio choice that can be evaluated with data on household asset positions. As usual, the same first-order conditions imply restrictions on asset prices given consumption and payoffs. In fact, a large literature in asset pricing uses household Euler equations to test assumptions on preferences and market structure. Since Euler equations describe an equilibrium relationship between observables, they can be tested without taking a stand on other features of the economy such as asset supply.

This section considers household Euler equations for housing and contrasts them with those for securities. We thus move from the decisions of a generic household to restrictions on asset prices due to optimization by an entire population of possibly heterogeneous households. In order not to clutter notation, we mostly continue our practice of not explicitly labeling individual characteristics and choices such as income and consumption. At the same time, the discussion emphasizes that there is a large number of households whose first-order conditions hold simultaneously and whose choices and characteristics are observable.

3.3.1 Families of Euler Equations

So far, we have taken as given a household's subjective probability P and written subjective conditional expectations as E_t. When discussing asset prices, it is useful to distinguish between investor beliefs that relate prices and choices, and the "physical" probability that governs the data-generating process and is therefore relevant for describing measures of conditional moments constructed from the data. For example, an econometrician may measure expected excess returns $E_t^0 R_{t+1} - R_t^f$ by regressing excess returns on public information. From now on we assume that household beliefs and the physical probability agree on probability zero events next period and use the random variable ξ_{t+1} to indicate a change of measure: for any random variable Y, $E_t[Y] = E_t^0[\xi_{t+1} Y]$. Under rational expectations, we have $\xi_{t+1} = 1$.

Pricing Securities

We denote a generic household's intertemporal marginal rate of substitution (MRS) adjusted by the change of measure by

$$M_{t+1} = \beta \frac{U'(g(c_{t+1}, h_{t+1}))g_1(c_{t+1}, h_{t+1})}{U'(g(c_t, h_t))g_1(c_t, h_t)} \xi_{t+1}. \tag{10}$$

From (8), any household MRS serves as a stochastic discount factor: returns satisfy $E_t^0 M_{t+1} R_{t+1} = 1$ and securities prices can be written as $q_t = E_t^0 M_{t+1} \pi_{t+1}$. If markets are complete, all MRSs are equated in equilibrium and there is a unique M_{t+1} that represents the prices of contingent claims normalized by one-step-ahead conditional probabilities under P_0.

The standard pricing equation is often used (together with the definition of covariance) to decompose asset prices into expected discounted payoffs plus risk premia:

$$q_t = E_t^0 \pi_{t+1} / R_t^f + cov_t^0 (M_{t+1}, \pi_{t+1}). \tag{11}$$

The risk premium required by investors is larger (and the price therefore lower) if a security pays off little when the MRS is high. A positive risk premium is equivalent to a positive expected excess return $E_t^0 R_{t+1} - R_t^f$. Measures of conditional moments $E_t^0 \pi_{t+1}$ or $E_t^0 R_{t+1}$ constructed from the data—for example, by regression on public information—imply that expected payoffs are much more stable than prices, and that expected excess returns are predictable. Similar results obtain for housing, as reviewed in Section 2.2. If investors have rational expectations and have no or mild risk aversion, this finding cannot be reconciled with (11)—the excess volatility puzzle.[h]

We say that an agent is a *marginal investor* for an asset if any small change in its price or return distribution changes his optimal position in that asset. This concept is key for understanding asset pricing in heterogeneous agent models: it tells us whose behavior changes along with asset prices. For example, shocks that mostly affect *infra*marginal agents (that is, agents who are not marginal) are unlikely to move prices. Conversely, if a shock moves the price, it must also affect the positions of marginal agents. In our setup, the first-order conditions (8) imply that all households are marginal for all assets. Asset prices thus change if and only if all households adjust their positions. This is true whether or not markets are complete.

House Prices with a Finite Number of Qualities

Indivisibility means that only few households may be marginal for houses of any given quality. Indeed, with a finite set of qualities $\mathcal{H} = \{h^1, \ldots, h^n\}$, a household who strictly prefers his optimal quality in the first stage problem (6) will not respond to a change in price. At the same time, for every quality h^k except the highest, there are marginal

[h] Eq. (11) indicates two reasons why asset prices could exhibit premia that are on average high but also volatile. First, if investors have rational expectations then the covariance of the MRS with payoffs must be negative and variable. Alternatively, investors may be more pessimistic than the econometrician (that is, ξ is high when π is low) and their relative pessimism moves over time.

investors who are indifferent at date t between h^k and the next highest quality. The indifference conditions

$$\widetilde{V}_t\left(w_t - p_t\left(h^k\right) - I\left(h^k\right), h^k\right) = \widetilde{V}_t\left(w_t - p_t\left(h^{k+1}\right) - I\left(h^{k+1}\right), h^{k+1}\right) \qquad (12)$$

relate price steps between quality levels to the characteristics of the marginal investors. The marginal investors are thus particularly important for pricing houses.

Restrictions on house values $p_t\left(h^k\right)$ are obtained by adding up price steps implied by (12). In applications, there is typically an additional household optimality condition that serves as a boundary condition. In particular, we assume in what follows that there is always a household who is indifferent between the worst quality house or no house at all. For such a household, the indifference condition (12) holds at $h^1 = 0$ and $p_t\left(h^1\right) = 0$. Alternatively, the price of the worst quality house may be given by its value in some alternative use that leaves the house vacant.

Example 1 There are two periods, two states of nature and three house qualities 0, h^1 and h^2. The only security is risk free with a zero interest rate. There is no maintenance and future house values are h^i in state 1 and zero in state 2. There is a continuum of households with linear utility in both goods as well as future wealth. Households share the same discount rate of zero and the same wealth, but differ in their subjective probability of the high price state, say ρ. The household characteristic ρ is distributed uniformly on $[0,1]$. We consider an allocation with $1 - \rho_2$ houses of quality h^2 and $\rho_2 - \rho_1$ houses of quality h^1.[i]

The following prices and individual choices are consistent with individual optimization. There are cutoff households with subjective probabilities ρ_1 and ρ_2 who are indifferent between zero and h^1, as well as h^1 and h^2, respectively. Households with beliefs ρ_1 determine the value of a house of quality h^1 as "dividend" (housing services) plus expected resale value, $p\left(h^1\right) = h^1 + \rho_1 h^1$. Households with ρ_2 value house quality h^2 as $p\left(h^2\right) = p\left(h^1\right) + (1+\rho_2)\left(h^2 - h^1\right)$. Both expressions satisfy (12). Households with $\rho \in [\rho_2, 1]$ choose quality h^2, households with $\rho \in [\rho_1, \rho_2]$ choose h^1 and households with $\rho < h^1$ choose zero. In this example, the second stage is trivial: agents are indifferent between current and future consumption. In the first stage problem, higher-probability households buy high quality houses. Lower probability households perceive those houses as too expensive.

House Prices with Continuous Quality

With continuous house quality, every household is marginal for houses of his own optimal quality, but not necessarily for any other quality. To see this, start from the first-order

[i] One way to think of this setup is as an equilibrium model with fixed supply. More generally, it simply describes a family of households who buy a set of houses, for example, all movers in a given period.

condition (7) and substitute for the derivatives of $\widetilde{V}_t$ using (8) and the envelope theorem to obtain

$$p_t'(h_t) = \frac{g_2(c_t, h_t)}{g_1(c_t, h_t)} - I'(h_t) + E_t^0\left[M_{t+1} p_{t+1}'(H_{t+1}(h_t)) H_{t+1}'(h_t)\right]. \tag{13}$$

A household who chooses h_t is indifferent between h_t and a slightly better or worse house: the slope of the equilibrium price function must equal the change in the "dividend" $g_2/g_1 - I'$ plus the change in the risk adjusted future value of the house. If now some range of houses becomes more expensive while prices around quality h_t remain unchanged, this does not affect the optimal choice of h_t. No household needs to be marginal for any quality other than his own.

The Euler equation (13) restricts the slope of the price function, much like (12) restricts price steps along a discrete quality ladder. Restrictions on house values are again derived using a boundary condition. To illustrate, we select for each quality one household who buys that quality, and denote his numeraire consumption and MRS by $\left(c_t^*(h), M_{t+1}^*(h)\right)$. We then integrate (13) starting from $p_t(0) = 0$ to write the house price at quality h as

$$p_t(h) = \int_0^h \frac{g_2(c_t^*(\widetilde{h}), \widetilde{h})}{g_1(c_t^*(\widetilde{h}), \widetilde{h})} d\widetilde{h} - I(h) + E_t^0\left[\int_0^h M_{t+1}^*(\widetilde{h}) p_{t+1}'(H_{t+1}(\widetilde{h})) H_{t+1}'(\widetilde{h}) d\widetilde{h}\right]. \tag{14}$$

With indivisibility, the "dividend" of a house of quality h reflects an average of intratemporal MRSs of households who purchase qualities less of equal to h. Similarly, risk adjustment reflects an average of intertemporal MRSs of those households.

A popular special case restricts price functions to be linear. Linear pricing can be derived from the assumption that developers can freely convert houses of different quality into each other, as discussed further in Section 3.4. With the same slope $p'(h_t) = \bar{p}_t$ at every quality level, the Euler equation (13) applies to the price per unit of quality $\bar{p}_t$. The value of a house of quality h is

$$\bar{p}_t h = \frac{g_2\left(c_t^*(h), h\right)}{g_1\left(c_t^*(h), h\right)} h - I'(h) h + E_t^0\left[M_{t+1}^*(h) \bar{p}_{t+1} h H_{t+1}'(h)\right]. \tag{15}$$

With linear pricing, markets for different quality housing are tied more tightly together. As a result, every household is marginal for every house, as is the case for securities. The dividend and risk adjusted payoff at quality h can then be related to the MRSs of households who buy quality h.

Example 2 To illustrate nonlinear pricing with a continuum of qualities, we adapt the simple example from above. The set of households is unchanged, but the set of qualities is now $\mathcal{H} = [0, 1 - \rho_1]$. We consider an allocation with θ_1 houses of quality zero and $1 - \theta_1$

houses of positive quality uniformly distributed along the interval. Without maintenance, the first order condition (13) simplifies to $p_t'(h) = 1 + \rho$. We again construct prices and choices that satisfy all optimality conditions. There is a cutoff household who has subjective probability ρ_1 and is indifferent between no house and an infinitesimal house. Households with $\rho < \rho_1$ buy no house, while households with $\rho > \rho_1$ buy a house of quality $h = \rho - \rho_1$. House values are $p_t(h) = h(1 + \rho_1) + \frac{1}{2}h^2$.

Again higher probability households buy better houses, which lower probability households perceive to be overpriced. Let ρ_0 denote the true probability of state 1. The stochastic discount factors for securities $M_{t+1}^*(h)$ are equal to $(h + \rho_1)/\rho_0$ in state 1 and $(1 - (h + \rho_1))/(1 - \rho_0)$ in state 2. Since the discount rate is zero and utility is linear, they differ only by the change of measure from the subjective probability of households who buy quality h to the true probability ρ_0.[j] Every stochastic discount factor correctly prices the riskless bond, the only available security.

So far the example emphasizes heterogeneity in risk assessment through beliefs. The essential feature, however, is only that agents disagree about the future value of houses. We can thus alternatively assume that there is no risk ($\rho_0 = 1$) but ρ represents households' discount factors. For the above choices to remain optimal, we also assume that there is no risk-free security so houses are the only traded assets. Prices are then the same as above: the interpretation is that more patient households buy larger houses since they want to save more. The absence of a risk-free security is important to ensure a solution to households' problems without borrowing constraints.

3.3.2 Limits to Arbitrage

In general, there need not exist a stochastic discount factor that prices all houses. This is a key difference between houses and divisible securities with tradable payoffs. The existence of a stochastic discount factor says that all investors who choose to buy assets discount risk-free payoffs at the same rate and pay the same risk premia per unit of payoff. In a frictionless market, these properties are guaranteed by the absence of arbitrage opportunities, which in turn is necessary for the existence to a solution to the investor's optimization problem.[k]

A stochastic discount factor need not exist because indivisibility and nontradability introduce limits to arbitrage. In fact, each friction separately is sufficient to preclude discount rates or risk premia to be equated across houses. If either the quantity of assets is restricted to zero or one, or if all dividends have to be consumed, then fewer arbitrage

[j] The example relies on differences in beliefs for tractability. For the issues discussed below, it does not matter whether differences in risk attitude stem from beliefs or other household characteristics such as risk aversion or nontradable income risk.

[k] If an investor perceives two assets with same exposure but different risk premia, he expects unlimited profits from shorting the expensive portfolio and buying the cheaper one.

trades are feasible or desirable and the absence of arbitrage places weaker restrictions on prices. We consider the mechanisms in turn and then draw conclusions for matching observed prices.

Indivisibility and the Valuation of Quality Steps

Example 2 above illustrates the role of indivisibility. Suppose there was a stochastic discount factor M_{t+1} pricing all houses. With two states of nature, M_{t+1} consists of two numbers. Since houses pay off zero in state 2, the risk-adjusted future payoff from a house of quality h would have to equal h multiplied by the value of M_{t+1} in state 1. However, in Example 2 the risk adjusted payoff is $\rho_1 h + \frac{1}{2}h^2$, a contradiction. The result does not depend on a continuum of house qualities—a similar contradiction can be shown in Example 1. Moreover, it does not depend on nontradability; in fact, in the examples the housing dividend per unit of quality $g_2/g_1 - I'$ is independent of h, as it would be if dividends could be sold at a per-unit price in a rental market.

Why do optimizing households not arbitrage away differences in the valuation of house payoffs? Consider the pricing equation (13): it resembles a standard pricing equation $q_t = E_t^0 M_{t+1}\pi_{t+1}$, except that it is applied only to the quality step from h to $h + dh$.[l] The pricing of that quality step reflects the valuation of buyers of h. Buyers of lower quality houses may not share the same valuation—in fact, in the examples they perceive a lower probability of a positive payoff and would like to short the quality step at h. However, quality steps are not by themselves traded in markets: households can only trade houses, that is, portfolios of quality steps. Moreover, households cannot sell houses short. As a result, they cannot in general generate a synthetic claim that replicates the change in payoff at a quality step.[m]

If other forces equate risk-adjustment factors, a stochastic discount factor exists even with indivisibility and short sale constraints. For example, suppose that housing risk is spanned by the securities, that is, for every house there exists a portfolio of securities with the same payoff profile. Every $M_{t+1}^*(h)$ is then a valid stochastic discount factor for all houses.[n] If optimizing investors can replicate houses by trading securities, they equate

[l] Another difference is that by our timing convention house prices are always "cum dividend"—they include the current flow payoff from housing—whereas securities prices are ex dividend. This convention is not central to the discussion that follows.

[m] The effect of indivisibility is different from that of short sale constraints with divisible securities. Indeed, in models with only short sale constraints and no other constraints a stochastic discount factor does exist: for any given risk, it reflects the MRS of the investors who are most optimistic about that risk and end up as the only investors exposed to that risk in equilibrium. As a result, investors do not differ in the risk premia they pay for risks they are actually exposed to.

[n] If housing risk is spanned, the marginal rates of substitution $M_{t+1}^*(h)$ are equated on all events over which house payoffs are constant and can be pulled out of the integral in (14). Integrating over $\tilde{h}$, we obtain a standard risk-adjusted payoff.

their assessment of housing risk. For example, in the special case when markets are complete, all $M_{t+1}^*(h)$ are equal.

Nontradability and Individual Specific Returns

We refer to $g_2/g_1 - I'$ as the dividend from housing because it records the flow benefit to homeowners, as does the dividend on a security such as equity. However, nontradability implies that the housing dividend may differ across households who consume h because those households have different consumption bundles and preferences. As a result, the returns earned on the same housing position may differ across households, in contrast to the return on securities.[o] Returns on owner-occupied housing are thus more difficult to observe than those on other assets, including rental housing where the dividend to the landlord can be observed in the rental market.

Nontradability implies that a stochastic discount factor need not exist even when the pricing of houses is linear. Indeed, (15) says that with linear pricing the MRS of buyers of quality h determines the price of assets and houses of quality h. However, it is not necessarily true that the same MRS determines house prices for any other quality $h' \neq h$. Arbitrage is limited because households who disagree about the required risk-free return on assets or on the risk premium on houses may also obtain different marginal benefits from housing services, or "marginal dividends." More patient or more optimistic households thus buy larger houses, while more impatient or more pessimistic households buy smaller houses.

3.3.3 Pricing Houses vs Pricing Equity

What are the testable restrictions on the prices of houses and other assets that are implied by optimizing behavior in our framework? The large literature on the pricing of equity employs two working hypotheses. The first is that equity, or firm capital, is a divisible asset that is priced linearly, so that it suffices to focus on the properties of a single per-unit price. Second, there exists a stochastic discount factor that can be inferred from optimality conditions of some investor, for example, certain households or institutional investors. Success of a model is then measured by whether the family of stochastic discount factors implied by the model can explain how the price of equity moves relative to dividends. Moreover, one can learn about desirable features of a model up front from a reduced form approach that postulates a specific functional form for the stochastic discount factor and infers its properties from securities prices.

The previous discussion shows that models of owner-occupied housing satisfy these two working hypotheses only under restrictive assumptions. On the one hand, indivisibility implies that pricing may be nonlinear for any given observable concept of

[o] In fact, when we select households with $\left(c_t^*(h), M_t^*(h)\right)$ such that (13) holds, it is not necessarily the case that all households who buy h share those characteristics.

quality—houses of different qualities are different assets. The challenge for a model is then not to reconcile movements in one price with many household MRSs, but rather to generate the right cross-sectional links between different prices and MRSs. On the other hand, when markets are sufficiently incomplete, limits to arbitrage preclude the existence of a stochastic discount factor altogether. In this case, reduced form frictionless pricing exercises do not help infer how pricing works—a more explicit analysis of frictions is called for.

Whether or not pricing is linear or a stochastic discount factor exists, models of optimizing households imply strong testable restrictions on the joint distribution of house prices, house quality choices and household characteristics. Suppose, for example, that according to the model, wealth is the only dimension of heterogeneity among households. Optimal choice of housing implies an assignment of house qualities to wealth levels. Given that assignment, (14) predicts a cross section of prices by quality. Success of a study then depends on how well it can match the cross-sectional comovement of wealth, quality and prices when compared to micro data. The restrictions are derived from household optimization alone, much like standard Euler equation tests.

Nonlinear Pricing and the Cross Section of House Prices

With indivisibility and nontradability, the cross section of house prices is especially informative about the merits of different models. In particular, nonlinear pricing can account for richer patterns in the cross section of capital gains than linear pricing. We have seen in Section 2.2 how capital gains systematically differ across the quality spectrum over the recent US boom–bust cycle. With linear pricing, capital gains are

$$\frac{p_{t+1}(H_{t+1}(h_t))}{p_t(h_t)}=\frac{\bar{p}_{t+1}}{\bar{p}_t}\frac{H_{t+1}(h_t)}{h_t}.$$

The conditional distribution of capital gains depends on current quality h_t only via actual changes in quality between t and $t+1$. In contrast, the effects of valuation are the same for all qualities. This feature implies that models with linear pricing have trouble generating the large differences in average capital gains across quality tiers. If pricing is instead nonlinear, then changes in the characteristics of marginal investors along the quality spectrum can also affect capital gains.

Nonlinear pricing of houses can reflect various dimensions of heterogeneity. Example 2 highlights how differences in risk assessment or discount factors affect *inter*temporal MRSs. However, even if all intertemporal MRSs agree, so that a stochastic discount factor exist, the *intra*temporal MRSs (7) are not necessarily equated because of nontradability. Nonlinear payoffs and hence prices can thus obtain even in a static setting or if all intertemporal MRSs agree so that a stochastic discount factor exists.

With nonlinear pricing, individual characteristics of marginal investors at a given quality matter for the relative price of that quality. The same property arises in markets that are segmented by quality. The difference between nonlinear pricing and segmentation is that nonlinear pricing creates spillovers in pricing across qualities. For example, changes in the preferences of households who buy low quality houses affect also the values of higher quality houses.

Volatility of House Values in Heterogeneous Agent Models

Indivisibility—and to some extent also nontradability—provide extra scope for heterogeneity of agents to affect the volatility of house prices. This is promising because standard heterogeneous agent models face a challenge when it comes to generating volatility. The challenge arises because optimizing households respond to shocks by reallocating assets until all Euler equations hold jointly. If a stochastic discount factor exists, discount rates $E_t^0 M_{t+1}$ and risk premia $cov_t^0(M_{t+1}, \pi_{t+1})$ are equated across agents. Any shocks to the distribution of agent characteristics or shocks that affect a subset of agents have only a muted impact on prices because portfolio adjustments keep MRSs similar. As the simplest example, if markets are complete, pure changes in the distribution of individual income risks are offset by portfolio adjustment and prices remain unchanged.

With indivisible housing and markets sufficiently incomplete so that housing risk is not spanned, intertemporal MRSs $M_{t+1}^*(h)$ are not equated. Suppose there is a shock that affects the income or beliefs of low quality home buyers. The shock can change the MRS of low quality buyers and hence the slope of the price function at low qualities, but have no effect on the MRS of high quality buyers. Reallocation of housing risk is limited since no household buys more than one house. As a result, the shock will likely have a stronger impact on house prices in the low quality segment than the high segment, and the aggregate market will move together with the price of low quality houses.

To illustrate the implication of cross-sectional shocks on risk premia in the standard pricing equation (14), we let $D_t(h)$ denote the housing dividend and rewrite the pricing equation as

$$p_t(h) = D_t(h) + E_t^0[p_{t+1}(H_{t+1}(h))]/R_t^f + h\, cov_t^{0,U}(M_{t+1}^*(h)), p'_{t+1}(H_{t+1}(h))H'_{t+1}(h)),$$

where we have exchanged expectation and integration, and used the fact that all $M_{t+1}^*(h)$ agree on the risk-free rate. The second term on the right-hand side is the expected present value of the house discounted at the risk-free rate. The notation $cov_t^{0,U}$ indicates that the random variables vary not only across states of nature, but also across qualities, where quality is uniformly distributed on $[0, h]$ by construction—this is because we have selected one household for quality level.

For securities, MRSs are all equal and risk premia depend on variation common to all MRSs and payoffs across states of nature. Any excess volatility of prices is due to changes in this common variation. With indivisible housing, excess volatility can also be due to changes of the cross-sectional distribution of agent characteristics. In particular, changes in the environment that affect only a subset of agents that buy low quality houses can shift the distribution and affect many prices and hence the aggregate market.

When pricing is linear, nontradability implies that MRSs are still not equated across investors. However, the same per-unit price $\bar{p}_t$ appears in all Euler equations (15). Hence, the per-unit price will only change if the Euler equations of buyers at all quality levels are affected. A shock that affects only a subset of households can thus only matter for prices if it also changes the Euler equation of high quality buyers. This requires changes in either the intertemporal or the intratemporal MRS of high quality buyers. Models with linear pricing thus imply that the distribution of house choices respond more strongly, which dampens the effect on prices. Overall, the scope for price volatility is reduced.

3.4 Equilibrium

In this section we take a first look at equilibrium. We close the frictionless model presented so far by introducing an exogenous supply of securities as well as an exogenous endowment of numeraire consumption. We also assume a fixed *aggregate* supply of housing services. To emphasize the role of indivisibility, we compare two stark special cases for technology that are common in applications: a fixed distribution of house qualities, and free conversion of house qualities into each other.

We take a general approach to expectation formation that can accommodate various concepts in the literature. We first define a *temporary equilibrium* for date t as a collection of prices and allocations such that markets clear given beliefs and agents' preferences and endowments. Following Grandmont (1977), temporary equilibrium imposes market clearing and individual optimization, but does not require that each agent's belief coincide with the physical probability P^0. We then discuss further restrictions on expectations and their role in quantitative work. In particular, we compare rational expectations equilibrium and self-confirming equilibrium—a common shortcut that simplifies computations in heterogeneous agent models—as well as temporary equilibria with directly measured expectations.

3.4.1 Housing Market Clearing

We denote the mass of households that makes decisions at date t by $\mathcal{I}_t$. For each individual $i \in \mathcal{I}_t$, the solution of the individual household problem delivers decision rules for consumption, savings and portfolio choice that depend on calendar time, the endogenous state variable cash on hand and current prices. Moreover, household decisions depend on preferences and in particular beliefs about future income, prices and asset payoffs. Let P_t^i be the belief of household i at date t and $h_t^i\left(p_t, q_t; w_t^i, P_t^i\right)$ be his housing demand at date t.[p]

[p] Here, P_t^i represents a probability on infinite sequences. Beliefs at different information sets therefore do not have to be derived as conditionals from a single probability. This generality is useful to accommodate, for example, beliefs that are derived from a forecasting model estimated with data up to date t.

We assume that there are always at least as many households as houses of positive quality.[q] We thus fix the mass of houses at $\mathcal{I}_t$ and let G_t denote the date t cumulative density function of available house qualities, defined on $[0, \infty)$. If the households' choice set $\mathcal{H}$ is finite, then G_t is a step function. If $G_t(0) > 0$, then not every household will be able to buy a house of positive quality in equilibrium. The housing market clears if at every quality $h > 0$, the number of households who choose a house of quality h or better is the same as the number of houses with these qualities:

$$\Pr\left(h_t^i\left(p_t, q_t;\ w_t^i, P_t^i\right) \geq h\right) = 1 - G_t(h). \tag{16}$$

3.4.2 Fixed Supply vs Linear Conversion

If the distribution of house qualities G_t is exogenous, prices adjust so that the household sector absorbs the given distribution. The endogenous objects in this case include equilibrium house prices—one for every quality level—as well as the assignment of individual houses to individual households. In general, house prices are nonlinear in quality and reflect the distributions of qualities and household characteristics. The simple examples of Section 3.3.2 show how this can happen: if we take the set of houses used there to describe an exogenous supply, then the prices and individual choices characterize an equilibrium given that supply.

The polar opposite of a fixed quality distribution is *linear conversion*. Suppose that the total housing stock (measured as the aggregate supply of housing services) is fixed at some number H_t, but that it can be divided up every period into individual houses without cost. Since the marginal transformation across quality types is now fixed at one, pricing must be linear. There is only one price that reflects the value of a unit of housing in terms of numeraire. The distribution of qualities G_t becomes an endogenous object that is determined in equilibrium subject to a constraint on the mean

$$\int_0^1 h dG_t(h) = H_t. \tag{17}$$

A fixed distribution is interesting in applications that consider the short-term response to shocks. It is also useful for longer-term analysis if the market can be viewed as a collection of segments fixed by geography or regulation such as zoning. In contrast, linear conversion is an interesting assumption in applications that consider long-run outcomes or when studying new developments where developers design the distribution of houses from scratch. Beyond these polar opposites, it could be interesting to explore intermediate cases of costly conversion by developers. The macroeconomics literature has yet to consider this explicitly.

[q] This assumption covers most applications we discuss below. Alternatively, we would have to develop further the use of a vacant house.

To decentralize an economy with linear conversion, we assume that there is a competitive developer sector that buys existing houses and sells new houses. The endogenous distribution of houses will then satisfy our earlier assumption that the number of houses is always less or equal than the number of households. Since households have no use for more than one house, developers never create more than $\mathcal{I}_t$ houses at date t. Moreover, competition among developers and linear conversion force linear pricing: the relative price of any two qualities must equal the unitary marginal rate of transformation.

With either technology, the housing component of equilibrium includes a price function $p_t(.)$ as well as an allocation of house qualities such that the market clearing condition (16) holds. In an *equilibrium with fixed quality distribution*, (16) holds for the exogenous cdf G_t. In contrast, an *equilibrium with linear conversion*includes an equilibrium distribution of house qualities G_t that satisfies (17) and moreover features a linear price function $p_t(h) = \bar{p}_t h$.

3.4.3 Temporary Equilibrium

We assume that household $i \in \mathcal{I}_t$ enters period t endowed with a house of quality $\bar{h}_t^i$, securities $\bar{\theta}_t^i$ as well as y_t^i units of numeraire. We allow for households in their last period of life who mechanically sell any housing and securities and consume all the proceeds. To accommodate long-lived securities, we write payoffs as price plus dividend, that is, $\pi_t = \hat{\pi}(q_t) + D_t$. For example, the Jth security is a risk-free one-period bond, so $\pi_{t,J} = 1$. If the jth security is equity then $\pi_{t,j} = q_{t,j} + D_{t,j}$ where $D_{t,j}$ is the dividend.[r]

In addition to a price function, a house allocation and—with linear conversion—a distribution of house qualities, a *date ttemporary equilibrium* consists of securities and consumption allocations as well as security prices such that housing, numeraire and securities markets clear at the optimal demand, with initial wealth evaluated at the equilibrium prices. The conditions for wealth, numeraire and securities are

$$
\begin{aligned}
w_t^i = y_t^i + \bar{\theta}_t^{i\top} \hat{\pi}_t(q_t) + p_t\left(\bar{h}_t^i\right); \quad i \in \mathcal{I}_t \\
\int_{\mathcal{I}_t} c_t^i\left(p_t, q_t; w_t^i, P_t^i\right) + I\left(h_t^i\left(p_t, q_t; w_t^i, P_t^i\right)\right) di = \int_{\mathcal{I}_t} \left(y_t^i + \theta_t^{i\top} D_t\right) di \\
\int_{\mathcal{I}_t} \theta_t^i\left(p_t, q_t; w_t^i, P_t^i\right) di = \int_{\mathcal{I}_t} \bar{\theta}_t^i di.
\end{aligned}
\tag{18}
$$

A *sequence of temporary equilibria* is a collection of date t temporary equilibria that are connected via the updating of endowments. In particular, for any household $i \in \mathcal{I}_t$ who was already alive at date $t-1$, we impose $\bar{h}_t^i = h_{t-1}^i\left(p_{t-1}, q_{t-1}; w_{t-1}^i, P_{t-1}^i\right)$ and similar for the securities holdings. Agents who enter the economy at date t are endowed only with labor

[r] The function $\hat{\pi}$ helps accommodate debt with longer but finite maturity. For example, if the kth security is a risk-free two-period zero-coupon bond, then $\pi_{t,k} = \hat{\pi}_{t,k} = q_{t,J}$ since the two-period bond turns into a one-period bond after one period.

income y_t^i. While a sequence of temporary equilibria tracks the distribution of asset holdings over time, it still does not restrict expectations.

3.4.4 Rational Expectations Equilibrium vs Self-confirming Equilibrium

A *rational expectations equilibrium* is a sequence of temporary equilibria such that $P_t^i = P^0$ for every period t and agent i. Beliefs thus coincide with the physical probability for all events: all agents agree with the econometrician on the distribution of all exogenous and endogenous variables. Rational expectations equilibrium is common in macroeconomic studies, especially when the model has few agents and assets or when there is no aggregate risk. In such cases, it is straightforward to move from the recursive formulation of decision problems to the definition of a recursive equilibrium that expresses prices as a function of a small set of state variables.

For the simplest example, suppose there is a representative agent. Since we have assumed a fixed supply of assets, there are no endogenous state variables. Prices only depend on current variables such as consumption as well as current variables required to forecast future exogenous variables such as income and asset payoffs. With rich heterogeneity, rational expectations equilibria become more difficult to characterize. With incomplete markets as well as other frictions described below, defining a recursive equilibrium may require a large dimensional state space that contains the distribution of not only wealth but also individual asset holdings—for example, housing and long term mortgages—as well as their dependence on age.

To avoid explicitly dealing with a large state space and the resulting complicated distribution of endogenous variables, studies with heterogenous agents and aggregate risk often look for a *self-confirming equilibrium* in which agent beliefs coincide with the physical probability P^0 only on a subset of events.[s] A common approach follows Krusell and Smith (1998) and parametrizes agent beliefs about future prices with "forecast functions" that map future prices to a simple set of current predictor variables (such as the current cross-sectional mean of asset holdings) and shocks. A self-confirming equilibrium requires that the forecast functions match prices also under the physical probability.

Self-confirming equilibrium imposes different restrictions on allocations and prices than rational expectations equilibrium since the forecast functions only involve a limited set of moments of the state variables. In general, there can be other self-confirming equilibria with other forecast functions, and there is no guarantee that any particular self-confirming equilibrium is a rational expectations equilibrium.[t] Applying self-confirming

[s] The labeling here follows Sargent (1999) who in turns builds on the game theoretic concept in Fudenberg and Levine (1998). Krusell and Smith (1998) refer to "approximate equilibria."

[t] At the same time, if there exists a recursive rational expectations equilibrium, then it is also a self-confirming equilibrium for *some* forecast function (not necessarily simple). In sufficiently tractable models, one can try out different forecast functions systematically so as to establish that a self-confirming equilibrium is indeed close to a rational expectations equilibrium. This route is taken by Krusell and Smith (1998), but not in the typical application on housing reviewed below.

equilibrium with a given forecast function thus calls for justifications of assumptions on beliefs, perhaps by appealing to bounded rationality.

3.4.5 Temporary Equilibrium with Measured Expectations

An alternative approach implements temporary equilibria by directly measuring expectations about future variables that are relevant for agent decisions. The temporary equilibrium then provides a map from technology and the distribution of household characteristics *as well as expectations* into prices and allocations. To specify beliefs, one relevant source is survey data which can be informative in particular about the cross-sectional relationship between expectations and other characteristics (for example, Piazzesi and Schneider, 2009a). Alternatively, expectations about prices can be specified using a forecasting model (Landvoigt et al., 2015).

Temporary equilibrium with measured expectations also simplifies computation. It is helpful to think of the computation of equilibrium in two steps—first individual optimization given prices and then finding market clearing prices. To find temporary equilibrium prices for a given trading period means finding a solution to the nonlinear equation system (18) in as many unknowns as there are prices. This is in contrast to rational expectations equilibrium where one looks for an entire price function. Since the price finding step for temporary equilibrium is easier, the optimization step can be made more difficult: the concept lends itself well to models with a rich asset structure, for example, with many house types or many risky assets.

A conceptual difference between temporary equilibrium with measured expectations and rational expectations equilibrium is that the modeler does not a priori impose a connection between expectations at any given date and model outcomes at future dates. Of course, if the model is well specified, then this does not matter for the fit of the model: any rational expectations equilibrium gives rise to a sequence of temporary equilibria given the set of beliefs that agents hold in the rational expectation equilibrium. With a well specified model, that same set of beliefs should be apparent in expectation surveys or in a good forecasting model.

The conceptual difference is thus in how we assess the fit of a misspecified model and how we achieve identification of parameters. Rational expectations equilibrium and self-confirming equilibrium view both prices and the cross section of endowments as a function of state variables. To identify parameters that affect the coefficients in prices and decision rules requires controlled variation of the state variables. The concepts are thus most easily and most commonly applied when variables display recurrent patterns: the empirical moments of prices and other variables can then be compared to the stationary equilibrium implied by the model. In contrast, temporary equilibrium can be implemented even with data on only a single trading period. Prices are then a single set of numbers and endowments are measured directly. Identification of parameters that affect prices comes from cross-sectional variation in prices and allocations.

There is also a difference in how we deal with misspecification and counterfactuals. Rational expectations insist that expectations are "consistent with the model," so beliefs are as misspecified as the model itself. Moreover, counterfactuals—such as changes in a policy parameter—vary expectations in a way that is consistent with the model. Temporary equilibrium with measured expectations instead emphasizes that expectations are "consistent with the data" at the initial equilibrium. As a result, there is no prediction on how expectations change with parameters; any counterfactual requires a reassessment of the assumptions on expectations.[u]

There are two reasons why the use of temporary equilibrium with measured expectations is particularly attractive in models of housing. First, as we have discussed, there are payoffs from including a rich set of assets, in particular houses of many different qualities. Second, the postwar data on housing is shaped by the two boom periods—the 1970s and the 2000s—that saw several unusual shocks, as discussed in Section 4.5. Given this data situation, identification of a stationary equilibrium price function from regular patterns is less powerful. In contrast, there is much to learn from the cross section and from data on expectations for both boom episodes.

3.5 Production and Land

In this section, we describe models of housing supply that are common in the applications below. We start from a general setup that allows for land and structures as separate factors of production. We then explain when housing can nevertheless be represented by the single state variable "quality," as we have done throughout this chapter. Finally, we review additional restrictions on house prices derived from firm optimization.

Consider a general production function at the property level. When a new structure of size k^0 is paired with a lot of size l, initial house quality is $h = F^0\left(k^0, l\right)$. Once a house has been built, its lot size remains the same, whereas the structure may depreciate or improve. With a stream of investments i_t, the quality of a house of age τ is given by

$$h_{t+\tau} = z_{t+\tau} F^{\tau}\left(k_t^0, i_{t+1}, \ldots, i_{t+\tau}, l_t\right), \tag{19}$$

where $z_{t+\tau}$ is a productivity shock. The production function F^{τ} may depend on the vintage τ.

Both new structures and improvements to existing houses are produced by a construction sector from capital K_t^c and labor N_t^c. As before, the mass of houses is $\mathcal{I}_t$ and we index individual houses by $j \in [0, \mathcal{I}_t]$. We further assume that it is costless to scrap an existing house. Construction output—or residential investment—is then

[u] Predictions on expectations can be obtained by imposing more structure on expectation formation, for example, via learning rules. For a survey on learning in macroeconomics, see Evans and Honkapohja (2009).

$$\int_0^{\mathcal{I}_t} \left(k_t^0(j) + i_t(j)\right) dj = I_t^c = Z_t^c F^c\left(K_t^c, N_t^c\right), \tag{20}$$

where F^c and Z_t^c are the production function and the productivity shock for the construction sector, respectively.

We distinguish the construction sector labeled c from the rest of the business sector–labeled y—that makes numeraire from capital and labor. Capital in both sectors is made from numeraire one for one without adjustment costs and depreciates at constant rates δ^c and δ^y. The resource constraints for numeraire and the capital accumulation equations are

$$\begin{aligned} C_t + I_t^y + I_t^c &= Z_t^y F^y\left(K_t^y, N_t^y\right), \\ K_{t+1}^s &= (1-\delta^s)K_t^s + I_t^s, s = y, c. \end{aligned} \tag{21}$$

It remains to describe how costly it is to change the distribution of existing individual housing units. We distinguish different scenarios below.

In each case, the definition of equilibrium is amended by adding (*i*) construction output as a separate intermediate good that trades in a competitive market at the relative price p_t^c, (*ii*) both types of capital as securities in the households' problems that trade at a price of one and yield a net return equal to the marginal product of capital less depreciation, (*iii*) as market clearing conditions for construction output and numeraire (20) and the first equation in (21), respectively, (*iv*) labor income as labor times the competitive wage in the household budget constraint.

3.5.1 From Land and Structures to House Quality

In principle, the above technology could give rise to rich dynamics for the distribution of house types. For example, if different vintages of houses have different capital–land ratios, they may yield the same housing services, but depreciate at different rates. The macroeconomics literature has by and large sidestepped this issue with assumptions that allow housing to be summarized by one number, quality. We now discuss several special assumptions that accomplish the same outcome even when land is present. The simplest approach is to leave out land altogether, as in the literature on home production. Housing is then identified with structures only.

3.5.2 The Tree Model

Another simple approach is a "tree model" of housing that can motivate setups with a fixed or slow-moving quality distribution. Suppose that structures depreciate at rate δ, but that a house remains inhabitable (that is, yields positive housing services) only as long as structures and land are always paired in exact proportions.[v] All owners who hold

[v] In terms of the above notation, assume first that $F^0(k, l) = l$ if $k = \kappa l$ and $F^0(k, l) = 0$ otherwise, so every inhabitable house built must have a structure–land ratio of κ. Assume further that future quality F^τ is equal to l_t if $i_s = \delta k_s^0$ for all $s = t, \ldots, t + \tau$ and zero otherwise.

a house from one period to the next then make the improvement $i_t = \delta k_t^0$ every period. In other words, a house works like a tree that yields fruit equal to housing services less improvements.

The tree model implies that the state of a house can be summarized by a single variable, quality. From the perspective of households, quality is constant as long as maintenance is performed, the case of "essential maintenance" discussed in Section 3. When the distribution of lots is fixed, one can apply the definition of equilibrium with a fixed quality distribution from Section 3.4. Alternatively, we could add a technology by which lots are converted. For example, if it was possible for developers to freely redivide lots, then we would obtain an equilibrium with linear conversion.

3.5.3 A Frictionless Model

Suppose that the production of housing from land and structures has constant returns and that structures depreciate at a constant rate. Suppose further that houses are produced by a competitive developer sector who can linearly convert both land and structures. We thus have a frictionless model with two factors of production.[w] All houses built at the same point in time will share the same ratio of structures to land. From the perspective of households, the change in house quality depends on the land share together with the depreciation rate of structures. The household problem thus looks like one with geometric depreciation of quality, determined endogenously from the equilibrium land share.

The frictionless model imposes a supply-side restriction on house prices that must hold together with Euler equations from the household side discussed earlier. Indeed, from the first-order condition of a developer, we have

$$\bar{p}_t F_1^0(K_t, L) = p_t^c,$$

where K_t is aggregate structures, L is aggregate land, assumed constant, and p_t^c is the relative price of construction output. If there are many structures, then the scarcity of the fixed factor land drives up the per-unit price $\bar{p}_t$ of housing. Since aggregate structures move slowly over time, this type of model typically has trouble generating a lot of volatility in house prices relative to the price of construction output. The problem is similar to that encountered by models of the firm without adjustment costs to capital.

[w] In terms of the above notation, let

$$F^\tau(k_t^0, i_{t+1}, \ldots, i_{t+\tau}, l_t) = F^0(k_{t+\tau}, l_t),$$

where $k_{t+\tau} = (1-\delta)k_{t+\tau-1}$ is recursively defined.

3.5.4 Land as a Flow Constraint

An alternative frictionless model uses land as a constraint on the flow of new housing, as opposed to as a factor of production for all housing as above. Since the model assumes linear conversion, we write technology directly in terms of aggregate quality:

$$H_t = (1-\delta)H_{t-1} + \widetilde{F}^h\left(Z_t^c F^c\left(K_t^c, N_t^c\right), \bar{L}\right). \tag{22}$$

Here, $\widetilde{F}^h$ is a constant returns production function that transforms construction output (that is, housing investment) and a constant flow of new land into new housing. The technology is decentralized via competitive firms.

The flow constraint approach also reduces the state variables to only house quality. It does so by applying the depreciation rate directly to the bundle of land and structures. Even though different vintages of new houses will generally have different land shares, they are nevertheless assumed to depreciate at the same rate. The flow constraint also differs from the frictionless model above in the restriction on prices. Firm first-order conditions deliver

$$\bar{p}_t \widetilde{F}_1^h\left(Z_t^c F^c\left(K_t^c, N_t^c\right), \bar{L}\right) = p_t^c.$$

The ratio of house prices to the price of construction output now relates to residential investment, which is much more volatile than the level of capital.

3.6 Rental Housing

So far we have focused on owner-occupied housing, that is, we have forced households to own a house if they want to consume housing services. We now modify the model to allow for rental housing. We discuss implications for portfolio choice and discuss how additional restrictions on house prices can be derived from household as well as from landlord decisions to invest in tenant-occupied housing.

We continue to assume that households have exactly one residence that is now either owned or rented. We denote the quality of a rented residence by s_t and the rental rate at that quality by $p_t^s(s_t)$. We then modify the second-stage problem to

$$\begin{aligned} \widetilde{V}_t\left(\widetilde{w}_t, h_t\right) &= \max_{c_t, \alpha_t} U(g(c_t, h_t + s_t I_{h_t=0})) + \beta E_t[V_{t+1}(w_{t+1})] \\ w_{t+1} &= \left(\widetilde{w}_t - c_t - p_t^s(s_t)\right) R_{t+1}(\alpha_t) + p_{t+1}(H_{t+1}(h_t)) + y_{t+1}. \end{aligned} \tag{23}$$

In the budget constraint, expenditure now includes rent. The indicator function in the objective ensures that only households who have not chosen to own (that is, $h_t = 0$) obtain utility from a rented residence.

To handle the landlord side of renting, we assume that tenant-occupied houses of a given quality are held in real estate investment trusts (REITs) and households can purchase shares in those trusts subject to short-sale constraints. REIT shares then enter the second stage problem much like standard securities. The dividend earned by the REIT from a house of quality h_t is given by the rent net of maintenance cost $p_t^s(h_t) - I_r(h_t)$. We allow maintenance cost to be higher when the house is tenant occupied than when it is owner occupied.

The formulation here thus introduces one advantage of ownership—lower maintenance cost—that is traded off against the disadvantage of bearing housing price risk. This approach to studying rental markets and tenure choice in an otherwise frictionless equilibrium model goes back to Henderson and Ioannides (1983). Their paper also provides microfoundations for the difference in maintenance cost using a moral hazard problem between landlord and tenant. A closely related approach assumes that homeowners receive more housing services from owned houses. In addition to the tradeoff studied here, differences in tax treatment as well as the interaction of tenure choice with collateral constraints and transaction costs are also important; they are discussed further below.

3.6.1 Optimality Conditions and Tenure Choice

Renters' first-order condition is one of intratemporal choice between the two goods, housing services and numeraire. We focus on the case of a continuum of qualities. With a smooth rent function, a household who rents a house of quality h must be indifferent between renting that house or renting a slightly better or worse house:

$$p_t^{s\prime}(h_t) = \frac{g_2(c_t, h_t)}{g_1(c_t, h_t)}. \tag{24}$$

Much like for owner occupiers, a renter of quality h_t is marginal for houses of quality h_t, but not necessarily for house of any other quality. As a result, the rent function can in general be nonlinear—a linear rent function obtains under special assumptions such as when rental houses of different qualities can be converted one for one.

The first-order conditions for REIT shares at different quality levels work like those for stocks of different companies. The intertemporal MRS of a landlord household serves as a stochastic discount factor for tenant-occupied houses. Without frictions, the typical landlord household will build a diversified portfolio that contains houses of all qualities. For tenant-occupied houses, discount rates and risk-adjustment factors are thus also equated across quality levels. This does not mean, however, that prices become linear in quality: rent and hence the dividend to the landlord is generally nonlinear due to indivisibility in the rental market.

The presence of a rental market separates the roles of housing as a consumption good and asset. While owners must commit more savings toward the housing asset and bear housing risk, renters simply pay the flow expenditure of housing services. At the same time, the difference in maintenance cost implies that the rent for a house of given quality may be higher than the dividend that a household would earn if he instead were to own the house. In the current setup with indivisibility as the only friction, we would thus expect households who perceive a higher risk-adjusted payoff from housing to become owners.

3.6.2 The User Cost of Housing

Consider a household who is indifferent between owning and renting a house of quality h. Suppose further that housing risk is spanned so that the stochastic discount factor is the intertemporal MRS of an indifferent household.[x] The indifference condition now equates the rent $p_t^s(h)$ to the "user cost of housing," that is, price less discounted payoff. Equivalently, we can write the current price as

$$p_t(h_t) = p_t^s(h_t) - I(h_t) + E_t[M_{t+1} p_{t+1}(H_{t+1}(h_t))]. \tag{25}$$

Here, the payoff from ownership includes the maintenance cost $I(h_t)$ of an owner-occupied house. We thus obtain a conventional asset pricing equation for houses at quality h.

An alternative derivation starts from the first-order condition of landlords and assumes that there is free conversion between tenant and owner-occupied houses. We can then use the landlord's MRS as a stochastic discount factor:

$$p_t(h_t) = p_t^s(h_t) - I_r(h_t) + E_t[M_{t+1} p_{t+1}(H_{t+1}(h_t))]. \tag{26}$$

For both equations to hold at the same time, we must either have no difference in maintenance cost, or the intertemporal MRSs of landlords and owners must be different. This might be, for example, because landlords are more optimistic than owners and are thus willing to incur more housing risk.

If we solve the user cost (25) forward, and impose a transversality condition on the expected weighted house price in the distant future, the price of a house of quality h can be written as the present value of future rents

$$p_t(h_t) = E_t\left[\sum_{\tau=0}^{\infty} \prod_{j=1}^{\tau} M_{t+j}\left(p_{t+\tau}^s(h_{t+\tau}) - I(h_t)\right)\right]. \tag{27}$$

Since we have assumed that housing risk is spanned, we can further aggregate across quality levels and obtain pricing equations for the entire housing market.

Applied studies often take (27) as a starting point and construct a reduced-form pricing kernel. The test is analogous to testing whether a particular candidate stochastic discount factor prices equity given observable prices and dividends. As we have seen, user-cost equations hold only under special assumptions. We also emphasize that even when those assumptions are met, they represent additional restrictions on prices that hold on top of the equations already discussed above that characterize optimal quality choice conditional on owning or renting.

[x] This is true in particular if the household is a landlord and there is free conversion between tenant and owner occupancy—the household can then assemble REITs portfolios with the same payoffs as any individual house. Of course, the indifferent household may not be a landlord—in the presence of short-sale constraints not all households need to participate in the market for tenant-occupied housing.

3.7 Collateral Constraints

Much of the literature captures the role of housing as collateral by a linear constraint on the amount of short term risk-free debt, our Jth security:

$$-q_{t,J}\theta_{t,J} \le \phi_t p_t(h_t). \tag{28}$$

Households who take out a mortgage must make a large enough downpayment so that the loan-to-value ratio remains below ϕ_t. The maximum loan to value ratio can be random—exogenous variation in ϕ_t is a popular example of a "financial shock" that either loosens or tightens household borrowing capacity. We also shut down borrowing opportunities through risky securities by imposing short sale constraints $\theta_{t,j} \ge 0$ for $j = 1, \ldots, J-1$.

The downpayment constraint (28) goes back to theoretical work on optimal savings by Artle and Varaiya (1978). Slemrod (1982) used it in an early quantitative life cycle model. In 1990s several papers explored equilibrium effects. In static setups, Shleifer and Vishny (1992) stressed the potential for asset fire sales, while Stein (1995) considered its role in generating comovement of house prices and housing volume. Kiyotaki and Moore (1997) emphasized the amplification effects from collateral constraints in a dynamic model. Detemple and Serrat (2003) and Chien and Lustig (2009) study economies with contingent claims subject to collateral constraints. Geanakoplos (2011) endogenizes the downpayment constraint in a model that allows for default.

While the simple constraint (28) provides a tractable way to capture the benefit of housing as collateral, it leaves out several features of observed mortgages. First, while it is in principle possible for the price to drop below the face value of the mortgage over the next period, the chance of this happening is negligible in most quantitative studies. In contrast, in the data many households with long-term mortgages are "under water." Moreover, a key decision for households is whether to prepay and/or refinance mortgages in response to changes in house prices or interest rates. The simple constraint effectively assumes that refinancing is costless, so that an increase in house prices translates directly into higher borrowing capacity. While it may capture the basic tradeoffs well when the period length is relatively long, or when adjustment of mortgage terms is cheap, several applications discussed below show that details of mortgage contracts can matter significantly for quantitative results.

3.7.1 *Household Optimization*

The collateral constraint restricts the choice of the risk-free security in the second stage problem (5): we thus modify that problem by adding the constraints $-\left(\widetilde{w}_t - c_t\right)(1-\alpha'\iota) \le \phi_t p_t(h_t)$ and $\alpha \ge 0$. Denoting the multipliers on these constraint by ν_t and μ_t, respectively, the first order conditions (8) become

$$\begin{aligned} U'(g(c_t,h_t))g_1(c_t,h_t) &= \beta E_t[V'(w_{t+1})]R_t^f + \nu_t \\ \nu_t \iota &= \beta E_t\left[V'(w_{t+1})\left(R_{t+1} - \iota R_t^f\right)\right] + \mu_t. \end{aligned} \tag{29}$$

As long as the constraints do not bind, the conditions are unchanged. If a household runs up against his borrowing constraint, however, the marginal cost of borrowing includes not only the expected repayment, but also the shadow cost of the constraint. This affects indifference conditions at both the borrowing/lending and portfolio choice margins. In particular, if the borrowing constraint is tight (high ν_t) and the expected excess return on a risky security is low, then it may be optimal to not hold that security at all ($\mu_{t,j} > 0$).

If housing serves as collateral, its marginal benefit in (6) reflects its marginal collateral benefit, in addition to the utility benefit from housing services and the expected capital gain. To compare the three components, we focus on the case of continuous housing quality. The counterpart of (13) is

$$p_t'(h_t)\left(1-\phi_t\left(1/R_t^f - E_t^0 M_{t+1}\right)\right) = \frac{g_2(c_t,h_t)}{g_1(c_t,h_t)} - I'(h_t) + E_t^0\left[M_{t+1}p_{t+1}'(H(h_t))H_{t+1}'(h_t)\right]. \tag{30}$$

On the left hand side, the collateral benefit is expressed as a percentage discount to the pricing step p'. From (29), the discount is zero if the household is unconstrained (that is, $\nu_t = 0$ and $E_t M_{t+1} R_t^f = 1$). It is higher if the lower is the intertemporal MRS: collateral is more useful if the household has a greater need for borrowing.

3.7.2 Savings and Portfolio Choice

The constraints imply that household net worth $p_t(h_t) + q_t'\theta_t$ is nonnegative. This feature is useful for matching household portfolios in the data since negative net worth is not common. It also implies that borrowing does not move future income to the present, in contrast to a simple permanent income model. Instead borrowing is a portfolio choice decision, undertaken in order to build a large enough housing position. The forces discussed in Section 3.2 remain at work: households with a lot of future income should choose leveraged housing positions, especially if their labor income is uncorrelated with housing payoffs.

In the cross section, optimal savings depend on the relative abundance of current wealth relative to future income as well as the remaining life span. When wealth is low relative to income, households do not save at all. Young households with low wealth–income ratios save to be able to make a downpayment. As soon as they have saved enough, they build leveraged portfolios in housing and also some attractive other assets, such as stocks. Older households have higher wealth–income ratios and are thus long in all assets.

As wealth rises relative to income, households start saving until their savings rate approaches an unconstrained optimal savings rate that depends on the distribution of returns—it is constant when returns are iid. Younger households have a longer planning horizon and therefore spread their savings over more years. This effect tends to increase the savings by the young. However, middle aged households have more income, so that they can save more. The higher savings rates of young households dominate when labor income is not important, which means at high wealth–income ratios. For empirically relevant ranges of the wealth–income ratio, the higher savings of the middle aged dominate and create a hump-shaped wealth pattern, which we also see in the data.

Another implication is that constrained households are more reluctant to buy risky securities. Indeed, consider the first-order conditions (29) for households who hold securities: constrained households are indifferent between risky securities and risk-free investment only if the marginal utility weighted expected excess return is strictly positive. In contrast to housing, securities do not come with collateral benefits, and thus require higher premia in order to be held. This feature helps in applications to explain why young households with low cash relative to income do not hold equity even though the equity premium is high.

3.7.3 The Pricing of Securities

The first order conditions (29) suggest that the presence of a collateral constraint might help generate more volatile expected excess returns on risky securities, and hence help resolve the volatility puzzle. Indeed, changes in the tightness of the constraint do affect conditional risk premia. However, a problem with this effect is that it also tends to generate volatility in the risk-free interest rate. Combining the first-order conditions, we obtain

$$U'(g(c_t, h_t))g_1(c_t, h_t) = \beta E_t[V'(w_{t+1})R_{t+1}].$$

The marginal condition for the level returns of risky securities is thus the same as without a collateral constraint. In applications that generate volatility in expected excess returns, that volatility is typically due to volatility in the risk-free rate moves, as opposed to volatility in conditional risky returns as in the data.

3.7.4 House Prices

The presence of a collateral constraint also alters the pricing of houses. The most immediate effect is that if constrained households buy houses, then the collateral benefit increases house prices, holding fixed payoffs and the households' intertemporal MRS. This is a liquidity effect that occurs even with linear pricing and when dividends are tradable. Dividing (29) by the big bracket on the left hand side, we have that housing payoffs are discounted at a lower rate to price in the collateral benefit.

Whether the liquidity effect is important for price movements in a heterogeneous agent model depends on market structure and the presence of other constraints. Collateral constraints provide an important example why households can be affected differently by shocks—for example, the financial shock ϕ_t affects (30) if and only if the household is constrained. At the same time, as discussed in Section 3.3, shocks alter a family of Euler equations via both price and quantity adjustment. The effect on prices will be higher if market structure requires price adjustment because quantities do not move.

To illustrate, suppose ϕ_t increases to relax the downpayment constraint. In the typical population, some households are constrained while others are unconstrained. Suppose now the model assumes linear pricing because houses of different quality can be converted freely. In order for a housing boom to occur, the price per unit of housing will move only if the shock is strong enough to alter the valuation of payoff by unconstrained households; otherwise quantity adjustment will provide more housing for constrained households accompanied by a smaller price reaction. In contrast, with nonlinear pricing and indivisibility, the shock can strongly affect the prices of houses bought by constrained households, without a big impact on the Euler equation of the unconstrained. With limited quantity adjustment, the overall effect on prices can thus be bigger.

3.8 Transaction Costs

We now introduce a proportional transaction cost κ whenever a household sells a house. This tractable and popular specification is often motivated by the rule of thumb that about 6% of the house price are typically paid to the seller's agent in a transaction. It was first studied by Flemming (1969) in a deterministic context and by Grossman and Laroque (1990) in a stochastic model. Beyond these direct costs, it is plausible that most households face other moving costs, either pecuniary—such as changing local services—or possibly nonpecuniary, for example, disutility from leaving a familiar environment. Such costs sometimes motivate a fixed component to moving costs. In what follows we work only with proportional costs since those are sufficient to understand the key effects.

Once transaction costs are taken into account, the existing house becomes *illiquid* and its quality at the beginning of the period $\tilde{h}_t = H_t(h_{t-1})$ becomes a separate state variable in the household problem. We thus write the value function as $V_t(w_t, \tilde{h}_t)$ where w_t is total wealth at the beginning of period t as before. We introduce separate notation for $\tilde{h}_t$ since it depends not only on quality chosen in the previous period, but may also depend on random events such as depreciation. The presence of transaction costs does not affect choices in the second stage problem from Section 3.2. To keep track of the new state variable, we only need to modify the expected continuation utility in the objective to $E_t[V_{t+1}(w_{t+1}, H_{t+1}(h_t))]$.

Let $m_t \in \{0,1\}$ denote the moving choice. The first stage problem is now

$$V_t(w_t, \tilde{h}_t) = \max_{m_t, h_{t+1} \in \mathcal{H}} m_t \tilde{V}_t\left(w_t - \kappa p_t(\tilde{h}_t) - p_t(h_t), h_t\right) + (1 - m_t)\tilde{V}_t(w_t - p_t(\tilde{h}_t), \tilde{h}_t) \quad (31)$$

The first term is the utility of a mover who sells the old house, incurs the transaction cost and buys a new house. The second term is the utility of a stayer: house quality remains unchanged, and the disposable funds for consumption and securities in the second stage problem consist of *liquid wealth*, that is, wealth net of the illiquid house.

To illustrate the benefits of illiquid housing, consider the model with continuous quality. The marginal benefit of house quality at the beginning of the period consists of the effect of housing on wealth as well as the direct benefit. From the envelope theorem, the total marginal benefit is

$$V_{t,1}p'(\widetilde{h}_t) + V_{t,2} = m_t \widetilde{V}_{t,1}^{\text{move}}(1-\kappa)p_t'(\widetilde{h}_t) + (1-m_t)\widetilde{V}_{t,2}^{\text{stay}}, \tag{32}$$

where the subscripts in $\widetilde{V}_t^{\text{move}}$ and $\widetilde{V}_t^{\text{stay}}$ indicate whether $\widetilde{V}_t$ is evaluated at the first or second arguments in (31). A mover household, enjoys the marginal benefit of liquid funds conveyed by an extra unit of house quality. In contrast, a stayer household experiences no increase in liquid fund and only enjoys the continuation utility benefit of house quality.

The household problem illustrates three key new features of pricing introduced by transaction costs. First, only movers can be marginal investors in housing in any given period. Since housing has low turnover, the characteristics of only a few people matter directly for determining prices. Second, the value of housing depends less on future prices if moving is less likely. Indeed, (32) shows that the price matters more the higher is m_t. In the extreme case where households know they will never move in the future, their benefit from housing is independent of future prices. Finally, transaction costs lower marginal benefit, and this effect is capitalized into house prices. Other things equal, we thus expect lower prices in markets with higher turnover.

Transaction costs also alter portfolio choice tradeoffs described earlier. First, they make ownership more expensive than renting, and more so for households who expect to move again quickly. In a market with heterogenous agents, the price will compensate the average investor for future transaction costs. It is more likely then that frequent movers prefer renting. Second, households with rising income profiles may leverage even more so they can lock in a large housing position early and do not have to move later. Finally, collateral constraints are more likely to bind even for rich households: whether constraints bind depends on the amount of liquid resources $\widetilde{w}_t$ in the second stage problem. With transaction costs, household may let $\widetilde{w}_t$ decline even though total wealth w_t is large.[y]

4. THEORY VS DATA

We are now ready to discuss work that quantifies the framework in Section 3 and studies its implications in various applications.

4.1 Magnitudes

At the core of any quantitative work based on the framework in Section 3 is the individual household problem. For a problem in which households may choose to buy an

[y] The issue is compounded in a model with long term mortgages that are costly to adjust so that the mortgage position also becomes illiquid. The household then faces a liquidity constraint unless he either sells the house or adjusts the mortgage. As long as he does neither, a change in house prices does not alter funds available for spending.

individual house, it is important to correctly specify the risk-return trade-offs involved. As discussed in Section 2.2, the prices of individual houses are highly volatile. Moreover, a large component of this volatility is idiosyncratic. House prices may also covary with income and other asset prices. These return moments can be taken from empirical studies that estimate their means and covariances with micro data, such as individual property level data and the PSID. Below we discuss whether and how the magnitudes matter in applications.

4.1.1 Preference Parameters

Since housing expenditure shares in the data are similar over time as well as across households (as discussed in Section 2.1), a common specification of the aggregator (2) over housing consumption and nonhousing consumption is Cobb–Douglas. The preference parameter is set equal to the expenditure share on housing, which is roughly 20%.

The choice of the risk aversion parameter depends on whether the portfolio choice problem involves other assets such as stocks. As discussed in Section 2.2, high transaction costs and high volatility lower the Sharpe ratio of individual houses and thereby reduce their attractiveness. In the absence of more attractive assets, a household problem with low risk aversion around 5 will have reasonable implications for optimal portfolios. When the problem allows households to invest in more attractive assets such as stocks, low risk aversion will typically lead to extreme optimal portfolios that exploit the equity premium. To explain observed household portfolios, higher risk aversion or higher perceived risk about stock returns are needed, or high participation costs in the stock market.

4.1.2 Shocks

Exogenous moving shocks capture reasons for moving that are exogenous to the model. The probability of such shocks can be estimated from the American Housing Survey which asks households about their reasons for moving. Roughly a third of movers provide reasons that are unrelated to the economic reasons for moving captured in the models. Examples are disasters such as fires or floods, marriage, divorce, death of spouse, etc. This 1/3 probability is multiplied by the overall probability of moving which is roughly 1/10 per year, resulting in a 1/30 probability for an exogenous move per year.

Households face exogenous survival probability that depend on age. These survival probabilities can be taken from life tables published by the National Center of Health Statistics.[z]

The volatility of individual house prices has a large idiosyncratic component. As discussed in Section 2.2, the volatility of exogenous idiosyncratic shocks is around 9–15% per year. A small component of individual house prices also correlates with aggregate income and other asset prices (such as stock prices). This component can be estimated by assuming that house prices grow at the aggregate growth rate of the economy.

[z] Their website is http://www.cdc.gov/nchs/products/life_tables.htm

A common specification for individual income is

$$\log y_{it} = f(t, Z_{it}) + v_{it} + \varepsilon_{it} \tag{33}$$

where $f(t, Z_{it})$ is a deterministic function of age and a vector of other individual characteristics Z_{it}, ε_{it} is an idiosyncratic temporary shock distributed $N(0, \sigma_\varepsilon^2)$ and permanent income v_{it} is given by

$$v_{it} = v_{i,t-1} + u_{it}$$

where u_{it} is distributed as $N(0, \sigma_u^2)$ and is uncorrelated with ε_{it}.

Individual log income is the sum of the age profile, the permanent component v_{it} and a transitory shock ε_{it}. The deterministic age profile is a third-order polynomial in age, which is estimated to match the observed hump-shaped life-cycle profile of income. Carroll (1997) and Gourinchas and Parker (2002) assume that the process for the persistent component v_{it} is a random walk as in the last equation. Hubbard et al. (1995) estimate an AR(1) for v_{it} and find that the autocorrelation coefficient is indeed close to one. Cocco et al. (2005) report estimates for the standard deviation σ_u of persistent shocks around 10–13% per year in table 3, depending on education. Their estimate for the standard deviation of σ_ε of transitory shocks is around 22–31%. It is common to somewhat reduce these numbers to account for measurement error in the PSID. For example, Campbell and Cocco (2003) use 2% for σ_u and 14% for σ_ε.

The transitory shock ε_{it} is uncorrelated across households. The persistent shock u_{it} can be decomposed into an aggregate component ξ_t and an idiosyncratic component ω_{it},

$$u_{it} = \xi_t + \omega_{it}.$$

The aggregate component ξ_t helps to introduce correlation between individual labor income and aggregate variables, such as aggregate income or asset prices.

The process (33) is specified for income received in periods t before retirement τ. After retirement, income may be a fraction λ of permanent labor income in the last working year

$$\log y_{it} = \log \lambda + f(\tau, Z_{i\tau}) + v_{i\tau} \quad \text{for } t > \tau.$$

This approach is taken in Cocco, Gomes, and Maenhout (2005) , who estimate λ as the ratio between the average income for retirees in a given education group to the average labor income in the year before retirement. The estimate is between 68% and 94% in their table 2.

With this specification of the income process, households do not face any further risks after they retire. This assumption abstracts from a number of risks that older households face, especially uncertain life spans and out-of-pocket medical expenses. Recent work has made progress to quantify such risks. For example, De Nardi et al. (2010) estimate large and volatile medical expenses for retired singles. Moreover, they find that the volatility of shocks to medical expenses increases with age and permanent income. In a life cycle model, the risk of living long and requiring expensive medical care is an important reason to save for many older high-income households. More empirical work is needed that quantifies these risks for nonsingle households as well as distinguishes the savings motives in the presence of these health risks from bequest motives. In the meantime, it seems reasonable to assume the individual income process (33) for $t > \tau$ and thereby to allow for shocks during retirement.

4.1.3 Other Housing Parameters

Houses depreciate at a rate between 1.5% and 3%, as discussed in Section 2.1. With the assumption of "essential maintenance," the depreciation rate is also the fraction of the house value that is spent on maintenance. Transaction costs vary across cities and states as well as the price spectrum within cities. They are between 6% in real estate fees (for example, in California) and 10% when moving costs are included.

4.2 Consumption, Savings, and Portfolio Choice

The literature on consumption-savings problems is concerned with the facts in Section 2.5. Empirical work documents cross-sectional patterns of consumption and portfolios, and measures properties of returns and income that are relevant for optimal portfolio choice. In order to confront theory and data, a common approach is to quantify a household problem with frictions as discussed in Section 3. Some studies impose equilibrium but nevertheless emphasize cross-sectional patterns. Much of the work discussed in this section precedes the financial crisis and focuses on cross-sectional patterns that are a key feature of any quantitative study.

We divide the literature into five groups. The first considers quantitative models with housing and one other asset. The focus then is on consumption and savings in housing vs other goods or assets, respectively The second group tackles explicitly the choice of equity portfolios with return properties as in the data. This is a more challenging problem since it requires not only matching facts on housing but household behavior toward equity, a well known puzzle in its own right. Third, we consider a set of papers that looks for reduced form evidence on specific mechanisms at work in portfolio choice models, especially the role of housing as a hedge. We then discuss the effects of more complex mortgage products, as well as the effects of house prices on consumption.

Quantitative models can successfully explain wealth and portfolio patterns over the life cycle. The models predict that wealth is positive and hump shaped, as discussed in Section 9. Moreover, the models imply that young households hold highly leveraged portfolios in housing, while older and richer households have positive positions in many assets, including bonds and stocks. According to the models, the hump shape in the wealth position will translate into hump-shaped positions in other assets such as houses and stocks. These age patterns are roughly consistent with the data, especially for housing. However, the models struggle to explain the high concentration in wealth we observe in the data, especially the extreme concentration in stock wealth. The extensive margins are also hard to match for these models. It remains a puzzle why so many middle-class households choose not to participate in the stock market. It is also difficult to quantitatively match the homeownership rate along various dimensions of heterogeneity such as income and wealth.

4.2.1 Housing and Savings Over the Life Cycle

Early work on housing choice over the life cycle considered savings via multiple capital goods without price risk. Households face a two asset special case of the problem with collateral constraints in Section 3.7. Fernandez-Villaverde and Krueger (2010) consider a household with a finite horizon who accumulates capital used in production as well as a stock of durables that enters the utility function. The income process has idiosyncratic shocks and a deterministic age profile. The collateral constraint is important to explain the accumulation of durables early in life, as described in Section 3.7.

Yang (2009) narrows the definition of durables to housing consumption and focuses on the accumulation of housing. The key new feature in her setup is transaction costs for adjusting the housing stock, as in Section 3.8. Those costs are shown to be important for matching the slow downsizing of the housing stock late in life that is observed in the data. Both papers conclude that a standard life cycle model is broadly successful at explaining the hump-shaped patterns in nondurable consumption, durables, and wealth by cohort.

Focus on cohort averages omits variation along the extensive margins, that is who owns and who rents. A number of papers explore the various determinants of tenure choice discussed in Section 3.6. A new feature in these paper is uninsurable house price risk that may correlate with income risk. Li and Yao (2007) study tenure decisions in an environment where renting is expensive; rents are a higher fraction of the house value than the sum of maintenance and mortgage rates. The paper confirms the earlier findings regarding hump-shaped patterns in nonhousing consumption. A new feature in the model is a hump-shaped homeownership rate, which is the overall pattern shown in their fig. 8(a). The homeownership rate in the model shown in fig. 7(a) is a more extreme function of age than the data: all households aged 30 years and below rent, while all households aged 40–80 years own. This discrepancy illustrate the difficulty associated with quantitatively accounting for the extensive margin. The paper studies a number of counterfactuals in which older households benefit from house price increases, while younger households loose.

While Li and Yao (2007) abstract from taxes and directly assume that renting is costly, Díaz and Luengo-Prado (2008) embed the US tax system into their model. The paper carefully compares housing costs for renters and homeowners. It finds that rental equivalence approach (as used in the NIPA tables) overestimates the costs of owner-occupied housing services by roughly 11%. Reasons include the differential tax treatment of renter-occupied vs owner-occupied housing services, the tax deductability of mortgage interest rates and transaction costs in housing markets.

Chambers et al. (2009a,b) study an equilibrium model with tenure choice. with long-term mortgage contracts. The model parameters are estimated with 1994 data. Table 2 in Chambers et al. (2009b) shows that the 1994 model predictions match the homeownership rate as a function of age quite well. Its predicts, however, that all households with income in the upper 40% of the income distribution should own—again, illustrating how difficult it is to match the extensive margin along observed dimensions of heterogeneity.

Attanasio et al. (2012) match the homeownership rate by age and education in a setup with two discrete house sizes: flats and houses. The paper documents that transaction costs are crucial for both homeownership and the property ladder. Lower transaction costs increase the homeownership rate because they increase the number of young households who find it optimal to buy a flat before upgrading to a house.

Home Equity as a Buffer Stock for Consumption Smoothing

Hurst and Stafford (2004) study a life cycle problem in which homeowners may want to use the equity from their house as a buffer stock to smooth their consumption. When homeowners with low savings in liquid assets (such as checking accounts or stocks) experience an adverse income shock, they may have to drastically lower their consumption. To avoid a painful cut in consumption, these homeowners may want to refinance into a mortgage with a larger principal. While refinancing might not necessarily lower the costs of their mortgage, it helps their desire to smooth their consumption.

Hurst and Stafford provide empirical support for this mechanism with micro data from the PSID. Households who were unemployed between 1991 and 1996, and who had zero liquid assets going into 1991, were 25% more likely to refinance than otherwise similar households. They also were more likely to extract equity during the refinancing process.

The life cycle problem in Hurst and Stafford is not designed to be quantitative. For example, it has constant house prices and a fixed house that cannot be sold, the income process is iid, and mortgages are interest-only. Chen et al. (2013) introduce a choice between renting and owning, house price risk, aggregate and idiosyncratic persistent income risk, long-term mortgages, and various frictions (such as loan-to-value and loan-to-income constraints.) When the observed historical paths for house prices, aggregate income and interest rates are taken as given, the model predicts a dramatic increase in mortgage debt during the 2000s house price boom. A significant portion of the debt increase is associated with home equity extraction in the model as well as in the data.

Mian and Sufi (2011) provide new empirical evidence on the importance of this mechanism with micro data from the recent housing boom. The paper documents that existing homeowners—households who already owned their home in 1997—started to borrow significantly more during the early 2000s. The tendency to extract equity was strongest among young homeowners with low credit scores and high credit card utilization rates, while homeowners with good credit scores did not extract more equity from their house.

4.2.2 Household Portfolio Choice

Accounting for risk in household portfolios requires combining the illiquidity and collateralizability of housing with a richer menu of securities. Portfolio choice then depends on risk in multiple tradable assets, as described in Section 3.2. Houses now enable households to borrow and invest their liquid funds in assets with more attractive return properties, such as stocks. When transaction costs are high, illiquid houses act as undiversifiable background risk (similar to nontradable labor income) in portfolio choice.

Myopic Investors

Early work focused on the risk return tradeoffs in models with myopic investors. Berkovec and Fullerton (1992) study a two period general equilibrium model in which households consume housing and choose a portfolio of owner-occupied housing, housing as an investment, stocks, and bonds. Ownership is attractive because of tax subsidies, but exposes owners to undiversifiable risk. Indeed, the paper estimates the variance of house prices as the sum of national, regional and intraregional effects on house prices, resulting in a volatility of 8.2% per year.

Starting from the current US tax system, the paper runs counterfactuals to eliminate subsidies, namely that owner-occupied housing services are not taxable, nominal mortgage interest is deductable, and that there is an extra deduction for property taxes. Starting from the current US tax system, the effects are a priori ambiguous: while abolishing subsidies lowers the average return on housing, it also reduces the variance of returns—the government becomes a silent partner who shares both gains and losses on the house. The overall effect on homeownership then depends on risk attitudes and tax brackets.

Flavin and Yamashita (2002) study portfolio choice by myopic investors with an emphasis on the illiquidity of housing. The setup resembles the second stage problem from Section 3.2: the position in housing is predetermined. Households have mean variance preferences and the focus is on the asset portfolio: there is no explicit consumption margin and no labor income. The portfolio share on housing thus acts as a constraint on the problem of choosing a portfolio of financial assets, namely short and long bonds, stocks and a mortgage. Bonds and stocks cannot be sold short and there is a collateral constraint: the mortgage cannot exceed the value of the house.

Flavin and Yamashita construct the returns on an individual house from PSID data. The housing return has a high volatility as in Table 1, and a zero correlation with financial returns. The solution to the portfolio choice problem that includes housing is an efficient frontier that achieves the minimum-variance portfolio for a given expected return subject to the housing constraint. The constraint is matched to average portfolio shares on housing for various cohorts in the PSID. As discussed in Section 2, these observed portfolio shares decline in age.

For households with a high portfolio share on housing, the optimal portfolio involves the maximum possible amount of mortgage borrowing. Since leverage is risky, any remaining funds are invested in a safer financial portfolio consisting of mostly bonds, while the shorting constraint binds for the short bond. For households with a lower portfolio share on housing, the position in housing is less leveraged. These households choose more risk in their remaining portfolio by increasing their portfolio weight on stocks. Higher risk aversion lowers the risk in the optimal portfolio by reducing leverage and shifting the remaining portfolio toward bonds.

A high portfolio share on housing is typical of young households, while middle-aged households have a lower portfolio share. By connecting the magnitude of the initial housing constraint with data on age profiles, the mean-variance benchmark provides intuition for why younger households hold a lower portfolio share in stocks than older households.

Housing and Other Assets Over the Life Cycle

Cocco (2005) studies the consumption–portfolio choice problem of an owner–occupier household with finite horizon. The household receives a nontradable income process (33) with both transitory and persistent shocks. The household can choose stocks, bonds, housing and a mortgage. The returns on stocks are iid and uncorrelated with aggregate income risk, while the price of the house is perfectly correlated with aggregate income risk. The real interest rate on bonds and the (higher) mortgage rate are constant.

The consumption–portfolio problem has several important constraints. The first two of these constraints are similar to those in Flavin and Yamashita (2002). First, bonds and stocks cannot be shorted. Second, there is a downpayment constraint; the mortgage cannot exceed a fraction of the house value. A new feature in Cocco's setup is that households choose the size of their house (while the house is fixed and acts as a constraint in Flavin and Yamashita). A third constraint is that houses have a minimum size. Together with the downpayment constraint, the minimum size creates a strong motive to save for young households, especially in the absence of a rental market. There are additional frictions in the form of transaction costs for housing and a one-time fixed cost to participate in the stock market.

The model generates low rates of stock market participation among poorer households—consistent with the data—who are not willing to pay the fixed costs to participate. Households with enough wealth get a large mortgage and invest most of their portfolio in housing; they still choose not to participate in the stock market. Richer households participate in the stock market and increase their portfolio share on stocks with wealth. Over the life cycle, the model with housing is successful at predicting that young households are house poor: they take a large mortgage and buy a house, while they do not participate in the stock market. As they grow older, they pay down their mortgage and invest more in the stock market, as in the data.

Yao and Zhang (2005) study a life cycle problem in which households can choose between owning and renting a house. The possibility to rent is important for younger and poorer households who do not have enough savings to afford the downpayment.

Older, wealthier households choose to own a house. The downpayment is equity in the house, which acts as a buffer against income shocks. Once they own a house, households have riskier portfolios because of the leveraged position in housing. But homeowners still invest a larger fraction of their (nonhousing) portfolio in stocks for diversification reasons, because of the low correlation between stock and housing returns.

4.2.3 Housing as a Hedge

Section 3.2 emphasizes that once risk is explicitly taken into account, the attractiveness of housing depends on the covariance of housing returns with other random state variables in the future. Those state variables include, among others, (*i*) labor income, a component of future wealth (*ii*) the price of rental housing which affects continuation utility in a problem with a rental market and (*iii*) house prices in other markets if the household is subject to moving shocks or has the option to move across different markets. We now consider evidence on these effects.

Housing as a Hedge Against Income Risk

Housing is riskier for households whose incomes covary positively with house prices. For these households, housing is not as good a hedge against income risk. These households will thus tilt their portfolios away from housing toward other assets. Cocco (2005) shows that this effect is quantitatively small in his life cycle model. For example, raising the correlation coefficient between income and house prices from 0 to 0.33 lowers the portfolio share on housing by 1 percentage point. The effect is small because housing is not only an investment but also a consumption good.

Davidoff (2006) provides empirical evidence on the effect. The paper first uses time series data to estimate the covariance between income and house prices in various regions and industries. The paper then predicts the value of owner-occupied housing as well as tenure choices in the 1990 census with the estimated covariances. The results show that a one-standard deviation increase in income–price covariance is associated with a $7500 reduction in the value of the housing investment for owners. They also show that a higher income–price covariance has a negligible effect on the probability of renting.

Housing as a Hedge Against Rent Risk

A common and reasonable assumption is that every household needs to consume some housing services. In a setup with a rental market as in Section 3.6, those services can be obtained either in a rental market or by buying a housing asset that promises a stream of housing services. The rental market is a spot market, where housing services are sold at the current rental rate which fluctuates over time. By buying a house, households can lock in a known price for a stream of future housing services. They still face house price risk in case they need to sell the house later because, for example, they want to move to a new city.

Sinai and Souleles (2005) compare the two sources of risk in a simple spatial model with two locations. Households choose whether to rent or own a single housing unit to maximize their expected wealth net of the housing costs. There is a fixed number of housing units equal to the number of households. The stochastic processes for rents in the two locations are exogenous. Rents are AR(1) processes with correlated shocks. After a known number years, households move from one to the other location. The price of owner-occupied housing units is determined endogenously and clears the housing market. In the model, both the demand for homeownership and equilibrium price–rent ratios tend to increase with expected tenure, the volatility of rents and the correlation between rents across locations.

Table 1 of Sinai and Souleles documents a 2.9% volatility of real rents at the MSA level during the years 1990–98, almost half the volatility of MSA real house prices. Much of this volatility is variation across MSAs. For example, rent volatility ranges from 1.7% in Fort Lauderdale to 7.2% in Austin. Tables 2 and 3 documents that both the probability of owning estimated from a probit model and price–rent ratios are higher in areas with higher mean tenure rates and rent volatility.

Housing as a Hedge Against Future House Prices

Lu (2008) solves a life cycle problem with many locations. The problem assumes that households know that they will want to move in the future, sell their house in the current location and buy a house in the new location. Whether or not the current house can act as a hedge for the future house purchase depends on the correlation between house prices across locations. The conventional wisdom is that correlation in house prices across housing markets is low. Since house prices within MSA are more correlated than across MSAs, the hedging motive will be more important for moves within metropolitan areas. The paper documents some evidence on the importance of such within-MSA moves. It reports that among households in the PSID from 1968 to 1997, 62% of them traded up later by buying a more expensive house (in real terms). Among households who traded up, 71.3% of them moved within the same metropolitan area.

Sinai and Souleles (2013) document that the correlation of house prices across MSAs is indeed low. They estimate this correlation with annual observations on the OFHEO constant-quality MSA-level house price index over the years 1980–05. The simple unweighted median correlation in real house price growth across MSAs is 0.35. Sinai and Souleles argue that households do not move randomly across MSAs. Instead, households move between housing markets that are highly correlated. The paper computes the household's own expected correlation in house prices across MSAs by weighing each correlation with the probability that the household will move to that MSAs. The data for moving from one MSA to another MSA is from the US Department of the Treasury's County-to-County Migration Patterns. The resulting expected correlation is 0.60 for the median household.

4.2.4 Mortgage Choice and Refinancing

Mortgages are often modeled as short-term debt contracts, as we did in Section 3.7. In this case, the collateral constraints (28) can capture home equity lines of credit. Most mortgages are long-term debt contracts, however. Recent work has therefore started to incorporate longer maturities as well as other features, such as fixed vs floating mortgage rates, deferred amortization, prepayment penalties, etc. Much more work is needed in this area to understand the recent foreclosure crisis, the welfare losses associated with certain contracts more broadly, and their implications for financial regulation.

Fixed vs Adjustable Rates

Campbell and Cocco (2003) study the choice between a fixed-rate mortgage and an adjustable-rate mortgage in a life cycle model. The household receives the nontradable real labor income process (33). The growth rate in house prices experiences iid shocks. The only other asset is a short-term real bond with an interest rate that is also hit by iid shocks. Expected inflation is an AR(1), so that inflation is an ARMA(1,1). The nominal short-term interest rate is the sum of expected inflation and the real rate. Longer-term nominal interest rates are determined with the expectations hypothesis. Adjustable mortgage rates include a constant default premium, while fixed rates include a default premium as well as a compensation for prepayment risk, both are constant as well.

The household buys a house with a minimum downpayment and finances the remaining balance with either an adjustable or fixed rate mortgage. A nominal fixed-rate mortgage without prepayment option is a highly risky contract, because the real present value of its future payments is sensitive to inflation. The prepayment option insures households against a surprising fall in nominal interest rates, because they can refinance at the lower rate. The option is not free, however—it is priced into a higher fixed rate. During times of low inflation and low real rates, the fixed rate mortgage is thus an expensive form of borrowing. An adjustable-rate mortgage is safe because the real present value of its future payments is unaffected by inflation. However, it comes with real payments that vary over time with expected inflation and real rates. These high payments may coincide with adverse income shocks and low house prices, so that homeowners may not be able to borrow more to meet these payments.

The optimal choice between the two mortgage contracts compares the expected costs for the homeowner over the life of the mortgage with the risks associated with higher or lower realizations of these costs. The expected costs for the homeowner are either the expected adjusted rate over the life of the mortgage or the known fixed rate. The risks associated with higher cost realizations matter more for homeowners who are either risk averse or close to their borrowing constraints. These homeowners tend to have low savings, large houses relative to their income and volatile incomes. The horizon matters for computing the expected adjustable rate over the life of the mortgage. For homeowners who are likely to move in the near future, the current adjustable rate matters more. These homeowners will compare the current adjustable rate with the fixed rate and opt for the rate that is currently cheaper. Since fixed rates include the cost of the prepayment option and are longer maturities interest rates, the cheaper rate will on average be the adjustable 1-year rate.

More generally, the difference between the fixed rate and the expected adjustable rate over the life of the contract is determined by risk premia (as well as the cost of the prepayment option). These risk premia vary over time. Koijen et al. (2009) compute a time series these risk premia and show that they highly correlate with the actual share of adjustable-rate mortgages among newly originated mortgages. The expected adjustable rate can be computed, for example, with survey data on interest rate forecasts, VARs or some other estimated time series process, or under the assumption that beliefs are extrapolative. Badarinza, Campbell, and Ramadorai (2016) investigate the share of adjustable-rate mortgages in cross-country data. They find that low expected adjustable rates over short horizons, such as a year or a few years, relative to fixed rates are associated with a high share of adjustable rate mortgages.

Deferred Amortization Contracts

Piskorski and Tchistyi (2010) is a theoretical study of optimal mortgage design in a setup in which income by an impatient household is stochastic and unobservable by the lender. The household needs to borrow from the lender to be able to buy a house. The paper shows that the optimal contract is a combination of an interest-only mortgage and an equity line of credit—an alternative mortgage product that offers deferred amortization. The intuition behind the result is that deferred amortization helps borrowing-constrained households to smooth their consumption.

Chambers et al. (2009a,b) study mortgage choice in a quantitative general equilibrium model with tenure choice and long-term mortgage contracts. The model parameters are estimated with 1994 data. The model is recomputed with 2005 data by offering households a range of mortgage contracts with lower downpayment constraints, other forms of deferred amortization, and lower closing costs. The paper finds that these new mortgage contracts have enabled many borrowing-constrained renters to buy a house. It concludes that these mortgage innovations can explain around 70% of the large increase in the homeownership rate from 1994 to 2005.

Cocco (2013) provides empirical evidence that supports this consumption-smoothing mechanism with data from the British Household Panel Survey. The survey collects detailed housing information from a group of households over time (for example, about the type of mortgage, the year the mortgage began, the amount borrowed, monthly payments, etc.) The paper documents that, at least since 2001, households who choose alternative mortgages are better educated and have higher subsequent income growth These mortgages are used to buy expensive houses with high loan-to-value ratios. Amromin et al. (2013) document similar evidence for alternative mortgages in the United States.

Suboptimal Borrower Behavior in Mortgage Markets

Mortgages are complex products. Mortgage lenders do not have the incentives to make these contracts comparable, unless forced by regulation. Households make their mortgage choice infrequently and cannot learn much from their past mistakes. In this situation, it is not surprising that mortgage choices are not made optimally.

Woodward and Hall (2012) show that new home buyers vastly overpay for their mortgages. They use data on a sample of 30-year fixed-rate mortgages insured by the Federal Housing Administration to show that borrowers do not push brokers toward competitive pricing. Most borrowers would benefit from comparing quotes from a larger number of brokers. Borrowers would also benefit from comparing quotes of mortgages that do not involve any up-front cash payments, such as points. These findings hold especially for less educated borrowers.[aa]

A large literature on mortgage-backed securities documents that households' refinancing behavior is suboptimal. For example, Schwartz and Torous (1989) and Stanton (1995) show that many households do not refinance their fixed-rate mortgage when market rates fall below their locked-in contact rate. Other households refinance even though market rates are above their locked-in contract rate. Agarwal et al. (2013) develop a formula for the (S,s) inaction range for refinancing in the presence of fixed costs. Anderson et al. (2015) document suboptimal refinancing behavior in Denmark, especially for older, less educated and lower income households.

4.2.5 Consumption Response to Higher House Prices

House price booms are often associated with higher aggregate household consumption. What are the mechanisms that explain the consumption increase? There are two related issues. The first is to measure the marginal propensity to consume (MPC) out of housing wealth for different groups of consumers. The second is to identify what exogenous shocks might have given rise to the joint movement in house prices and consumption. For example, was the boom generated by changes in financial conditions, or rather by an increase in household income.

The household problem from Part 2 suggests potential determinants of the MPC out of housing wealth. Consider first the frictionless problem from Section 3.2. Here, an increase in the house price has three possible effects: it changes the relative price of housing services, it may change expectations of returns on housing or other assets in the future (that is, it may change the continuation utility V_{t+1}), and it changes current wealth (or cash on hand). Only the first effect is unique to housing which has a nontradable dividend—the latter two effects are shared by any other security.

[aa] Woodward and Hall (2012) also show that minority households overpay more for their mortgages. Important early work on discrimination in mortgage markets is the paper by Munnell et al. (1996). These authors show that minorities are more than twice as likely to be denied a mortgage as whites.

Berger et al. (2015) provide conditions on the problem such that only the last effect prevails. In particular, they consider permanent price changes that do not alter return expectations, and they assume Cobb–Douglas felicity so that income and substitution effects of the relative price of housing services cancel. They also point out that the result does not depend on the presence of incomplete markets, a rental market or a collateral constraint of the type (28)—indeed, the result is due to the fact that cash in hand is the only state variable that house prices affect which is true in all of these cases. The result does not hold once transaction costs for either housing or mortgages are added.

Consumption and House Prices in Life Cycle Models

Many studies have analyzed aggregate data on consumption during housing booms. For example, Muellbauer and Murphy (1990) argue that in the UK house prices in the 1980s generated a wealth effect on aggregate consumption that was enabled by financial liberalization. The liberalization allowed households to extract more wealth from the value increase in their illiquid housing investment. King (1990) and Pagano (1990) question the importance of wealth effects in accounting for the high correlation between house prices and consumption in the United Kingdom. They argue that higher income growth expectations account for the increase in consumption and also for higher house prices.

Micro evidence on household consumption helps distinguish between competing mechanism. For example, Attanasio and Weber (1994) argue that in basic life cycle models (with a single good and a single asset), wealth effects vs higher income expectations have different predictions for the consumption of younger vs older households. Older households have more wealth and have shorter horizons over which to spread an increase in their wealth. Therefore older households will increase their consumption more than younger households in response to a 1% increase in wealth. Younger households respond more to income shocks, because they have more human wealth. The paper uses micro data from the UK family expenditure survey (FES) to document that the 1980s consumption boom was driven in large part by strong consumption by young households.

In a life cycle model with housing as a collateral asset, the predictions of these mechanisms are less obvious. In this setup, higher house prices not only increase the wealth of homeowners as in the basic model, but also relax collateral constraints and thereby enable the young to consume more. Attanasio et al. (2011) solve such a life cycle problem with exogenous house price and income processes in which the collateral constraint (28) is only imposed in the period when a house is bought or the mortgage amount changes. They use the observed aggregate time series for house prices and income to extract two shock series. The paper then feeds the two shocks separately into the model and analyzes how various age cohorts adjust their consumption to a particular shock. The quantitative results show that the intuition from the basic life cycle model carries over to this model with housing: higher house prices lead to stronger consumption responses by older households, while higher income causes stronger consumption responses by young households. The paper again concludes that the evidence suggests that higher income expectations or common shocks that affect both income and house prices are more important than pure wealth effects.

Homeowners who want to consume more in response to higher house values need to adjust their portfolio position either by selling their house or by borrowing more against their house. When transaction costs are high in housing and mortgage markets, the costs of adjusting the portfolio may not make it optimal to cash out. Indeed, Berger et al. (2015) show that their theoretical result does not apply in the presence of transaction costs. They find that a model with transaction costs around 5% has approximately the same consumption elasticities than a model without transaction costs. With higher transaction costs, around 10%, the MPC × house value formula overstates consumption elasticities, especially for younger households.[ab]

Models with short-term mortgages make it easy for households to extract cash from their house and may overstate consumption elasticities. Gorea and Midrigan (2015) consider a model in which long-term mortgages are costly to refinance. When these costs are selected to match the share of mortgages that are refinanced, consumption elasticities are substantially lower.

Reduced Form Estimates and Housing Supply Elasticities as Instruments

Are consumption elasticities for individual households large enough for house price increases to generate quantitatively big effects on consumption? Reduced form estimates of the consumption elasticity vary widely across studies. Case et al. (2005) provide reduced-form evidence on the consumption elasticity to house price changes with aggregate data from many countries. Their estimate ranges from 0.02 to 0.17. Carroll et al. (2011) also use aggregate data and estimate an immediate (next quarter) consumption elasticity of 0.02, with an eventual elasticity of 0.09. Attanasio et al. (2009) use micro data from the UK family expenditure survey to estimate consumption elasticities across households. They regress the level of consumption on changes in house price and other demographic variables. The paper obtains an average elasticity of 0.15 and higher elasticities for young households. Campbell and Cocco (2007) also use the FES and obtain a much larger average elasticity of around 1.2 and higher elasticities for older homeowners than for younger renters.[ac]

Reduced form regressions should ideally have exogenous variations in house prices on their right hand side. The identification of such variation is tricky. Even if we had a good identification strategy to isolate such exogenous variation in the data, it is not possible to directly compare the observed consumption responses in the regressions with

[ab] Kaplan and Violante (2014) show that households who invest a large fraction of their wealth in an asset with high transaction costs have high MPCs.

[ac] Lustig and Van Nieuwerburgh (2010) collect data from various US metro areas to document that risk sharing between regions is reduced when the value of housing is low. More specifically, regional consumption is more sensitive to regional income when housing collateral is scarce.

those implied by a life cycle model. The response of consumption to an exogenous increase in house prices includes any general equilibrium effects of higher house prices on consumption. For example, higher house prices may encourage more residential investment and employment, and thereby increase consumption. These GE effects are typically not included in the model.

To address the identification problem, Mian et al. (2013) use IV regressions with the local housing supply elasticity index constructed by Saiz (2010) discussed in Section 2.1 as instrument. The instrument provides a source of exogenous variation in the exposure of different geographical areas to a common aggregate house price shock. Intuitively, areas with an inelastic housing supply (such as San Francisco and Boston) should experience larger house price changes than areas with a highly elastic housing supply (such as Omaha and Kansas City). The paper estimates high consumption elasticities between 0.34 and 0.38 with Mastercard data that measures credit-card spending on nondurables and house prices from Core Logic. Kaplan et al. (2016a) confirm these estimates with store-level sales from the Kilts-Nielsen Retail Scanner Dataset and Zillow house prices.

To interpret the causality of these elasticities, the housing supply elasticity instrument has to be valid. The instrument satisfies the first-stage requirement: areas with steep slopes, bodies of water and zoning restrictions tend to experience higher house price growth during booms, so that the instrument is correlated with house prices (for example, table 2 in Saiz, 2010 and table A2 in Stroebel and Vavra, 2015). A more difficult requirement to satisfy is the second stage exclusion restriction. In a standard IV approach, the supply constraints must be uncorrelated with omitted demand factors. Saiz (2010), however, documents that supply constraints are associated with high demand. For example, land-constrained areas have higher incomes, are more creative (in the sense of more patents per capita) and attract more tourists (measured by tourist visits per person.) As skilled workers sort into more attractive areas, their productivity/income growth will increase the demand for amenities and house prices. A detailed exposition of this argument is in Davidoff (2016).[ad]

4.3 Housing Over the Business Cycle

The literature on housing over the business cycle is concerned with the facts presented in Fig. 2. As for quantities, residential investment and consumption of housing services are procyclical, with residential investment being more volatile than other investment and leading the cycle. Moreover, the price of housing is procyclical and comoves positively

[ad] Various papers try to provide more direct evidence on the exclusion restriction. For example, table 5 in Mian and Sufi (2011) shows that IRS per capita wage growth is negatively correlated with supply elasticities, indicating that more constrained areas such as San Francisco experience higher wage growth. Other measures of income growth, however, appear uncorrelated with supply elasticities. Stroebel and Vavra (2015) provide additional evidence that measures of income growth are not correlated with supply constaints.

with housing investment. At the same time, the literature aims to account at least as well, or possibly better, for standard business cycle facts such as the volatility, cyclicality, autocorrelation of GDP, nonresidential investment, consumption, hours worked, as well as wages and interest rates and possibly mortgage debt.

We divide the literature into two parts. Early work focused on frictionless representative agent models; the key difference to the standard real business cycle model (RBC) is the presence of two final goods, one of which is either housing services or a "home good" with a large housing component. Papers in this line of research differ mostly in the production technology, and the bulk of the empirical work provides new evidence on technology by sector. More recent work has emphasized simple heterogeneity of agents, usually a borrower and a lender type, as well as nominal rigidities. These papers differ mostly in the asset structure and empirical work often provides new evidence on financial variables.

Models in this section are quantified using a mix of parameters from earlier literature and new estimates. Some papers work with observable shock processes—for example, sectoral TFP—which allows them to estimate the shock process in a first step before computing an equilibrium of the model. Other papers jointly estimate parameters of preferences, technology and the shock processes using GMM or maximum likelihood approaches. In all cases, model performance is assessed by comparing the empirical distribution of a set of observables to the joint distribution of those variables implied by a stationary rational expectations equilibrium of the model economy.

While much progress has been made in understanding the role of different shocks and model ingredients, the basic facts of housing over the business cycle remain puzzling. In particular, we do not yet have a joint account of the volatility and lead-lag behavior of residential investment together with the volatility of house prices. This is in part by design: most models in this section are solved by linearization around a balanced growth path and do not allow for changes in uncertainty. As a result, asset prices move only with changes in expected cash flow or interest rates which limits the scope for volatility. A promising area for future work is to place more emphasize on mechanisms for price volatility and draw tighter connections to the micro evidence on portfolios discussed in Section 4.2.

4.3.1 Home Production

Home productions models are two sector stochastic growth models. The "market" sector produces a market good using business capital and "market labor"—identified with hours as conventionally measured. The "home" sector produces a home good using home capital—identified with housing and consumer durables—together with home labor. Market output is used to make either type of capital—we can define technology as in (21) and assume that construction capital equals home capital that directly provides utility. In line with the features of housing stressed earlier, home capital is an asset with a nontradable dividend, the return of which is difficult to measure directly. Of course, nontradability and indivisibility of housing have no bite for model properties when there is only one agent.

In a frictionless two-good model, a positive TFP shock to sector A induces reallocation of labor away from sector B and hence lower output in that sector. Hours worked and output in sector B are thus more volatile than what one would expect if there were only TFP shocks to sector B itself. The home production literature exploits this mechanism to generate more volatile market hours and output than a standard RBC model. Suppose sector B is the business or market sector, then hours worked and GDP—the series usually targeted by business cycle models—correspond to hours and output in sector B. Sector A is the household sector which produces home goods using housing capital and work at home. Home good TFP shocks can then help increase the volatility of hours and output, especially if they are imperfectly correlated with business TFP.[ae]

At the same time, sectoral reallocation gives rise to a "comovement puzzle." Indeed if sectoral TFP shocks were uncorrelated, output, labor and investment would all be negatively correlated across sectors: it makes sense to move both labor and capital toward the most productive sector. The home production literature shows that this force helps make hours and GDP more volatile. However, it also makes home and business investment negatively correlated, whereas residential and nonresidential investment are both procyclical in the data. There is therefore a tension between the promise of the mechanism for labor reallocation and its implications for capital reallocation. A second puzzle follows from the input–output structure of the models. A typical assumption is that capital for both home and business use is produced by the business sector only. Consider now the response to a perfectly correlated shock to both sectors: it makes sense to shift factors to the business sector in order to build capital before increasing investment and production in the home sector. This force make home investment lag the business cycle, again contrary to the data. If the effect is strong enough, such as when the elasticity of substitution between home capital and labor is high, we can further have negative correlation of investment across sectors even with strong positive correlation of TFP.

Progress in the literature has been to compare specifications of technology that might overcome these two puzzles. Roughly, comovement obtains more easily if shocks affect sectors similarly and there are reasons not to move capital. Greenwood and Hercowitz (1991) consider highly correlated shocks together with a low elasticity of substitution between capital and labor in the home sector. In Hornstein and Praschnik (1997), all capital is produced by a durables good sector that uses nondurables as an intermediate input. Gomme et al. (2001) assume time to build in the business sector. Chang (2000) studies capital adjustment costs. The upshot of this literature is that comovement can be obtained with technologies justified by standard input–output matrices.

[ae] See Benhabib, Rogerson and Wright (1991) and Greenwood et al. (1995) for an exposition of the main mechanism.

The lead-lag pattern of residential investment has been a tougher nut to crack. Fisher (2007) proposes a model in which home capital serves as an input into business production. The idea is that workers who live in better houses are more rested and deliver higher quality work. This type of technology cannot be justified by standard NIPA input–output accounting; it is instead motivated by a regional level estimation of a production function that takes the new effect of home capital on business output into account. With that effect and appropriate elasticities, it can make sense to build home capital first in response to productivity shocks.[af]

4.3.2 Land and House Prices

Davis and Heathcote (2005) incorporate land into a two-sector stochastic growth model. Their setup is more directly geared toward housing than the typical home production model—the "home good" is explicitly identified with housing services. A simplified version of their technology is given by (21)–(22): housing services are provided by a housing asset produced by a construction sector, and while there are no adjustment costs to capital, a limited flow of new land induces an adjustment cost to housing. These assumptions on technology have been adopted by a number of later papers. The paper itself has a richer structure with input–output links between construction and other sectors via intermediate goods derived from NIPA sectoral accounts.

The model is driven by sectoral TFP shocks and produces comovement of residential and business investment, where the former is substantially more volatile, but does not lead the cycle. At the heart of the model is the construction sector, which is labor intensive and subject to particularly volatile TFP shocks. A positive construction TFP shock is amplified by hiring and generates a lot of construction output. The response of residential investment is larger than for business investment since housing is more construction intensive and depreciates more slowly. At the same time, the input–output structure ensures that comovement still obtains, but it does not allow for residential investment to lead the cycle.

The model-implied house price is procyclical but negatively correlated with residential investment. Its volatility is less than one third of that in the data. The key effect here is that a positive construction TFP shock not only increases residential investment, but also makes housing cheaper. At the same time, TFP shocks to other sectors can make the prices of all long lived assets, including the housing asset, procyclical. Put together, these results again illustrate the promise and limitations of sectoral productivity shocks as a driving force of housing. It is tricky to come up with input–output structures that generate the right quantity dynamics. Once prices are explicitly considered, further challenges arise.

[af] Recently Kydland et al. (2012) have shown that both the lead-lag behavior of residential investment and the prevalence of long term fixed rate mortgages are special features of US data. They provide a model in which residential investment leads the cycle because the cost of housing depends on forward looking long term yields in the United States, but less so in other countries.

4.3.3 Household Debt and Nominal Rigidities

A number of papers in the early 2000s extended New Keynesian models to allow for housing and collateral constraints along the lines of Section 3.7. Early work was concerned with the response to monetary policy, described further below.[ag] To illustrate the business cycle properties of such frameworks, we focus below on the results of Iacoviello and Neri (2010) (IN). On the firm side, that paper combines nominal rigidities, the technology of Davis and Heathcote, capital adjustment costs and free linear conversion of houses. There are two types of households who differ in discount factors and no rental markets so that housing dividends are nontradable. The model features many shocks and is estimated using consumption, house prices, inflation, the nominal interest rate as well as housing and nonhousing investment, hours and wages.

Heterogeneity in discount factors gives rise to a borrower-saver household sector. Impatient borrower households borrow and run into collateral constraints, whereas patient saver households are unconstrained in equilibrium. Borrowers are always constrained near the steady state, which allows for linear solutions.[ah] The assumption of linear conversion implies that there is a per-unit price of housing. Nontradability of dividends nevertheless allows for a steady state in which both types of households own housing. This makes the model different from linear two-agent models of equity pricing, in which the agent with the highest valuation of a tradable asset is typically the only owner.

Three key features distinguish New Keynesian borrower-saver models from the models discussed so far. First, a "housing preference shock" increases the felicity from housing. Together with the shock to construction productivity, it is the most important driver of house prices and residential investment. Since it increases housing demand rather than supply, it also makes those two variables move together. At the same time, it lowers comovement of business and residential investment. This tension implies that the model has trouble matching jointly the volatility and cyclicality of house prices and investment, as well as the lead-lag behavior of investment, even though it does generate volatile house prices (IN table 4).

Second, the models feature nominal rigidities which amplify "demand" shocks such as those to housing preference. In particular, with sticky wages, housing preference shocks have much larger effects on residential investment (IN fig. 2). Stickiness of prices is less

[ag] A related early borrower-saver business cycle model is Campbell and Hercowitz (2005) who study borrowing collateralized by durables with a constant price. They show that lower downpayment requirements allow borrower households to better smooth labor supply and hence lower the volatility of aggregate hours. They use this effect to relate financial innovation in the early 1980s to the Great Moderation of the US economy.

[ah] Linear solution imply symmetric business cycles. Allowing for occasionally binding constraints could alter dynamics by introducing nonlinear dynamics; for example, the response to shocks could be stronger in downturn when constraints bind, giving rises to asymmetric cycles as in the data. Guerrieri and Iacoviello (2015) develop a model to study such effects.

relevant since house prices are flexible. At the same time, however, sticky wages worsen the comovement problem: a construction productivity shock no longer increases business investment (IN fig. 4). Nominal rigidities also matter in that they allow other shocks—eg, to monetary policy and markups—to feed through to the housing sector.

The heterogeneity of households is not particularly important for the behavior of investment and house prices (IN figs. 2–4). Linear conversion of housing matters here: housing (as well as other capital) satisfies the Euler equation of the patient unconstrained investor, so investment and price dynamics look much like in a representative agent model. At the same time, the presence of collateral constrained households matters for the response of consumption to shocks. In particular, changes in housing wealth will affect aggregate consumption more. In a model with nominal rigidities, this also translates into effects on output.

4.3.4 Financial Frictions in the Business Sector

With financial frictions in the household sector, house prices can matter for output through their effects on demand. If businesses face collateral constraints, then real estate values can also affect firms' cost. For example, in Iacoviello (2005), entrepreneurs borrow using housing as collateral. Liu et al. (2013) estimate a model in which firms borrow against land as collateral. Housing or land preference shocks can then serve as a driver of the business cycle together with the price of land and the level of business debt.

In the wake of the financial crisis, it has become common to introduce shocks that directly change borrowing or intermediation costs. Some papers have studied such shocks in models with housing. For example, Dorofeenko et al. (2014) add financing constraints as well as risk shocks to the construction sector. Risk shocks then increase the volatility of house prices although this comes at the cost of overstating the volatility of residential investment. Gerali et al. (2010) estimate a model of the Euro Area. Their estimation backs out an important role for shocks to a frictional banking sector that lends to households and firms against collateral.

4.3.5 Effects of Monetary Policy

A growing literature studies the effect of monetary policy shocks in New Keynesian models with heterogenous households, following Aoki et al. (2004) and Iacoviello (2005). The goal is to match the impulse response to a change in the short term nominal interest rate obtained from structural VARs. A stylized fact is that an expansionary monetary policy shock—a decline in the short rate—increases house prices and residential investment along with output (see, for example, Calza et al. (2013) for evidence for a cross section of countries). The goal of the literature is to account for this fact as well as to show whether the presence of heterogenous agents and housing is an important force behind impulse responses for other variables.

As a benchmark, consider the response to a monetary policy shock in a New Keynesian model with a representative agent. With sticky prices, a decline in the nominal short rate generates a decline in the real short rate. From the Euler equation, the representative agent would like to substitute away from expensive future consumption and increase current consumption. Since firms are on their labor demand curve, hiring and output increase to provide extra consumption—monetary policy stimulates the economy. The Euler equation also says that the return on housing should decline—this can happen either through a drop in the dividend (an increase in the relative consumption of housing) or a drop in house prices. Finally, the return on investment declines and so does residential investment.

Suppose now instead that the short rate declines in model with heterogeneous agents and collateral constraints. Assume also that housing is priced linearly. A change in the real rate directly affects the Euler equation of unconstrained agents. Again the return on housing has to decline as well and this happens in part via an increase in housing consumption by the unconstrained—which decreases dividends—and in part through a drop in the house price. The quantity adjustment is not very large, so that the price response typically looks similar to a representative agent model. A key difference to the representative agent model is that the price change now tightens the collateral constraint and lowers consumption of constrained agents. As a result, the consumption and output responses are typically much larger than in a representative agent model, and they are driven to a much smaller extent by intertemporal substitution.

Iacoviello (2005) studies the above mechanism in a two-agent model with borrower and saver households. Aoki et al. (2004) consider savers and an entrepreneurial housing sector. Monacelli (2009) compares the implications of models with and without collateral constraints with evidence on the consumption response for durables and nondurables. Rubio (2011) introduces long term debt in a model without capital and shows that effects of monetary policy are stronger with variable rate mortgages, since real interest rate movements have larger effects. Calza et al. (2013) present SVARs evidence that monetary policy has larger effects in countries with more variable mortgages; as well as a model with capital that generates qualitatively similar effects. Garriga et al. (2013) consider a flexible price model and emphasize that variable-rate mortgages generate important nominal rigidities in their own right.

4.3.6 Rich Household Sector

Much of the literature on business cycles and monetary policy has built on traditional macro models with limited heterogeneity. In light of results on portfolio choice discussed earlier, there is considerable promise in models that allow for richer heterogeneity in both households and houses as well as for aggregate risk. Early work in this direction abstracted from house price risk. Silos (2007) studies a model with two capital stocks that also accounts for the cross section and time series properties of housing and wealth positions.

Iacoviello and Pavan (2013) allow for a rental market and emphasize the procyclicality of debt. Another interesting direction is to explicitly incorporate geography (for example, Van Nieuwerburgh and Weill (2010)).

The literature on monetary policy shocks has also been moving toward models with a richer household sector. For example, Kaplan et al. (2016b) consider a perpetual youth model with borrowing constraints and a subset of illiquid assets (including housing). Wong (2016) considers an overlapping generations model with long term mortgages and highlights the role of heterogeneity by age for the transmission mechanism. All of these papers show that the details of how the household sector is modeled matter for the strength of impulse responses.

4.4 Asset Pricing with Housing

This section summarizes work that studies regular patterns in asset prices implied by models with housing. Similarly to the business cycle analysis in the previous section, model exercises compare empirical distributions in the data to stationary equilibria implied by the model. The key difference is that explicit nonlinear solutions allow for time variation in risk implied by the role of housing as a consumption good or collateral asset. Changes in the risk return tradeoff then affect the pricing of all assets including housing.

The upshot from this literature is that the presence of housing introduces slow movement in the stochastic discount factor that lines up with observed movements in risk premia. At the same time, rational expectations versions of the models here do not generate sufficient volatility to price risky assets, unless risk aversion is large. It is an open question how much the channels described here can contribute once they are combined with less restrictive assumptions on expectations.

4.4.1 Housing as a Consumption Good

The standard consumption-based asset pricing model focuses on consumption risk: the value of an asset depends on the comovement of its return with a single factor, aggregate consumption growth. In a model with housing, households worry not only about future consumption growth, but also about the future composition of the consumption bundle (c_t, s_t). With frictionless rental markets, composition risk can be measured by the expenditure share of housing in the overall consumption bundle. Assets are then valued also for whether they provide a hedge against this second risk factor.

More formally, Piazzesi et al. (2007) assume a power utility function $U(C) = C^{1-1/\sigma}/(1-1/\sigma)$ over the CES aggregator $C = g(c, s)$, and assume a frictionless rental market. The pricing kernel (10) can then be written as

$$M_{t+1} = \beta \left(\frac{c_{t+1}}{c_t} \right)^{-1/\sigma} \left(\frac{1-x_{t+1}}{1-x_t} \right)^{\frac{\varepsilon-\sigma}{\sigma(\varepsilon-1)}}. \tag{34}$$

where x_t is the expenditure share on housing consumption. If $\sigma < 1 < \varepsilon$, then households worry both generally about recessions—low consumption growth—and in particular about "severe recessions" in which the expenditure share on housing consumption is low.

The pricing kernel (34) is observable since the housing expenditure share x_t is available in the NIPA tables. Use of expenditure shares avoids reliance on problematic measures of housing quantities s_t. Fig. 1 shows movements in x_t over the postwar period. The key feature is that the expenditure share contains a slow moving component that lines up with the low frequency component in the price dividend ratio on equity: both series are high in the 1960s, low in the 1970s and recover in the 1980s. These movements are predictable and occur at frequencies that are much lower than business cycle frequencies.

Low frequency movements in the housing share induce movements in stock prices that are in line with the data. For example, agents' concern with severe recessions increases risk premia on assets that pay off little when the expenditure share on housing drops, and more so when the housing share is already currently low. Comovement of x_t with the price dividend ratio implies that equity is such an asset. Since the expenditure share is stationary, the price-dividend ratio on stocks is persistent but mean reverting. This mean reversion explains why the price-dividend ratio forecasts excess returns on stocks. The model also implies that the housing expenditure share should predict excess stock returns, which it does in the data.

Since movements in the housing share are small, large risk premia obtain only if the exponent in (34) is sufficiently large. This can happen for two reasons. On the one hand, suppose that the intratemporal elasticity of consumption is close to one. Since household desire constant expenditure shares, the prospect of a drop in the housing share causes them large discomfort and requires high risk premia on equity even when risk aversion is low. At the same time, however, the intratemporal Euler equation (24) implies very large volatility in rents. On the other hand, high risk premia obtain without high rent volatility when risk aversion is large. In this case, the role of housing is still important in generating time variation in risk premia.

4.4.2 Adjustment Costs and Production

The same asset-pricing implications continue to hold when housing is costly to adjust (see, for example, Stokey, 2009). Adjustment costs typically alter the optimal consumption allocation—for example, consumption is constant or depreciates at a constant rate as long as there is no adjustment. At the same time, the Euler equation (8) for other securities still holds. The pricing kernel (34) continues to be observable with quantity data on housing and nonhousing consumption, or with data on nonhousing consumption and the expenditure share x_t. The argument further extends to setups with preferences over consumption and housing that deviate from expected utility. In this case, the pricing kernel has to be evaluated with continuation utility (10).

Flavin and Nakagawa (2008) measure the pricing kernel with quantity data on housing consumption. More specifically, they use square footage to measure housing consumption. An important disadvantage of this quantity-based measure is that it does not capture quality differences that would be reflected in dollar expenditures and therefore the expenditure share x_t as in (34). For example, a 2000 square foot house with a view will provide more utility than the same square footage without view. This quality difference will be reflected in a higher rent for the house with a view and an associated higher expenditure share x_t on housing.

Jaccard (2011) studies a two-sector model with production of housing. There is habit formation over the consumption bundle $g(c_t, s_t)$ and leisure. The presence of adjustment costs in housing production together with habit formation helps to generate volatile house prices. Habit formation also helps to generate a sizable equity premium as well as comovement between hours worked and output.

4.4.3 Housing as a Collateral Asset

Lustig and Van Nieuwerburgh (2005) consider the asset pricing implications of a heterogenous agents model with uninsurable idiosyncratic income risk and collateral constraints. The collateral constraint is similar to (28), except that the set of securities is a complete set of one-period-ahead contingent claims and any state contingent promise must be backed by the value of housing in the relevant state of nature next period. The presence of contingent claims allows an aggregation result that expresses the pricing kernel M_{t+1} as an aggregate consumption term as in (34) multiplied by a term that depends on the "housing collateral ratio," that is, the ratio of housing wealth relative to human wealth.

The housing collateral ratio now serves as a second state variable that describes variation in investors' required compensation for an additional risk factor. Indeed, investors perceive recessions as particularly severe when the housing collateral ratio is low and collateral constraints are more likely to bind. Moreover, if the current collateral ratio is already low, opportunities for smoothing uninsurable income shocks through collateralized borrowing are poor and required risk premia are high. Empirically, measures of the housing collateral ratio predict stock returns and also help explain the cross section of stock returns.

The paper further shows that large movements in risk premia are associated with large movements in the riskless interest rate. Indeed, if opportunities to borrow are currently low, then the supply of all contingent claims falls, which drives up the prices of all claims as well as their sum, the price of a riskless bond. This logic is not limited to models with collateral constraints on contingent claims but also applies with the constraint (28) or when default is punished by autarky. Quantitatively, it prevents rational expectations models with borrowing constraints from generating high and volatile equity premia without excessively volatile interest rates, unless risk aversion is high.

4.5 Housing Boom–Bust Cycles

A growing body of work tries to understand the mechanisms behind large house price swings and their quantitative importance. Two boom–bust episodes stand out—they were associated with high nationwide house prices both in the United States as well as many other industrialized countries. The first occurred during the Great Inflation of the 1970s, as documented in fig. 2 of Piazzesi and Schneider (2008). During the boom, houses in high quality segments of the US housing market appreciated by 11% *more* than low quality segments, as shown in table 2 of Poterba (1991). The second boom happened during the 2000s, when many countries experienced large increases in mortgage debt together with large house prices increases, as documented by Tsatsaronis and Zhu (2014). During this boom, houses in high quality segments of US housing markets appreciated *less* than low quality segments, as discussed in Section 2.2.

The typical account of a boom episode consists of one or more "shocks," that is, changes in the economic environment, together with a mechanism for how the economy responds to the shocks. Broadly, candidate shocks are changes to macroeconomic conditions that affect income and assets other than housing, changes in financial conditions that affect the ability to borrow given house prices, as well as changes in government policy and expectations about future house values. How exactly the shocks and the mechanism are modeled depends on how much of the response of the economy is endogenous in a given model exercise.

4.5.1 Overview of the Results

Studies of the 1970s housing boom show that the Great Inflation depressed user costs, especially for richer households. The lower user costs can quantitatively account for both higher overall house values as well as higher house values in high quality segments. Higher mortgage interest-rate tax deductions increased the attractiveness of homeownership. They can explain a large share of the overall increase in real house prices. The higher deductions especially benefitted households in higher tax brackets, which accounts for the higher appreciation of high quality segments. In surveys, young households reported to have higher inflation expectations and thereby lower perceived real rates than older households. This disagreement about inflation expectations and real rates across generations is consistent with the increase in credit during this episode. As a consequence, young households borrowed more at rates that they perceived as low and bought houses, pushing up prices.

User costs were again low during the 2000s boom. Credit was easy to get—with low interest rates and relaxed downpayment constraints, enabled partly by an inflow of foreign savings as well as an increase in securitization. The lower interest rates raised the present value of future housing services and thus house values across the board. The relaxation of downpayment constraints mattered mostly for poor households who were able to borrow more and buy houses, driving up house prices especially in the low quality segments of the housing market. Richer households increasingly bought low quality houses and neighborhoods gentrified, further pushing up prices in these low quality segments. All studies, however, find it difficult to quantitatively account for the entire increase in house prices. This suggests that expectations played a role during the 2000s boom. As long as households were expecting house prices to grow at trend together with income (instead of mean reverting to lower levels), it is possible to quantitatively explain the boom.

There has been much progress in our understanding of boom–bust episodes. Micro data—including on household behavior and survey expectations—have helped sort out the importance of competing mechanisms. At the same time, the nature of the shock that started the housing boom is yet not well understood. Changes in housing preferences, expectations, foreign capital inflows or downpayment constraints are essentially standins for changes in various market participants' attitudes toward housing and housing credit. To understand what generates these changes requires theories of expectation formation, financial innovation as well as international capital market integration.

Another open question is the precise role of the US government during the recent boom. It is clear that many policies (for example, associated with the 1994 National Homeownership Strategy developed by the US Department of Housing and Urban Development) encouraged poor households to take out large mortgages and buy houses, especially in low quality segments. How much did these policies contribute to the boom? A related question is whether the government should promote homeownership in the first place, given that it involves a large undiversified investment and potential welfare costs in default.

4.5.2 The 1970s Boom

Poterba (1984) investigates the user cost equation with Census data from the 1970s housing boom. His findings show that high expected inflation substantially lowered the user costs of housing. High expected inflation pushes up mortgage rates and thereby increases the mortgage tax subsidy. This mechanism is able to explain a 30% increase in real house prices during the 1970s.

Poterba (1991) calculates that user costs dropped especially for households in high tax brackets. The reason is that high mortgage rates translate into a larger mortgage tax subsidy for households who earn high incomes that are taxed at higher rates. Lower user costs for richer households increase the demand for more expensive houses. Tables 3 and 4 in the paper indeed find higher capital gains for more expensive houses during the 1970s boom, while cheaper houses appreciated less percentage-wise.

Piazzesi and Schneider (2009a) study an equilibrium model with three assets—houses, stocks, and nominal bonds. Households solve life cycle consumption–portfolio choice problems with an exogenous nontradable income process (33). The paper computes temporary equilibria as described in Section 3.4 in this model. The benchmark household beliefs about future returns and income dynamics are estimated with historical data. Moreover, these dynamics feature a large idiosyncratic component in house price volatility. When the model is evaluated during the 1970s, the temporary equilibrium concept is useful for exploring the implications of higher expected inflation as well as higher inflation volatility.

When evaluated with 1990s data on income and asset endowments, the temporary equilibrium of this model is successful at matching observed asset prices as well as life cycle patterns in wealth and portfolio weights on houses, stocks and nominal bonds. In particular, the model predicts that young households borrow to buy a house and do not participate in the stock market. As they get older, households pay down their mortgage and start saving in nominal bonds and stocks.

The model is evaluated with endowment data from the Survey of Consumer Finances in the 1960s, 1970s, and 1990s. The model predicts a 25% dip in aggregate wealth during the 1970s—which is exactly the pattern we observe in the data. There are three separate mechanisms that contribute to the drop in household wealth during the Great Inflation in the model. First, the 1970s experienced a demographic shift toward more young households—the Baby Boomers—who have lower savings rates. Second, capital losses from realized inflation lowered wealth and hence savings, especially for older households. Third, lower savings were not counteracted by a large increase in interest rates, because the outside supply of bonds to the household sector also fell.

While aggregate household wealth dropped, the portfolio composition looks similar across all three periods at benchmark beliefs which do not take into account higher expected inflation rates during the 1970s. When all households believe in the high expected inflation rate from the 1970 consensus forecasts in the Michigan survey, they increase their portfolio away from stocks toward housing. This shift happens because high expected inflation generates tax effects that favor housing investments: the returns on housing are essentially untaxed, while mortgage interest rate payments are tax deductable. Disagreement about inflation expectations shifts the portfolio further toward housing. The reason is that young households expect high inflation and perceive a low real interest rate. They therefore borrow more and buy housing. The two inflation mechanisms—higher mean inflation and disagreement across cohorts—explain roughly half of the portfolio shift toward housing observed in the data.[ai] The remaining shift can be attributed to lower stock return expectations in times with high expected inflation, which lead to a large decline in price–dividend ratios for stocks while the

[ai] Relatedly, Piazzesi and Schneider (2008) study a model in which some households suffer from inflation illusion. These households confuse changes in the nominal interest rates with changes in real interest rates, while smart households understand the Fisher equation. The model predicts a nonmonotonic relationship between the price–rent ratio and nominal interest rates: house prices are high when nominal rates are either particularly high (as in the 1970s) or low (as in the 2000s).

housing market was booming. The resulting negative comovement of house and stock prices is an important step toward our understanding of the 1970s.

4.5.3 The 2000s Boom

We divide studies of the 2000s boom into three groups by the type of exercise they undertake. One set of papers evaluates versions of the user cost equation (27): it asks whether reasonable scenarios for interest rates and housing payoff expectations—as well as other parameters of the user cost equation such as taxes—are consistent with high house prices. Second, studies that employ small open economy models take securities prices—in particular interest rates—from the data and endogenously determine only house prices and allocations. Finally, papers that work with closed economy models jointly determine house prices and the prices of other assets.

As usual these three approaches are complementary. Indeed, user cost studies (as well as more generally studies of Euler equations) or small open economy models do not explain why interest rates move. At the same time, they evaluate a given model mechanism without taking a stand on the explicit shock structure as well as the details of who participates in securities markets. They thus generate conclusions that are robust to those details. While a closed economy exercise is in principle more ambitious as it makes those details explicit and takes a stand on the nature of the shocks, it is also more prone to misspecification.

User Cost Calculations

Himmelberg et al. (2005) study user costs leading up to the recent housing boom. Their approach assumes that future payoffs can be discounted at the current long-term interest rate. They conclude that the large decline in long rates during the early 2000s can explain the house price boom during that time. Glaeser et al. (2013) show that discounting all future payoffs at the low 2000s long rate is crucial for this quantitative result. In an environment in which low current rates are allowed to mean revert in the future, the magnitude of the boom is significantly reduced. They conclude that optimistic expectations played an important role in the housing boom.

House Prices in Small Open Economies

Kiyotaki et al. (2011) study a small open economy in which households solve life cycle problems, choose between renting and owning, and face collateral constraints as in Section 3.7. In the model, housing is a capital stock that is produced with land and capital. The paper compares steady states with looser collateral constraints: downpayment constraints that range from 10% to 100%. The findings in their table 3 show that varying the downpayment constraint has large quantitative effects on the homeownership rate: while only 46% of households own a home when it is not possible to borrow against housing, 90% of households own a house when the downpayment constraint is 10%.

Despite their large effects on extensive margins, Kiyotaki et al. show that lower downpayment constraints have negligible effects on house prices. The price–rent ratio is essentially constant across all steady states in table 3. This outcome is intuitive, because all homeowners in the model are marginal investors and determine the per unit price of housing. With looser collateral constraints, there is an inflow of new home buyers. However, these new buyers do not affect the per unit price of housing because the Euler equations also hold for rich households. Their table 4 studies how these results quantitatively depend on the scarcity of land for the production of housing. Kermani (2012) studies these mechanisms in a continuous-time model with a representative agent.

Sommer et al. (2013) solve a similar model but without production. Instead, the overall housing supply is fixed and there is free conversion of housing units. The paper also finds small quantitative effects of looser collateral constraints and lower interest rates, and considers higher income expectations. Chu (2014) assumes that the supply of rental housing and the supply of owner-occupied housing are fixed separately and cannot be converted into each other. As a result, looser collateral constraints have larger effects on house prices. In particular, the value of owner-occupied housing appreciates more than rental housing. The bond market in the model clears; income shocks are assumed to be more volatile in 2005 which keeps the equilibrium interest rate constant over time (instead of matching the lower interest rates observed in the data.)

Landvoigt et al. (2015) study an assignment model with indivisible and illiquid houses in a metro area. The housing demand of movers is derived from a life cycle consumption and portfolio choice problem with transaction costs and collateral constraints. As in Section 3.4, house prices are determined in a temporary equilibrium to induce households with lower demand for housing services to move into lower quality houses. The distribution of equilibrium prices thus depends on the distribution of mover characteristics as well as the distribution of house qualities. While the market for all house qualities clears, the metro area is a small open economy.

Landvoigt (2015) measure continuous distributions for movers and house qualities with micro data from San Diego County for 2 years: 2000 and 2005, the peak of the boom. The distribution of mover characteristics—age, income, and wealth—is measured with data from the American Community Survey. The 2005 distribution shows that movers were richer than in 2000. Moreover, the 2005 house-quality distribution has fatter tails than in 2000—relatively more houses traded at the low and the high end of the quality spectrum than in intermediate ranges.

To measure the distribution of house qualities, Landvoigt (2015) assume that house quality is a one-dimensional index. Therefore, house quality can be measured by price in the base year 2000. The paper documents that 2005 house prices are strictly increasing in 2000 prices. This monotonicity implies that for every 2005 quality level, there is a unique initial 2000 quality level so that the average house of that initial quality resembled the given house in 2005. The 2000 distribution of house qualities is simply the distribution of transaction prices in that year. The 2005 distribution of house qualities can be constructed from the 2005 distribution of transaction prices using the monotonicity of the map from 2000 qualities to 2005 prices.[aj]

The paper compares the predictions for equilibrium prices in both years and derives the cross section of capital gains by quality. These predictions are compared to capital gains by quality in the data. Two key mechanisms allow the model to quantitatively match the observed cross section of capital gains by quality from 2000 to 2005. The first mechanism is cheaper credit: looser collateral constraints and lower mortgage rates in 2005 allowed poorer households to borrow more and increase their demand for housing, especially at the low end of the quality spectrum. Richer households were not affected much by lower downpayment constraints. But these richer households are not marginal investors for low quality houses (as discussed in Section 3.3.1). Therefore, the higher housing demand by poor households translates into higher prices of low quality houses.

The second mechanism is that more low quality houses transacted in 2005. When the distribution of movers is assigned to the distribution of houses in 2005, the marginal buyer of a low quality house is richer compared to 2000 and pushes up low-end prices. Both mechanisms generate capital gains that monotonically decline in house quality.

Whether or not the model quantitatively matches capital gains by quality depends on expectations. An advantage of temporary equilibria is that we can find out how much expectations matter. Under the assumption that households in 2005 were expecting house prices to continue to grow at the same rate as labor income and easy credit conditions to remain, the model implies the same capital gains from 2000 to 2005 as in the data. Under the assumption that households in 2005 foresee that future house prices and credit conditions will return to their 2000 values, capital gains as a function of house quality are shifted down until expensive houses do not appreciate in value. Our conclusion is that easy credit and fatter tails in the house quality distribution predict a monotonically declining pattern in capital gains. To quantitatively explain capital gains, expectations are important. In particular, expectations in 2005 cannot be pessimistic about the future.

Closed Economy and the Determination of Interest Rates

The closed economy models considered in the literature all assume costless conversion and thus linear pricing, which by design reduces the quantitative importance of looser collateral constraints on house prices. The per-unit price of housing enters the Euler equations of all investors, which includes rich investors for whom collateral constraints do not matter. Therefore, any change in collateral constraints will have small effects on

[aj] Epple et al. (2015) also assume house quality is a one-dimensional index. They estimate house prices as well as rental values as nonlinear functions of quality with data for various metro areas using a new structural estimation approach.

per-unit house prices. A key contribution of these models is to make the point that looser collateral constraints tend to push up equilibrium interest rates, so that a major force is needed to keep rates low during the boom.

Garriga et al. (2012) study a closed economy with production in two sectors without aggregate shocks and a representative household. The production of housing involves land and irreversible investment in structures. Foreign lenders determine mortgage rates. The collateral constraint is selected to match aggregate mortgage debt to housing wealth. Under the assumption of perfect foresight about looser collateral constraints and low mortgage rates in the future, the model is able to explain roughly half of the observed increase in national house price indices. Since housing and nonhousing consumption are strong complements, higher house prices do not lead to a large consumption increase (which would be counterfactual). The paper attributes the other half of the increase to expectations.

Favilukis et al. (2016) study a closed economy with households who solve life cycle problems with uninsurable labor income shocks as well as aggregate shocks. There is no rental market, so households have to buy in order to consume housing services. The paper solves the model under the assumption that foreigners bought more bonds during the 2000s and thereby increase the mortgage supply. The paper carefully measures the size of these bond purchases and quantifies their effect on equilibrium mortgage rates. Looser collateral constraints lower risk premia and thereby increase house prices by roughly half of the observed increase in national house prices.

The asset "house" in Favilukis et al. is a claim to the national housing stock. As discussed in Section 2.2, households in the data hold individual houses instead of such diversified claims. In fact, a diversified claim has much more attractive return properties than individual houses because national house price indices are not volatile. In panel B of table 5 of Favilukis et al., the equilibrium Sharpe ratio of the national housing stock is an impressive 0.82 compared a less attractive 0.37 Sharpe ratio for stocks. To better capture the Sharpe ratios of individual houses that households face in the data, the paper considers small idiosyncratic shocks to housing depreciation. These idiosyncratic shocks increase precautionary savings and thereby depress the equilibrium risk-free rate, but they do not match the high idiosyncratic component in the variance decomposition of individual housing returns.

Justiniano et al. (2015a) consider a closed economy in which patient households lend to impatient households until their lending reaches an exogenous supply limit. There are collateral constraints, so impatient households borrow to buy houses. The paper shows that looser collateral constraints increase the demand for houses and mortgages by the impatient households. As a consequence, both house prices and mortgage rates increase in equilibrium—contrary to what we saw in the data, where mortgage rates fell. The paper then argues that an exogenous increase in the credit supply limit increases borrowing while keeping mortgage rates low in equilibrium. It is important for this argument to assume that patient household have a fixed housing demand or buy houses in a different segment from impatient households, otherwise their Euler equation would determine house prices and thereby keep house prices low. Justiniano et al. (2015b) add poorer (subprime) borrowers to the model. They show that subprime borrowers increase their mortgage borrowing more than richer borrowers in response to an increase in the credit supply.

Landvoigt (2015) endogenizes the supply of mortgages in a closed-economy model with banks and aggregate risk. Households differ in their patience as well as their risk aversion. Banks issue deposits and equity to make mortgages. Looser collateral constraints increase the demand for housing and mortgage borrowing, but increase mortgage rates—contrary to what we observed in the data. Landvoigt introduces securitization, which allows banks to sell mortgages directly to risk-tolerant savers. The boom is initiated when banks underestimate the riskiness of new borrowers during the early 2000s and collateral constraints are relaxed. As banks securitize their mortgages and sell them as MBS to savers, risk premia decline, the supply of lending increases, and the model generates a boom–bust in house prices.

Expectations

The broad conclusion from existing studies of the 2000 boom is that expectations played a quantitatively important role. This conclusion is consistent with survey expectations about future house prices. For example, table 9 in Case and Shiller (2003) reports that homebuyers in 2003 were expecting house prices to appreciate between 9% and 15% each year over the next decade. Piazzesi and Schneider (2009b) document that at the peak of the recent boom, the fraction of households who believed that house prices would continue to increase doubled.

Recent research has started to capture such house price expectations. Piazzesi and Schneider (2009b) show that since only a small fraction of houses trade every year, a few exuberant households are enough to push up equilibrium house prices in these transactions. Barlevy and Fisher (2011) assume that a stream of new households enters every period with a certain probability and the stream may stop. Burnside et al. (2011) assume infectious-disease dynamics for expectations. Adam et al. (2012) study learning dynamics that temporarily decouple house prices from fundamentals.

Landvoigt (2016) uses micro data to estimate beliefs that rationalize the consumption–portfolio decisions of households in the SCF. The estimation finds that an important feature of beliefs is higher uncertainty about future house prices which increases the option value of default and thereby leverage during the housing boom.

Abstract

Dynamic economic models make predictions about impulse responses that characterize how macroeconomic processes respond to alternative shocks over different horizons. From the perspective of asset pricing, impulse responses quantify the exposure of macroeconomic processes and other cash flows to macroeconomic shocks. Financial markets provide compensations to investors who are exposed to these shocks. Adopting an asset pricing vantage point, we describe and apply methods for computing exposures to macroeconomic shocks and the implied compensations represented as elasticities over alternative payoff horizons. The outcome is a term structure of macroeconomic uncertainty.

1. INTRODUCTION

Impulse response functions quantify the impact of alternative economic shocks on future economic outcomes. In so doing, they provide a way to assess the importance of alternative sources of fluctuations. Building on the insights of Yule (1927) and Slutsky (1927), Frisch featured an important line of research on the "impulse and propagation problem" aimed at answering the question asking what are the sources of fluctuations and how they are propagated over time. An impulse, captured formally by the realization of a random shock, has an impact on an economic time series in all of the subsequent time periods. Response functions depict the intertemporal responses. Sims (1980) showed how to apply this approach in a tractable way to multivariate time series with a vector of underlying shocks, and he exposed the underlying challenges for identification. Subsequent research developed nonlinear counterparts to impulse response functions.

Macroeconomic shocks also play an important role in asset pricing. By their very nature, macroeconomic shocks cannot be diversified and investors exposed to those shocks require compensations. The resulting market-based remunerations differ depending on how cash flows are exposed to the alternative macroeconomic shocks. We call the compensations risk prices, and there is a term structure that characterizes these prices as a function of the investment horizon. In this chapter, we study methods for depicting this term structure and illustrate its use by comparing pricing implications across models. This leads us to formalize the exposure and pricing counterpart to impulse response functions familiar to macroeconomists. We call these objects shock-exposure and shock-price elasticities. Our calculations require either an empirical-based or model-based stochastic discount factor process along with a representation of how alternative cash flows with macroeconomic components respond to shocks.

There is an alternative way to motivate the calculations that we perform. A common characterization of risk aversion looks at local certainty equivalent calculations for small variance changes in consumption. We deviate in two ways. First, when making small changes, we do not use certainty as our benchmark but rather the equilibrium consumption from the stochastic general equilibrium model. This leads us to make more refined adjustments in the exposure to uncertainty. Second, movements in consumption at future dates could be induced by any of the macroeconomic shocks with occurrences at dates between tomorrow and this future date. Thus, similar to Hansen et al. (1999) and Alvarez and Jermann (2004), we have a differential measure depending on the specific shock and the dates of the impacts.

Empirical finance often focuses on the measurement of risk premia on alternative financial assets. In our framework, these risk premia reflect the exposure to uncertainty and the compensation for that exposure. Risk premia change when exposures change, when the prices of those exposures change, or both. We use explicit economic models to help us quantify these two channels by which risk premia are determined, but a more empirically based approach could also be applied provided that the uncertainty prices for shocks could be inferred. While there are interesting challenges in identification to explore, we will abstract from those challenges in this chapter.

Our chapter:

- defines and constructs a term structure of shock-exposure and shock-price elasticities applicable to nonlinear Markov models;

- compares these constructions to impulse response functions commonly used in macroeconomics;
- describes computational approaches pertinent for discrete-time and continuous-time models;
- applies the methods to continuous-time macroeconomic models with financing frictions proposed by He and Krishnamurthy (2013) and Brunnermeier and Sannikov (2014).

2. MATHEMATICAL FRAMEWORK

We introduce a framework designed to encompass a large class of macroeconomic and asset pricing general equilibrium models. There is an underlying stationary Markov model that is used to capture the stochastic growth of a vector of time series of economic variables. The Markov model emerges as the "reduced form" of a solution to a dynamic stochastic equilibrium model of the macroeconomy. Modeling stationary growth rates allows for inclusion of shocks that have permanent effects and nontrivial long-horizon implications for risk compensations. We provide a range of illustrative applications of this framework throughout the chapter, and we devote Section 7 to a more extensive exploration of nonlinear continuous-time models with financial constraints.

We start with a probability space $(\Omega, \mathcal{F}, P)$. On this probability space, there is an n-dimensional, stationary and ergodic Markov process $X = \{X_t : t \in \mathbb{N}\}$ and a k-dimensional process W of independent and identically distributed shocks. Unless otherwise specified, we assume that each W_t is a multivariate standard normal random variable. We will have more to say about discrete states and shocks that are not normally distributed in Section 3.5.

The Markov process is initialized at X_0. Denote $\mathfrak{F} = \{\mathcal{F}_t : t \in \mathbb{N}\}$ the completed filtration generated by the histories of W and X_0. We suppose that X is a solution to a law of motion

$$\begin{aligned} X_{t+1} &= \psi(X_t, W_{t+1}) \\ Y_{t+1} - Y_t &= \phi(X_t, W_{t+1}). \end{aligned} \tag{1}$$

The state vector X_t contains both exogenously specified states and endogenous ones. We presume full information in the sense that the shock W_{t+1} can be depicted in terms of $(X_t, Y_{t+1} - Y_t)$. In more general circumstances we would incorporate a solution to a filtering problem if we are to match an information structure to (X, Y), a filtering problem that is perhaps solved by economic agents.

Consistent intertemporal pricing together with the Markov property leads us to use a class of stochastic processes called multiplicative functionals. These processes are built from the underlying Markov process and will be used to model cash flows and stochastic discount factors. Since many macroeconomic time series grow or decay over time, we use the state vector X to model the growth rate of such processes. In particular, let the dynamics of a *multiplicative functional* M be defined as[a]

$$\log M_{t+1} - \log M_t = \kappa(X_t, W_{t+1}). \tag{2}$$

The components of Y are examples of multiplicative functionals. Since X is stationary, the process $\log M$ has stationary increments. A revealing example is the conditionally linear model

$$\kappa(X_t, X_{t+1}) = \beta(X_t) + \alpha(X_t) \cdot W_{t+1}$$

where $\beta(x)$ allows for nonlinearity in the conditional mean and $\alpha(x)$ introduces stochastic volatility.

We denote G a generic cash-flow process and S the equilibrium determined stochastic discount factor process, both modeled as multiplicative functionals. While we adopt a common mathematical formulation for both, G is expected to grow and S is expected to decay over time, albeit in stochastic manners.

Equilibrium models in macroeconomics and asset pricing build on the premise of utility-maximizing investors trading in arbitrage-free markets. Arbitrage-free pricing implies the existence of a strictly positive stochastic discount factor process S that can be used to infer equilibrium asset prices. Stochastic discount factors provide a convenient way to depict the observable implications of asset pricing models.[b] In this chapter, we consider a stochastic discount factor process that compounds the one-period stochastic discount factor increments in order to value multiperiod claims.

Definition 1 A stochastic discount factor S is a positive (with probability one) stochastic process such that for any $t, j \geq 0$ and payoff G_{t+j} maturing at time $t + j$, the time-t price is given by

$$\mathcal{Q}_t\left[G_{t+j}\right] = E\left[\left(\frac{S_{t+j}}{S_t}\right) G_{t+j} \mid \mathcal{F}_t\right]. \tag{3}$$

Notice that this definition does not restrict the date zero stochastic discount factor, S_0. This initialization may be chosen in a convenient manner. If markets are complete, then this stochastic discount factor is unique up to the initialization. Equations of the type (3) arise from investors' optimality conditions in the form of Euler equations. In an equilibrium model with complete markets, the stochastic discount factor is typically equated with the marginal rate of substitution of an unconstrained investor. The identity of such a person can change over time and across states. In some models with incomplete markets, the stochastic discount factor process ceases to be unique. There are different

[a] Multiplicative functionals are often initialized at one, or equivalently $\log M_0 = 0$. We will abuse this jargon a bit by allowing ourselves other possible initiations.

[b] See Hansen and Richard (1987) for an initial discussion of stochastic discount factors.

shadow prices for nontraded risk exposures but a common pricing of the exposures with explicit compensations in financial markets. With other forms of trading frictions, the pricing equalities can be replaced by pricing inequalities, still expressed using a stochastic discount factor.

In our framework, we will suppose that equilibrium stochastic discount factors inherit the multiplicative functional structure. Market frictions, portfolio constraints, and other types of market imperfections will then introduce distortions into formula (3). We will study such distortions in models with financial constraints in Section 7.

Notice that definition (3) of the stochastic discount factor involves an expectations operator. This expectations operator in general represents investors' beliefs about the future. Here, we have imposed rational expectations by assuming that investors' beliefs are identical to the data-generating probability measure P. This measure is that implied by historical evidence or by the fully specified model. Investors' beliefs, however, may differ from P and there exists alternative approaches to modeling these deviations in interesting ways. While the modeling of investors' beliefs is an important building block of the asset pricing framework, in this chapter we abstract from these considerations and impose rational expectations throughout the text.

3. ASSET PRICING OVER ALTERNATIVE INVESTMENT HORIZONS

We price cash flows exposed to macroeconomic uncertainty and modeled as multiplicative processes. Consider a generic cash flow process G, say the dividend process or an equilibrium consumption process. We start with a baseline payoff G_t maturing in individual periods $t = 0, 1, 2, \ldots$ and parameterize stochastic perturbations of this process. In particular, we derive measures that capture the sensitivity of expected payoff to exposure to alternative macroeconomic shocks, and the sensitivity of the associated risk compensations. We follow the convention in empirical finance by depicting compensations in terms of expected returns per unit of some measure of riskiness. The compensations differ depending upon which shock we target when we construct stochastic perturbations. The method relies on a comparison of the pricing of payoff G_t relative to another payoff that is marginally more exposed to risk in a particular way.

The cash flows G arising from equilibrium models will often have the form of multiplicative processes (2). A special case of such cash flows are payoffs that are positive functions of the Markov state, $\psi(X_t)$. These payoffs will be featured prominently in our subsequent analysis.

3.1 One-Period Pricing

We are interested in the pricing of payoffs maturing at different horizons, but we start with a simple one-period conditionally lognormal environment. This environment will provide an explicit link to familiar calculations in asset valuation. Suppose that

$$\log G_1 = \beta_g(X_0) + \alpha_g(X_0) \cdot W_1$$
$$\log S_1 - \log S_0 = \beta_s(X_0) + \alpha_s(X_0) \cdot W_1$$

where G_1 is the payoff to which we assign values and S_1 is the one-period stochastic discount factor used to compute these values. The one-period return on this investment is the payoff in period one divided by the period-zero price:

$$R_1 \doteq \frac{G_1}{Q_0[G_1]} = \frac{\left(\frac{G_1}{G_0}\right)}{E\left[\left(\frac{S_1}{S_0}\right)\left(\frac{G_1}{G_0}\right) \mid X_0\right]}.$$

The logarithm of the expected return can then be calculated explicitly as:

$$\begin{aligned} \log E[R_1 \mid X_0 = x] &= \log E\left[\left(\frac{G_1}{G_0}\right) \mid X_0 = x\right] - \log E\left[\left(\frac{S_1}{S_0}\right)\left(\frac{G_1}{G_0}\right) \mid X_0 = x\right] \\ &= \underbrace{-\beta_s(x) - \frac{|\alpha_s(x)|^2}{2}}_{\text{risk-free rate}} \underbrace{-\alpha_s(x) \cdot \alpha_g(x)}_{\text{risk premium}}. \end{aligned} \tag{4}$$

This compensation is expressed in terms of expected returns as is typical in asset pricing. Notice that we are using logarithms of proportional risk premia as a starting point.

Imagine applying this calculation to a family of such payoffs parameterized in part by α_g. The vector α_g defines a vector of exposures to the components of the normally distributed shock W_1. Then $-\alpha_s$ is the vector of shock "prices" representing the compensation for exposure to these shocks.

The risk prices in this conditionally lognormal model have a familiar conditional linear structure known from one-period factor models. In these models, the so-called factor loadings α_g on the individual shocks W_1 are multiplied by factor prices $-\alpha_s$. The total compensation in terms of an expected return is thus the product of the quantity of risk (risk exposure) and the price per unit of this risk. There are analogous simplifications for continuous-time diffusion models since the local evolution in such models is conditionally normal.

In a nonlinear multiperiod environment, this calculation ceases to be straightforward. We would, however, still like to infer measures of the quantity of risk and the associated price of the risk. We therefore explore a related derivation that will yield the same results in this one-period lognormal environment but will also naturally extend to a nonlinear setup and multiple-period horizons.

3.1.1 One-Period Shock Elasticities

We parameterize a family of random variables $H_1(\mathsf{r})$ indexed by r using

$$\log H_1(\mathsf{r}) = \mathsf{r}\nu(X_0) \cdot W_1 - \frac{\mathsf{r}^2}{2}|\nu(X_0)|^2 \tag{5}$$

where r is an auxiliary scalar parameter. The vector of exposures $\alpha_h(X_0)$ is normalized to

$$E\left[|\nu(X_0)|^2\right] = 1.$$

With this normalization,

$$E[H_1(\mathsf{r})|X_0] = 1.$$

Even when shocks are not normally distributed, we shall find it convenient to construct $H_1(\mathsf{r})$ to have a unit conditional expectation.

Given the baseline payoff G_t, form a parameterized family of payoffs $G_1H_1(\mathsf{r})$ given by

$$\log G_1 - \log G_0 + \log H_1(\mathsf{r}) = \underbrace{[\alpha_g(X_0) + \mathsf{r}\nu(X_0)]}_{\text{new shock exposure}} \cdot W_1 + \beta_g(X_0) - \frac{\mathsf{r}^2}{2}|\nu(X_0)|^2.$$

The new cash flow $G_1H_1(\mathsf{r})$ has shock exposure $\alpha_g(X_0) + \mathsf{r}\nu(X_0)$ and is thus more exposed to the vector of shocks W_1 in the direction $\nu(X_0)$. By changing r, we alter the magnitude of the exposure in direction $\nu(X_0)$. By choosing different vectors $\nu(X_0)$, we alter the combinations of shocks whose impact we want to investigate. A typical example of an $\nu(X_0)$ would be a coordinate vector e_j with a single one in jth place. In that case, we infer the pricing implications of the jth component of the shock vector W_1. In some applications it may be convenient to make $\nu(X_0)$ explicitly depend on X_0. For instance, Borovička et al. (2011) propose scaling of ν with X_0 in models with stochastic volatility.

The payoffs $G_1H_1(\mathsf{r})$ imply a corresponding family of logarithms of expected returns as in Eq. (4):

$$\log E[R_1(\mathsf{r}) \mid X_0 = x] = \log E\left[\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right] \\ - \log E\left[\left(\frac{S_1}{S_0}\right)\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right].$$

We are interested in comparing the expected return of the payoff $G_1H_1(\mathsf{r})$ relative to $G_1 = G_1H_1(0)$. Since our exposure direction $\nu(X_0)$ has a unit standard deviation, by differentiating with respect to r we compute an elasticity

$$\frac{d}{d\mathsf{r}} \log E[R_1(\mathsf{r}) \mid X_0 = x]|_{\mathsf{r}=0} \\ = \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0} - \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{S_1}{S_0}\right)\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0}.$$

This elasticity measures the sensitivity of the expected return on the payoff G_1 to an increase in exposure to the shock in the direction $\nu(x)$. The calculation leads us to define the counterparts of quantity and price elasticities from microeconomics:

1. The one-period *shock-exposure elasticity*

$$\varepsilon_g(x,1) = \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0} = \alpha_g(x) \cdot \nu(x)$$

measures the sensitivity of the expected payoff G_1 to an increase in exposure in the direction $\nu(x)$.

2. The one-period *shock-price elasticity*

$$\begin{aligned}\varepsilon_p(x,1) \;&= \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0} - \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{S_1}{S_0}\right)\left(\frac{G_1}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0} \\ &= -\alpha_s(x) \cdot \nu(x)\end{aligned}$$

measures the sensitivity of the compensation, in units of expected return, for this exposure.

Notice that the shock-exposure elasticity recovers the exposure vector $\alpha_g(x)$, and individual components of this vector can be obtained by varying the choice of the direction of the perturbation $\nu(x)$. Similarly, the shock-price elasticity recovers the vector of prices $-\alpha_s(x)$ associated with the risks embedded in the shock W_1.

In this one-period case, we replicated a straightforward decomposition of the expected return (4) into quantities and prices of risk. Now we move to the characterization of the asset pricing implications over longer horizons.

3.2 Multiperiod Investment Horizon

Consider the parameterized payoff $G_t H_1(\mathsf{r})$ with a date-zero price $E[S_t G_t H_1(\mathsf{r}) \mid X_0 = x]$. This is a payoff maturing at time t that has the same growth rate as payoff G_t except period one when the growth rate is stochastically perturbed by $H_1(\mathsf{r})$. The logarithm of the expected return (yield to maturity) is

$$\begin{aligned}\log E[R_{0,t}(\mathsf{r}) \mid X_0 = x] \doteq \log E\left[\left(\frac{G_t}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right] \\ - \log E\left[\left(\frac{S_t}{S_0}\right)\left(\frac{G_t}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right].\end{aligned}$$

Following our previous analysis, we construct two elasticities:

1. *shock-exposure elasticity*

$$\varepsilon_g(x,t) = \frac{d}{d\mathsf{r}} \log E\left[\left(\frac{G_t}{G_0}\right) H_1(\mathsf{r}) \mid X_0 = x\right]\Bigg|_{\mathsf{r}=0}$$

2. *shock-price elasticity*

$$\varepsilon_p(x,t)=\frac{d}{d\mathsf{r}}\log E\left[\left(\frac{G_t}{G_0}\right)H_1(\mathsf{r})\mid X_0=x\right]\Bigg|_{\mathsf{r}=0}-\frac{d}{d\mathsf{r}}\log E\left[\left(\frac{S_t}{S_0}\right)\left(\frac{G_t}{G_0}\right)H_1(\mathsf{r})\mid X_0=x\right]\Bigg|_{\mathsf{r}=0} \tag{6}$$

These elasticities are functions of the investment horizon t, and thus we obtain a term structure of elasticities. The dependence on the current state $X_0 = x$ incorporates possible time variation in the sensitivity of expected returns to exposure to shocks.

3.3 A Change of Measure and an Impulse Response for a Multiplicative Functional

Notice that the shock elasticities defined in the previous section have a common mathematical structure expressed using the multiplicative functionals $M = S$ and $M = SG$. Given a multiplicative functional M, we define

$$\varepsilon(x,t)=\frac{d}{d\mathsf{r}}\log E\left[\left(\frac{M_t}{M_0}\right)H_1(\mathsf{r})\mid X_0=x\right]\Bigg|_{\mathsf{r}=0}. \tag{7}$$

Taking the derivative in (7), we obtain

$$\varepsilon(x,t)=\nu(x)\cdot\frac{E\left[\left(\frac{M_t}{M_0}\right)W_1\mid X_0=x\right]}{E\left[\left(\frac{M_t}{M_0}\right)\mid X_0=x\right]}. \tag{8}$$

Thus a major ingredient in the computation is the covariance between $\left(\frac{M_t}{M_0}\right)$ and W_1 conditioned on X_0.

The random variable $H_1(r)$ given by (5) is positive and has expectation equal to unity conditioned on X_0. Multiplication by this random variable has the interpretation of changing the probability distribution of W_1 from having mean zero to having a mean given by $\mathrm{r}\nu(X_0)$. Thus given a multiplicative process M

$$\begin{aligned}E\left[\left(\frac{M_t}{M_0}\right)H_1(\mathsf{r})\mid X_0=x\right]&=E\left(H_1(\mathsf{r})E\left[\left(\frac{M_t}{M_0}\right)\mid X_0,W_1\right]\mid X_0=x\right)\\&=\widetilde{E}\left(E\left[\left(\frac{M_t}{M_0}\right)\mid X_0,W_1\right]\mid X_0=x\right)\end{aligned}$$

where $\widetilde{E}$ presumes that the random vector W_1 is distributed as a multivariate normal with mean $\mathrm{r}\nu(x)$ consistent with our multiplication by $H_1(\mathsf{r})$.

3.4 Long-Horizon Pricing

Shock elasticities depict the term structure of risk as we change the maturity of priced payoffs. To aid our understanding of the overall shape of the term structure of elasticities, we characterize the long-horizon limits of these shock elasticities. We provide a characterization for a general multiplicative process that takes the form of a factorization. A multiplicative process is a product of a geometric constant growth or decay process, a positive martingale, and a ratio of a function of the Markov state in date zero and date t. Since the factorization is applicable to any member of a general class of multiplicative processes, we apply it to both stochastic discount factor processes and positive cash flow processes.

As in Hansen and Scheinkman (2009) and Hansen (2012), we use Perron–Frobenius theory to provide a factorization of multiplicative processes. Given a multiplicative process M, solve the equation

$$E\left[\left(\frac{M_t}{M_0}\right)e(X_t) \mid X_0 = x\right] = \exp(\eta t)e(x) \tag{9}$$

for an unknown function $e(x)$ that is strictly positive and an unknown number η. The solution is independent of the choice of the horizon t.

Consider the pair (e, η) that solves (9) and form

$$\frac{\widetilde{M}_t}{\widetilde{M}_0} \doteq \exp(-\eta t)\frac{e(X_t)}{e(X_0)}\left(\frac{M_t}{M_0}\right). \tag{10}$$

The stochastic process $\widetilde{M}$ is a martingale under P, since

$$\begin{aligned} E\left[\widetilde{M}_{t+1} \mid \mathcal{F}_t\right] &= \frac{\exp[-\eta(t+1)]}{e(X_0)}\frac{M_t}{M_0}\widetilde{M}_0\, E\left[\frac{M_{t+1}}{M_t}e(X_{t+1}) \mid \mathcal{F}_t\right] \\ &= \exp(-\eta t)\frac{e(X_t)}{e(X_0)}\frac{M_t}{M_0}\widetilde{M}_0 = \widetilde{M}_t. \end{aligned}$$

Consequently, expression (10) can be reorganized as

$$\frac{M_t}{M_0} = \exp(\eta t)\frac{e(X_0)}{e(X_t)}\frac{\widetilde{M}_t}{\widetilde{M}_0}. \tag{11}$$

This formula provides a multiplicative decomposition of the multiplicative functional M into a deterministic drift $\exp(\eta t)$, a stationary function of the Markov state $e(x)$, and a martingale $\widetilde{M}$. This martingale component will be critical in characterizing long-term pricing implications.

Associated with the martingale $\widetilde{M}$ is a probability measure $\widetilde{P}$ such that for every measurable function Z of the Markov process between dates zero and t,

$$E\left(\widetilde{M}_t Z \mid X_0 = x\right) = \widetilde{E}\,(Z \mid X_0 = x)$$

where $\widetilde{E}\,(\cdot \mid X_0 = x)$ is the conditional expectation operator under the probability measure $\widetilde{P}$.[c]

In finite state spaces, Eq. (9) can be posed as a matrix problem with a solution that is an eigenvector with positive entries.

Example 3.1 In a finite-state Markov chain environment, Eq. (9) is a standard eigenvalue problem. Let realized value of the X_t be represented as alternative coordinate vectors. Suppose the ratio $\frac{M_{t+1}}{M_t}$ satisfies

$$\frac{M_{t+1}}{M_t} = (X_{t+1})'\mathbf{M}X_t$$

for some square matrix $\mathbf{M}$. In the same way, represent the one-period transition probabilities as a matrix $\mathbf{P}$. For $t = 1$, Eq. (9) becomes a vector equation

$$(\mathbf{P}^*\mathbf{M})\mathbf{e} = \exp(\eta)\mathbf{e}$$

where the operator * depicts elementwise multiplication, $(\mathbf{P}^*\mathbf{M})_{ij} = \mathbf{P}_{ij}\mathbf{M}_{ij}$. When

$$\sum_{j=0}^{\infty} \lambda^j (\mathbf{P}^*\mathbf{M})^j$$

has all strictly positive entries for some $0 < \lambda < 1$, the Perron–Frobenius theorem implies the existence of a unique normalized strictly positive eigenvector $\mathbf{e}$ associated with the largest eigenvalue $\exp(\eta)$ of the matrix $\mathbf{P}^*\mathbf{M}$. Then $e(X_t)$ in formula (9) is $\mathbf{e} \cdot X_t$.

In continuous state spaces, this factorization may not yield a unique strictly positive solution $e(x)$. Hansen and Scheinkman (2009) and Borovička et al. (2015) provide selection criteria based on the stochastic stability of the probability measure implied by the martingale component to guarantee uniqueness. Stochastic stability ensures that we have a valuable way to compute limiting approximations once we change measures. Here, we will assume that we have selected such a solution.[d]

[c] In order to completely define the measure $\widetilde{P}$, we also need to specify the unconditional probability distribution. For instance, $\widetilde{M}_0$ can be initiated to make $\widetilde{P}$ stationary. Since all pricing results in this chapter utilize conditional probability distributions, we abstract from these considerations here.

[d] Our formulation presumes an underlying Markovian structure. See Qin and Linetsky (2014b) for a more general starting point and an analogous factorization.

Factorization (11) leads to a characterization of long-horizon limits for the shock elasticities. Using this factorization in expression (7), we obtain[e]

$$\varepsilon(x,t) = \nu(x) \cdot \frac{\widetilde{E}[\hat{e}(X_t) W_1 \mid X_0 = x]}{\widetilde{E}\,[\hat{e}(X_t) \mid X_0 = x]}$$

where $\hat{e}(x) \doteq 1/e(x)$. Under technical assumptions the long-maturity limit for the shock elasticity is given by

$$\lim_{t\to\infty} \varepsilon(x,t) = \nu(x) \cdot \widetilde{E}\,[W_1 \mid X_0 = x].$$

The sensitivity of long-horizon payoffs to current shocks is therefore determined by the martingale components of the stochastic discount factor and the cash flow, and their implications for the expectations of shock W_1 as captured by the implied change in probability measures.

3.5 Non-Gaussian Frameworks

While we have made special reference to normally distributed shocks, our mathematical structure does not require this. We have featured perturbations $H_1(\mathsf{r})$ that are positive and expectations one. Risk prices in financial economics are denominated in terms of expected mean compensation per unit of risk. With normally distributed shocks, we measure risk in units of standard deviations. Provided that we adopt an interpretable way to denominate risk prices for other distributions, our methods continue to apply beyond the conditionally Gaussian framework. For instance, Zviadadze (2016) constructs shock elasticities in a stochastic environment with autoregressive gamma processes.

Another example are regime-shift models that may include both normally distributed shocks along with uncertain regimes. Exposure to macroeconomic regime-shift risk is of interest and can be characterized using shock elasticities by structuring appropriately the random variable $H_1(\mathsf{r})$. These switches can be exogenous (eg, exogenously modeled periods of low or high growth and volatility) or endogenous (eg, interest rate at the zero lower bound, financial sector in a period of binding financial constraints, or regime changes in government policies). We develop shock elasticities for regime-shift risk in Borovička et al. (2011).

For Markov chain models used to capture the regime shift dynamics of exogenous shocks see David (2008), Chen (2010), or Bianchi (2015) for some recent examples in the asset pricing literature and Liu et al. (2011) and Bianchi et al. (2013) in

[e] See Hansen and Scheinkman (2012) for a version of this result for a continuous-time diffusion model.

macroeconomic modeling. Regime switches are also utilized to model time variation in government policies, see Sims and Zha (2006), Liu et al. (2009), and Bianchi (2012) for regime switching in monetary policy rules, Davig et al. (2010, 2011) and Bianchi and Melosi (2016) for fiscal policy applications, and Chung et al. (2007) and Bianchi and Ilut (2015) for a combination of both. Farmer et al. (2011) and Foerster et al. (2014) analyze solution and estimation techniques in Markov chain models in conjunction with perturbation approximation methods. In Borovička and Hansen (2014), we introduce a tractable exponential-quadratic framework that permits semi-analytical formulas for shock elasticities and encompasses a large class of models solved using perturbation techniques.

4. RELATION TO IMPULSE RESPONSE FUNCTIONS

Impulse responses to specific structural shocks are a common way of representing the dynamic properties of macroeconomic models. As we mentioned previously, this idea goes back at least to Frisch (1933). Our elasticity computations change exposures of cash flows to shocks and explore the consequences for valuation. These constructs are closely related and in some circumstances are mathematically identical to impulse response functions. We explore these connections in this section.

To relate our elasticity calculation to an impulse response function, consider the conditional expectation

$$E\left[\left(\frac{M_t}{M_0}\right) \mid X_0, W_1 = w\right]$$

for alternative choices of w. Changing the value of w gives rise to the impulse response of M_t to a shock at date one. Instead of conditioning on alternative realized values of the shock at date one, as we have seen our computations are equivalent to changing the date zero distribution of W_1. A similarity in perspectives emerges because this distributional change could include a mean shift in the distribution for W_1. In practice, empirical macroeconomists typically study expectations of the logarithms of macroeconomic time series, often using linear models. For asset pricing it is important that we work with expectations of levels of macroeconomic quantities and cash flows, and account for nonlinearities. To compute shock *elasticities* we are lead to study the impact on the logarithm of the conditional expectation of M_t as developed in formula (7). In the remainder of this section, we consider two special cases in which the link to impulse functions is particularly close.

4.1 Lognormality

When M is a lognormal process, the impulse response functions for $\log M$ match exactly our shock elasticity as we will now see.

A linear vector-autoregression (VAR) model is a special case of the framework (1). Specifically X is a linear vector-autoregression with autoregression coefficient matrix $\bar{\mu}$ and shock-exposure matrix $\bar{\sigma}$:

$$X_{t+1} = \bar{\mu} X_t + \bar{\sigma} W_{t+1}. \tag{12}$$

We assume that the absolute values of eigenvalues of the matrix $\bar{\mu}$ are strictly less than one. Analogously, we introduce a multiplicative process M (constructed in general form in (2)) with evolution:

$$\log M_{t+1} - \log M_t = \bar{\beta} \cdot X_t + \bar{\alpha} \cdot W_{t+1}. \tag{13}$$

The shock W_{t+1} is distributed as a multivariate standard normal. With this construction of the multiplicative process M, we first study the responses of $\log M$.

4.1.1 Impulse Response Functions

Let $\nu(x) = \bar{\nu}$ where $\bar{\nu}$ is a vector with norm one. In typical applications, $\bar{\nu}$ is a coordinate vector. The impulse response function of $\log M_t$ for the linear combination of shocks chosen by the vector $\bar{\nu}$ is given by

$$E[\log M_t - \log M_0 \mid X_0 = x, W_1 = \bar{\nu}] - E[\log M_t - \log M_0 \mid X_0 = x, W_1 = 0] = \bar{\nu} \cdot \bar{\varrho}_t.$$

where the coefficients satisfy the recursions implied by (12) and (13). From (13), we have the recursion:

$$\bar{\varrho}_{t+1} - \bar{\varrho}_t = \left(\bar{\zeta}_t\right)' \bar{\beta} \tag{14}$$

with initial condition $\bar{\varrho}_1 = \bar{\alpha}$, and from (12):

$$\bar{\zeta}_{t+1} = \bar{\mu} \bar{\zeta}_t \tag{15}$$

with initial condition $\bar{\zeta}_1 = \bar{\sigma}$. Solving these recursions gives:

$$\begin{aligned} \bar{\zeta}_t &= \bar{\mu}^{t-1} \bar{\sigma} \\ \bar{\varrho}_t &= \bar{\alpha} + \left[(I - \bar{\mu})^{-1} \left(I - \bar{\mu}^{t-1} \right] \bar{\sigma} \right)' \bar{\beta}. \end{aligned} \tag{16}$$

The impulse response function in the linear model is thus a sequence of deterministic coefficients $\bar{\nu} \cdot \bar{\varrho}_t$. The first term, $\bar{\alpha} \cdot \bar{\nu}$, represents the immediate response arising from realization $\bar{\nu}$ of the current shock, while the remaining terms capture the subsequent propagation of the shock through the dynamics of state vector X as it influences $\log M$ in the future.

4.1.2 Shock Elasticities

Consider now our elasticity calculation. Write $\log M_t$ as its moving-average representation:

$$\log M_t = \sum_{j=0}^{t-1} \overline{\varrho}_j \cdot W_{t-j} + E(\log M_t \mid \mathcal{F}_0),$$

or equivalently

$$\begin{aligned}\log M_t - \log M_0 &= \sum_{j=1}^{t} \overline{\varrho}_j \cdot W_{t-j+1} + E(\log M_t - \log M_0 \mid X_0) \\ &= \sum_{j=1}^{t-1} \overline{\varrho}_j \cdot W_{t-j+1} + \overline{\varrho}_t \cdot W_1 + E(\log M_t - \log M_0 \mid X_0).\end{aligned}$$

Since the shocks W_t are independently distributed as a multivariate standard normals over time,

$$E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x, W_1 = w\right] = \exp\left(\frac{1}{2}\sum_{j=1}^{t-1} \overline{\varrho}_j \cdot \overline{\varrho}_j\right) \exp\left(\overline{\varrho}_t \cdot W_1\right) \exp\left(E[\log M_t - \log M_0 \mid X_0]\right).$$

Using formula (8), we compute:

$$\varepsilon(x,t) = \frac{E\left[\left(\frac{M_t}{M_0}\right) W_1 \mid X_0 = x\right]}{E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]} = \frac{E[\exp(\overline{\varrho}_t \cdot W_1) W_1 \mid X_0 = x]}{E[\exp(\overline{\varrho}_t \cdot W_1)]} = \overline{\varrho}_t.$$

The second equality follows by observing that

$$\frac{\exp(\overline{\varrho}_t \cdot W_1)}{E[\exp(\overline{\varrho}_t \cdot W_1)]}$$

is strictly positive and has conditional expectation one. Multiplication by this random variable is equivalent to changing the distribution of W_1 from a multivariate standard normal to a multivariate normal with mean $\overline{\varrho}_t$. To summarize, in this lognormal case, the shock elasticities do not depend on the Markov state and they coincide with the impulse responses measured by $\overline{\nu} \cdot \overline{\varrho}_t$ for $t = 1, 2, \ldots$.

Consider in particular the shock-price elasticity (6). Notice that this shock-price elasticity consists of the difference of shock elasticities for G and SG, and thus we are lead to compute impulse response functions for $\log G$ and $\log S + \log G$. The additivity of the construction implies that the impulse response function coefficients for the latter are $\overline{\nu} \cdot \overline{\varrho}_{s,t} + \overline{\nu} \cdot \overline{\varrho}_{g,t}$, and thus the resulting shock-price elasticity corresponds to the impulse response function of $-\log S$, with coefficients $-\overline{\nu} \cdot \overline{\varrho}_{s,t}$.

4.1.3 Long-Term Pricing Revisited

In this example, as discussed in Hansen et al. (2008) there is a close link between the factorization described in Section 3.4 and the additive decompositions of linear time series. Beveridge and Nelson (1981) and Blanchard and Quah (1989) extracted a martingale component in linear models and used it to characterize the impact of permanent shocks.[f]

Consider solving

$$E\left[\left(\frac{M_1}{M_0}\right)e(X_1)\mid X_0=x\right]=\exp(\eta)e(x)$$

for the pair (e, η), where the evolution of M is given by (13). In this special case, a straightforward calculation using formulas for lognormals gives:

$$\begin{aligned}\log e(x) &= E\left(\sum_{j=0}^{\infty}\overline{\beta}\cdot X_{t+j}|X_t=x\right)\\ &=(\overline{\beta})'(I-\overline{\mu})^{-1}x,\end{aligned}$$

and[g]

$$\eta=\frac{1}{2}|\overline{\alpha}'+\overline{\beta}'(I-\overline{\mu})^{-1}\overline{\sigma}|^2.$$

Under the change of measure associated with the martingale $\widetilde{M}$ in the multiplicative factorization, W_1 has a mean equal to

$$\overline{\sigma}'(I-\overline{\mu}')^{-1}\overline{\beta}+\overline{\alpha}$$

which is independent of the state vector. Notice that this is also the limiting value of $\overline{\varrho}_t$ as given in (16). In this lognormal example

$$\log M_{t+1}-\log M_t+\log e(X_{t+1})-\log e(X_t)=\left[\overline{\beta}'(I-\overline{\mu}')^{-1}\overline{\sigma}+\overline{\alpha}'\right]W_{t+1}$$

where the right-hand side gives the permanent shock to $\log M$ as constructed in Beveridge and Nelson (1981) and Blanchard and Quah (1989). In VAR analyses, transitory shocks are typically constructed as linear combinations of W_{t+1} that are uncorrelated with this permanent shock. On the other hand $\log e(X_{t+1})$ and its innovation are typically correlated with the permanent shock.

This simple connection between permanent shocks and permanent components to pricing ceases to hold in more general nonlinear environments. Hansen (2012) has a more

[f] Hansen (2012) constructs an additive decomposition of $\log M$ in a continuous-time version of our nonlinear framework.

[g] If we were to include a constant included in the evolution of $\log M$, this would be added to η.

complete discussion of the relation between the permanent component to $\log M$ and the martingale component to M outside this lognormal specification.

4.2 Continuous-Time Diffusions

In this section, we focus on a framework with uncertainty modeled using Brownian shocks, and apply it to models with financial constraints in Section 7. While the Brownian information setup is not without loss of generality, it provides tools for a pedagogically transparent treatment and shows the close connection between shock elasticities and impulse responses. In Borovička et al. (2011) we also consider jumps in the form of regime shifts in continuous-time Markov chains and applications to consumption-based asset pricing models.

Let X be a Markov diffusion on $\mathcal{X} \subseteq \mathbb{R}^n$:

$$dX_t = \mu(X_t)dt + \sigma(X_t)dW_t$$

with initial condition $X_0 = x$. Here, $\mu(x)$ is an n-dimensional vector and $\sigma(x)$ is an $n \times k$ matrix for each vector x in $\mathbb{R}^n$. In addition W is a k-dimensional Brownian motion. We use this underlying Markov process to construct a multiplicative process M via:

$$\log M_t = \log M_0 + \int_0^t \beta(X_u)du + \int_0^t \alpha(X_u) \cdot dW_u \tag{17}$$

where $\beta(x)$ is a scalar and $\alpha(x)$ is a k-dimensional vector, or, in differential notation,

$$d\log M_t = \beta(X_t)dt + \alpha(X_t) \cdot dW_t. \tag{18}$$

Thus M_t depends on the initial conditions $(X_0, M_0) = (x, m)$ and the innovations to the Brownian motion W between dates zero and t. Let $\{\mathcal{F}_t : t \geq 0\}$ be the (completed) filtration generated by the Brownian motion between time zero and time t along with any initial information captured by $\mathcal{F}_0$.

As before, stochastic discount factors and cash flows in this environment are specific versions of a multiplicative process M. This multiplicative process is exposed to two types of risk. The first source of risk exposure is the "local," or infinitesimal, risk in term $\alpha(X_u) \cdot dW_u$ in (17). The second source of risk comes from the time variation in X_t and the state dependence of coefficients $\beta(x)$ and $\alpha(x)$, and is manifested over longer horizons.

4.2.1 Haussmann–Clark–Ocone Formula

There is a natural counterpart to a moving-average representation for diffusions. Importantly, the moving-average coefficients are, in general, state dependent. They entail computing so-called Malliavin derivatives of the date-u shock to the process $\log M_t$ for $t \geq u$, denoted $\mathcal{D}_u \log M_t$. We do not develop Malliavin differentiation as a formal mathematical construct but instead proceed heuristically.[h] This calculation of a Malliavin derivative gives the random response to a shock at date-u and is only restricted to be t-measurable where $t \geq u$. By forming the date-u conditional expectation we get the expected response as of the date of the shock. The computation is localized by making the time interval over which the shock acts on the process $\log M_t$ arbitrarily small, which allows for the formal construction of a derivative.

The calculation of $\mathcal{D}_u \log M_t$ has two uses analogous to the lognormal example we examined earlier. First, the (random) impulse response function for $\log M$

$$\varrho_t(X_0) = \nu(X_0) \cdot E(\mathcal{D}_0 \log M_t \mid F_0) = \nu(X_0) \cdot E[\mathcal{D}_0(\log M_t - \log M_0) \mid X_0]$$

for $t \geq 0$ where $\nu(X_0)$ determines which conditional linear combination of the shocks is subject to an impulse. The resulting responses depend on conditioning information captured by X_0, in contrast to lognormal models in which responses depend only on the horizon $t \geq 0$. Relatedly we obtain the Haussmann–Clark–Ocone formula for the process $\log M$ that cumulates the impact shocks at various dates as a stochastic integral:

$$\log M_t = \int_0^t E(\mathcal{D}_u \log M_t \mid F_u) \cdot dW_u + E(\log M_t \mid \mathcal{F}_0),$$

where we may think of $E(\mathcal{D}_u \log M_t \mid F_u)$ as the counterpart to a coefficient vector in a moving-average representation. These random variables satisfy recursions analogous to (14) and (15). For a more detailed construction, see Borovička et al. (2014).

We use the rules of Malliavin differentiation (analogous to more familiar forms of differentiation):

$$\mathcal{D}_u M_t = M_t \mathcal{D}_u \log M_t,$$

implying that the impulse response function for the process M is

$$\begin{aligned}\nu(X_0) \cdot E(\mathcal{D}_0 M_t | \mathcal{F}_0) &= \nu(X_0) \cdot E(M_t \mathcal{D}_0 \log M_t | \mathcal{F}_0)\\ &= M_0 \nu(X_0) \cdot E\left[\left(\frac{M_t}{M_0}\right) \mathcal{D}_0(\log M_t - \log M_0) | X_0\right)\end{aligned}$$

for $t \geq 0$.

4.2.2 Shock Elasticities for Diffusions

The construction of shock elasticities in Section 3 perturbs the cash flow by exposing it to a specified shock in the next period. In the continuous-time model, we devise a perturbation of M over a short time interval $[0, \mathrm{r}]$ and then study the implications as $\mathrm{r} \searrow 0$. The resulting construction exploits the local linearity of continuous-time models with Brownian shocks.

[h] For a textbook treatment of Malliavin calculus see Di Nunno et al. (2009) or Nualart (2006).

Specifically, we construct the process H^{r} such that

$$\log H_t^{\mathrm{r}} = \int_0^{\mathrm{r}\wedge\mathrm{t}} \nu(X_u)\cdot dW_u - \frac{1}{2}\int_0^{\mathrm{r}\wedge\mathrm{t}} |\nu(X_u)|^2 du,$$

where $\mathrm{r}\wedge\mathrm{t} = \min\{\mathrm{r},\mathrm{t}\}$. Notice that this process is exposed to the Brownian shock on the time interval $[0,\mathrm{r}]$, with exposure vector $\nu(x)$, and stays constant after r. We assume that $\nu(x)$ is restricted so that the process H^{r} is a martingale. We use H^{r} to construct the perturbed process MH^{r}:

$$\log M_t + \log H_t^{\mathrm{r}} = \log M_0 + \int_0^t \beta(X_u)du - \frac{1}{2}\int_0^{\mathrm{r}\wedge\mathrm{t}} |\nu(X_u)|^2 du + \int_0^t \alpha(X_u)\cdot dW_u + \int_0^{\mathrm{r}\wedge\mathrm{t}} \nu(X_u)\cdot dW_u$$

Notice that on the interval $[0,\mathrm{r}]$, the exposure of the perturbed process to the Brownian shock is

$$[\alpha(X_u) + \nu(X_u)]\cdot dW_u.$$

As r ↘ 0, we are perturbing $\log M$ over an arbitrarily small interval.

As in Borovička et al. (2014), we define the shock elasticity for M at horizon t as

$$\varepsilon(x,t) = \lim_{\mathrm{r}\searrow 0} \frac{1}{\mathrm{r}} \log E\left[\left(\frac{M_t}{M_0}\right) H_t^{\mathrm{r}} \mid X_0 = x\right]$$

and show that this limit can be expressed as

$$\begin{aligned} \varepsilon(x,t) &= \nu(x)\cdot \frac{E\left(\mathcal{D}_0 \frac{M_t}{M_0} \mid X_0 = x\right)}{E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]} \\ &= \nu(x)\cdot \frac{E\left[\left(\frac{M_t}{M_0}\right)\mathcal{D}_0 \log M_t \mid X_0 = x\right)}{E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]}. \end{aligned} \tag{19}$$

The first equality in (19) is a limiting version of (8) divided by $E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]$ since the Haussmann–Clark–Ocone formula applied to $\frac{M_t}{M_0}$ has a contribution

$$E\left(\mathcal{D}_0 \frac{M_t}{M_0} \mid X_0 = x\right) dW_0$$

for the date zero increment. The limiting covariance between $\frac{M_t}{M_0}$ and dW_0 is therefore $E\left(\mathcal{D}_0 \frac{M_t}{M_0} \mid X_0 = x\right)$. From the second equality in (19), these elasticities coincide with the diffusion counterpart to impulse responses $\mathcal{D}_0(\log M_t - \log M_0)$ for $\log M_t - \log M_0$ weighted by

$$\frac{\left(\frac{M_t}{M_0}\right)}{E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]}$$

when averaging over future outcomes. For the lognormal model, the weighting is inconsequential. In Borovička et al. (2011), we provide details of this derivation and some related calculations including the following alternative formula relevant for computation:

$$\varepsilon(x,t) \doteq \nu(x) \cdot \left[\sigma(x)'\left(\frac{\partial}{\partial x}\log E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]\right) + \alpha(x)\right]. \tag{20}$$

The shock-elasticity formula (20) has a natural interpretation. The sensitivity of the multiplicative process M to a shock in the next instant consists of two terms. The term $\alpha(x)$ represents the direct impact of the Brownian shock on the evolution of M in expression (18). The partial derivative with respect to x captures the sensitivity of the conditional expectation to movements in the state vector, and it is multiplied by the exposure matrix $\sigma(x)$ to express the sensitivity with respect to the shock vector W. The use of the derivative of the logarithm in (18) justifies the term shock *elasticity*. The instantaneous short-term elasticity is $\alpha(x) \cdot \nu(x)$.[i]

5. DISCRETE-TIME FORMULAS AND APPROXIMATION

In the preceding sections, we developed formulas for shock-price and shock-exposure elasticities for a wide class of models driven by a state vector with Markov dynamics (1). We now present a tractable implementation that, when applicable, makes the computations straightforward to apply. The discussion draws on methods developed in Borovička and Hansen (2014).[j] We also provide Matlab software implementing the

[i] The instantaneous shock-price elasticity is $-\alpha_s(x) \cdot \nu(x)$ which coincides with the notion of a risk price vector that represents the compensation for exposure to Brownian increments.

[j] See Nakamura et al. (2016) for another discrete-time implementation of these methods.

solution methods described in this section including a toolkit that computes shock elasticities for models solved using Dynare.[k]

We start by introducing a convenient exponential-quadratic framework that we use for modeling the state vector X and the resulting multiplicative processes. In this framework, conditional expectations of multiplicative processes and the shock elasticities are available in a convenient functional form. We then consider a special class of approximate solutions to dynamic macroeconomic models constructed using perturbation methods. We show how to approximate the equilibrium dynamics, additive and multiplicative functionals, and the resulting shock elasticities. By construction, the dynamics of these approximate solutions will be nested within the exponential-quadratic framework.

5.1 Exponential-Quadratic Framework

We study dynamic systems for which the state vector can be partitioned as $X = \left(X_1', X_2'\right)'$ where the two components follow the laws of motion:

$$\begin{aligned} X_{1,t+1} &= \Theta_{10} + \Theta_{11} X_{1,t} + \Lambda_{10} W_{t+1} \\ X_{2,t+1} &= \Theta_{20} + \Theta_{21} X_{1,t} + \Theta_{22} X_{2,t} + \Theta_{23}(X_{1,t} \otimes X_{1,t}) \\ &\quad + \Lambda_{20} W_{t+1} + \Lambda_{21}(X_{1,t} \otimes W_{t+1}) + \Lambda_{22}(W_{t+1} \otimes W_{t+1}). \end{aligned} \tag{21}$$

We restrict the matrices Θ_{11} and Θ_{22} to have stable eigenvalues. Notice that the restrictions imposed by the triangular structure imply that the process X_1 is linear, while the process X_2 is linear conditional on the evolution of X_1.

The class of multiplicative functionals M that interest us satisfies, for $Y = \log M$, the restriction

$$\begin{aligned} Y_{t+1} - Y_t &= \Gamma_0 + \Gamma_1 X_{1,t} + \Gamma_2 X_{2,t} + \Gamma_3(X_{1,t} \otimes X_{1,t}) \\ &\quad + \Psi_0 W_{t+1} + \Psi_1(X_{1,t} \otimes W_{t+1}) + \Psi_2(W_{t+1} \otimes W_{t+1}). \end{aligned} \tag{22}$$

In what follows we use a $1 \times k^2$ vector Ψ to construct a $k \times k$ symmetric matrix $\text{sym}[\text{mat}_{k,k}(\Psi)]$ such that[l]

$$w'(\text{sym}[\text{mat}_{k,k}(\Psi)])w = \Psi(w \otimes w).$$

[k] Dynare is a freely available Matlab/Octave toolkit for solving and analyzing dynamic general equilibrium models (see http://www.dynare.org). Our software is available at http://borovicka.org/software.html.

[l] In this formula $\text{mat}_{k,k}(\Psi)$ converts a vector into a $k \times k$ matrix and the sym operator transforms this square matrix into a symmetric matrix by averaging the matrix and its transpose. Appendix A introduces convenient notation for the algebra underlying the calculations in this and subsequent sections.

This representation will be valuable in some of the computations that follow. We use additive functionals to represent stochastic growth via a technology shock process or aggregate consumption, and to represent stochastic discounting used in representing asset values.

The system (21)–(22) is rich enough to accommodate stochastic volatility, which has been featured in the asset pricing literature and to a lesser extent in the macroeconomics literature. For instance, the state variable $X_{1,t}$ can capture a linear process for conditional volatility, and $X_{2,t}$ the conditional growth rate of cash flows. The coefficient Ψ_1 in (22) then determines the time variation in the conditional volatility of the growth rate of M, while Λ_{21} in (21) impacts the conditional volatility of the changes in the growth rate. In Section 5.2, we will map the solution obtained using perturbation approximations into this framework as well.

A virtue of parameterization (21)–(22) is that it gives quasi-analytical formulas for our dynamic elasticities. The implied model of the stochastic discount factor has been used in a variety of reduced-form asset pricing models. Later we will use an approximation to deduce this dynamical system.

We illustrate the convenience of this functional form by calculating the logarithms of conditional expectations of multiplicative functionals of the form (22). Consider a function that is linear-quadratic in $x = (x_1', x_2')'$:

$$\log f(x) = \Phi_0 + \Phi_1 x_1 + \Phi_2 x_2 + \Phi_3 (x_1 \otimes x_1). \tag{23}$$

Then conditional expectations are of the form:

$$\begin{aligned} \log E\left[\left(\frac{M_{t+1}}{M_t}\right) f(X_{t+1}) \mid X_t = x\right] &= \log E[\exp(Y_{t+1} - Y_t) f(X_{t+1}) \mid X_t = x] \\ &= \Phi_0^* + \Phi_1^* x_1 + \Phi_2^* x_2 + \Phi_3^* (x_1 \otimes x_1) \\ &= \log f^*(x) \end{aligned} \tag{24}$$

where the formulas for Φ_i^*, $i = 0, \ldots, 3$ are given in Appendix A. This calculation maps a function f into another function f^* with the same functional form. Our multiperiod calculations exploit this link. For instance, repeating these calculations compounds stochastic growth or discounting. Moreover, we may exploit the recursive Markov construction in (24) initiated with $f(x) = 1$ to obtain:

$$\log E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right] = \Phi_{0,t}^* + \Phi_{1,t}^* x_1 + \Phi_{2,t}^* x_2 + \Phi_{3,t}^* (x_1 \otimes x_1)$$

for appropriate choices of $\Phi_{i,t}^*$.

5.1.1 Shock Elasticities

To compute shock elasticities given in (8) under the convenient functional form, we construct:

$$\frac{E\left[\left(\frac{M_t}{M_0}\right)W_1 \mid X_0 = x\right]}{E\left[\left(\frac{M_t}{M_0}\right) \mid X_0 = x\right]} = \frac{E\left[\left(\frac{M_1}{M_0}\right)E\left[\left(\frac{M_t}{M_1}\right) \mid X_1\right]W_1 \mid X_0 = x\right]}{E\left[\left(\frac{M_1}{M_0}\right)E\left(\frac{M_t}{M_1} \mid X_1\right) \mid X_0 = x\right]}.$$

Notice that the random variable:

$$L_{1,t} = \frac{\left(\frac{M_1}{M_0}\right)E\left(\frac{M_t}{M_1} \mid X_1\right)}{E\left[\left(\frac{M_1}{M_0}\right)\left(\frac{M_t}{M_1} \mid X_1\right) \mid X_0 = x\right]} \tag{25}$$

has conditional expectation one. Multiplying this positive random variable by W_1 and taking expectations is equivalent to changing the conditional probability distribution and evaluating the conditional expectation of W_1 under this change of measure. Then under the transformed measure, using a complete-the-squares argument we may show that W_1 remains normally distributed with a covariance matrix that is no longer the identity and a mean conditioned on $X_0 = x$ that is affine in x_1. The formulas are given in Appendix B. Thus the shock elasticity function $\varepsilon(x, t)$ can be computed recursively using formulas that are straightforward to implement. We show in Appendix B that the resulting shock elasticity function is also affine in the state x_1.

5.2 Perturbation Methods

In macroeconomic models, the equilibrium Markov dynamics (1) is typically ex ante unknown and needs to be solved for from a set of equilibrium conditions. We now describe a solution method for dynamic general equilibrium models that yields a solution in the form of an approximate law of motion that is a special case of the exponential-quadratic functional form analyzed in Section 5.1. This solution method, based on Holmes (1995) and Lombardo and Uhlig (2014), constructs a perturbation approximation where the first- and second-order terms follow the restricted dynamics (21).

For the purposes of approximation, we consider a family of models parameterized by q and study first- and second-order approximations around this limit system in which $\mathsf{q} = 0$. For each q, we consider the system (equations

$$0 = E(g[X_{t+1}(\mathsf{q}), X_t(\mathsf{q}), X_{t-1}(\mathsf{q}), \mathsf{q}W_{t+1}, \mathsf{q}W_t, \mathsf{q}] \mid \mathcal{F}_t). \tag{26}$$

The $\mathsf{q} = 0$ equation system is one without shocks, and more generally small values q will make the shocks less consequential. There are well-known saddle-point stability conditions on the system (26) that lead to a unique equilibrium of the linear approximation (see Blanchard and Kahn, 1980 or Sims, 2002), and we assume that these are satisfied. Following Holmes (1995) and Lombardo and Uhlig (2014), we form an approximating system by deducing the dynamic evolution for the pathwise derivatives with respect to q and evaluated at $\mathsf{q} = 0$. Our derivation will be admittedly heuristic as is much of the related literature in macroeconomics.

To build a link to the parameterization in Section 5.1, we feature a second-order expansion:

$$X_t(\mathsf{q}) \approx X_{0,t} + \mathsf{q}X_{1,t} + \frac{\mathsf{q}^2}{2}X_{2,t},$$

where $X_{m,t}$ is the mth order, date t component of the stochastic process. We abstract from the dependence on initial conditions by restricting each component process to be stationary. Our approximating process will similarly be stationary.[m] The expansion leads to laws of motion for the component processes $X_{1,\cdot}$ and $X_{2,\cdot}$. The joint process $(X_{1,\cdot}, X_{2,\cdot})$ will again be Markov, although the dimension of the state vector under the approximate dynamics doubles.

5.2.1 Approximating State Vector Dynamics

While $X_t(\mathsf{q})$ serves as a state vector in the dynamic system (26), the state vector itself depends on the parameter q. Suppose that $\mathcal{F}_t$ is the σ-algebra generated by the infinite history of shocks $\{W_j : j \leq t\}$. For each dynamic system, we presume that the state vector $X_t(\mathsf{q})$ is $\mathcal{F}_t$ measurable and that in forecasting future values of the state vector conditioned on $\mathcal{F}_t$ it suffices to condition on X_t. Although $X_t(\mathsf{q})$ depends on q, the construction of $\mathcal{F}_t$ does not. We now construct the dynamics for each of the component processes. The result will be a recursive system that has the same structure as the triangular system (21).

Define $\bar{x}$ to be the solution to the equation:

$$\bar{x} = \psi(\bar{x}, 0, 0),$$

which gives the fixed point for the deterministic dynamic system. We assume that this fixed point is locally stable. That is $\psi_x(\bar{x}, 0, 0)$ is a matrix with stable eigenvalues, eigenvalues with absolute values that are strictly less than one. Then set

$$X_{0,t} = \bar{x}$$

for all t. This is the zeroth-order contribution to the solution constructed to be time invariant.

In computing pathwise derivatives, we consider the state vector process viewed as a function of the shock history. Each shock in this history is scaled by the parameter q, which results in a parameterized family of stochastic processes. We compute derivatives with respect to this parameter where the derivatives themselves are stochastic processes.

[m] As argued by Lombardo and Uhlig (2014), this approach is computationally very similar to the pruning approach described by Kim et al. (2008) or Andreasen et al. (2010).

Given the Markov representation of the family of stochastic processes, the derivative processes will also have convenient recursive representations. In what follows we derive these representations.

Using the Markov representation, we compute the derivative of the state vector process with respect to q, which we evaluate at $\mathsf{q}=0$. This derivative has the recursive representation:

$$X_{1,t+1} = \psi_q + \psi_x X_{1,t} + \psi_w W_{t+1}$$

where ψ_q, ψ_x, and ψ_w are the partial derivative matrices:

$$\psi_q \doteq \frac{\partial \psi}{\partial \mathsf{q}}(\bar{x},0,0), \quad \psi_x \doteq \frac{\partial \psi}{\partial x'}(\bar{x},0,0), \quad \psi_w \doteq \frac{\partial \psi}{\partial w'}(\bar{x},0,0).$$

In particular, the term $\psi_w W_{t+1}$ reveals the role of the shock vector in this recursive representation. Recall that we have presumed that $\bar{x}$ has been chosen so that ψ_x has stable eigenvalues. Thus the first derivative evolves as a Gaussian vector autoregression. It can be expressed as an infinite moving average of the history of shocks, which restricts the process to be stationary. The first-order approximation to the original process is:

$$X_t \approx \bar{x} + \mathsf{q} X_{1,t}.$$

In particular, the approximating process on the right-hand side has $\bar{x} + \mathsf{q}(I - \psi_x)^{-1}\psi_q$ as its unconditional mean.

We compute the pathwise second derivative with respect to q recursively by differentiating the recursion for the first derivative. As a consequence, the second derivative has the recursive representation:

$$\begin{aligned} X_{2,t+1} = {} & \psi_{qq} + 2\left(\psi_{xq} X_{1,t} + \psi_{wq} W_{t+1}\right) \\ & + \psi_x X_{2,t} + \psi_{xx}(X_{1,t} \otimes X_{1,t}) + 2\psi_{xw}(X_{1,t} \otimes W_{t+1}) + \psi_{ww}(W_{t+1} \otimes W_{t+1}) \end{aligned} \tag{27}$$

where matrices ψ_{ij} denote the second-order derivatives of ψ evaluated at $(\bar{x},0,0)$ and formed using the construction of the derivative matrices described in Appendix A.2. As noted by Schmitt-Grohé and Uribe (2004), the mixed second-order derivatives ψ_{xq} and ψ_{wq} are often zero using second-order refinements to the familiar log approximation methods.

The second-derivative process $X_{2,\cdot}$ evolves as a stable recursion that feeds back on itself and depends on the first derivative process. We have already argued that the first derivative process $X_{1,t}$ can be constructed as a linear function of the infinite history of the shocks. Since the matrix ψ_x has stable eigenvalues, $X_{2,t}$ can be expressed as a linear-quadratic function of this same shock history. Since there are no feedback effects from $X_{2,t}$ to $X_{1,t+1}$, the joint process $(X_{1,\cdot}, X_{2,\cdot})$ constructed in this manner is necessarily stationary.

The dynamic evolution for $(X_{1,\cdot}, X_{2,\cdot})$ is a special case of the triangular system (21) given in Section 5.1. When the shock vector W_t is a multivariate standard normal, we can utilize results from Section 5.1 to produce exact formulas for conditional expectations of exponentials of linear-quadratic functions in $(X_{1,t}, X_{2,t})$. We exploit this construction in the subsequent section. For details on the derivation of the approximating formulas, see Appendix A.

5.3 Approximating the Evolution of a Stationary Increment Process

Consider the approximation of a parameterized family of multiplicative processes with increments given by:

$$\log M_{t+1}(\mathsf{q}) - \log M_t(\mathsf{q}) = \kappa[X_t(\mathsf{q}), \mathsf{q} W_{t+1}, \mathsf{q}]$$

and an initial condition $\log M_0$. We use the function κ in conjunction with q to parameterize implicitly a family of additive functionals. We approximate the resulting additive functionals by

$$\log M_t \approx \log M_{0,t} + \mathsf{q} \log M_{1,t} + \frac{\mathsf{q}^2}{2} \log M_{2,t}$$

where the processes on the right-hand side have stationary increments.

Following the steps of our approximation of X, the recursive representation of the zeroth-order contribution to $\log M$ is

$$\log M_{0,t+1} - \log M_{0,t} = \kappa(\bar{x}, 0, 0) \doteq \bar{\kappa};$$

the first-order contribution is

$$\log M_{1,t+1} - \log M_{1,t} = \kappa_q + \kappa_x X_{1,t} + \kappa_w W_{t+1}$$

where κ_x and κ_w are the respective first derivatives of κ evaluated at $(\bar{x}, 0, 0)$; and the second-order contribution is

$$\begin{aligned}\log M_{2,t+1} - \log M_{2,t} = {} & \kappa_{qq} + 2\left(\kappa_{xq} X_{1,t} + \kappa_{wq} W_{t+1}\right) \\ & + \kappa_x X_{2,t} + \kappa_{xx}(X_{1,t} \otimes X_{1,t}) + 2\kappa_{xw}(X_{1,t} \otimes W_{t+1}) \\ & + \kappa_{ww}(W_{t+1} \otimes W_{t+1})\end{aligned}$$

where the κ_{ij}'s are the second derivative matrices constructed as in Appendix A.2. The resulting component additive functionals are special cases of the additive functional given in (22) that we introduced in Section 5.1.

5.3.1 Approximating Shock Elasticities

We could compute corresponding second-order approximations for the elasticities of multiplicative processes. Alternatively, since the approximating processes satisfy the structure given in Section 5.1, we have the formulas that we described earlier at our disposal and the supporting software. See Borovička and Hansen (2014) for further discussion.

5.4 Related Approaches

There also exist ad hoc approaches which mix orders of approximation for different components of the model or state vector. The aim of these methods is to improve the precision of the approximation along specific dimensions of interest, while retaining tractability in the computation of the derivatives of the function ψ. Justiniano and Primiceri (2008) use a first-order approximations but augment the solution with heteroskedastic innovations. Benigno et al. (2010) study second-order approximations for the endogenous state variables in which exogenous state variables follow a conditionally linear Markov process. Malkhozov and Shamloo (2011) combine a first-order perturbation with heteroskedasticity in the shocks to the exogenous process and corrections for the variance of future shocks. These solution methods are designed to produce nontrivial roles for stochastic volatility in the solution of the model and in the pricing of exposure to risk. The approach of Benigno et al. (2010) or Malkhozov and Shamloo (2011) gives alternative ways to construct the functional form used in Section 5.1.

5.5 Recursive Utility Investors

The recursive utility preference specification of Kreps and Porteus (1978) and Epstein and Zin (1989) warrants special consideration. By design, this specification of preferences avoids presuming that investors reduce intertemporal, compound consumption lotteries. Instead investors may care about the intertemporal composition of risk. It is motivated in part by an aim to allow for risk aversion to be altered without changing the elasticity of intertemporal substitution. Anderson et al. (2003), Maenhout (2004), and others extend the literature on risk-sensitive control by Jacobson (1973), Whittle (1990), and others and provide a "concern for robustness" interpretation of the utility recursion. Under this alternative interpretation the decision maker explores the potential misspecification of the transition dynamics as part of the decision-making process. This perspective yields a substantially different interpretation of the utility recursion. In establishing these connections in the control theory and economics literatures, it is sometimes advantageous to parameterize the utility recursion in a manner that depends explicitly on the parameter q. Borovička and Hansen (2013) and Bhandari et al. (2016) explore the resulting implications for approximations analogous to those studied here. Among other things, they provide a rationale for the first-order adjustments for recursive utility as suggested by Tallarini (2000), and they show novel ways in which higher-order adjustments are more impactful.

6. CONTINUOUS-TIME APPROXIMATION

Many interesting macroeconomic models specified in continuous time, including those we analyze in Section 7, require the application of numerical solution techniques. In the construction of shock elasticities, the central object of interest is the conditional expectation of M in (19). Consider the more general problem

$$\phi_t(x) \doteq E\left[\left(\frac{M_t}{M_0}\right)\phi_0(X_t) \mid X_0 = x\right] \tag{28}$$

with a given function ϕ_0. The conditional expectation of M is obtained by setting $\phi_0(x) \equiv 1$.

6.1 An Associated Partial Differential Equation

For the purposes of computation, we evaluate ϕ_t recursively. Given $\phi_{t-\Delta t}$ for small Δt, exploiting the time homogeneity of the underlying Markov process and applying the Law of Iterated Expectations gives:

$$\phi_t(x) = E\left[\left(\frac{M_{\Delta t}}{M_0}\right)\phi_{t-\Delta t}(X_{\Delta t}) \mid X_0 = x\right].$$

Itô's lemma applied to the product in the conditional expectation gives the linear, second-order partial differential equation:

$$\begin{aligned} \frac{\partial}{\partial t}\phi_t &= \left(\beta + \frac{1}{2}|\alpha|^2\right)\phi_t + \left[\frac{\partial}{\partial x}\phi_t\right] \cdot (\mu + \sigma\alpha) \\ &+ \frac{1}{2}\mathrm{tr}\left[\sigma'\left(\frac{\partial}{\partial x \partial x'}\phi_t\right)\sigma\right] \end{aligned} \tag{29}$$

with terminal condition ϕ_0 where tr(·) denotes the trace of the matrix argument. Eq. (29) is a generalization of the Kolmogorov backward equation for multiplicative processes of the type (17). The resulting partial differential equation can be solved using standard numerical techniques for differential equations.

6.2 Martingale Decomposition and a Change of Measure

To study the long-run implications for pricing, we proposed the extraction of a martingale component from the dynamics of the stochastic discount factors and cash flows by solving the Perron–Frobenius equation (9) for the strictly positive eigenfunction $e(x)$ and the associated eigenvalue η. In the Markov diffusion setup we localize this problem by computing

$$\lim_{t \to 0} \frac{E[M_t e(X_t) | X_0 = x] - \exp(\eta t) e(x)}{t} = 0.$$

Defining the infinitesimal operator

$$\mathbb{B}f(x) \doteq \frac{d}{dt} E[M_t f(X_t) | X_0 = x] \bigg|_{t=0}$$

we have

$$\mathbb{B}f = \left(\beta + \frac{1}{2}|\alpha|^2\right) f + (\sigma\alpha + \mu) \cdot \frac{\partial f}{\partial x} + \frac{1}{2} \mathrm{tr}\left(\sigma\sigma' \frac{\partial^2 f}{\partial x \partial x'}\right)$$

and we can write the limiting Perron–Frobenius equation as

$$\mathbb{B}e = \eta e \tag{30}$$

which is a second-order partial differential equation for the function $e(x)$ and a number η. Eq. (30) is known as the Sturm–Liouville equation. Notice that it is identical to the partial differential equation (29) when we are looking for an unknown discounted stationary function $\phi_t(x) = \exp(\eta t) e(x)$ with initial condition $\phi_0(x) = e(x)$. As before, there are typically multiple strictly positive solutions to this equation. Hansen and Scheinkman (2009) show that there is at most one such solution that preserves stochastic stability of the state vector X. We implicitly assume that we always choose such a solution.[n]

In line with the discussion from Section 3.4, we can now define the martingale $\widetilde{M}$ as[o]

$$\frac{\widetilde{M}_t}{\widetilde{M}_0} \doteq \exp(-\eta t) \frac{e(X_t)}{e(X_0)} \frac{M_t}{M_0}. \tag{31}$$

Applying Itô's lemma, we find that

$$d \log \widetilde{M}_t = \widetilde{\alpha}(X_t) \cdot dW_t - \frac{1}{2} |\widetilde{\alpha}(X_t)| dt$$

with

$$\widetilde{\alpha}(x) = \left[\sigma'(x) \frac{\partial}{\partial x} \log e(x) + \alpha(x)\right].$$

This implies that under the probability measure $\widetilde{P}$, the Brownian motion evolves as

$$dW_t = \widetilde{\alpha}(x) dt + d\widetilde{W}_t$$

where $\widetilde{W}$ is a Brownian motion under $\widetilde{P}$. It also implies that we can write the dynamics of the state vector under the change of measure as

[n] See also Borovička et al. (2015), Qin and Linetsky (2014a), Qin et al. (2016), Walden (2014), or Park (2015) for problems closely related to solving for the eigenvalue–eigenfunction pair (η, e).

[o] We note that the solution obtained using the localized version of the Perron–Frobenius problem may yield a process $\widetilde{M}$ that is only a local martingale. See Hansen and Scheinkman (2009) and Qin and Linetsky (2014b) for details and additional assumptions that assure $\widetilde{M}$ is a martingale. We will assume that such conditions are satisfied in the discussion that follows.

$$dX_t = \left[\mu(X_t) + \sigma(X_t)\,\tilde{\alpha}(X_t)\right]dt + \sigma(X_t)d\tilde{W}_t.$$

Inverting Eq. (31), we obtain the analog of the martingale decomposition in discrete time:

$$\frac{M_t}{M_0} = \exp(\eta t)\frac{e(X_0)}{e(X_t)}\frac{\tilde{M}_t}{\tilde{M}_0}. \tag{32}$$

To implement the factorization of the multiplicative functional M, we compute the strictly positive eigenfunction $e(x)$ and the associated eigenvalue η by solving the Perron–Frobenius problem (30). Since analytical solutions are often not available, we must rely on numerical methods. Pryce (1993) gives various numerical solution techniques for this problem. Notice that since there are typically infinitely many strictly positive solutions $e(x)$, it is necessary to determine which of these solutions is the relevant one.

An alternative approach is to utilize the time-dependent PDE (29) and exploit the fact that η is the principal eigenvalue, ie, one associated with the most durable component. In that case, one can start with an initial condition $\phi_0(x)$ that serves as a guess for the eigenfunction, and iterate on (29) to solve for $\phi_t(x)$ as $t \to \infty$. For large t, the solution should behave as

$$\phi_t(x) \approx \exp(\eta t)e(x)$$

and thus

$$\eta = \frac{\partial}{\partial t}\log\phi_t(x)\bigg|_{t\to\infty} \approx \frac{1}{\Delta t}\left[\log\phi_{t+\Delta t}(x) - \log\phi_t(x)\right]\bigg|_{t\to\infty}$$

and since the eigenfunction is only determined up to scale, we can use any proportional rescaling of ϕ_t as $e(x) \approx \exp(-\eta t)\phi_t(x)|_{t\to\infty}$.

6.3 Long-Term Pricing

We now apply the decomposition (32) in the shock elasticity formula (19) to obtain:

$$\varepsilon(x,t) \doteq \nu(x)\cdot\left[\sigma(x)'\left(\frac{\partial}{\partial x}\log e(x) + \frac{\partial}{\partial x}\log\tilde{E}\left[\frac{1}{e(X_t)}\,|\,X_0 = x\right]\right) + \alpha(x)\right].$$

Taking the limit as $t \to \infty$, the conditional expectation in brackets converges to a constant provided that we select a martingale that induces a probability measure under which X is stochastically stable. See Hansen and Scheinkman (2009) and Hansen (2012) for further discussion. Therefore,

$$\lim_{t\to\infty}\varepsilon(x,t) = \nu(x)\cdot\left[\sigma(x)'\frac{\partial}{\partial x}\log e(x) + \alpha(x)\right].$$

6.4 Boundary Conditions

The construction of shock elasticity functions requires solving the conditional expectations of M, for instance, by solving the partial differential equation (29). This requires proper specification of the boundary conditions not only in terms of the terminal condition $\phi_0(x)$ but also at the boundaries of the state space for the state vector X_t. The boundary behavior of the diffusion X is a central and often economically important part of the equilibrium, as we will see in the models with financial frictions discussed in Section 7. In those models, the state variable is a univariate diffusion and there are well understood characterizations of the boundary behavior based on the classical Feller boundary classification.[P] The textbook treatment of the boundary conditions for problem (28) typically abstracts from the impact of the multiplicative process M. While a detailed discussion of the boundary characterization is beyond the scope of this chapter, we briefly discuss how the inclusion of M can alter the analysis. In what follows, we utilize the martingale decomposition introduced in Section 3.4 and draw connections to the treatment of boundaries for scalar diffusions.

We represent the conditional expectation (32) using a Kolmogorov equation under the change of measure induced by $\widetilde{M}$. Using the martingale factorization (32) we write (28) as

$$\phi_t(x) \doteq E\left[\exp(\eta t)\frac{e(X_0)}{e(X_t)}\frac{\widetilde{M}_t}{\widetilde{M}_0}\phi_0(X_t) \mid X_0 = x\right].$$

Define

$$\psi_t(x) \doteq \exp(-\eta t)\frac{\phi_t(x)}{e(x)} = \widetilde{E}\left[\frac{\phi_0(X_t)}{e(X_t)} \mid X_0 = x\right] = \widetilde{E}\left[\psi_0(X_t) \mid X_0 = x\right] \tag{33}$$

with the initial condition $\psi_0(x) = \phi_0(x)/e(x)$. This converts the boundary condition problem into a standard Kolmogorov backward equation (Eq. (28) with $M \equiv 1$), albeit under the probability measure $\widetilde{P}$. Under $\widetilde{P}$, the diffusion X satisfies the law of motion

$$dX_t = \widetilde{\mu}(X_t)dt + \sigma(X_t)d\widetilde{W}_t,$$

$$\widetilde{\mu}(x) = \mu(x) + \sigma(x)\sigma'(x)\frac{\partial}{\partial x}\log e(x) + \sigma(x)\alpha(x)$$

and the associated generator

$$\widetilde{\mathbb{B}}f = \widetilde{\mu} \cdot \frac{\partial f}{\partial x} + \frac{1}{2}\mathrm{tr}\left(\sigma\sigma'\frac{\partial^2 f}{\partial x \partial x'}\right)$$

corresponds to the generator of a diffusion with infinitesimal variance $\sigma^2(x)$ and infinitesimal mean $\widetilde{\mu}(x)$ under $\widetilde{P}$.

[P] See the seminal work by Feller (1952) and Feller (1957). Karlin and Taylor (1981), Borodin and Salminen (2002), or Linetsky (2008) offer summarizing treatments.

The boundary characterization under $\widetilde{P}$ and the associated boundary conditions for $\psi_t(x)$ follow from formulas from Section 6.4. The character of the boundary can change under $\widetilde{P}$, although a reflecting boundary remains reflecting to preserve local equivalence of measures P and $\widetilde{P}$. Observe that Eq. (33) introduces a relationship between the conditional expectation given by $\phi_t(x)$ and the eigenfunction $e(x)$. For instance, when the boundary point x_b is reflecting, the appropriate boundary condition is[q]

$$\frac{\partial}{\partial x}\psi_t(x)\bigg|_{x=x_b}=0.$$

When both $\phi_t(x)$ and $e(x)$ are strictly positive at the boundary, this implies that

$$\frac{\partial}{\partial x}\log\phi_t(x)\bigg|_{x=x_b}=\frac{\partial}{\partial x}\log e(x)\bigg|_{x=x_b}$$

equalizing logarithmic slopes of the conditional expectation (28) and the eigenfunction $e(x)$ at the boundary.

7. MODELS WITH FINANCIAL CONSTRAINTS IN CONTINUOUS TIME

Recently, there has been renewed interest in nonlinear stochastic macroeconomic models with financing restrictions. The literature was initiated by Bernanke and Gertler (1989) and Bernanke et al. (1999), and it has been revived and extended since the advent of the financial crisis. Continuous-time models have been featured in He and Krishnamurthy (2013), Brunnermeier and Sannikov (2014), Di Tella (2015), Moreira and Savov (2016), Adrian and Boyarchenko (2012), or Klimenko et al. (2016). Differential equation methods give the equilibrium solutions, and the resulting dynamics exhibit quantitatively substantial nonlinearity. The nonlinearity emerges because of financing constraints that bind only in a specific part of the state space.[r]

To preserve tractability, models typically assume a low-dimensional specification of the state space. In this section, we analyze two such models, He and Krishnamurthy (2013) and Brunnermeier and Sannikov (2014). Both models utilize frameworks that are judiciously chosen to lead to a scalar endogenous state variable that follows the diffusion

$$dX_t=\mu(X_t)dt+\sigma(X_t)dW_t. \tag{34}$$

The endogenous state represents the allocation of wealth between households and financial experts, capturing the capitalization of the financial sector relative to the size of the

[q] This assumes that the so-called scale measure is finite at the boundary, see, eg, Borodin and Salminen (2002).

[r] See Bocola (2016) or Bianchi (2016) for discrete-time models solved using global to account for financing constraint that binds only occasionally.

economy. When the capitalization is low, the financial constraint is binding, and asset valuations are more sensitive to aggregate shocks.

Both papers also feature an exogenous process that introduces aggregate risk into their model economies. He and Krishnamurthy (2013) construct an endowment economy with a permanent shock to the aggregate dividend. On the other hand, Brunnermeier and Sannikov (2014) feature endogenous capital accumulation with a shock to the quality of the capital stock. In this section, we utilize the continuous-time tools developed in Section 6 to study the state dependence in asset pricing implications of the two models. We refer the reader to the respective papers for a detailed discussions of the underlying economic environments.

7.1 Stochastic Discount Factors

Stochastic discount factors and priced cash flows in the models we analyze can be written as special cases of multiplicative functionals introduced in Section 4.2:

$$d\log S_t = \beta(X_t)dt + \alpha(X_t) \cdot dW_t \tag{35}$$

with coefficients $\beta(x)$ and $\alpha(x)$ determined in equilibrium. In an arbitrage-free, complete market environment, there exists a unique stochastic discount factor that represents the prices of the traded securities.

In economies with financial market imperfections and constraints, this ceases to be true. There are two key features that are of interest to us. First, financial markets in these economies are segmented, and different investors can own specific subsets of assets. This implies the existence of alternative stochastic discount factors for individual investors that have to agree only on prices of assets traded between investors. Second, assets are valuable not only for their cash flows but also because their ownership can relax or tighten financing constraints faced by individual investors. Given the potential for these constraints to be binding, asset values include contributions from the shadow prices of these constraints.

7.2 He and Krishnamurthy (2013)

He and Krishnamurthy (2013) construct an economy populated by two types of agents, specialists and households. There are two assets in the economy, a safe asset earning an infinitesimal risk-free rate r_t and a risky asset with return R_t that is a claim on aggregate dividend

$$d\log D_t = \left(g_d - \frac{1}{2}\sigma_d^2\right)dt + \sigma_d dW_t \doteq \overline{\beta}_d dt + \overline{\alpha}_d dW_t. \tag{36}$$

7.2.1 Households and Specialists

Households have logarithmic preferences and therefore consume a constant fraction of their wealth, $C_t^h = \rho A_t^h$, where ρ is the time-preference coefficient. A fraction λ of households can only invest into the safe asset, while a fraction $1 - \lambda$ invests a share α_t^h of their wealth through an intermediary managed by the specialists who hold a portfolio with return $d\widetilde{R}_t$. Aggregate wealth of the households therefore evolves as

$$dA_t^h = \left(\ell D_t - \rho A_t^h\right)dt + A_t^h r_t dt + \alpha_t^h (1-\lambda) A_t^h \left(d\widetilde{R}_t - r_t dt\right),$$

where ℓD_t is households' income, modeled as a constant share ℓ of the dividend.

Specialists are endowed with CRRA preferences over their consumption stream C_t with risk aversion coefficient γ and trade both assets. Their stochastic discount factor is

$$\frac{S_t}{S_0} = e^{-\rho t}\left(\frac{C_t}{C_0}\right)^{-\gamma}. \tag{37}$$

This stochastic discount factor also prices all assets traded by specialists. The law of motion for their wealth is given by

$$dA_t = -C_t dt + A_t r_t dt + A_t\left(d\widetilde{R}_t - r_t dt\right).$$

The intermediary combines all wealth of the specialists A_t with the households' wealth invested through the intermediary $\alpha_t^h(1-\lambda)A_t^h$ and invests a share α_t of the combined portfolio into the risky asset. The return on the intermediary portfolio then follows

$$d\widetilde{R}_t = r_t dt + \alpha_t (dR_t - r_t dt).$$

The risky asset market clears, so that the wealth invested into the risky asset equals the market price of the asset, P_t

$$\alpha_t\left(A_t + \alpha_t^h(1-\lambda)A_t^h\right) = P_t.$$

7.2.2 Financial Friction

The critical financial friction is introduced into the portfolio choice of the household. Motivated by a moral hazard problem, the household is not willing to invest more than a fraction m of the specialists' wealth through the intermediary, which defines the *intermediation constraint*

$$\alpha_t^h(1-\lambda)A_t^h \le m A_t. \tag{38}$$

Because of logarithmic preferences, the portfolio choice α_t^h of the household is static. The household is also not allowed to sell short any of the assets, so that it solves

$$\max_{\alpha_t^h \in [0,1]} \alpha_t^h E\left[d\widetilde{R}_t - r_t dt \mid \mathcal{F}_t\right] - \frac{1}{2}\left(\alpha_t^h\right)^2 Var\left[d\widetilde{R}_t - r_t dt \mid \mathcal{F}_t\right]$$

subject to the intermediation constraint (38).

The parameter m determines the tightness of the intermediation constraint. This constraint will be endogenously binding when the wealth of the specialists becomes sufficiently low relative to the wealth of the household. In that case, risk sharing partially breaks down and the specialists will have to absorb a large share of the risky asset in their portfolio. As an equilibrium outcome, risk premia increase and the wealth of the specialists becomes more volatile, which in turn induces larger fluctuations of the right-hand side of the constraint (38). Without the intermediation constraint, the model reduces to an endowment economy populated by agents solving a risk-sharing problem with portfolio constraints.

7.2.3 Equilibrium Dynamics

The equilibrium in this model is conveniently characterized using the wealth share of the specialists, $X_t \doteq A_t / P_t \in (0,1)$, that will play the role of the single state variable with endogenously determined dynamics (34) where the coefficients $\mu(x)$ and $\sigma(x)$ are given by the relative wealth accumulation rates of households and specialists, and the equilibrium price of the claim on the risky cash flow. He and Krishnamurthy (2013) show that both boundaries $\{0,1\}$ are entrance boundaries.

Given the homogeneity in the model, we can write the consumption of the specialists as

$$\begin{aligned} C_t &= D_t(1+\ell) - C_t^h = D_t\left[(1+\ell) - \frac{C_t^h}{A_t^h}\frac{A_t^h}{P_t}\frac{P_t}{D_t}\right] \\ &= D_t[(1+\ell) - \rho(1-X_t)\pi(X_t)] \end{aligned}$$

where $\pi(x)$ is the price-dividend ratio for the claim on the dividend stream. The price-dividend ratio is determined endogenously as part of the solution to a set of differential equations. Given a solution for the price-dividend ratio $\pi(x)$, we construct the stochastic discount factor (37).

The top row of Fig. 1 shows the drift and volatility coefficients of the state variable process X, and the associated stationary density. When the specialists' wealth share X_t is low (below $x^* = 0.091$), the intermediation constraint binds. As $X_t \to 0$, the intermediation capacity of the specialists decreases, which increases the expected return on the risky asset, thereby increasing the rate of wealth accumulation of the specialists. On the other hand, when $X_t \to 1$, the economy is unconstrained, risk premia are low, and situation reverses. The drift coefficient $\mu(x)$ in the top left panel reflects these effects.

In the moment when the constraints start binding (to the left of the point $x^* = 0.091$), volatility $\sigma(x)$ of the experts' wealth share starts rising. Ultimately, this volatility has to decline to zero as $X_t \to 0$ to prevent the experts' wealth share from hitting the zero boundary with a positive probability, but the volatility of experts' wealth *level* keeps rising as we approach the boundary.

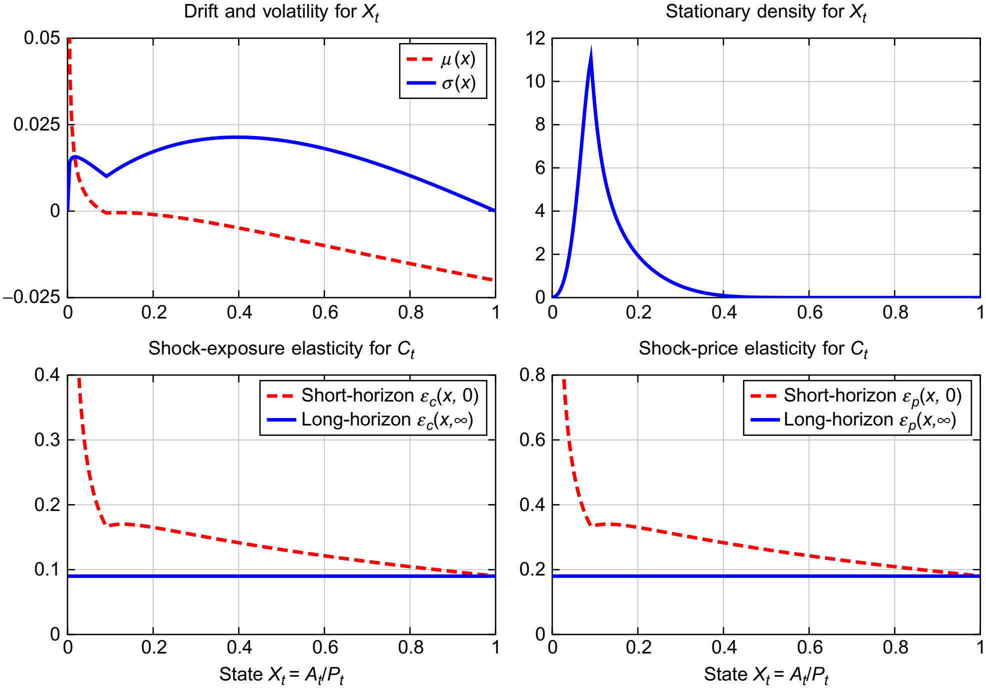

Fig. 1 Dynamics of the experts' wealth share $X_t = A_t/P_t$ (*horizontal axis*), shock-exposure and shock-price elasticities for the He and Krishnamurthy (2013) model. *Top left panel* shows the drift and volatility coefficients for the evolution of X_t, while *top right panel* the stationary density for X_t. *Panels in the bottom row* show the short- and long-horizon shock elasticity for the experts' consumption process C_t. The intermediation constraint (38) binds in the interval $X_t \in (0, 0.091)$, and $x^* = 0.091$ corresponds to the 35.3% quantile of the stationary distribution of X_t.

7.2.4 Stochastic Discount Factor and Cash Flows

Aggregate dividend D_t in (36) follows a geometric Brownian motion with drift. This directly implies a constant shock-exposure elasticity

$$\varepsilon_d(x,t) = \sigma_d.$$

Time variation in expected returns on the claim on the aggregate dividend thus must come solely from the time variation in prices of risk. In particular, the consumption process of specialists is:

$$\frac{C_t}{C_0} = \left(\frac{D_t}{D_0}\right)\left[\frac{(1+\ell) - \rho(1-X_t)\pi(X_t)}{(1+\ell) - \rho(1-X_0)\pi(X_0)}\right]. \tag{39}$$

Notice that the consumption of specialists has the same long-term stochastic growth as the aggregate dividend process. Since the dividend process D is a geometric Brownian motion, we immediately obtain the martingale factorization of C with

$$\begin{aligned} e_c(x) &= [(1+\ell) - \rho(1-x)\pi(x)]^{-1} \\ \eta_c &= g_d \\ \tilde{C}_t &= \exp(-\eta_c t) D_t \end{aligned}$$

where $\tilde{C}$ is the martingale component of C. Analogously, the stochastic discount factor of the specialists (37) is decomposed as

$$\begin{aligned} e_s(x) &= [(1+\ell) - \rho(1-x)\pi(x)]^{\gamma} \\ \eta_s &= -\rho - \gamma g_d + \frac{1}{2}\sigma_d^2 \gamma(\gamma+1) \\ \tilde{S}_t &= \exp[(-\eta_s - \rho)t](D_t)^{-\gamma} \end{aligned}$$

where $\tilde{S}$ is the martingale component.

These factorization results indicate a simple form for the long-horizon limits of the shock elasticities. The consumption and dividend processes share the same martingale component, and thus, assuming $\nu(x) = 1$, their shock-exposure elasticities imply

$$\lim_{t\to\infty} \varepsilon_c(x,t) = \lim_{t\to\infty} \varepsilon_d(x,t) = \sigma_d.$$

Similarly, the shock-price elasticities for the two cash-flow processes have the common long-horizon limit

$$\lim_{t\to\infty} \varepsilon_p(x,t) = \gamma\sigma_d.$$

As we have just verified, the intermediation constraint does not have any impact on prices of long-horizon cash flows. Long-horizon shock elasticities behave as in an economy populated only by unconstrained specialists with risk aversion γ who consume the whole dividend stream D_t. The intermediation constraint only affects the stationary part $e_s(x)$ of the stochastic discount factor.[s] As a consequence, long-term risk adjustments in this model are the same as those implied by a model with power utility function and consumption equal to dividends. The financing constraint induces deviations in short-term risk prices, which we now characterize.

7.2.5 Shock Elasticities and Term Structure of Yields

The blue solid lines in the bottom row of Fig. 1 represent the long-horizon shock-exposure and shock-price elasticities. These results are contrasted with the infinitesimal shock-exposure and shock-price elasticities, depicted with red dashed lines, that are equal to the volatility coefficients $\alpha_c(x)$ and $\alpha_s(x)$ in the differential representation (35) for the experts' consumption process (39) and stochastic discount factor process (37), respectively.

[s] Without the intermediation constraint and the debt constraint ($\lambda = 0$), the economy reduces to a complete-market risk-sharing problem between households and specialists and will converge in the long run to a homogeneous-agent economy populated only by households when $\gamma > 1$.

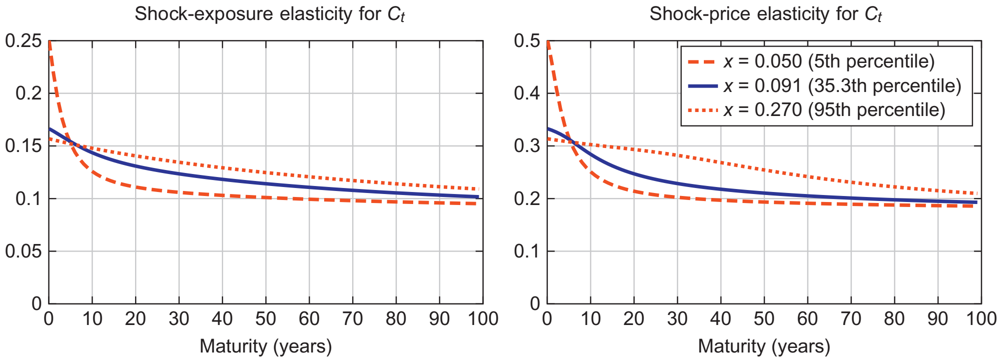

Fig. 2 Shock-exposure and shock-price elasticities for the He and Krishnamurthy (2013) model. *Individual lines* correspond to alternative choices of the current state, the experts' wealth share $X_0 = x$. The *solid line* represents the state in which the intermediation constraint (38) starts binding ($x = 0.091$), corresponding to the 35.3% quantile of the stationary distribution of X_t. The *dashed line* corresponds to the 5% quantile of the stationary distribution of X_t (intermediation constraint tightly binding), while the *dotted line* corresponds to the 95% quantile.

Fig. 2 depicts these shock elasticities evaluated at three different points in the state space. These elasticities were computed numerically.[t] A remarkable feature of the model is the following. The short-horizon consumption cash flows are more exposed to risk as revealed by a larger shock-price elasticity in the constrained region of the state space ($x = 0.05$). This finding is reversed for long-horizon cash flows, showing that the term structure of risk prices is much more strongly downward sloping for low values of the state variable. Since the state variable responds positively to shocks, low realizations of the state variable are the consequence of adverse shocks in the past.

Fig. 3 explores the implications for yields on dividends and experts' consumptions for alternative payoff horizons computed as logarithms of expected returns to the respective payoffs. While the yields on dividends and experts' consumption are initially increasing in maturity, this is all the more so when x is low. The yields are monotone over all horizons except when x is low, in which case the yields eventually decline a bit. The same effect is even more pronounced for the risk-free yield curve except the eventual decline is even slighter. Excess yields are therefore downward sloping for the experts' consumption process, and are lower for longer maturities for low values of x in contrast to high values.[u]

[t] We solved Eq. (29) for $M = C$ and $M = SC$, with $\phi_0(x) = 1$ using an implicit finite difference scheme. We used the solution for $\pi(x)$ constructed using the code from He and Krishnamurthy (2013).

[u] For empirical evidence and modeling of the downward sloping term structure of risky yields see van Binsbergen et al. (2012, 2013), Ai et al. (2013), Belo et al. (2015), Hasler and Marfè (2015), Lopez et al. (2015), or van Binsbergen and Koijen (2016).

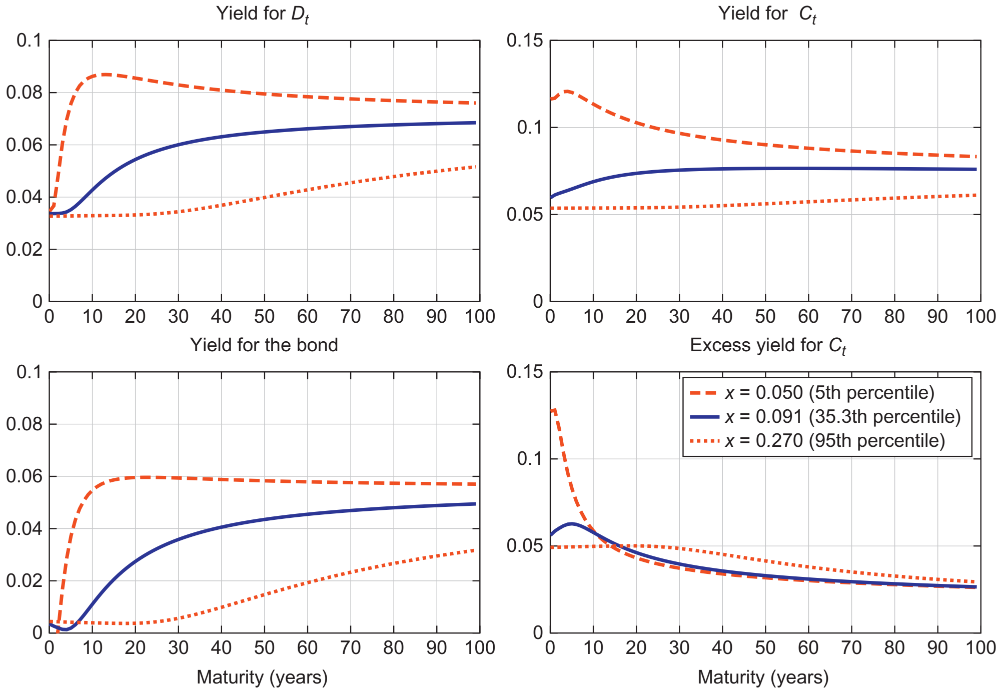

Fig. 3 Yields and excess yields for the He and Krishnamurthy (2013) model. Parameterization and description as in Fig. 2.

7.3 Brunnermeier and Sannikov (2014)

Brunnermeier and Sannikov (2014) construct a model with endogenous capital accumulation, populated by two types of agents, households and experts. The experts have access to a more productive technology for output and new capital than the households. The state variable of interest is the wealth share of experts, defined as

$$X_t = \frac{N_t}{Q_t K_t}$$

where N_t is the net worth of the experts and $Q_t K_t$ is the market value of capital. The equilibrium stock of capital evolves as

$$d \log K_t = \beta_k(X_t) dt + \overline{\alpha}_k dW_t$$

where the rate of accumulation of aggregate capital, $\beta_k(X_t)$, is determined by the wealth share of experts along with a standard local lognormal adjustment. The shock dW_t alters the quality of the capital stock.

7.3.1 Households and Experts

In the baseline model, both households and experts have linear preferences and differ in their time-preference coefficients, r and ρ, respectively, assuming that $\rho > r$. In particular, the preferences for experts are given by

$$E\left[\int_0^\infty e^{-\rho t} d\mathcal{C}_t \mid \mathcal{F}_0\right]$$

where Cu_t is the cumulative consumption and as such is restricted to be a nondecreasing process. In contrast, the cumulative consumption of the household can have negative increments. The linearity in their preferences implies a constant equilibrium rate of interest r.

7.3.2 Financial Friction

In the model, experts are better at managing the capital stock, making it more productive. This creates a natural tendency to move the capital from the hands of the households to the hands of the experts, who in turn issue financial claims on this capital to the households. Absent any financial frictions, the experts would instantly consume the total value of their own net worth (given their higher impatience and linear utility), and accept households' capital under management by issuing equity claims.

Brunnermeier and Sannikov (2014) assume that experts cannot issue any equity and have to finance all capital purchases using risk-free borrowing. This naturally creates a leveraged portfolio on the side of the experts. When the wealth share of experts X_t decreases, they can intermediate households' capital only by increasing their leverage, and the price of capital $Q(X_t)$ has to fall in order to generate a sufficiently high expected return on capital for the experts to hold this leveraged portfolio.

7.3.3 Equilibrium Dynamics

In equilibrium, the expected return on capital has to balance the hedging demand on the side of the experts with the supply of capital from households. Experts' hedging motive (limited willingness to hold a leveraged portfolio) arises from the fact that a leveraged portfolio generates a low return after an adverse realization of the shock dW_t which, at the same time, decreases X_t and therefore increases the future expected return on capital.

On the other hand, when the wealth share of experts X_t increases, the price of capital $Q(X_t)$ increases, and the expected return falls. Define the marginal value of experts' wealth $\Theta_t = \theta(X_t)$ through

$$\Theta_t N_t = E\left[\int_t^\infty e^{-\rho(s-t)} d\mathcal{C}_s \mid \mathcal{F}_t\right]$$

where $d\mathcal{C}$ is the cumulative consumption process of the experts. Linearity of preferences implies that experts' consumption is zero as long as $\Theta_t > 1$. As X_t increases, it reaches an endogenously determined threshold $\bar{x}$ for which $\theta(\bar{x}) = 1$. At this point, the marginal utility of wealth equals the marginal utility of consumption, and experts consume out of their wealth. Consequently, the equilibrium dynamics for the wealth share of experts is given by

$$dX_t = \mu(X_t)dt + \sigma(X_t)dW_t - X_t d\zeta_t,$$

where $\mu(x)$ and $\sigma(x)$ are endogenously determined coefficients that depend on relative rates of wealth accumulation of experts and households, and the consumption rate of experts $d\zeta_t \doteq d\mathcal{C}_t / N_t > 0$ only if $X_t = \bar{x}$. Formally, the right boundary for the stochastic process X_t behaves as a reflecting boundary. See Brunnermeier and Sannikov (2014) for the construction of μ and σ.

7.3.4 Stochastic Discount Factor and Cash Flows

We now turn to the study of asset pricing implications in the model. To construct the shock elasticities, we construct the coefficients $\beta(x)$ and $\alpha(x)$ for the evolution of the stochastic discount factor and priced cash flows modeled as multiplicative functionals (35).

The marginal utility of wealth implies the following stochastic discount factor of the experts:

$$\frac{S_t}{S_0} = \exp(-\rho t)\frac{\theta(X_t)}{\theta(X_0)}.$$

The coefficients $\beta_s(x)$ and $\alpha_s(x)$ in the equation for the evolution of the stochastic discount factor functional can be constructed by applying Ito's lemma to this expression taking account of the functional dependence given by $\theta(x)$ and the evolution of X. Observe that this stochastic discount factor does not contain a martingale component. Nevertheless, since the equilibrium local risk-free interest rate is r,

$$\exp(rt)\frac{S_t}{S_0} = \exp[(r-\rho)t]\frac{\theta(X_t)}{\theta(X_0)}$$

must be a positive local martingale. As such, its expectation conditioned on date t information could decline in t implying that long-term interest rates could be higher and in fact converge to ρ. More generally, from the standpoint of valuation, the fat right tail of the process $\theta(X_t)$ could have important consequences for valuation even in the absence of a martingale component for the stochastic discount factor process.

As a priced cash flow, we consider the aggregate consumption flow process C^a given by

$$C_t^a = [a_e\psi(X_t) + a_h[1-\psi(X_t)] - \iota(X_t)]K_t \tag{40}$$

where $\iota(x)$ is the aggregate investment rate, $\psi(x)$ is the fraction of the capital stock owned by the experts, and $a_e > a_h$ are the output productivities of the experts and households, respectively. Thus C_t^a is equal to aggregate output net of aggregate investment. Aggregate consumption is therefore given as a stationary fraction of aggregate capital. Thus aggregate consumption flow and capital stock processes share a common martingale component.[v]

7.3.5 Shock Elasticities and Term Structure of Yields

The top left panel in Fig. 4 depicts the drift and volatility coefficients for the state variable X_t. At the right boundary $\bar{x}$, the experts accumulated a sufficiently large share of capital and start consuming. Given their risk neutrality, the boundary behaves as a reflecting boundary.

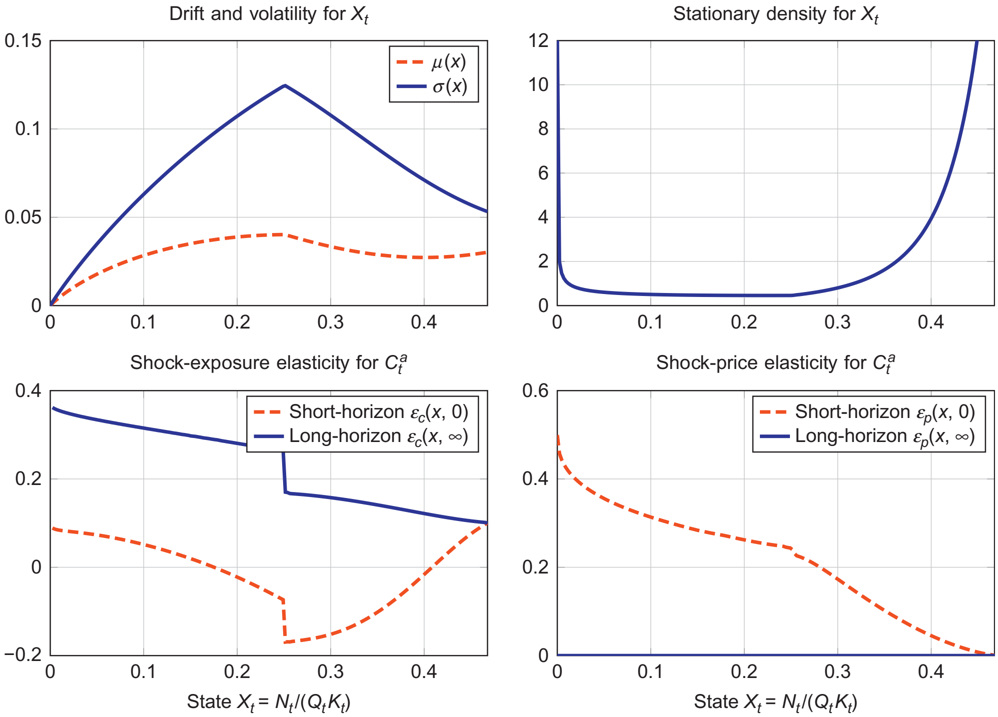

Fig. 4 Dynamics of the experts' wealth share $X_t = N_t/(Q_tK_t)$ (*horizontal axis*), shock-exposure and shock-price elasticities for the Brunnermeier and Sannikov (2014) model. *Top left panel* shows the drift and volatility coefficients for the evolution of X_t, while *top right panel* the stationary density for X_t. *Panels in the bottom row* show the short- and long-horizon shock elasticity for the aggregate consumption process C^a. The intermediation constraint binds in the interval $X_t \in (0, 0.25)$, and $x^* = 0.25$ corresponds to the 15% quantile of the stationary distribution of X.

[v] Brunnermeier and Sannikov (2014) also consider an extension where experts and households are endowed with logarithmic utilities. In that case consumption of both households and experts is given as constant fractions of their respective net worth, and the stochastic discount factor of the experts inherits the martingale component from the reciprocal of the aggregate capital process.

At the left boundary, the situation is notably different. Experts' ability to intermediate capital is limited by their own net worth, and hence their portfolio choice corresponds to an effectively risk averse agent. The left boundary is natural and nonattracting.

The existence of a stationary distribution, depicted in the second panel of Fig. 4, arises from a combination of two forces. Experts are more impatient, so whenever they accumulate a sufficient share of capital, they start consuming, which prevents them from taking over the whole economy. On the other hand, when their wealth share falls, their intermediation ability becomes scarce, the expected return on capital rises, and they use their superior investment technology to accumulate wealth at a faster rate than households.

The stationary density has peaks at each of the two boundaries. The positive drift coefficient $\mu(x)$ implies that there is a natural pull toward the right boundary, creating the peak in the density there. However, whenever a sequence of shocks brings the economy close to the left boundary, solvency constraints imply that it takes time for experts to accumulate wealth again, and the economy spends a long period time in that part of the state space. Economically, most times are "good" times when intermediation is fully operational, with rare periods of protracted "financial crises."

The bottom row of Fig. 4 plots the shock elasticities for the aggregate consumption process (40). Observe that the short-horizon exposure elasticity is negative in a part of the state space, making aggregate consumption countercyclical there. The long-horizon elasticities are noticeably higher, and particularly high when the intermediation constraint binds. The discontinuity at $X_t = x^*$ is caused by the change in consumption behavior in the moment when the intermediation constraint starts binding.

Given that the stochastic discount factor has no martingale component, the long-horizon shock-price elasticity is zero. On the other hand, the short-horizon price of risk varies strongly with the wealth share of the experts. This state dependence is also confirmed in Fig. 5 which plots the shock elasticity functions for selected points in the state space. Shock-exposure elasticities for the aggregate consumption process $\{C_t^a : t \geq 0\}$ increase with maturity, while the shock-price elasticities vanish as $t \to \infty$. Notice that there is a sign reversal in the exposure elasticities for aggregate consumption. The shock-exposure elasticities are initially negative but eventually become positive in the middle part of the state space, mirroring the bottom left panel of Fig. 4. This pattern emerges because the equilibrium investment responses over short horizons lead to more substantial longer-term consumption responses in the constrained states. Nevertheless, the shock-price elasticities are positive for all horizons and states that we consider.

Finally, Fig. 6 plots the yields on risk-free bonds and claims on horizon-specific cash flows from aggregate consumption. In line with the nonmonotonicity of the shock-exposure elasticities across states in Fig. 4, the short-maturity yields are also nonmonotonic, being lowest, and in fact lower than the risk-free rate, in the center of the distribution of the state X_t.

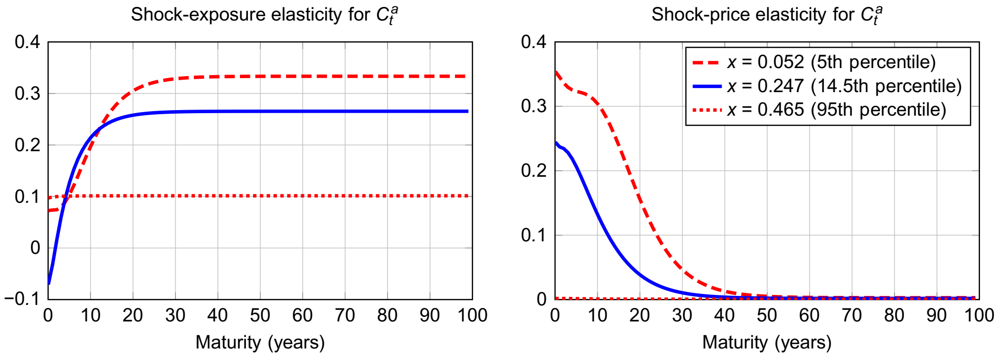

Fig. 5 Shock-exposure and shock-price elasticities for the Brunnermeier and Sannikov (2014) model. *Individual lines* correspond to alternative choices of the current state, the experts' wealth share $X_0 = x$. The *solid line* represents the state in which the intermediation constraint starts binding ($x = 0.247$), corresponding to the 14.5% quantile of the stationary distribution of X_t. The *dashed line* corresponds to the 5% quantile of the stationary distribution of X_t (intermediation constraint tightly binding), while the *dotted line* corresponds to the 95% quantile.

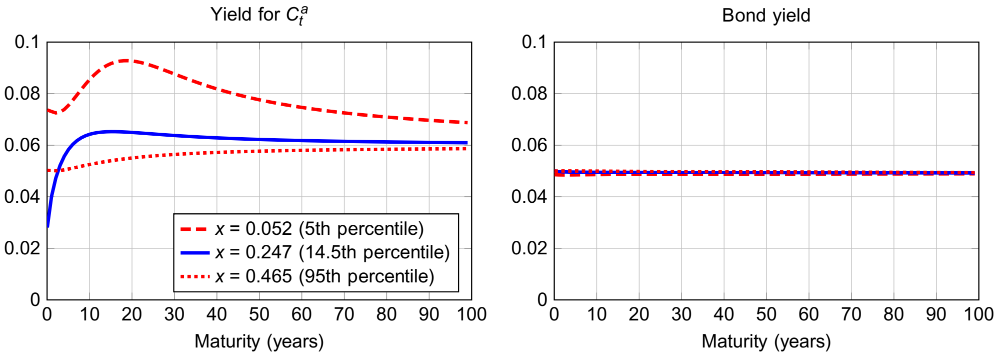

Fig. 6 Yields and excess yields for the Brunnermeier and Sannikov (2014) model. Parameterization and description as in Fig. 5.

8. DIRECTIONS FOR FURTHER RESEARCH

In this chapter, we developed dynamic value decompositions (DVDs) for the study of intertemporal asset pricing implications of dynamic equilibrium models. We constructed *shock elasticities* as building blocks for these decompositions. The DVD methods are distinct but potentially complementary to the familiar Campbell and Shiller (1988) decomposition. Campbell and Shiller use linear VAR methods to quantify the impact of (discounted) "cash flow shocks" and "expected return shocks" on price-dividend ratios. In general these shocks are correlated and are themselves combinations of shocks that are fundamental to structural models of the macroeconomy. Our aim is to explore pricing implications of models in which alternative macroeconomic shocks are identified and their impact quantified. We replaced linear approximation with local sensitivity analysis, and we characterized how cash flows are exposed to alternative macroeconomic shocks and what the corresponding price adjustments are for these exposures. We showed that shock elasticities are mathematically and economically related to impulse response functions. The shock elasticities represent sensitivities of expected cash flows to alternative macroeconomic shocks and the associated market implied compensations when looking across differing investment horizons.

We apply these DVD methods to a class of dynamic equilibrium models that feature financial frictions and segmented markets. The methods uncover the ways financial frictions contribute to pricing of alternative cash flows and to the shape of the term structure of macroeconomic risk prices.

There are two extensions of our analysis that require further investigation. First, risk prices are only well defined relative to an underlying probability distribution. In this chapter, we have not discussed the consequences for pricing when investors inside our models use different probability measures than the data-generating measure presumed by an econometrician. Typically, researchers invoke an assumption of rational expectations to connect investor perceptions with the data generation. More generally, models of investors that allow for subjective beliefs, learning, ambiguity aversion, or concerns about model misspecification alter how we interpret market-based compensations for exposure to macroeconomic fluctuations. For instance, see Hansen (2014) for further discussion. Incorporating potential belief distortions into the analysis should be a valuable extension of these methods.

Second, we left aside empirical and econometric aspects of the identification of shocks and measurement of risk premia. The empirical finance literature has made considerable progress in the characterization and measurement of the term structure of risk premia in various asset markets. The challenge for model building is to connect these empirical facts to specific sources of macroeconomic risks and financial market frictions of model economies. Our methodology suggests a way to make these connections, but further investigation is required.

Finally, we refrained from the discussion of implications for policy analysis. Financial frictions create economic externalities that can potentially be rectified by suitable policy actions. Since asset prices enter these financial constraints, understanding their behavior is an important ingredient to meaningful policy design. Forward looking asset prices provide both a source of information about private sector beliefs and an input into the regulatory challenges faced in the conduct of policy. Our methods can help to uncover asset pricing implications for alternative potential policies.

APPENDICES

Appendix A Exponential-Quadratic Framework

Let $X = (X_1', X_2')'$ be a $2n \times 1$ vector of states, $W \sim N(0, I)$ a $k \times 1$ vector of independent Gaussian shocks, and $\mathcal{F}_t$ the filtration generated by $(X_0, W_1, \ldots, W_t)$. In this appendix, we show that given the law of motion from Eq. (21)

$$\begin{aligned} X_{1,t+1} &= \Theta_{10} + \Theta_{11} X_{1,t} + \Lambda_{10} W_{t+1} \\ X_{2,t+1} &= \Theta_{20} + \Theta_{21} X_{1,t} + \Theta_{22} X_{2,t} + \Theta_{23} (X_{1,t} \otimes X_{1,t}) \\ &\quad + \Lambda_{20} W_{t+1} + \Lambda_{21} (X_{1,t} \otimes W_{t+1}) + \Lambda_{22} (W_{t+1} \otimes W_{t+1}) \end{aligned} \tag{A.1}$$

and a multiplicative functional $M_t = \exp(Y_t)$ whose additive increment is given in Eq. (22):

$$\begin{aligned} Y_{t+1} - Y_t &= \Gamma_0 + \Gamma_1 X_{1,t} + \Gamma_2 X_{2,t} + \Gamma_3 (X_{1,t} \otimes X_{1,t}) \\ &\quad + \Psi_0 W_{t+1} + \Psi_1 (X_{1,t} \otimes W_{1,t+1}) + \Psi_2 (W_{t+1} \otimes W_{t+1}), \end{aligned} \tag{A.2}$$

we can write the conditional expectation of M as

$$\log E[M_t \mid \mathcal{F}_0] = (\overline{\Gamma}_0)_t + (\overline{\Gamma}_1)_t X_{1,0} + (\overline{\Gamma}_2)_t X_{2,0} + (\overline{\Gamma}_3)_t (X_{1,0} \otimes X_{1,0}) \tag{A.3}$$

where $(\overline{\Gamma}_i)_t$ are constant coefficients to be determined.

The dynamics given by (A.1) and (A.2) embed the perturbation approximation constructed in Section 5.2 as a special case. The Θ and Λ matrices needed to map the perturbed model into the above structure are constructed from the first and second derivatives of the function $\psi(x, w, \mathsf{q})$ that captures the law of motion of the model, evaluated at $(\bar{x}, 0, 0)$:

$$\begin{array}{llll} \Theta_{10} = \psi_q & \Theta_{11} = \psi_x & \Lambda_{10} = \psi_w & \\ \Theta_{20} = \psi_{qq} & \Theta_{21} = 2\psi_{xq} & \Theta_{22} = \psi_x & \Theta_{23} = \psi_{xx} \\ \Lambda_{20} = 2\psi_{wq} & \Lambda_{21} = 2\psi_{xw} & \Lambda_{22} = \psi_{ww} & \end{array}$$

where the notation for the derivatives is defined in Appendix A.2.

A.1 Definitions

To simplify work with Kronecker products, we define two operators vec and $\text{mat}_{m,n}$. For an $m \times n$ matrix H, $\text{vec}(H)$ produces a column vector of length mn created by stacking the columns of H:

$$h_{(j-1)m+i} = [\text{vec}(H)]_{(j-1)m+i} = H_{ij}.$$

For a vector (column or row) h of length mn, $\text{mat}_{m,n}(h)$ produces an $m \times n$ matrix H created by "columnizing" the vector:

$$H_{ij} = [\mathrm{mat}_{m,n}(h)]_{ij} = h_{(j-1)m+i}.$$

We drop the m, n subindex if the dimensions of the resulting matrix are obvious from the context. For a square matrix A, define the sym operator as

$$\mathrm{sym}(A) = \frac{1}{2}(A + A').$$

Apart from the standard operations with Kronecker products, notice that the following is true. For a row vector $H_{1\times nk}$ and column vectors $X_{n\times 1}$ and $W_{n\times 1}$

$$H(X \otimes W) = X'[\mathrm{mat}_{k,n}(H)]' W$$

and for a matrix $A_{n\times k}$, we have

$$X'AW = (\mathrm{vec}A')'(X \otimes W). \tag{A.4}$$

Also, for $A_{n\times n}$, $X_{n\times 1}$, $K_{k\times 1}$, we have

$$\begin{aligned}(AX) \otimes K &= (A \otimes K)X\\ K \otimes (AX) &= (K \otimes A)X.\end{aligned}$$

Finally, for column vectors $X_{n\times 1}$ and $W_{k\times 1}$,

$$(AX) \otimes (BW) = (A \otimes B)(X \otimes W)$$

and

$$(BW) \otimes (AX) = \left[B \otimes A_{\bullet j}\right]_{j=1}^{n} (X \otimes W)$$

where

$$\left[B \otimes A_{\bullet j}\right]_{j=1}^{n} = [B \otimes A_{\bullet 1} \quad B \otimes A_{\bullet 2} \quad \dots \quad B \otimes A_{\bullet n}].$$

A.2 Concise Notation for Derivatives

Consider a vector function $f(x, w)$ where x and w are column vectors of length m and n, respectively. The first-derivative matrix f_i where $i = x$, w is constructed as follows. The kth row $[f_i]_{k\bullet}$ corresponds to the derivative of the kth component of f

$$[f_i(x,w)]_{k\bullet} = \frac{\partial f^{(k)}}{\partial i'}(x,w).$$

Similarly, the second-derivative matrix is the matrix of vectorized and stacked Hessians of individual components with kth row

$$\left[f_{ij}(x,w)\right]_{k\bullet} = \left(\mathrm{vec}\frac{\partial^2 f^{(k)}}{\partial j \partial i'}(x,w)\right)'.$$

It follows from formula (A.4) that, for example,

$$x'\left(\frac{\partial^2 f^{(k)}}{\partial x \partial w'}(x,w)\right)w = \left(\operatorname{vec}\frac{\partial^2 f^{(k)}}{\partial w \partial x'}(x,w)\right)'(x\otimes w) = [f_{xw}(x,w)]_{k\bullet}(x\otimes w).$$

A.3 Conditional Expectations

Notice that a complete-the-squares argument implies that, for a $1\times k$ vector A, a $1\times k^2$ vector B, and a scalar function $f(w)$,

$$\begin{aligned} &E[\exp(B(W_{t+1}\otimes W_{t+1}) + AW_{t+1})f(W_{t+1})\,|\,\mathcal{F}_t] \\ &\quad = E\left[\exp\left(\frac{1}{2}W'_{t+1}(\mathrm{mat}_{k,k}(2B))W_{t+1} + AW_{t+1}\right)f(W_{t+1})\,|\,\mathcal{F}_t\right] \\ &\quad = |I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2B)]|^{-1/2}\exp\left(\frac{1}{2}A(I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2B)])^{-1}A'\right)\widetilde{E}\,[f(W_{t+1})\,|\,\mathcal{F}_t] \end{aligned} \tag{A.5}$$

where $\widetilde{\cdot}$ is a measure under which

$$W_{t+1}\sim N\big((I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2B)])^{-1}A', (I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2B)])^{-1}\big).$$

We start by utilizing formula (A.5) to compute

$$\begin{aligned} \bar{Y}(X_t) &= \log E[\exp(Y_{t+1} - Y_t)\,|\,\mathcal{F}_t] = \Gamma_0 + \Gamma_1 X_{1,t} + \Gamma_2 X_{2,t} + \Gamma_3(X_{1,t}\otimes X_{1,t}) \\ &\qquad + \log E\left[\exp\left(\left[\Psi_0 + X'_{1t}[\mathrm{mat}_{k,n}(\Psi_1)]'\right]W_{t+1} + \frac{1}{2}W'_{t+1}[\mathrm{mat}_{k,k}(\Psi_2)]W_{t+1}\right)\,|\,\mathcal{F}_t\right] \\ &= \Gamma_0 + \Gamma_1 X_{1,t} + \Gamma_2 X_{2,t} + \Gamma_3(X_{1,t}\otimes X_{1,t}) \\ &\quad -\frac{1}{2}\log|I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)]| + \frac{1}{2}\mu'(I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)])^{-1}\mu \end{aligned}$$

with μ defined as

$$\mu = \Psi'_0 + [\mathrm{mat}_{k,n}(\Psi_1)]X_{1,t}.$$

Reorganizing terms, we obtain

$$\bar{Y}(X_t) = \overline{\Gamma}_0 + \overline{\Gamma}_1 X_{1,t} + \overline{\Gamma}_2 X_{2,t} + \overline{\Gamma}_3(X_{1,t}\otimes X_{1,t}) \tag{A.6}$$

where

$$\begin{aligned} \overline{\Gamma}_0 &= \Gamma_0 - \frac{1}{2}\log|I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)]| + \frac{1}{2}\Psi_0(I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)])^{-1}\Psi'_0 \\ \overline{\Gamma}_1 &= \Gamma_1 + \Psi_0(I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)])^{-1}[\mathrm{mat}_{k,n}(\Psi_1)] \\ \overline{\Gamma}_2 &= \Gamma_2 \\ \overline{\Gamma}_3 &= \Gamma_3 + \frac{1}{2}\mathrm{vec}\left[[\mathrm{mat}_{k,n}(\Psi_1)]'(I_k - \mathrm{sym}[\mathrm{mat}_{k,k}(2\Psi_2)])^{-1}[\mathrm{mat}_{k,n}(\Psi_1)]\right]'. \end{aligned} \tag{A.7}$$

For the set of parameters $\mathcal{P} = (\Gamma_0, \ldots, \Gamma_3, \Psi_0, \ldots, \Psi_2)$, Eqs. (A.7) define a mapping

$$\bar{\mathcal{P}} = \bar{\mathcal{E}}(\mathcal{P}),$$

with all $\overline{\Psi}_j = 0$. We now substitute the law of motion for X_1 and X_2 to produce $\bar{Y}(X_t) = \widetilde{Y}(X_{t-1}, W_t)$. It is just a matter of algebraic operations to determine that

$$\begin{aligned}\widetilde{Y}(X_{t-1}, W_t) &= \log E[\exp(Y_{t+1} - Y_t) \mid \mathcal{F}_t] \\ &= \widetilde{\Gamma}_0 + \widetilde{\Gamma}_1 X_{1,t-1} + \widetilde{\Gamma}_2 X_{2,t-1} + \widetilde{\Gamma}_3 (X_{1,t-1} \otimes X_{1,t-1}) \\ &\quad + \widetilde{\Psi}_0 W_t + \widetilde{\Psi}_1 (X_{1,t-1} \otimes W_t) + \widetilde{\Psi}_2 (W_t \otimes W_t)\end{aligned}$$

where

$$\begin{aligned}\widetilde{\Gamma}_0 &= \overline{\Gamma}_0 + \overline{\Gamma}_1 \Theta_{10} + \overline{\Gamma}_2 \Theta_{20} + \overline{\Gamma}_3 (\Theta_{10} \otimes \Theta_{10}) \\ \widetilde{\Gamma}_1 &= \overline{\Gamma}_1 \Theta_{11} + \overline{\Gamma}_2 \Theta_{21} + \overline{\Gamma}_3 (\Theta_{10} \otimes \Theta_{11} + \Theta_{11} \otimes \Theta_{10}) \\ \widetilde{\Gamma}_2 &= \overline{\Gamma}_2 \Theta_{22} \\ \widetilde{\Gamma}_3 &= \overline{\Gamma}_2 \Theta_{23} + \overline{\Gamma}_3 (\Theta_{11} \otimes \Theta_{11}) \\ \widetilde{\Psi}_0 &= \overline{\Gamma}_1 \Lambda_{10} + \overline{\Gamma}_2 \Lambda_{20} + \overline{\Gamma}_3 (\Theta_{10} \otimes \Lambda_{10} + \Lambda_{10} \otimes \Theta_{10}) \\ \widetilde{\Psi}_1 &= \overline{\Gamma}_2 \Lambda_{21} + \overline{\Gamma}_3 \left(\Theta_{11} \otimes \Lambda_{10} + \left[\Lambda_{10} \otimes (\Theta_{11})_{\bullet j} \right]_{j=1}^{n} \right) \\ \widetilde{\Psi}_2 &= \overline{\Gamma}_2 \Lambda_{22} + \overline{\Gamma}_3 (\Lambda_{10} \otimes \Lambda_{10}).\end{aligned} \tag{A.8}$$

This set of equations defines the mapping

$$\widetilde{\mathcal{P}} = \widetilde{\mathcal{E}}(\bar{\mathcal{P}}).$$

A.4 Iterative Formulas

We can write the conditional expectation in (A.3) recursively as

$$\log E[M_t \mid \mathcal{F}_0] = \log E\left[\exp(Y_1 - Y_0) E\left[\frac{M_t}{M_1} \mid \mathcal{F}_1\right] \mid \mathcal{F}_0\right].$$

Given the mappings $\bar{\mathcal{E}}$ and $\widetilde{\mathcal{E}}$, we can therefore express the coefficients $\bar{\mathcal{P}}$ in (A.3) using the recursion

$$\bar{\mathcal{P}}_t = \bar{\mathcal{E}}\left(\mathcal{P} + \widetilde{\mathcal{E}}(\bar{\mathcal{P}}_{t-1})\right)$$

where the addition is by coefficients and all coefficients in $\bar{\mathcal{P}}_0$ are zero matrices.

A.5 Coefficients Φ_i^*

In the above calculations, we constructed a recursion for the coefficients in the computation of the conditional expectation of the multiplicative functional M. A single iteration of this recursion can be easily adapted to compute the coefficients $\mathbf{\Phi}_i^*$, $i=0, \ldots, 3,$ in the conditional expectation in Eq. (24) for an arbitrary function $\log f(x)$.

1. Associate $\log f(x_{t+1}) = \bar{Y}(x_{t+1})$ from Eq. (A.6), ie, set $\overline{\Gamma}_i$, $i=0, \ldots, 3$, in Eq. (A.6) equal to the desired $\mathbf{\Phi}_i$ from Eq. (23). These are the coefficients in set $\bar{\mathcal{P}}$.
2. Apply the mapping $\tilde{\mathcal{E}}\,(\bar{\mathcal{P}})$, ie, compute $\tilde{\Gamma}_i$, $i=0, \ldots, 3$, and $\tilde{\mathbf{\Psi}}_i$, $i=0, 1, 2$, using (A.8). This yields the function $\log \tilde{f}\,(x_t, w_{t+1}) \equiv \log f(x_{t+1})$, with coefficient set $\tilde{\mathcal{P}}$.
3. Add to these coefficients $\tilde{\Gamma}_i$ and $\tilde{\mathbf{\Psi}}_i$ the corresponding coefficients Γ_i and $\mathbf{\Psi}_i$ of $Y_{t+1} - Y_t$ from Eq. (A.2), ie, form coefficient set $\mathcal{P} + \tilde{\mathcal{E}}\,(\bar{\mathcal{P}})$.
4. Apply the mapping $\bar{\mathcal{E}}\left(\mathcal{P} + \tilde{\mathcal{E}}(\bar{\mathcal{P}})\right)$, ie, compute (A.7) where on the right-hand side the coefficients Γ_i and $\mathbf{\Psi}_i$ (coefficient set $\mathcal{P}$) are replaced with coefficients computed in the previous step, ie, set $\mathcal{P} + \tilde{\mathcal{E}}\,(\bar{\mathcal{P}})$.
5. The resulting coefficients $\overline{\Gamma}_i$, $i=0, \ldots, 3$, are the desired coefficients $\mathbf{\Phi}_i^*$.

Appendix B Shock Elasticity Calculations

In this appendix, we provide details on some of the calculations underlying the derived shock elasticity formulas for the convenient functional form from Section 5.1.1. In particular we show, using a complete-the-squares argument, that under the transformed measure generated by the random variable $L_{1,t}$ from (25) the shock W_1 remains normally distributed with a covariance matrix:

$$\tilde{\Sigma}_t = \left[I_k - 2\,\mathrm{sym}\left(\mathrm{mat}_{k,k} \left[\mathbf{\Psi}_2 + \mathbf{\Phi}_{2,t-1}^* \Lambda_{22} + \mathbf{\Phi}_{3,t-1}^* (\Lambda_{10} \otimes \Lambda_{10}) \right] \right) \right]^{-1},$$

where I_k is the identity matrix of dimension k.[w] We suppose that this matrix is positive definite. The conditional mean vector for W_1 under the change of measure is:

$$\tilde{E}\,[W_1 \mid X_0 = x] = \tilde{\Sigma}_t \left[\mu_{t,0} + \mu_{t,1} x_1 \right],$$

where $\tilde{E}$ is the expectation under the change of measure and the coefficients $\mu_{t,0}$ and $\mu_{t,1}$ are given in the following derivation.

Thus the shock elasticity is given by:

$$\begin{aligned} \varepsilon(x,t) &= \nu(x) \cdot E[L_{1,t} W_1 \mid X_0 = x] \\ &= \nu(x)' \tilde{\Sigma}_t \left[\mu_{t,0} + \mu_{t,1} x_1 \right]. \end{aligned}$$

The shock elasticity function in this environment depends on the first component, x_1, of the state vector. Recall from (21) that this component has linear dynamics. The

[w] This formula uses the result that $(\Lambda_{10} W_1) \otimes (\Lambda_{10} W_1) = (\Lambda_{10} \otimes \Lambda_{10})(W_1 \otimes W_1)$.

coefficient matrices for the evolution of the second component, x_2, nevertheless matter for the shock elasticities even though these elasticities do not depend on this component of the state vector.

B.1 Shock Elasticities Under the Convenient Functional Form

To calculate the shock elasticities in Section 5.1.1, utilize the formulas derived in Appendix A to deduce the one-period change of measure

$$\log L_{1,t} = \log M_1 + \log E\left(\frac{M_t}{M_1} \mid X_1\right) - \log E\left[M_1 E\left(\frac{M_t}{M_1} \mid X_1\right) \mid X_0 = x\right].$$

In particular, following the set of formulas (A.8), define

$$\begin{aligned}
\mu_{0,t} &= \left[\mathbf{\Psi}_1 + \mathbf{\Phi}^*_{1,t-1}\Lambda_{1,0} + \mathbf{\Phi}^*_{2,t-1}\Lambda_{20} + \mathbf{\Phi}^*_{3,t-1}(\mathbf{\Theta}_{10}\otimes\Lambda_{10} + \Lambda_{10}\otimes\mathbf{\Theta}_{10})\right]' \\
\mu_{1,t} &= \operatorname{mat}_{k,n}\left[\mathbf{\Psi}_1 + \mathbf{\Phi}^*_{2,t-1}\Lambda_{21} + \mathbf{\Phi}^*_{3,t-1}\left(\mathbf{\Theta}_{11}\otimes\Lambda_{10} + \left[\Lambda_{10}\otimes(\mathbf{\Theta}_{11})_{\bullet j}\right]_{j=1}^{n}\right)\right] \\
\mu_{2,t} &= \operatorname{sym}\left[\operatorname{mat}_{k,k}\left(\mathbf{\Psi}_2 + \overline{\Gamma}_2\Lambda_{22} + \overline{\Gamma}_3(\Lambda_{10}\otimes\Lambda_{10})\right)\right].
\end{aligned}$$

Then it follows that

$$\begin{aligned}
\log L_{1,t} \; &= (\mu_{0,t} + \mu_{1,t}X_{1,0})' W_1 + (W_1)'\mu_{2,t}W_1 \\
&\quad -\frac{1}{2}\log E\left[\exp\left((\mu_{0,t} + \mu_{1,t}X_{1,0})' W_1 + (W_1)'\mu_{2,t}W_1\right) \mid \mathcal{F}_0\right].
\end{aligned}$$

Expression (A.5) then implies that

$$\begin{aligned}
E[L_{1,t}W_1 \mid \mathcal{F}_0] &= \widetilde{E}[W_1 \mid \mathcal{F}_0] \\
&= \left(I_k - 2\mu_{2,t}\right)^{-1}\left(\mu_{0,t} + \mu_{1t}X_{1,0}\right).
\end{aligned}$$

The variance of W_1 under the $\widetilde{\cdot}$ measure satisfies

$$\widetilde{\Sigma}_t = \left(I_k - 2\operatorname{sym}\left[\operatorname{mat}_{k,k}\left(\mathbf{\Psi}_2 + \overline{\Gamma}_2\Lambda_{22} + \overline{\Gamma}_3(\Lambda_{10}\otimes\Lambda_{10})\right)\right]\right)^{-1}.$$

B.2 Approximation of the Shock Elasticity Function

In Section 5.3.1, we constructed the approximation of the shock elasticity function $\varepsilon(x,t)$. The first-order approximation is constructed by differentiating the elasticity function under the perturbed dynamics

$$\varepsilon_1(X_{1,0},t) = \frac{d}{d\mathsf{q}}\nu(X_0(\mathsf{q}))\cdot\left.\frac{E[M_t(\mathsf{q})W_1 \mid X_0 = x]}{E[M_t(\mathsf{q}) \mid X_0 = x]}\right|_{\mathsf{q}=0} = \nu(\bar{x})\cdot E[Y_{1,t}W_1 \mid X_0 = x].$$

The first-derivative process $Y_{1,t}$ can be expressed in terms of its increments, and we obtain a state-independent function

$$\varepsilon_1(t) = \nu(\bar{x}) \cdot E\left[\sum_{j=1}^{t-1} \kappa_x (\psi_x)^{j-1} \psi_w + \kappa_w\right]'$$

where κ_x, ψ_x, κ_w, ψ_w are derivative matrices evaluated at the steady state $(\bar{x}, 0)$.

Continuing with the second derivative, we have

$$\begin{aligned}
\varepsilon_2(X_{1,0}, X_{2,0}, t) \; &= \frac{d^2}{d\mathsf{q}^2} \nu(X_0(\mathsf{q})) \cdot \frac{E[M_t(\mathsf{q}) W_1 \mid X_0 = x]}{E[M_t(\mathsf{q}) \mid X_0 = x]}\bigg|_{\mathsf{q}=0} \\
&= \nu(\bar{x}) \cdot \left\{ E\left[(Y_{1,t})^2 W_1 + Y_{2,t} W_1 \mid \mathcal{F}_0\right] - 2E[Y_{1,t} W_1 \mid \mathcal{F}_0] E[Y_{1,t} \mid \mathcal{F}_0] \right\} \\
&\quad + 2\left[\frac{\partial \nu}{\partial x'}(\bar{x})\right] X_{1,0} \cdot E[Y_{1,t} W_1 \mid \mathcal{F}_0].
\end{aligned}$$

However, notice that

$$\begin{aligned}
E\left[(Y_{1,t})^2 W_1 \mid \mathcal{F}_0\right] &= 2\left(\sum_{j=0}^{t-1} \kappa_x (\psi_x)^j X_{1,0}\right) \left(\sum_{j=1}^{t-1} \kappa_x (\psi_x)^{j-1} \psi_w + \kappa_w\right)' \\
E[Y_{1,t} W_1 \mid \mathcal{F}_0] &= \left(\sum_{j=1}^{t-1} \kappa_x (\psi_x)^{j-1} \psi_w + \kappa_w\right)' \\
E[Y_{1,t} \mid \mathcal{F}_0] &= \sum_{j=0}^{t-1} \kappa_x (\psi_x)^j X_{1,0}
\end{aligned}$$

and thus

$$E\left[(Y_{1,t})^2 W_1 \mid \mathcal{F}_0\right] - 2E[Y_{1,t} W_1 \mid \mathcal{F}_0] E[Y_{1,t} \mid \mathcal{F}_0] = 0.$$

The second-order term in the approximation of the shock elasticity function thus simplifies to

$$\varepsilon_2(X_{1,0}, X_{2,0}, t) = \nu(\bar{x}) \cdot E[Y_{2,t} W_1 \mid \mathcal{F}_0] + 2\left[\frac{\partial \nu}{\partial x'}(\bar{x})\right] X_{1,0} \cdot E[Y_{1,t} W_1 \mid \mathcal{F}_0].$$

The expression for the first term on the right-hand side is

$$\begin{aligned}
E[Y_{2,t} W_1 \mid \mathcal{F}_0] \; &= E\left[\sum_{j=0}^{t-1} \left(Y_{2,j+1} - Y_{2,j}\right) W_1 \mid \mathcal{F}_0\right] = 2\mathrm{mat}_{k,n}(\kappa_{xw}) X_{1,0} \\
&\quad + 2\sum_{j=1}^{t-1} \left[\psi_w' \left(\psi_x'\right)^{j-1} \mathrm{mat}_{n,n}(\kappa_{xx}) (\psi_x)^j + \mathrm{mat}_{k,n}\left[\kappa_x (\psi_x)^{j-1} \psi_{xw}\right]\right] X_{1,0} \\
&\quad + 2\sum_{j=1}^{t-1} \sum_{k=1}^{j-1} \left[\psi_w' \left(\psi_x'\right)^{k-1} \mathrm{mat}_{n,n}\left[\kappa_x (\psi_x)^{j-k-1} \psi_{xx}\right] (\psi_x)^k\right] X_{1,0}.
\end{aligned}$$

To obtain this result, notice that repeated substitution for $Y_{1,j+1} - Y_{1,j}$ into the above formula yields a variety of terms but only those containing $X_{1,0} \otimes W_1$ have a nonzero conditional expectation when interacted with W_1.

ACKNOWLEDGMENTS

We would like to thank John Heaton and Vadim Linetsky for helpful comments. Spencer Lyon and Victor Zhorin provided excellent research assistance.

Abstract

This chapter is on quantitative models of sovereign debt crises in emerging economies. We interpret debt crises broadly to cover all of the major problems a country can experience while trying to issue new debt, including default, sharp increases in the spread and failed auctions. We examine the spreads on sovereign debt of 20 emerging market economies since 1993 and document the extent to which fluctuations in spreads are driven by country-specific fundamentals, common latent factors and observed global factors. Our findings motivate quantitative models of debt and default with the following features: (i) trend stationary or stochastic growth, (ii) risk averse competitive lenders, (iii) a strategic repayment/borrowing decision, (iv) multiperiod debt, (v) a default penalty that includes both a reputation loss and a physical output loss, and (vi) rollover defaults. For the quantitative evaluation of the model, we focus on Mexico and carefully discuss the successes and weaknesses of various versions of the model. We close with some thoughts on useful directions for future research.

1. INTRODUCTION

This chapter is about sovereign debt crises, instances in which a government has trouble selling new debt. An important example is when a government is counting on being able to roll over its existing debt in order to service it over time. When we refer to trouble selling its debt, we include being able to sell new debt but only with a large jump in the spread on that debt over comparable risk-free debt, failed auctions, suspension of payments, creditor haircuts and outright default. So our notion of a debt crisis covers all of the major negative events that one associates with sovereign debt issuance.

We focus on debt crises in developing countries because the literature has focused on them and because these countries provide the bulk of our examples of debt crises and defaults. However, the recent debt crises in the European Union remind us that this is certainly not always the case. While the recent crises in the EU are of obvious interest, they come with a much more complicated strategic dimension, given the role played by the European Central Bank and Germany in determining the outcomes for a country like, say, Greece. For this reason we will hold to a somewhat more narrow focus. Despite this, we see our analysis as providing substantial insight into sovereign debt crises in developed countries as well.

This chapter will highlight quantitative models of the sovereign debt market. We will focus on determining where the current literature stands and where we need to go next. Hence, it will not feature an extensive literature survey, though we will of course survey the literature to some extent, including a brief overview at the end of the chapter. Instead, we will lay out a fairly cutting-edge model of sovereign debt issuance and use that model and its various permutations to gauge the successes and failures of the current literature as we see them.

The chapter will begin by considering the empirical evidence on spreads. We will examine the magnitude and volatility of spreads on sovereign debt among developing countries. We will seek to gauge the extent to which this debt features a risk premium in addition to default risk. We will also seek to characterize the extent to which the observed spread is driven by country-specific fundamentals, global financial risk and uncertainty factors, or other common drivers. To do this, we will estimate a statistical model of the spread process in our data, and this statistical model will feature several common factors that we estimate along with the statistical model. The facts that emerge from this analysis will then form the basis on which we will judge the various models that we consider in the quantitative analysis.

The chapter will then develop a quantitative model of sovereign debt that has the following key features: risk-averse competitive lenders, since it will turn out that risk premia are substantial, and a strategic sovereign who chooses how much to borrow and whether or not to repay, much as in the original Eaton and Gersovitz (1981) model. The sovereign will issue debt that has multiperiod maturity. While we will take the maturity of the debt to be parametric, being able to examine the implications of short and long maturity is an important aspect of the analysis. Default by the sovereign will feature two punishments: a period of exclusion from credit markets and a loss in output during the period of exclusion. Pure reputation effects are known to fail (Bulow and Rogoff, 1989) and even coupling them with a loss of saving as well as borrowing does not generate a sufficient incentive to repay the sorts of large debts that we see in the data. Hence, we include the direct output cost as well.

Our model will feature both fundamental defaults, in which default is taking place under the best possible terms (fixing future behavior). The model will also allow for rollover or liquidity defaults, in which default occurs when lending takes place under the worst possible terms (again, fixing future behavior) as in Cole and Kehoe (2000). We include both types of defaults since they seem to be an important component of the data. Doing so, especially with multiperiod debt maturity, will require some careful modeling of the timing of actions within the period and a careful consideration of both debt issuance and debt buybacks. In addition, the possibility of future rollover crises will affect the pricing of debt today and the incentives to default, much as in the original Calvo (1988) model.

We will consider two different growth processes for our borrowing countries. The first will feature stochastic fluctuations around a deterministic trend with constant growth. The second will feature stochastic growth shocks. We include the deterministic trend process because the literature has focused on it. However, the notion that we have roughly the same uncertainty about where the level of output of a developing country will be in 5 years and in 50 years seems sharply counterfactual, as documented by Aguiar and Gopinath (2007). Hence our preferred specification is the stochastic growth case and, so, we discuss this case as well.

There will be three shocks in the model. The first is a standard output shock that will vary depending on which growth process we assume. The second is a shock to lender wealth. The third is a belief-coordination shock that will determine whether a country gets the best or the worst possible equilibrium price schedule in a period. An important question for us will be the extent to which these shocks can generate movements in the spread that are consistent with the patterns we document in our empirical analysis of the data.

The chapter will examine two different forms of the output default cost. The first is a proportional default cost as has been assumed in the early quantitative analyses and in the theoretical literature on sovereign default. The second form is a nonlinear output cost such as was initially pioneered by Arellano (2008). In this second specification, the share of output lost in default depends positively on (predefault) output. Thus, default becomes a more effective mechanism for risk sharing compared to the proportional cost case. As noted in Chatterjee and Eyigungor (2012), adding this feature also helps to increase the volatility of sovereign spreads.

2. MOTIVATING FACTS

2.1 Data for Emerging Markets

We start with a set of facts that will guide us in developing our model of sovereign debt crises. Our sample spans the period 1993Q4–2014Q4 and includes data from 20 emerging markets: Argentina, Brazil, Bulgaria, Chile, Colombia, Hungary, India, Indonesia, Latvia, Lithuania, Malaysia, Mexico, Peru, Philippines, Poland, Romania, Russia, South Africa, Turkey, and Ukraine. For each of these economies, we have data on GDP in US dollars measured in 2005 domestic prices and exchange rates (real GDP), GDP in US dollars measured in current prices and exchange rates (nominal GDP), gross external debt in US dollars (debt), and market spreads on sovereign debt.[a]

Tables 1 and 2 report summary statistics for the sample.[b] Table 1 documents the high and volatile spreads that characterized emerging market sovereign bonds during this period. The standard deviation of the level and quarterly change in spreads 676 and

[a] Data source for GDP and debt is Haver Analytics' Emerge database. The source of the spread data is JP Morgan's Emerging Market Bond Index (EMBI).

[b] Note that Russia defaulted in 1998 and Argentina in 2001, and while secondary market spreads continued to be recorded post default, these do not shed light on the cost of new borrowing as the governments were shut out of international bond markets until they reached a settlement with creditors. Similarly, the face value of debt is carried throughout the default period for these economies.

Table 1 Sovereign spreads: Summary statistics

Country	Mean $r - r^*$	Std dev $r - r^*$	Std dev $\Delta(r - r^*)$	95th pct $\Delta(r - r^*)$	Frequency crisis
Argentina	1525	1759	610	717	0.18
Brazil	560	393	174	204	0.09
Bulgaria	524	486	129	155	0.03
Chile	146	57	34	34	0.00
Colombia	348	206	88	245	0.05
Hungary	182	154	57	88	0.02
India	225	54	47	85	0.00
Indonesia	285	137	98	73	0.02
Latvia	157	34	16	17	0.00
Lithuania	246	92	48	98	0.00
Malaysia	175	122	75	81	0.03
Mexico	345	253	134	127	0.05
Peru	343	196	84	182	0.06
Philippines	343	153	75	136	0.04
Poland	191	138	54	67	0.01
Romania	271	102	49	68	0.00
Russia	710	1096	478	175	0.06
South Africa	226	116	68	99	0.03
Turkey	395	217	95	205	0.05
Ukraine	760	607	350	577	0.11
Pooled	431	676	229	158	

229 basis points, respectively. Table 2 reports an average external debt-to-(annualized) GDP ratio of 0.46. This level is low relative to the public debt levels observed in developed economies. The fact that emerging markets generate high spreads at relatively low levels of debt-to-GDP reflects one aspect of the "debt intolerance" of these economies documented by Reinhart et al. (2003).

The final column concerns "crises," which we define as a change in spreads that lie in the top 5% of the distribution of quarterly changes. This threshold is a 158 basis-point jump in the spread. By construction, 5% of the changes are coded as crises; however, the frequency of crises is not uniform across countries. Nearly 20% of Argentina's quarter-to-quarter changes in spreads lie above the threshold, while many countries have no such changes.

While many of the countries in our sample have very high spreads, only two—Russia in 1998 and Argentina in 2001—ended up defaulting on their external debt, while a third, Ukraine, defaulted on its internal debt (in 1998). This highlights the fact that periods of high spreads are more frequent events than defaults. Nevertheless, it is noteworthy that the countries with the highest mean spreads are the ones that ended up defaulting during this period. This suggests that default risk and the spread are connected.

Table 2 Sovereign spreads: Summary statistics

Country	Mean $\frac{B}{4{*}Y}$	Corr $(\Delta(r - r^{*}),\Delta y)$	Corr $(r - r^{*},\%\Delta B)$	Corr $(\Delta(r - r^{*}),\%\Delta B)$

2.2 Statistical Spread Model

To further evaluate the empirical behavior of emerging market government bond spreads, we fit a statistical model to our data. In this model a country's spread is allowed to depend on country-specific fundamentals as well as several mutually orthogonal common factors (common across emerging markets) that we will implicitly determine as part of the estimation. To do this, we use EMBI data at a quarterly frequency. We have data for $I=20$ countries from 1993:Q4–2015:Q2 (so $T=87$), with sporadic missing values. If we index a country by i and a quarter by t, then we observe spreads, debt-to-GDP ratios, and real GDP growth: $\{s_{it}, b_{it}, g_{it}\}_{i=1,t=1}^{I,T}$. We also suppose that there are a set of J common factors that impact all the countries (though perhaps not symmetrically): $\{\alpha_t^j\}_{j=1}^{J}$.

We specify our statistical model as follows:

$$s_{it} = \beta_i b_{it} + \gamma_i g_{it} + \sum_{j=1}^{J} \delta_i^j \alpha_t^j + \kappa_i + \epsilon_{it}, \tag{1}$$

where ϵ_{it} is a mean-zero, normally distributed shock with variance σ_i^2. Notice that we allow for the average spread and innovation volatility to vary across countries. In the estimation we impose the constraint that $\delta_i^j \geq 0$ for all i, so we are seeking common factors that cause all spreads to rise and fall together.

These common factors are permitted to evolve as follows. Let α_t be the J-dimensional vector of common factors at time t. Then

$$\alpha_t = \Gamma \alpha_{t-1} + \eta_t \tag{2}$$

where η_t is a J-dimensional vector of normally distributed i.i.d. innovations orthogonal to each other. Because we estimate separate impact coefficients for each common factor, we normalized the innovation volatilities to 0.01. We restrict Γ to be a diagonal matrix, ie, our common factors are assumed to be orthogonal and to follow AR(1) processes.

To estimate this model, we transform it into state-space form and apply MLE. We apply the (unsmoothed) Kalman Filter to compute the likelihood for a given parameterization. When the model encounters missing values, we will exclude those values from the computation of the likelihood and the updating of the Kalman Filter. Thus, missing values will count neither for nor against a given parameterization.

Table 3 reports the explanatory power of the country-specific fundamentals as well as the two global factors. Specifically, we construct a variance decomposition following the algorithm of Lindeman et al. (1980) as outlined by Gromping (2007). This procedure constructs the average marginal R^2 in the case of correlated regressors by assuming a uniform distribution over all possible permutations of the regression coefficients. We can see

Table 3 Country-specific variance decomposition average marginal R^2

Country (i)	b_{it}	g_{it}	α_t^1	α_t^2	R^2	Obs.
Argentina	0.16	0.01	0.20	0.02	0.39	39
Brazil	0.28	0.01	0.52	0.05	0.87	81
Bulgaria	0.18	0.01	0.44	0.27	0.90	59
Chile	0.05	0.13	0.38	0.21	0.77	63
Colombia	0.20	0.05	0.55	0.16	0.95	55
Hungary	0.28	0.19	0.05	0.12	0.64	63
India	0.10	0.26	0.32	0.32	1.00	8
Indonesia	0.09	0.07	0.38	0.45	0.99	43
Latvia	0.03	0.03	0.86	0.08	1.00	9

Turkey	0.05	0.09	0.77	0.04	0.94	74
Ukraine	0.02	0.26	0.20	0.41	0.89	44

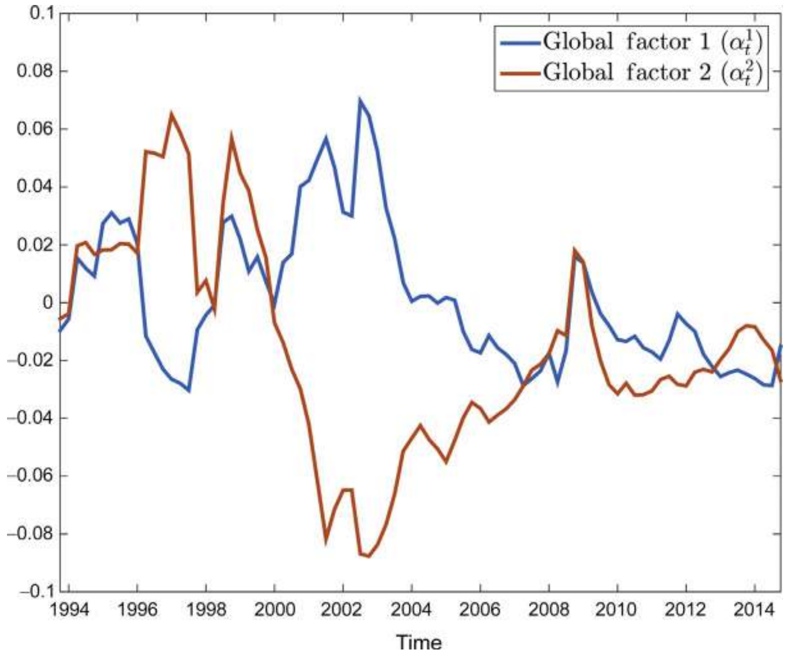

Fig. 1 Estimated common factors.

from this table first that our regressors explain much of the variation for many of the countries (as high as 99.88% for India). We can also see that country-specific fundamentals, here in the form of the debt-to-GDP ratio and the growth rate of output, explain only a modest amount of the variation in the spreads; typically less than 20%. This means that much of the movement in the spreads is explained by our two orthogonal factors.

Fig. 1 plots our two common factors.[c] Given the importance our estimation ascribes to them, we sought to uncover what is really driving their movements. To do this, we use a regression to try to construct our estimated common factors from the CBOE VIX, S&P 500 Diluted Earnings P/E ratio, and the LIBOR.[d] These regressors are standard measures of foreign financial-market uncertainty, price of risk and borrowing costs, respectively. These results are reported in table 4. The top panel reports the results from regressing the level of the factors on the level of foreign financial variables and the bottom reports the comparable regressions in first differences. We find that the foreign financial variables explain a modest amount of the variation in the level of the common factors: Each has an R^2 less than 0.3. To the extent that these objects do explain the common factors, however, it seems as if common factor 1 is driven primarily by measures of investor

[c] See Longstaff et al. (2011) for a related construction of a global risk factor.

[d] The LIBOR is almost perfectly correlated with the fed funds rate, so for precision of estimates we exclude the latter.

Table 4 Common factor regressions: Levels

Index		VIX	P/E ratio	LIBOR	R^2
Levels					
α_t^1	Coefficient	$8.32e-4$ (3.36e−4)	$2.00e-3$ (6.31e−4)	$9.75e-4$ (1.1e−3)	
	Var decomp	0.10	0.17	0.02	0.29
α_t^2	Coefficient	$6.1383e-4$ (5.0460e−4)	−0.0017 (9.4742e−4)	0.0088 (0.0017)	
	Var decomp	$-4.0795e-5$	−0.0058	0.2722	0.27
First differences					
α_t^1	Coefficient	0.001 (0.002)	−0.001 (0.001)	−0.001 (0.002)	
	Var decomp	0.30	0.06	0.00	0.35
α_t^2	Coefficient	0.001 (<0.001)	0.001 (0.001)	0.002 (0.003)	
	Var decomp	0.05	<0.01	0.01	0.06

uncertainty and the price of risk, while common factor 2 is driven primarily by world interest rates. In first differences, the foreign factors explain a third of the variation in the first factor but very little of the second factor.

There is an additional surprising finding about how risk pricing impacts our spreads. The coefficient on the P/E ratio for the level specification is *positive* in common factor 1, where it has a substantial impact. Since an increase in the price of risk will drive down the P/E ratio, this means that our spreads are rising when the market price of risk is falling. This is the opposite of what our intuition might suggest. This coefficient reverses sign in the first-difference specification, reflecting that the medium run and longer correlation between the P/E ratio and our first factor has the opposite sign of the quarter-to-quarter correlation. The first-difference specification is what has been studied in the literature (Longstaff et al., 2011; Borri and Verdelhan, 2011). These results show that the foreign risk premium may influence spreads differentially on impact vs in the longer run.

2.3 Excess Returns

We turn next to the relationship between spreads and defaults. One of the striking facts here is that spreads "over-predict" future defaults in that ex post returns exceed the return on risk-free assets. Hence, risk premia play an important role.

The fact that spreads are compensating lenders for more than the risk-neutral probability of default is suggested by the statistics reported in Table 1. The average spread is relatively high, and there are significant periods in which spreads are several hundred basis points. However, the sample contains only two defaults: Russia in 1998 and Argentina in 2001.

To explore this more systematically, we compute the realized returns on the EMBI+ index, which represents a value-weighted portfolio of emerging country debt constructed by JP Morgan. In Table 5, we report the return on this portfolio for the full

Table 5 Realized bond returns

Period	EMBI+	2-Year treasury	5-Year treasury
1993Q1–2014Q4	9.7	3.7	4.7
1993Q1–2003Q4	11.1	5.4	6.3
2004Q1–2014Q4	8.2	2.0	3.1

sample period the index is available, as well as two subperiods. The table also reports the returns to the portfolio of US Treasury securities of 2 years and 5 years maturity. We offer two risk-free references, as the EMBI+ does not have a fixed maturity structure and probably ranges between 2 and 5 years.

The EMBI+ index paid a return in excess of the risk-free portfolio of 5 to 6%. This excess return is roughly stable across the two subperiods as well. Whether the realized return reflects the ex ante expected return depends on whether our sample accurately reflects the population distribution of default and repayment. The assumption is that by pooling a portfolio of bonds, the EMBI+ followed over a 20 year period provides a fair indication of the expected return on a typical emerging market bond. Of course, we cannot rule out the possibility that this sample is not representative. Nevertheless, the observed returns are consistent with a fairly substantial risk premium charged to sovereign borrowers.

2.4 Deleveraging

The data from emerging markets can also shed light on debt dynamics during a crisis. Table 2 documents that periods of above-average spreads are associated with reductions in the face value of gross external debt. The pooled correlation of spreads at time t and the percentage change in debt between $t-1$ and t is -0.19. The correlation of the *change* in spread and debt is roughly zero. However, a large change in the spread (that is, a crisis period) is associated with a subsequent decline in debt. In particular, regressing the percent change in debt between t and $t+1$ on the indicator for a crisis in period t generates a coefficient of -1.6 and a t-stat of nearly 3. This relationship is robust to the inclusion of country fixed effects. This implies that a sharp spike in spreads is associated with a subsequent decline in the face value of debt.

2.5 Taking Stock

Our empirical analysis has led us to a set of criteria that we would like our model to satisfy. Specifically:

1. Crises, and particularly defaults, are low probability events;
2. Crises are not tightly connected to poor fundamentals;

3. Spreads are highly volatile;
4. Rising spreads are associated with deleveraging by the sovereign; and
5. Risk premia are an important component of sovereign spreads.

In considering which features of real-world economies are important in generating these patterns, the first thing to recognize is that sovereign debt lacks a direct enforcement mechanism: most countries default despite having the physical capacity to repay. Yet, countries seem perfectly willing to service significant amounts of debt most of the time (rescheduling of debts and outright default are relatively rare events). Without any deadweight costs of default, the level of debt that a sovereign would be willing to repay is constrained by the worst punishment lenders can inflict on the sovereign, namely, permanent exclusion from all forms of future credit. It is well known that this punishment is generally too weak, quantitatively speaking, to sustain much debt (this is spelled out in a numerical example in Aguiar and Gopinath, 2006). Thus, we need to posit substantial deadweight costs of default.

Second, defaults actually occurring in equilibrium reflect the fact that debt contracts are not fully state-contingent, and default provides an implicit form of insurance. However, with rational risk-neutral lenders who break even, on average, for every loan they make to sovereigns, the deadweight cost of default (which does not accrue to lenders) makes default an actuarially unfair form of insurance against bad states of the world for the sovereign. And, with risk-averse lenders, this insurance-through-default becomes even more actuarially unfair. Given fairly substantial deadweight costs of default and substantial risk aversion on the part of lenders, the insurance offered by the possibility of default appears to be quite costly in practice. The fact that countries carry large external debt positions despite the costs suggests that sovereigns are fairly impatient.

However, while myopia can explain in part why sovereigns borrow, it does not necessarily explain why they default. As noted already, default is a very costly form of insurance against bad states of the world. This fact—via equilibrium prices—can be expected to encourage the sovereign to stay away from debt levels for which the probability of default is significant. This has two implications. First, when crises/defaults do materialize, they come as a surprise, which is consistent with these events being low probability. Unfortunately, the other side of this coin is that getting the mean and volatility of spreads right is a challenge for quantitative models. Getting high and variable spreads means getting periods of high default risk as well as substantial variation in expected future default risk. This will be difficult to achieve when the borrower has a strong incentive to adjust his debt-to-output level to the point where the probability of future default is (uniformly) low.

3. ENVIRONMENT

Our environment is a simplified version of the one introduced in ACCS (2016). The analysis focuses on a sovereign government that makes consumption and savings/

borrowing decisions on behalf of the denizens of a small open economy facing a fluctuating endowment stream. The economy is small relative to the rest of the world in the sense that the sovereign's decisions do not affect any world prices, including the world risk-free interest rate. However, the sovereign faces a segmented credit market in that it can only borrow from a set of risk-averse potential lenders with limited wealth. In this section, we proceed by describing the economy of which the sovereign is in charge, the sovereign's decision problem and the lenders' decision problem. We then give the definition of an equilibrium and discuss issues related to equilibrium selection. We conclude the section by briefly describing how we compute the model.

3.1 The Economy

3.1.1 Endowments

Time is discrete and indexed by $t = 0, 1, 2, \ldots$. The economy receives a stochastic endowment $Y_t > 0$ each period. We assume that

$$\ln Y_t = \sum_{s=1}^{t} g_s + z_t, \tag{3}$$

where g_t and z_t follow first-order Markov processes. This specification follows Aguiar and Gopinath (2006, 2007) and nests the endowment processes that have figured in quantitative studies. In particular, setting $g_t = g$ generates a deterministic linear trend. More generally, g_t can be random, which corresponds to the case of a stochastic trend. In either case, z_t is transitory (but potentially persistent) fluctuations around trend growth. In this chapter we will study both specifications in some detail.

3.1.2 Preferences

The economy is run by an infinitely-lived sovereign government. The utility obtained by the sovereign from a sequence of aggregate consumption $\{C_t\}_{t=0}^{\infty}$ is given by:

$$\sum_{t=0}^{\infty} \beta^t u(C_t),\ 0 < \beta < 1 \tag{4}$$

and

$$u(C) = \begin{cases} C^{1-\sigma}/(1-\sigma) & \text{for } \ \sigma \geq 0 \text{ and } \sigma \neq 1 \\ \ln(C) & \text{for } \ \sigma = 1 \end{cases} \tag{5}$$

It is customary to assume that the sovereign has enough instruments to implement any feasible consumption sequence as a competitive equilibrium and, thus, abstract from the problem of individual residents of the economy. This does not mean that the government necessarily shares the preferences of its constituents, but rather that it is the relevant decision maker vis-a-vis international financial markets.[e]

3.1.3 Financial Markets and the Option to Default

The sovereign issues noncontingent bonds to a competitive pool of lenders. Bonds pay a coupon every period up to and including the period of maturity, which, without loss of generality, we normalize to r^* per unit of face value, where r^* is the (constant) international risk-free rate. With this normalization, a risk-free bond will have an equilibrium price of one. For tractability, bonds are assumed to mature randomly as in Leland (1994).[f] Specifically, the probability that a bond matures next period is a constant $\lambda \in [0,1]$. The constant hazard of maturity implies that all bonds are symmetric before the realization of maturity at the start of the period, regardless of when they were issued. The expected maturity of a bond is $1/\lambda$ periods and so $\lambda = 0$ is a consol and $\lambda = 1$ is a one-period bond. When each unit of a bond is infinitesimally small and any given unit matures independently of all other units, a fraction λ of any nondegenerate portfolio of bonds will mature with probability 1 in any period. With this setup, a portfolio of sovereign bonds of measure B gives out a payment (absent default) of $(r^* + \lambda)B$ and has a continuation face value of $(1 - \lambda)B$.

We will explore the quantitative implications of different maturities, but in any given economy, bonds with only one specific λ are traded. The stock of bonds at the start of any period—inclusive of bonds that will mature in that period—is denoted B. We do not restrict the sign of B, so the sovereign could be a creditor ($B < 0$) or a debtor ($B > 0$). If $B < 0$, the sovereign's (foreign) assets are assumed to be in risk-free bonds that mature with probability λ and pay interest (coupon) of r^* until maturity. The net issuance of bonds in any period is $B' - (1 - \lambda)B$, where B' is the stock of bonds at the end of the period. If the net issuance is negative, the government is either purchasing its outstanding debt or accumulating foreign assets; if it is positive, it is either issuing new debt or deaccumulating foreign assets.

If the sovereign is a debtor at the start of a period, it is contractually obligated to pay λB in principal and r^*B in interest (coupon) payments. The sovereign has the option to default on this obligation. The act of default immediately triggers exclusion from international financial markets (ie, no saving or borrowing is permitted) starting in the next period. Following the period of mandatory exclusion, exclusion continues with constant probability $(1 - \xi) \in (0,1)$ per period. Starting with the period of mandatory exclusion and continuing for as long as exclusion lasts, the sovereign loses a proportion $\phi(g, z)$ of

[e] In particular, one interpretation of the environment is that C_t represents public spending and Y_t the available revenue that is allocated by the government.

[f] See also Hatchondo and Martinez (2009), Chatterjee and Eyigungor (2012), and Arellano and Ramanarayanan (2012).

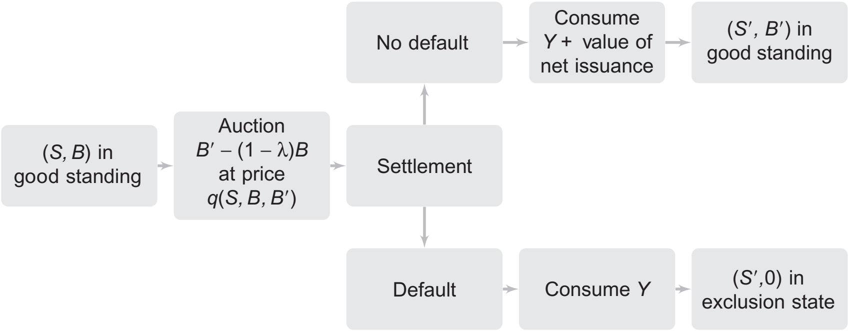
(nondefault state) output Y. When exclusion ends, the sovereign's debts are forgiven and it is allowed to access financial markets again.

3.1.4 Timing of Events

The timing of events within a period is depicted in Fig. 2. A sovereign in good standing observes S, the vector of current-period realizations of all exogenous shocks, and decides to auction $B' - (1-\lambda)B$ units of debt, where B' denotes the face value of debt at the start of the next period. If the sovereign does not default at settlement, it consumes the value of its endowment plus the value of its net issuance (which could be positive or negative) and proceeds to the next period in good standing.

If the sovereign defaults at settlement, it does not receive the auction proceeds and it is excluded from international credit markets. Thus it consumes its endowment and proceeds to the next period in which it is also excluded from borrowing and lending. We assume that the amount raised via auction, if any, is disbursed to all existing bondholders in proportion to the face value of their bond positions, ie, each unit of outstanding bonds is treated equally and receives $q(S,B,B')(B' - (1-\lambda)B)/B'$. The implication is that as long as $B > 0$ purchasers of newly issued bonds suffer an immediate loss following default. If the sovereign defaults at settlement after purchasing bonds (ie, after a buyback of existing debt), we assume that it defaults on its new payment obligations along with any remaining outstanding debt (this is a simplification relative Aguiar et al., 2016). Thus the sovereign consumes its endowments in this case as well (and moves on to the next period in a state of financial exclusion).

Our timing regarding default deviates from that of Eaton and Gersovitz (1981), which has become the standard in the quantitative literature. In the Eaton–Gersovitz timing, the bond auction occurs after that period's default decision is made. That is, the government is the Stackelberg leader in its default decision in a period. Thus newly auctioned bonds do not face any within-period default risk and, so, the price of bonds depend only on the exogenous states S and the amount of bonds the sovereign exits a period with, B'. Our timing expands the set of equilibria relative to the Eaton–Gersovitz timing, and in



No default
Consume Y + value of net issuance
(S', B') in good standing
(S, B) in good standing
Auction $B' - (1-\lambda)B$ at price $q(S, B, B')$
Settlement
Default
Consume Y
(S',0) in exclusion state

Fig. 2 Timing within a Period.

particular allows a tractable way of introducing self-fulfilling debt crises, as explained in Section 3.5.[g] It is also worth pointing out that implicit in the timing in Fig. 2 is the assumption that there is only one auction per period. While this assumption is standard, it does allow the sovereign to commit to the amount auctioned within a period.[h]

3.2 The Sovereign's Decision Problem

We will state the sovereign's decision problem in recursive form. To begin, the vector $S \in \mathscr{S}$ of exogenous state variables consists of the current endowment Y and current period realizations of the endowment shocks g and z; it also contains W, the current period wealth of the representative lender, as this will affect the supply of foreign credit; and it contains $x \in [0,1]$, a variable that indexes investor beliefs regarding the likelihood of a rollover crisis (explained more in Section 3.5). Both W and x are stochastic and assumed to follow first-order Markov processes. We assume that all conditional expectations of the form $\mathbb{E}_S f(S', \cdot)$ encountered below are well defined.

Let $V(S, B)$ denote the sovereign's optimal value conditional on S and B. Working backwards through a period, at the time of settlement the government has issued $B' - (1-\lambda)B$ units of new debt at price $q(S,B,B')$ and owes $(r^* + \lambda)B$. If the government honors its obligations at settlement, its payoff is:

$$V^R(S,B,B') = \begin{cases} u(C) + \beta \mathbb{E}_S V(S',B') & \text{if } C \geq 0 \\ -\infty & \text{otherwise} \end{cases}. \tag{6}$$

where

$$C = Y + q(S,B,B')[B' - (1-\lambda)B] - (r^* + \lambda)B. \tag{7}$$

If the sovereign defaults at settlement, its payoff is:

$$V^D(S) = u(Y) + \beta \mathbb{E}_S V^E(S') \tag{8}$$

where

$$V^E(S) = u(Y(1-\phi(g,z))) + \beta \mathbb{E}_S \left[\xi V(S',0) + (1-\xi) V^E(S')\right] \tag{9}$$

[g] The timing in Fig. 2 is adapted from Aguiar and Amador (2014b), which in turn is a modification of Cole and Kehoe (2000). The same timing is implicit in Chatterjee and Eyigungor's ((2012)) modeling of a Cole–Kehoe type rollover crisis. In both setups, the difference relative to Cole and Kehoe is that the sovereign is not allowed to consume the proceeds of an auction if it defaults. This simplifies the off-equilibrium analysis without materially changing the results. See Auclert and Rognlie (2014) for a discussion of how the Eaton–Gersovitz timing in some standard environments has a unique Markov equilibrium, thus ruling out self-fulfilling crises.

[h] For an exploration of an environment in which the government cannot commit to a single auction, see Lorenzoni and Werning (2014) and Hatchondo and Martinez (undated).

is the sovereign's value when it is excluded from financial markets and incurs the output costs of default. Recall that ξ is the probability of exiting the exclusion state and, when this exit occurs, the sovereign reenters financial markets with no debt. Note also that the amount of new debt implied by B' is not relevant for the default payoff as the government does not receive the auction proceeds if it defaults at settlement.

Finally, the current period value function solves:

$$V(S,B) = \max\left\langle \max_{B' \leq \theta Y} V^R(S,B,B'),\, V^D(S)\right\rangle, \forall\ S \text{ and } B. \tag{10}$$

The upper bound θY on the choice of B' rules out Ponzi schemes.

Let $\delta(S,B,B')$ denote the policy function for default at settlement conditional on B'. For technical reasons, we allow the sovereign to randomize over default and repayment when it is indifferent, that is, when $V^R(S,B,B') = V^D(S)$. Therefore, $\delta(S,B,B') : \mathscr{S} \times \mathbb{R} \times (-\infty,\ \theta Y] \rightarrow [0,1]$ is the probability the sovereign defaults at settlement, conditional on (S,B,B'). Let $A(S,B) : \mathscr{S} \times \mathbb{R} \rightarrow (-\infty,\ \theta Y]$ denote the policy function that solves the inner maximization problem in (10) when there is at least one B' for which C is strictly positive. The policy function of consumption is implied by those for debt and default.

3.3 Lenders

We assume financial markets are segmented and only a subset of foreign investors participates in the sovereign debt market. This assumption allows us to introduce a risk premium on sovereign bonds as well as to explore how shocks to foreign lenders' wealth influence equilibrium outcomes in the economy, all the while treating the world risk-free rate as given. For simplicity, all period t lenders participate in the sovereign bond market for one period and are replaced by a new set of lenders.

We assume there is a unit measure of identical lenders each period. Let W_i be the wealth of an individual lender in the current period (W is the *aggregate* wealth of investors and is included in the state vector S in this capacity). Each lender allocates his wealth across two assets: the risky sovereign bond and an asset that yields the world risk-free rate r^*. Lenders must hold nonnegative amounts of the sovereign bond but can have any position, positive or negative, in the risk-free asset. The lender's utility of next period (terminal) wealth, $\widetilde{W}_i$, is given by

$$k(\widetilde{W}_i) = \begin{cases} \widetilde{W}_i^{1-\gamma}/(1-\gamma) & \text{for } \gamma \geq 0 \text{ and } \gamma \neq 1 \\ \ln(\widetilde{W}_i) & \text{for } \gamma = 1 \end{cases}.$$

Note that $\widetilde{W}_i$ is distinct from the W' that appears in S' (next period's exogenous state vector) as the latter refers to the aggregate wealth of next period's new cohort of lenders.

The one-period return on sovereign bonds depends on the sovereign's default decision within the current period as well as on next period's default decision. Let $\widetilde{D}$ and $\widetilde{D}'$

denote the sovereign's realized default decisions, either 0 (no default) or 1 (default), at settlement during the current and next period, respectively. A lender who invests a fraction (or multiple) μ of his current wealth W_i has random terminal wealth $\widetilde{W}_i$ given by

$$(1-\mu)W_i(1+r^*)+\mu W_i/q(S,B,B')\,[(1-\widetilde{D})(1-\widetilde{D}')]\,[r^*+\lambda+(1-\lambda)q(S',B',B'')],\tag{11}$$

where,

$$\begin{aligned}&\widetilde{D}=1 \text{ with probability } \delta(S,B,B')\\&\widetilde{D}'=1 \text{ with probability } \delta(S',B',A(S',B'))\\&B''=A(S',B').\end{aligned}\tag{12}$$

The wealth evolution equation omits terms that are only relevant off equilibrium; namely, it omits any payments from the settlement fund after a default. These will always be zero in equilibrium.

The representative lender's decision problem is how much sovereign debt to purchase at auction. Specifically:

$$L(W_i,S,B,B')=\max_{\mu\geq 0}\mathbb{E}_S\left[k\left(\widetilde{W}_i\right)\middle|B,B'\right],$$

subject to (11) and the expressions in (12). The solution to the lender's problem implies an optimal $\mu(W_i,S,B,B')$.

The market-clearing condition for sovereign bonds is then

$$\mu(W,S,B,B')\cdot W=q(S,B,B')\cdot B' \text{ for all feasible } B'>0,\tag{13}$$

where W is the aggregate wealth of the (symmetric) lenders. The condition requires that the bond price schedule be consistent with market clearing for any potential $B'>0$ that raises positive revenue. This is a "perfection" requirement that ensures that when the sovereign chooses its policy function $A(S,B)$, its beliefs about the prices it will face for different choices of B' are consistent with the "best response" of lenders. There are no market-clearing conditions for $B'\leq 0$; the sovereign is a small player in the world capital markets and, thus, can save any amount at the world risk-free rate.

Differentiation of the objective function of the lender with respect to μ gives an FOC that implies

$$q(S,B,B')=\frac{\mathbb{E}_S[\widetilde{W}^{-\gamma}(1-\widetilde{D})(1-\widetilde{D}')(r^*+\lambda+(1-\lambda)q(S',A(S',B')))]}{(1+r^*)\mathbb{E}_S[\widetilde{W}^{-\gamma}]}\tag{14}$$

where $\widetilde{W}$ is evaluated at $\mu(W,S,B,B')$.

Eq. (14) encompasses cases that are encountered in existing quantitative studies. As noted already, in the Eaton–Gersovitz timing of events there is no possibility of default at settlement. This means $\delta(S,B,B')=0$ and the pricing of bonds at the end of the current period reflects the possibility of default in future periods only. This means $\delta(S',B',B''(S',B'))$ does not depend on B'', only on (S',B'). Thus, q depends on (S,B') only. If lenders are risk neutral and debt is short term ($\gamma=0$ and $\lambda=1$), $q(S,B,B')$ is simply the probability of repayment on the debt next period; if lenders are risk neutral but debt is long term ($\gamma=0$ and $\lambda>0$)

$$q(S,B,B')=\frac{\mathbb{E}_S(1-D(S',B'))(r^*+\lambda+(1-\lambda)q(S',A(S',B')))]}{(1+r^*)}. \tag{15}$$

3.4 Equilibrium

Definition 1 (Equilibrium) Given a first-order Markov process for S, an *equilibrium* consists of a price schedule $q:\mathscr{S}\times\mathbb{R}\times(-\infty,\theta Y]\rightarrow[0,1]$; sovereign policy functions $A:\mathscr{S}\times\mathbb{R}\rightarrow(-\infty,\theta Y]$ and $\delta:\mathscr{S}\times\mathbb{R}\times(-\infty,\theta Y]\rightarrow[0,1]$; and lender policy function $\mu:\mathbb{R}^+\times\mathscr{S}\times\mathbb{R}\times(-\infty,\theta Y]\rightarrow\mathbb{R}$; such that: (i) $A(S,B)$ and $\delta(S,B,B')$ solve the sovereign's problem from Section 3.2, conditional on $q(S,B,B')$; (ii) $\mu(W,S,B,B')$ solves the representative lender's problem from Section 3.3 conditional on $q(S,B,B')$ and the sovereign's policy functions; and (iii) market clearing: Eq. (13) holds.

3.5 Equilibrium Selection

Because the default decision is made at the time of settlement, the equilibrium of the model features defaults that occur due to lenders' refusal to roll over maturing debt. To see how this can occur, consider the decision problem of a lender who anticipates that the sovereign will default at settlement on new debt issued in the current period, ie, the lender believes $\delta(S,B,B')=1$ for all (feasible) $B'>(1-\lambda)B$. Then, the lender's optimal μ is 0 and the market-clearing condition (13) implies that $q(S,B,B')=0$ for $B'>(1-\lambda)B$. In this situation, the most debt the sovereign could exit the auction with is $(1-\lambda)B$ and consistency with lender beliefs requires that $V^D(S)\geq V^R(S,B,(1-\lambda)B)$.[i] On the other hand, for a given stock of debt and endowment, there may be a positive price schedule that can also be supported in equilibrium. That is, if $q(s,B,\tilde{B})>0$ for some $\tilde{B}>(1-\lambda)B$ (which necessarily implies that lenders do not anticipate default at settlement for $B'=\tilde{B}$) and $V^D(S)<V^R(S,B,\tilde{B})$, the sovereign would prefer issuing new bonds to help pay off maturing debt and thus find it optimal to repay at settlement. Defaults caused by lenders offering the adverse equilibrium price schedule when a more generous price schedule that induces repayment is also an equilibrium price schedule are called *rollover crises*. A default that occurs because there is no price schedule that can induce

[i] If this condition is violated, the sovereign would strictly prefer to honor its obligation even after having acquired some small amount of new debt, contrary to lender beliefs

repayment (because endowments are too low and/or debt is too high) is called a *fundamental default*.

We incorporate rollover crises via the belief shock variable x. We assume that x is uniformly distributed on the unit interval, and we denote values of $x \in [0,\pi)$ as being in the crisis zone and values of $x \in [\pi, 1]$ as being in the noncrisis zone. In the crisis zone, a rollover crisis occurs *if* one can be supported in equilibrium. That is, a crisis occurs with $q(S, B, B') = 0$ for all $B' > (1-\lambda)B)$ if $V^R(S,B,(1-\lambda)B) < V^D(S)$*and* $x(S) \in [0,\pi)$. On the other hand, if a positive price of the debt can be supported in equilibrium, conditional on the sovereign being able to roll over its debt, then this outcome is selected if $x(S) \in [\pi,1]$. If S is such that $V^R(S,B,(1-\lambda)B) \geq V^D(S)$, then no rollover crisis occurs even if $x(S) \in [0,\pi)$. We let π index the likelihood a rollover crisis, if one can be supported in equilibrium.

We end this section with a comment on the incentive to buy back debt in the event of a failed auction, defined as a situation where lenders believe that $\delta(S,B',B) = 1$ for all $B' > (1-\lambda)B$ (either because of a rollover crisis or because of a solvency default). With a failed auction and long-term debt, the government has an incentive to buy back its debt on the secondary market if the price is low enough and then avoid default at settlement. For instance, this incentive will be strong if $q(S,B,B') = 0$ for $B' < (1-\lambda)B$. In this case, the sovereign could purchase its outstanding debt at zero cost and if

$$u(Y + (r^* + \lambda)B) + \beta\mathbb{E}_S V^R(S', B, 0) > u(Y) + \beta\mathbb{E}_S V^E(S'),$$

the sovereign's incentive to default at settlement will be gone. But, then, a lender would be willing to pay the risk-free price for the last piece of debt and outbid the sovereign for it.

To square the sovereign's buyback incentives with equilibrium, we follow Aguiar and Amador (2014b) and assume that in the case of a failed auction, the price of the debt $q(S, B, B')$ for $B' \leq (1-\lambda)B$, is high enough to make the sovereign just indifferent between defaulting on the one hand and, on the other, paying off its maturing debt and buying back $(1-\lambda)B - B'$ of its outstanding debt. Given this indifference, we further assume that the sovereign randomizes between repayment and default following a buyback, with a mixing probability that is set so that current period lenders are willing to hold on to the last unit of debt in the secondary market in the event of a buyback (more details on the construction of the equilibrium price schedule are provided in the computation section).

3.6 Normalization

Since the endowment Y has a trend, the state vector S is unbounded. To make the model stationary for computation we normalize the nonstationary elements of the state vector S by the trend component of Y_t,

$$G_t = \exp\left(\sum_1^t g_s\right). \tag{16}$$

The elements of the normalized state vector s are (g, z, w, x), where w is W/G. Since Y/G is a function of z only and z already appears in S, s contains one less element than S. It will be convenient to use the same notation defined above for functions of S for functions of the normalized state vector s. Normalizing both sides of the budget constraint (7) by G and denoting C/G by c, B/G by b and B'/G by b' yields the normalized budget constraint

$$c = \exp(z) + q(s, b, b')[b' - (1-\lambda)b] - (r^* + \lambda)b. \tag{17}$$

Here we are imposing the restriction that the pricing function is homogeneous of degree 0 in the trend endowment G and, so, denote it by $q(s,b,b')$.[j]

Next, since $u(C) = G^{1-\sigma}u(c)$, we guess $V^R(S,B,B') = G^{1-\sigma}V^R(s,b,b')$ and $V(s,b) = G^{1-\sigma}V(S,B)$. This gives

$$V^R(s, b, b') = u(c) + \beta \mathbb{E}_s g'^{1-\sigma} V(s', b'/g'). \tag{18}$$

Analogous guesses for the value functions under default and exclusion yield

$$V^D(s) = u(\exp(z)) + \beta \mathbb{E}_s g'^{1-\sigma} V^E(s') \tag{19}$$

and

$$V^E(s) = u(\exp(z)(1 - \phi(g, z))) + \beta \mathbb{E}_s g'^{1-\sigma}\left[\xi V(s', 0) + (1-\xi) V^E(s')\right]. \tag{20}$$

So,

$$V(s, b) = \max\left\langle \max_{b' \le \theta \exp z} V^R(s, b, b'),\, V^D(s)\right\rangle, \forall\ s \text{ and } b. \tag{21}$$

We denote the sovereign's default decision rule from the stationarized model by $\delta(s,b,b')$ and we denote by $a(s,b)$ the solution to $\max_{b' \le \theta \exp z} V^R(s, b, b'))$, provided repayment is feasible at (s,b).

Turning to the lender's problem, observe that given constant relative risk aversion, the optimal μ (the fraction devoted to the risky bond) is independent of the investor's wealth. Let $\mu(1,s,b,b')$ be the optimal μ of a lender with unit wealth. The FOC associated with the optimal choice of μ implies a normalized version of (14), namely,

[j] In particular, we are assuming that prices are functions of the ratios of debt and lenders' wealth to trend endowment but not of the level of trend endowment G itself. One could conceivably construct equilibria where this is not the case by allowing lender beliefs to vary with the level of trend endowment, conditional on these ratios. We are ruling out these sorts of equilibria.

$$q(s,b,b') = \frac{\mathbb{E}_s[\widetilde{w}^{-\gamma}(1-D)(1-D')(r^* + \lambda + (1-\lambda)q(s',b',a(s',b')))]}{(1+r^*)\mathbb{E}_s[\widetilde{w}^{-\gamma}]}, \tag{22}$$

where $\widetilde{w}$ is the terminal wealth of the lender with unit wealth evaluated at $\mu(1,s,b,b')$ and the expectation is evaluated using the sovereign's (normalized) decision rules.

The normalized version of the key market-clearing condition is then

$$\mu(1,s,b,b') \cdot w = q(s,b,b') \cdot b' \text{ for all feasible } b' > 0. \tag{23}$$

For a given pricing function $0 \leq q(s,b,b') \leq 1$, standard Contraction Mapping arguments can be invoked to establish the existence of all value functions. For this, it is sufficient to bound b' from below by some $\underline{b} < 0$, ie, impose an upper limit on the sovereign's holdings of foreign assets (in addition to the upper limit on its issuance of debt to rule out Ponzi schemes), and assume that $\beta \mathbb{E} g'^{1-\sigma}|g < 1$ for all $g \in \mathcal{G}$.

3.7 Computation

Computing an equilibrium of this model means finding a price function $q(s,b,b')$ and associated optimal stationary decision rules $\delta(s,b,b')$, $a(s,b)$ and $\mu(1,s,b,b')$ that satisfy the stationary market-clearing condition (23). That is, it means finding a collection of functions that satisfy

$$\mu(1,s,b,b') \cdot w = \left[\frac{\mathbb{E}_s[\widetilde{w}^{\,-\gamma}(1-\widetilde{D})(1-\widetilde{D}')(r + \lambda + (1-\lambda)q(s',b',a(s',b')))]}{(1+r^*)\mathbb{E}_s[\widetilde{w}^{\,-\gamma}]}\right] b' \;\; \forall\, s,\ b \text{ and } b'. \tag{24}$$

If such a collection can be found, an equilibrium in the sense of Definition 1 will exist in which all the nonstationary decision rules are scaled versions of the stationary decision rules, ie, $A(S,B) = a(s,b)G$, $\delta(S,B,B') = \delta(s,b,b')$ and $\mu(W,S,B,B') = \mu(1,s,b,b')wG$.

On the face of it, this computational task seems daunting given the large state and control space. It turns out, however, that (24) can be solved by constructing the solution out of the solution of a computationally simpler model. This simpler model adheres to the Eaton–Gersovitz timing, so $\delta(s,b,b') = 0$, and thus q is a function of s and b' only. But, unlike the standard Eaton–Gersovitz model, it is modified to have rollover crises.[k] The modification is as follows: If s is such that the belief shock variable $x(s)$ is in $(\pi,1]$ (ie, it is not in the crisis zone), the sovereign is offered $q(s,b')$ where b' can be any feasible choice of debt (think of this as the price schedule in "normal times"). But if $x(s)$ is in $[0,\pi]$, the sovereign is offered a truncated *crisis* price schedule in which $q(s,b') = 0$ for all $b' > (1-\lambda)b$ provided default strictly dominates repayment under the crisis price schedule;

[k] This model is described in section E of Chatterjee and Eyigungor (2012).

if the proviso is not satisfied, the sovereign is offered the normal (nontruncated) price schedule.

To see how this construction works, let $q(s,b')$ be the equilibrium price function of this rollover-modified EG model. That is, $q(s,b')$ satisfies

$$\mu(1,s,b')\cdot w = \left[\frac{\mathbb{E}_s[\widetilde{w}^{-\gamma}(1-D(s',b'))(r+\lambda+(1-\lambda)q(s',a(s',b')))]}{(1+r)\mathbb{E}_s[\widetilde{w}^{-\gamma}]}\right]b' \tag{25}$$

where $D(s,b)$ and $a(s,b)$ are the associated equilibrium policy functions. And let $V(s,b)$ and $V^D(s)$ be the associated value functions. Next, let $G(Q;s,b,b')$ be defined as the utility gap between repayment and default at settlement when the auction price is Q:

$$u[\exp(z(s))-(r^*+\lambda)b+Q(b'-(1-\lambda)b)]+\beta\mathbb{E}_s g'^{1-\sigma}V(s',b'/g')-V^D(s).$$

G encapsulates the incentive to default or repay at settlement in a model in which default at settlement is not permitted. The logic underlying the construction of the price schedule for the model in which default at settlement *is* permitted is this: If $G(s,b,b')$ evaluated at $Q = q(s,b')$ is nonnegative, $q(s,b,b')$ is set equal to $q(s,b')$, as there is no incentive to default at settlement; if $G(s,b,b')$ evaluated at $Q = q(s,b')$ is negative, $q(s,b,b')$ is set to 0 if the incentive to default is maintained at an auction price of zero, or it is set to some positive value between 0 and $q(s,b')$ for which the sovereign is indifferent between default and repayment.

1. For $b' \geq (1-\lambda)b$

$$q(s,b,b') = \begin{cases} 0 \text{ if } G(q(s,b');\, s,b,b') < 0 \\ q(s,b') \text{ if } G(q(s,b');\, s,b,b') \geq 0. \end{cases}$$

The top branch deals with the case where the sovereign's incentive to default at settlement is strictly positive after having issued debt at price $q(s,b')$. Since G is (weakly) increasing in Q in this case, the incentive to default at settlement is maintained at $Q = 0$ and, so, we set $q(s,b,b') = 0$. The bottom branch deals with the case where the sovereign (weakly) prefers repayment over default. In this case, the price is unchanged at $q(s,b')$.

2. For $b' < (1-\lambda)b$:

$$q(s,b,b') = \begin{cases} 0 \text{ if } G(0;\, s,b,b') < 0 \\ Q(s,b,b') \text{ if } Q \in [0,q(s,b')) \\ q(s,b') \text{ if } G(q(s,b');\, s,b,b') \geq 0. \end{cases}$$

The bottom branch offers $q(s,b')$ if $G(q(y,b');s,b,b') \geq 0$. If $G(q(y,b');s,b,b') < 0$, then two cases arise. Since G is weakly decreasing in Q, it is possible that there is a $Q\in [0,q(s,b'))$ for which the $G(Q;s,b,b')=0$. In this case, we set $q(s,b,b')=Q$. If there is no such Q, then $G(0;s,b,b') < 0$ and we set $q(s,b,b') = 0$.

Next, we verify that given $V(s,b)$ and $V^D(s)$ (the value functions under $q(s,b)$), the optimal action under $q(s,b)$ is also an optimal action under $q(s,b,b')$. First, consider (s,b) for which the optimal action is to choose $a(s,b)$. This implies that $G(q(s,b);s,b,a(b,s)) \geq 0$. Then, by construction, $q(s,b,b') = q(s,b)$ and the payoff from choosing $a(s,b)$ is the same as under $q(s,b)$ and this payoff will (weakly) dominate the payoff from choosing any other b' for which $q(s,b,b') = q(s,b')$ (by optimality). Furthermore, the payoff from any b' for which $q(s,b,b') \neq q(s,b)$ is never better than default. It follows that $a(s,b)$ (coupled with $\delta(s,b,a(s,b))$ $= 0$) is an optimal choice under $q(s,b,b')$. Next, consider (s,b) for which it is optimal to default under $q(s,b)$. This implies $G(q(s,b);s,b,b') < 0$ for all feasible b'. Then, by construction, default at settlement is the best option, or one of the best for all b' under $q(s,b,b')$.

Finally, we have to verify that $q(s,b,b')$ is consistent with market clearing. For (s,b,b') such that $q(s,b,b') = q(s,b)$, market clearing is ensured because the market clears (by assumption) under $q(s,b)$. For (s,b,b') such that $q(s,b,b') = 0$, market clearing is ensured trivially. For (s,b,b') such that $q(s,b,b') \in (0,q(s,b))$, market clearing can be ensured by selecting $\delta(s,b,b')$ appropriately. For instance, if lenders are risk-neutral, $\delta(s,b,b')$ is set to satisfy $q(s,b,b') = [1 - \delta(s,b,b')]q(s,b')$. Then, with probability $\delta(s,b,b')$ the sovereign defaults and the bonds are worthless, and with probability $1 - \delta(s,b,b')$, the sovereign repays and the bonds are worth $q(s,b')$. With risk-averse lenders, $\delta(s,b,b')$ can be similarly set to make lenders willing to lend b' at $q(s,b,b')$.[1]

We conclude the description of the construction of $q(s,b,b')$ by noting how it modifies the rollover price schedule under $q(s,b')$. Under $q(s,b')$, a rollover crisis is a price schedule with (a) $x(s) \in [0,\pi]$, (b) for $b \geq ((1 - \lambda)b$, $q(s,b') = 0$, and (c) $D(s,b) = 1$. Under $q(s,b,b')$, a rollover has (a) $x(s) \in [0,\pi]$, (b) for $b' \geq (1 - \lambda)b$, $q(s,b,b') = 0$ (which, in this case, is also $q(s,b')$) and (c) for $b' < (1 - \lambda)b$, $q(s,b,b')$ is given by the construction under (ii). Thus, the only modification to the crisis price schedule is to raise the prices associated with buybacks (as discussed earlier in Section 3.5).

In the rest of this section, we describe the iterative process by which the (stationary) equilibrium of the rollover-modified EG model is computed. First, the space of feasible b' is discretized. Second, the space of x (the belief shock variable) is also discretized with "crisis" equal to a value of 1, taken with probability π, and "normal" equal to a value of 0, taken with probability $(1 - \pi)$. Suppose that $\{q^k(s,b')\}$ is the price schedule at the start of iteration k. Let $a(s,b;q^k),D(s,b;q^k)\}$ be the sovereign's decision rules conditional

[1] If $\delta(s,b,b') = 0$ lenders would be just willing to lend b' at the price $q(s,b')$ (because they are willing to do so under $q(s,b')$). If the probability of default at settlement is kept at zero and the price of the bond is lowered to $q(s,b,b')$, there will be an excess demand for bonds. This excess demand can be choked off by lowering $\delta(s,b,b')$ sufficiently.

on $q^k(s,b')$. Then, for every feasible $b' > 0$ for which $q^k(s,b')b' > 0$, the price implied by the lender's optimal choice of μ and market clearing is

$$J^k(s,b')) = \frac{\mathbb{E}_s[\widetilde{w}^{-\gamma}(1-D(s',b';q^k))(r+\lambda+(1-\lambda)q^k(s',a(s',b';q^k)))]}{(1+r^*)\mathbb{E}_s[\widetilde{w}^{-\gamma}]}, \tag{26}$$

where, using (23), the $\mu(1,s,b';q^k)$ that appears in $\widetilde{w}$ is replaced by $[q^k(s,b)\cdot b']/w(s)$. If $|\max J^k(s,b') - q^k(s,b')|$ is less than some chosen tolerance $\epsilon > 0$, the iteration is stopped and the collection $\{q^k(s,b'),a(s,b;q^k),D(s,b;q^k),\mu(1,s,b';q^k)\}$ is accepted as an approximation of the equilibrium. If not, the price schedule is updated to

$$q^{k+1}(s,b') = \xi q^k(s,b') + (1-\xi)J^k(s,b'), \tag{27}$$

where $\xi \in (0,1)$ is a damping parameter (generally close to 1).

In a purely discrete model in which all shocks and all choices belong to discrete sets, the iterative procedure described above typically fails to converge for a wide choice of parameter values. The reason is that the equilibrium we are seeking is, in effect, a Nash equilibrium of a game between the sovereign and its lenders and we should not expect the existence of an equilibrium in *pure* strategies, necessarily. To remedy the lack of convergence, it is necessary to let the sovereign randomize appropriately between two actions that give virtually the same payoff. The purpose of the continuous i.i.d. shocks (z in the SG model and m in the DG model) is to provide this mixing. We refer the reader to Chatterjee and Eyigungor (2012) for a discussion of how continuous i.i.d. shocks allow robust computation of default models.

4. BENCHMARK MODELS

We calibrate two versions of the basic model under the assumption that rollover crises never happen. In one version, labeled DG, the endowment process of the sovereign and the wealth process of investors are modeled as independent stationary fluctuations around a common deterministic growth path. In the second version, labeled SG, the growth rates of endowments and investor wealth follow independent stationary processes with a common mean growth.

To calibrate the endowment process we use quarterly real GDP data for Mexico for the period 1980Q1–2015Q2. For the DG model, $G_t = (1+g)^t$ and log income is a stationary process plus a linear trend. The stationary component, z_t, is assumed to be composed of two parts: a persistent part e_t that follows an AR1 process and a purely transitory part m_t:

$$z_t = e_t + m_t, \quad m_t \sim N(0,\sigma_m^2) \text{ and } e_t = \rho_e e_{t-1} + v_t \quad v_t \sim N(0,\sigma_v^2) \tag{28}$$

As explained at the end of the previous section, the transitory shock m_t is required for robust computation of the equilibrium bond price function. We set $\sigma_m^2 = 0.000025$

and estimate (28) using standard state-space methods. The estimation gives $\rho_e = 0.85$ (0.045) and $\sigma_v^2 = 0.000139$ ($1.08e - 05$) (standard errors in parenthesis). The slope of the trend line implies a long-run quarterly growth rate of 0.56% (or annual growth rate of 2.42%).

For the SG model, the growth rate g_t is stochastic. Now, $\ln(Y_t) = \sum_0^t g_t + z_t$ and the growth rate of the period t endowment, $\ln(Y_t) - \ln(Y_{t-1}) \equiv \Delta y = g_t + z_t - z_{t-1}$. We assume

$$g_t = \alpha + \rho_g g_{t-1} + v_t, \quad v_t \sim N(0, \sigma_v^2) \text{ and } z_t \sim N(0, \sigma_z^2) \tag{29}$$

and use the observed growth rate of real GDP to estimate (29) using state-space methods. The estimation yields $\alpha = 0.0034$ (0.0012), $\rho_g = 0.45$ (0.12), $\sigma_v^2 = 0.000119$ (0.0000281) and $\sigma_z^2 = 0.000011$ ($8.12e - 06$). The estimates of α and ρ_g imply an average growth rate of 2.45% at an annual rate. These estimates are summarized in Table 6

Regarding $\phi(g,z)$, which determines the level of output under exclusion from credit markets, we assume

$$\text{for DG} : \phi(g, z) = d_0 \exp(z)^{d_1} \text{ and for SG} : \phi(g, z) = d_0 \exp(g)^{d_1}. \tag{30}$$

In either model, setting $d_1 = 0$ leads to default costs that are proportional to output. If $d_1 > 0$, then default costs rise more than proportionately with z in the DG model, and more than proportionately with g in the SG model.

We assume that g takes values in a finite set $\mathcal{G}$. In the deterministic growth case $\mathcal{G}$ is a singleton. The specification of z depends on what is being assumed for g. When g is stochastic, z is drawn from a distribution H with compact support $[-\bar{h}, \bar{h}]$ and continuous CDF. When g is deterministic, $z = e + m$, where e follows a first-order Markov process with values in a finite set $\mathcal{E}$ and m is drawn from H. In either case, z is first-order Markov in its own right (in the stochastic g case, trivially so) but it is *not* finite-state.

Aside from the parameters of the endowment process, there are 12 parameters that need to be selected. The model has 3 preference parameters, namely, β (the sovereign's discount factor), σ (the curvature parameter of the sovereign's utility function) and γ (the curvature parameter of the investors utility function). It has 2 parameters with respect to

Table 6 Parameters of endowment processes

Parameter	Description	DG	SG
–	Average annual growth rate of endowments	2.42	2.45
ρ_e	Autocorrelation of y	0.85	–
σ_v	Standard deviation of innovations to e or g	0.012	0.011
σ_m	Standard deviation of m	0.005	–
ρ_g	Autocorrelation of g	–	0.45
σ_z	Standard deviation of z	–	0.003

the bond market, namely, λ (the probability with which a bond matures), and r_f (the risk-free rate of return available to investors). It has 3 parameters with respect to the default state, namely, d_0 and d_1, the parameters of the $\phi(g,z)$ function, and ξ, the probability of reentry into credit markets from the exclusion state. Finally, there are 3 parameters governing the stochastic evolution of investor wealth w_t. For the DG version, w_t is defined as $\ln\left(W_t/\omega(1+g)^t\right)$ and for the SG version as $\ln(W_t/\omega Y_t)$, where ω controls the average wealth of investors relative to the sovereign. In either case w_t follows an AR1 process with persistence parameter ρ_w and unconditional variance σ_w^2.

Turning first to preference parameters, σ is set to 2, which is a standard value in the literature. The curvature parameter of the investor's utility function, γ, affects the compensation required by investors for default risk (risk premium). However, for any γ, the risk premium also depends on ω, as this determines the fraction of investor wealth that must reside in sovereign bonds in equilibrium. Thus, we can fix γ and vary ω to control the risk premium. With this in mind, γ was also set equal to 2.

With regard to the bond market parameters, we set the (quarterly) risk-free rate to 0.01. This value is roughly the average yield on a 3-month US Treasury bill over the period 1983–2015.[m] . The probability of a bond maturing, λ, is set to $1/8 = 0.125$ which implies that bonds mature in 2 years, on average. This is roughly consistent with the data reported in Broner et al. (2013) which show that the average maturity of bonds issued by Mexico during the Brady bonds era prior to the Tequila crisis (1993–95) was 2.5 years (postcrisis, the average maturity lengthened substantially).

The exclusion state parameters, d_0, d_1 and ξ, affect the value of the default option. The value of ξ was set to 0.125, which implies an average exclusion period of 2 years, on average. Settlements following default have generally been quick in the Brady era, so a relatively short period of exclusion seems appropriate.

Finally, we use the US P/E ratio as a proxy for investor wealth. We set the autocorrelation of the investor wealth process to 0.91, which is the autocorrelation of the P/E ratio at a quarterly frequency for the period 1993Q1–2015Q2. We assume that w takes values in a finite set $\mathscr{W}$ and its (first-order) Markov process has an unconditional mean $\omega > 0$, where ω determines the relative wealth of investors via-a-vis the sovereign.

These parameter choices are summarized in Table 7.

The remaining five parameters (β, d_0, d_1, ω, σ_w^2) are jointly determined to match moments in the data. The moments chosen are the average debt-to-GDP ratio for Mexico, the average EMBI spreads on Mexican sovereign debt, the standard deviation of the spread, the fraction of variation in Mexican spreads accounted for by the variation in investor wealth proxied by the variation in the US P/E ratio, and an annualized default frequency of 2%.[n]

[m] We use constant maturity yield computed by the Treasury and this data series begins in 1983Q3.

[n] If we date the beginning of private capital flows into emerging markets in the postwar era as the mid-1960s, Mexico has defaulted once in 50 years.

Table 7 Other parameters selected independently

Parameter	Description	Value
σ	Risk aversion of sovereign	2.000
γ	Risk aversion of investors	2.000
r_f	Risk-free rate	0.010
λ	Reciprocal of average maturity	0.125
ξ	Probability of exiting exclusion	0.125
ρ_w	Autocorrelation of wealth process	0.910

Table 8 Targets and model moments with proportional default costs

Description	Target	DG	SG
Debt-to-annual GDP	0.66	0.66	0.66
Average default freq	0.02	0.003	0.02
Average EMBI spread	0.03	0.001	0.03
R^2 of spreads on P/E	0.22	0.20	0.27

We do the moment matching exercise in two steps. First, we set the curvature parameter for default costs, d_1, to 0 so that default costs are simply proportional to output and we drop the standard deviation of spreads as a target. The results are shown in Table 8. The finding is that the SG model can be calibrated to the data quite well but the DG model could not. The DG model could get the debt-to-GDP ratio and the R^2 of the spreads on P/E regression, but the average spread and the average default frequency are an order of magnitude below their targets. These results echo those in Aguiar and Gopinath (2006).

Given the poor quantitative performance of the DG model with proportional costs, the rest of this chapter focuses on models with asymmetric default costs. We return to the proportional default cost and discuss its shortcomings in the next section after presenting our benchmark results.

5. BENCHMARK RESULTS WITH NONLINEAR DEFAULT COSTS

Table 9 reports the results of the moment matching exercise when all five parameters are chosen to match the four targets above and the standard deviation of spreads. As is evident, the performance of the DG model improves substantially and it can now deliver the target level of average spreads and default frequency.

A surprising finding is that neither model can match the observed spread volatility, which is an order of magnitude larger in the data than in the models. The finding is surprising because asymmetric default cost models have been successful in matching the volatility of spreads on Argentine sovereign bonds (the case that is most studied in the

Table 9 Targets and model moments with asymmetric default costs

Description	Target	DG	SG

Average default freq	0.02	0.02	0.02
Average EMBI spread	0.03	0.03	0.03
R^2 of spreads on P/E	0.22	0.23	0.26
SD of EMBI spread	0.03	0.005	0.002

Table 10 Parameters selected jointly

Parameter	Description	DG	SG
β	Sovereign's discount factor	0.892	0.842
d_0	Level parameter for default costs	0.075	0.068
d_1	Curvature parameter for default costs	10.0	10.0
ω	Wealth of investors relative to mean endowment	2.528	2.728
σ_w	SD of innovations to wealth	2.75	0.275

quantitative default literature). As explained later in the paper, the reason for the models' inability to match spread volatility is that neither z nor g is sufficiently volatile for Mexico (compared to Argentina) for the asymmetry in default costs to matter. Given this, the curvature parameter for default costs cannot be pinned down and we simply set it to a relatively large value and chose the remaining four parameters to match the other four targets.

The parameter values implied by this moment matching is reported in Table 10.

5.1 Equilibrium Price and Policy Functions

In this section we characterize the equilibrium bond price schedules and policy functions for debt issuance. We discuss the benchmark stochastic-growth (SG) and deterministic-growth (DG) versions of the model.

The price schedules and policy functions for our two growth cases are depicted in Fig. 3. As one can see from the first panel of the figure, the price schedules for the two different growth processes are quite similar. In both cases the price schedules are highly nonlinear, reflecting the positive feedback between the value of market access and q: the option to default lowers q for any B'/Y, which, in turn, lowers the value of market access and further increases the set of states in which default is optimal. Careful inspection will show that the DG schedule responds slightly less to an increase in debt right at the bend point.

The government's policy functions for debt issuance are depicted in the second panel of Fig. 3. These two functions exhibit an important difference. The striking fact about the

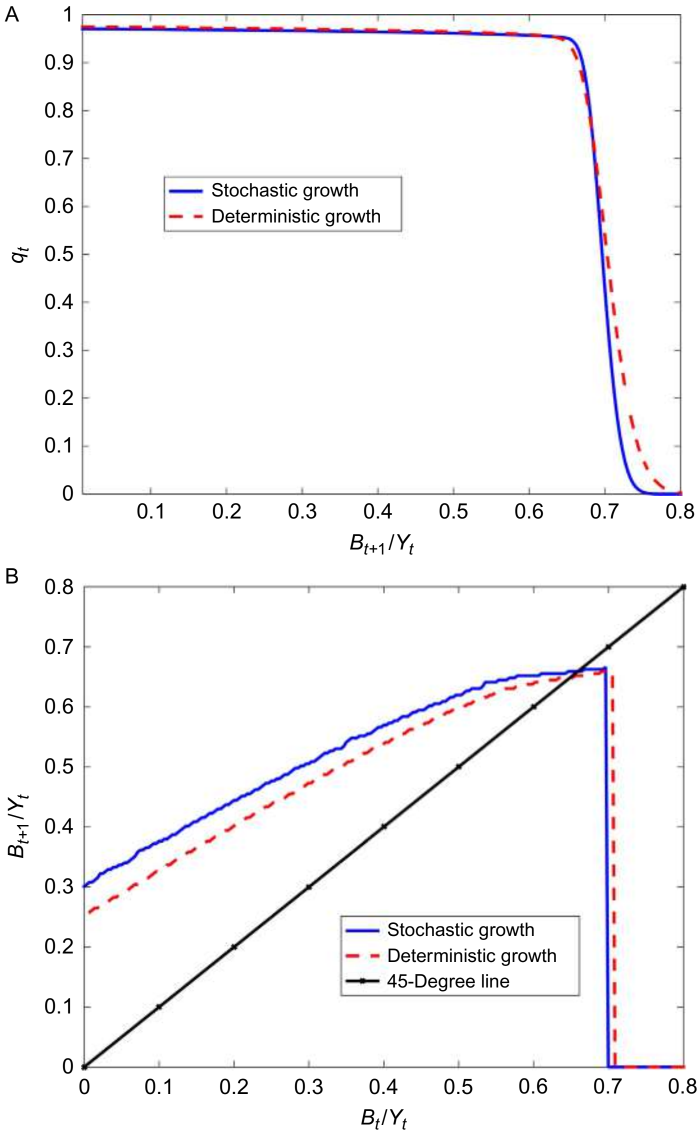

Fig. 3 Pricing schedules and policy functions. (A) Pricing schedules. (B) Policy functions.

SG debt policy functions is that it is quite flat around the 45-degree line: This implies that the optimal policy features sharp leveraging and deleveraging that offsets the impact of good and bad growth shocks, respectively, and returns B'/Y to the neighborhood of the crossing point quite rapidly. Notice also that the crossing point is not very far from the levels of debt for which default is triggered. This “distance to default,” and therefore the equilibrium spreads, are essentially determined by the output costs of default.

In contrast, the policy function for debt issuance for the DG economy depicts a significantly more modest leveraging and deleveraging response to deviations in the debt-to-output ratio around the 45-degree line. As we will see below, this will lead to sharp differences in the predicted outcomes of the two versions of our model.

We turn next to trying to understand how our model will respond to shocks. To do that we examine how our bond demand schedule responds to output and wealth shocks. These are plotted in Figs. 4 and 5, respectively. With respect to output shocks, we see a

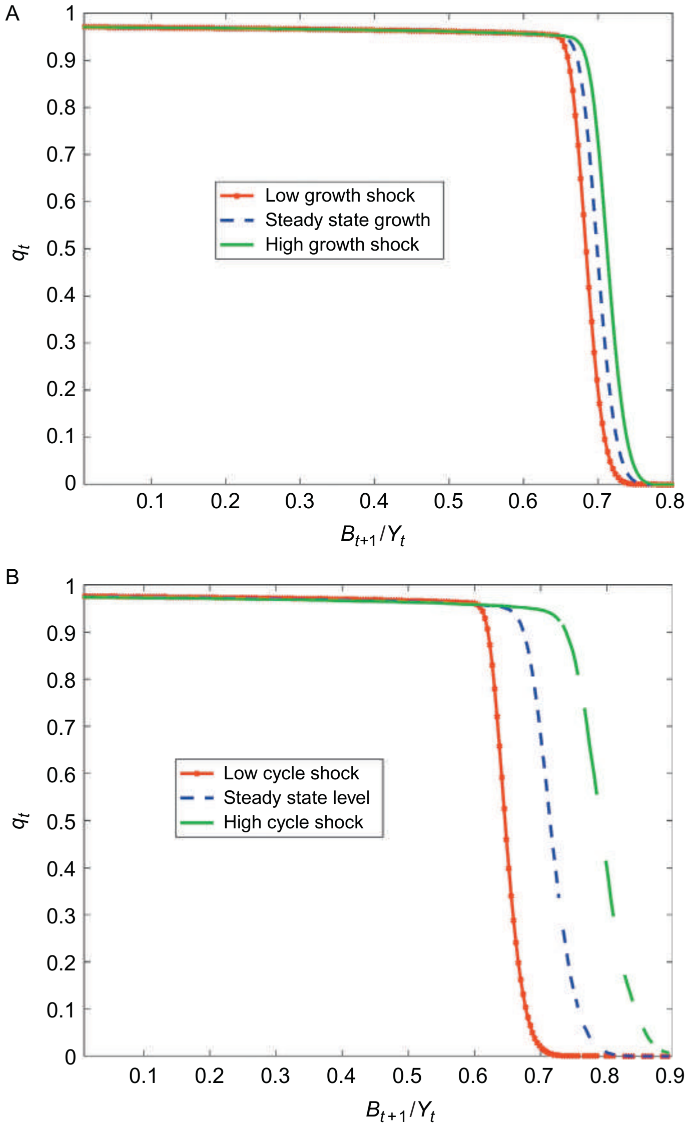

Fig. 4 Pricing schedules and output shocks. (A) Stochastic Schedule. (B) Deterministic Schedule.

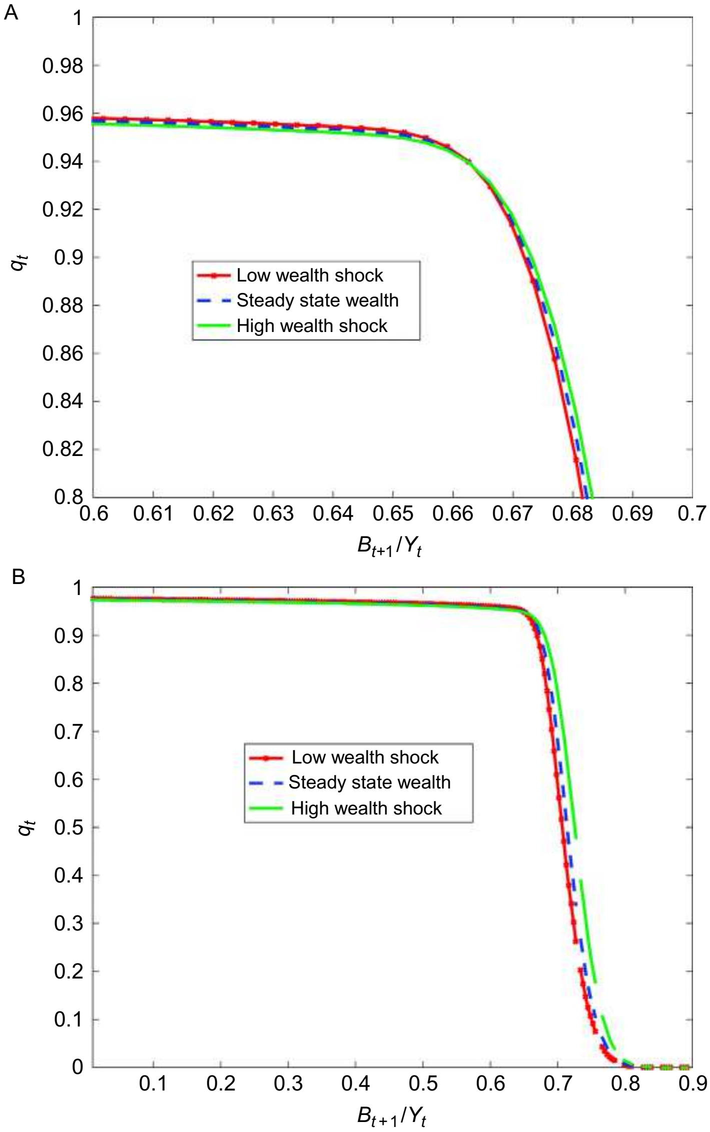

Fig. 5 Pricing schedules and wealth shocks. (A) Stochastic schedule. (B) Deterministic schedule.

fairly stark difference between our two models. Growth shocks have very little impact on the bond demand schedule in the SG model. But shocks that move output away from its deterministic trend have a fairly large effect in the DG version. This suggests that the stochastic growth version of our model will be much less responsive to output shocks than the deterministic growth version.

The reason for the difference in the response to output shocks between our two models stems from the interaction of two factors. First, when output is substantially below trend in the DG model, the agents in the economy anticipate that a recovery to trend is highly likely, making the future level of output look positive relative to the present. At the same time, our assumption of asymmetric default costs means that defaulting when output is below trend is less costly than defaulting when output has recovered to trend. Overall this creates a stronger incentive to default in the near term for given levels of B/Y and B', and this shifts in (out) the pricing schedule in response to a negative (positive) output shock. The shift in the price schedule offsets the country's desire for smoothing, but, at the same time, generates movement in the spread. Below we compare this to proportional default cost case and show that the shifts result mostly from the asymmetric default cost.

In contrast, negative growth shocks in the stochastic growth model make the expectation of future growth lower because these growth shocks are positively autocorrelated. Thus nonlinear output costs makes delaying default more attractive. In addition, the negative trajectory of output encourages the country to save, not borrow. The first effect dampens the shift in the price schedule, while the second effect dampens the incentive to borrow. Together this means that there is little or no increase in the spread today. As we will see, these differences will lead to differences in equilibrium outcomes such as the dispersion in debt-to-output levels and spreads.

Both models are quite unresponsive to wealth shocks. Interestingly, a wealth shock tends to twist the price schedule. For example, a positive wealth shock pushes out the price for high borrowing levels and but pulls it down for low borrowing levels. This last part arises from the increased incentive to dilute the current bonds in the future since the "price" of such dilution is not as high. We graphed the SG schedule on a magnified scale in order to make this twisting more apparent. This mechanism is explored in detail in Aguiar et al. (2016).

In the deterministic case, we see relatively large movements in the pricing schedule with shocks. In Fig. 6 we plot the pricing schedules for the proportional default cost case. In the DG model the price schedule does not respond to the output shock. This is because the expected positive trajectory of output makes the current debt-to-output ratio less onerous, while the proportionate default costs do not generate as strong an incentive to default today relative to the nonlinear case. Hence, the incentive to default is fairly stable and the price schedule does not shift in. At the same time, the feedback effect in the DG model with proportionate costs is so strong that the price schedule completely collapses past a certain B/Y ratio. This leads the country to stay sufficiently far inside of the collapse point that the probability of default tomorrow is virtually zero. In particular, it is very hard to generate a modest default probability and spread premium given this extreme pricing schedule. This is why this model is so hard to calibrate and why we get no volatility in the spread.

5.2 Boom-and-Bust Response

The sharp difference between our models comes from their responses to output shocks. To further understand the response of our models to growth rate shocks, we consider

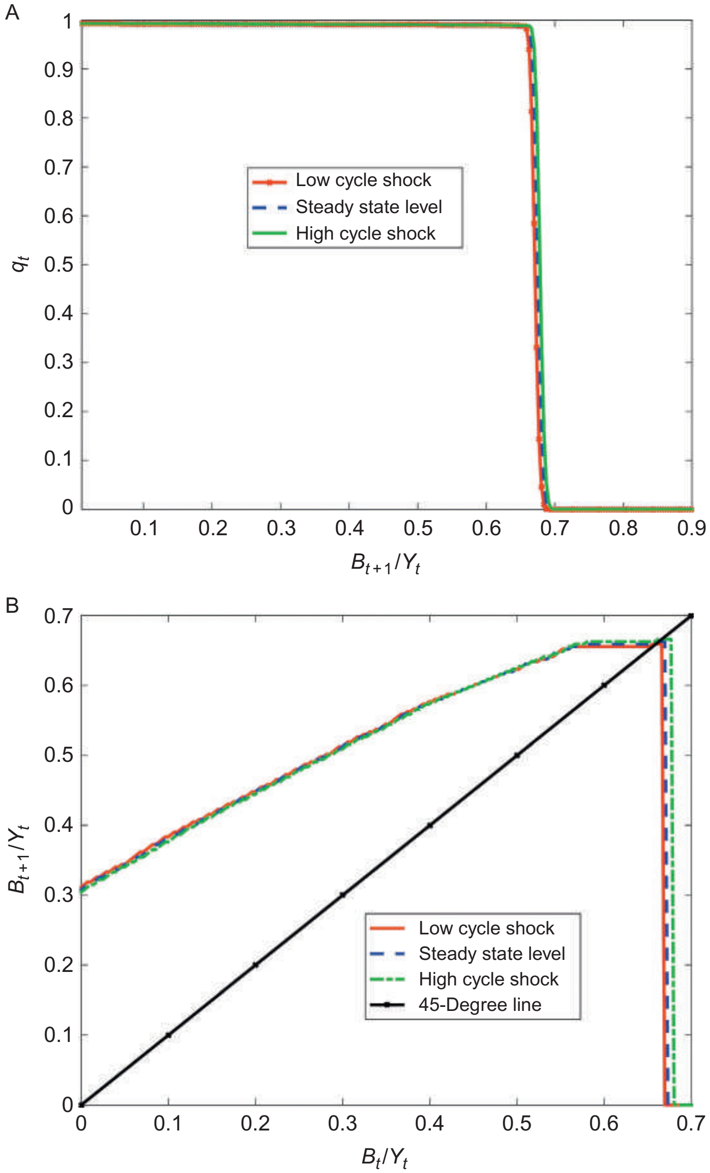

Fig. 6 DG model pricing schedule and policy function with proportionate costs. (A) Price schedule. (B) Policy function.

what happens after a sequence of positive shocks terminates in an negative shock. We refer to this as a boom-and-bust cycle.

In Fig. 7 we show the policy response to a series of positive output shocks of varying length, followed by a bad output shock. We also show the impact on the equilibrium spread. In both cases, the fairly high degree of persistence in our output shocks leads

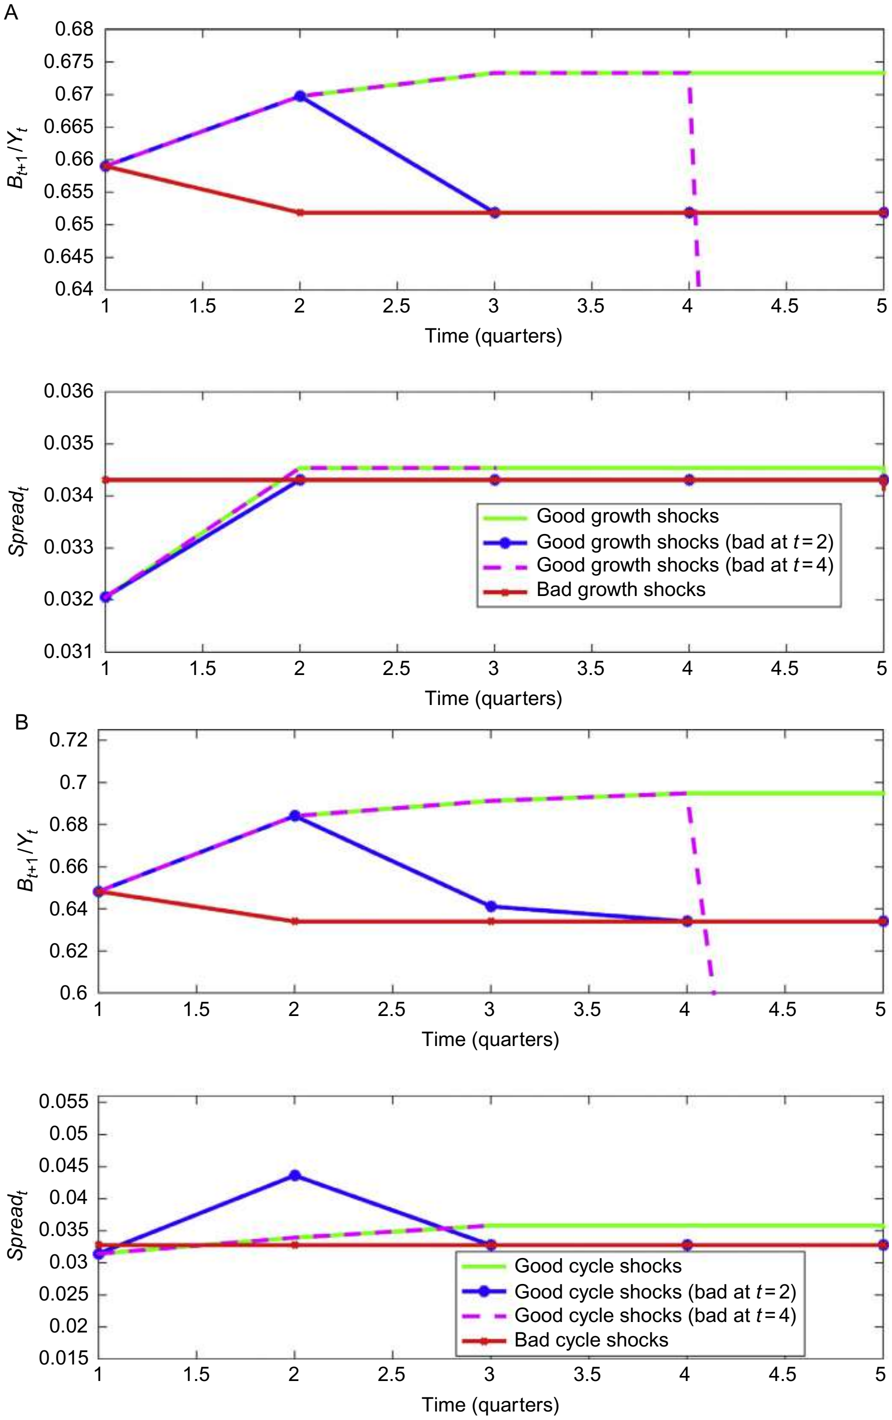

Fig. 7 Boom-and-bust cycle. (A) Stochastic. (B) Deterministic.

the government to borrow into a boom, raising the debt-to-output ratio. In the SG model, the government chooses to immediately delever in response to the negative output shock if it comes early enough in the boom; if it comes late, it defaults. The government in the DG model behaves similarly, except that it chooses to delever slightly more slowly in the case of a boom of intermediate length.

The spread behaves somewhat differently across the two versions of our model. In the SG version, the spread initially falls in respond to a positive output shock, but then it bounces back to essentially the same level as before in response to continued positive growth rate shocks because of the government's decision to lever up. More important, even in the period in which a negative growth rate shock first occurs, the government's decision to sharply delever means that the spread does not change in response to the negative shock. While the policy response of the government in the DG model is very similar to that of the SG model, the slightly slower deleveraging in response to a negative output shock leads to a sharp temporary rise in the spread.

5.3 Equilibrium Outcomes

In this section we lay out the results for both versions of our model with nonlinear output loses. Our first set of results are presented in Table 11. The first three statistics, which were targeted, match the long-run data for Mexico and are in the ball park for other emerging economies. The sixth statistic we report is the R^2 of a regression of the spread on the investor wealth shock w. This too is targeted to match the results of the regression of the spread on the US price-earnings ratio and is roughly in line with the data.

There are two nontargeted moments in Table 11. The first is the correlation of the average excess return and the growth rate of output. For the stochastic growth economy, the sign of this correlation is positive, which is surprising, since one would expect positive growth rate shocks to lower the spread. However, the magnitude of this correlation is in the ball park in that the correlation is quite weak as it is in the data. In the DG model this correlation is both of the wrong sign and also substantially higher. This reflects that

Table 11 Basic statistics: Stochastic and deterministic growth models

	Stochastic benchmark	Deterministic benchmark	Deterministic Argentina
Debt-to-GDP	0.66	0.66	0.28
Average default freq.	0.02	0.02	0.04
Average spread	0.03	0.03	0.06
SD of spreads	0.002	0.004	0.07
Corr of spreads with Δy or z	0.15	0.46	−0.76
R^2 of spreads on w	0.26	0.17	0.01

economy's greater responsiveness to output shocks, which we discussed earlier in reference to Fig. 4. Below we more closely examine the evidence on spreads and shocks using regression analysis to compare model and data results.

The other nontargeted moment is the standard deviation of the spread. This moment is too low, since it should be roughly equal to the average level of the spread. The fact that the spread's relative variation was still so low even with nonlinear default costs is surprising given that the literature has found that such costs can generate relatively realistic variation levels. However, the papers that have found this result have been calibrated to Argentina, which has a much more volatile output series.

To examine whether this might be at the root of our failure, we examined the implications of the DG model when we calibrate output to Argentina. When we calibrate our output process to Argentina, the autocorrelation coefficient for our output deviation from trend, z_t, rises from 0.853 to 0.930, thereby becoming more persistent. In addition, the standard deviation of z rises from 0.023 to 0.074, so the output deviations from trend are more volatile overall. All of the other model parameters are left unchanged. We report the results from this experiment in the last column of Table 11.

When we switch to the Argentine growth process for the deterministic model, the average debt-to-output level falls sharply, to 0.28, which is somewhat inconsistent with the fact that Argentina has a much higher value of this ratio than Mexico. In addition, the average spread rises sharply, to 0.06, and the volatility of the spread increases to 0.07. Both of these changes are consistent with the data in that Argentina has a much higher average spread and a much more volatile spread. This last finding indicates that the key to the literature's positive finding on spread volatility is the combination of nonlinear default costs and quite high output volatility. However, this story cannot explain the spread volatility in a country like Mexico with lower output volatility.

One other stark difference between the results with the Mexico and the Argentina output calibrations concerns the correlation of the spread and the percent deviation of output from trend. This has now become very negative. In Table 2 the average correlation in our sample was −0.27, and the highest value was only −0.56 for Malaysia. The correlation in Argentina was −0.35 and in Mexico it was −0.4. So a value of −0.76 with the Argentine calibration for output looks too high. Below in the regression analysis, we examine more closely the extent to which this success comes at the price of making spreads too dependent on output fluctuations.

The ergodic distributions of the debt-to-income ratio and the spread is depicted in Fig. 8. For the stochastic growth case, both the debt-to-income and the spread distributions are very tight and symmetric around their mean. The distribution of the debt-to-income ratio for the DG case is also symmetrical, but it is substantially more dispersed. For the spread distribution, the deterministic growth distribution is not completely symmetric and is again substantially more dispersed than the stochastic case. The greater dispersion in the debt-to-GDP ratio and the spread in the deterministic growth model is

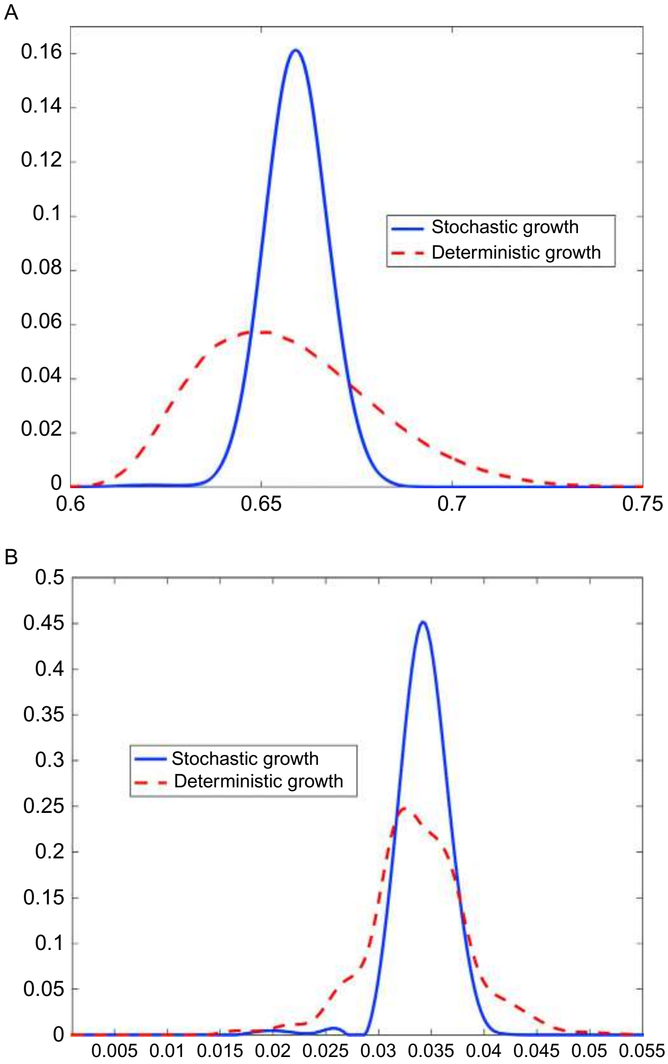

Fig. 8 Ergodic distributions. (A) Debt-to-income. (B) Spreads.

consistent with our earlier observation that the deterministic economy was more responsive to output shocks.

This spread can be decomposed into a default premium and a risk premium. Specifically, the risk premium is the standard difference between the expected implied yield on sovereign bonds and the risk-free interest rate. The default premium is the promised yield that would equate the expected return on sovereign bonds (inclusive of default) to a risk-free bond; that is, the yield that would leave a risk-neutral lender indifferent. The top panel of Fig. 9 depicts the risk premium and the bottom panel depicts the default

premium. In both cases the risk and default spreads quite similar to each other, suggesting that the two are moving closely in parallel. On average, roughly 60% is the default premium and the rest is risk premium. This reflects our calibration target of 3% average spread and 2% default probability.

To understand the circumstances in which we are getting defaults and crises in our models, we examine the share of defaults and crises with large negative output changes and large negative investor wealth shocks. These negative changes are 1.5 standard deviations relative to the unconditional distribution. We use negative growth rate realizations for output so we are using the same metric for both models. The results are reported in Table 12. The results imply that, in the SG model, defaults are almost always associated with negative growth rate shocks and almost never with negative wealth shocks. In the deterministic growth model, the dependence of defaults on negative output shocks is a bit weaker and investor wealth shocks play essentially no role. When we turn to spread crises, we see much less dependence on growth shocks in the SG model and again essentially no dependance on wealth shocks. This is because a very negative growth shock leads to either an immediate default or rapid deleveraging. In contrast, in the DG model, the dependence of spread crises on growth shocks is even higher than it is for defaults.

5.4 Simulation Regressions

To compare the model to the data more closely, we take our model-simulated data and regress the spread on a constant and our three shocks. Besides the benchmark versions of SG and DG, we also included the results when we calibrate the output process to Argentina in the DG case. The results are in Table 13. We have already reported the results of estimating our statistical model in Table 3. However, those regressions included our two common factors. To make a closer comparison with the model regressions, we examine regressions for several of our countries with just the financial controls we considered in decomposing the common factors. We believe that including these financial controls as important in making this comparison. In our model data the output and wealth shocks are orthogonal by construction. In the actual data, an important concern is the feedback from interest rate or risk premium shocks to growth (as emphasized by Neumeyer and Perri, 2005).

While our two benchmark models were calibrated to Mexico, which we view as representive of countries subject to sovereign debt crises, the data series are fairly short to evaluate these somewhat rare events. Hence, it is useful to compare our model regression results to a range of countries in the data. To aid in this comparison, we also consider the DG version of our model with a growth process calibrated to Argentina.

In the SG model the output shock is the growth rate, or g_t, while in the DG model it is the deviation from trend, or z_t. To make a consistent comparison to the data-based regressions, we did them both with the growth rate of output as the shock and with the deviation of log output from a linear trend. These results are reported in Tables 14 and 15.

When we examine the results for the SG benchmark model with nonlinear default costs, one sees that the debt-to-output ratio has a positive coefficient and is explaining 38% of the movements in the spread as measured by the marginal R^2. This finding is consistent with the data regressions where this variable always has a positive coefficient and explains almost half of the spread in three of our countries and virtually nothing in two of them. The marginal R^2 for the growth rate shock is 0.01, which is very consistent with our growth rate regressions in Table 14 and the sign of that coefficient is positive. The wealth shock explains 17% of the variation according to the marginal R^2. This too is consistent with the data, since in some countries the financial variables explain very little, and in several others, particularly Mexico, they explain a great deal.

There are two major surprises in the SG model regression. First, the sign of the output shock is positive in the SG model, indicating that positive growth rate shocks raise the spread. This is contrary to the sign of this term in the data regressions. However, this result seems consistent with the results we showed for a boom-bust cycle in Fig. 7. There, only the initial response to a good output shock was negative while a sequence of good output shocks led the government to raise its debt-to-output ratio and thereby induce an

increase in the spread. Note that this response is not present in the DG model. Instead, because the government was slower to delever, a sequence of positive shocks followed by a negative one led to a temporary jump upwards in the spread.

Second, the sign of the wealth factor is positive, indicating that an increase in investor wealth, which should lower risk pricing holding everything else fixed, actually raises the spread. This result is consistent, however, with our earlier surprise finding that the sign of the P/E ratio in the data regressions is positive, indicating that a fall in the risk premium in the data also raises the spread. We will seek to better understand this finding in our quantitative exercises below.

In the simulated data regressions from the DG benchmark and DG Argentine models we also see that the debt-to-output ratio explains 30% of the variation in output and that the sign of this term is positive. However, if we compare this explanatory power to the regressions in Table 15, this is high relative to what we find when we take the output shock to be a deviation from trend. The sign on the deviation is negative, as one would expect and as we see in the data. In the DG benchmark the explanatory power of the output shock is only 11% which is consistent with the regression results. However, the explanatory power of this variable under the Argentine growth process is over 50%, which is much higher than anything we see in the data regressions. Thus it does seem like the ability of the nonlinear output cost element to increase the spread volatility when the variability of output is sufficiently high comes at the expense of tying the spread much too closely to output fluctuations. In addition, the sign of the wealth term changes when we move from the benchmark to the Argentinian output calibration. However, the positive sign in the benchmark case is consistent with the positive sign of the P/E ratio in the data regressions.

5.5 Comparative Experiments

We want to examine how the equilibrium predictions of our two benchmark models respond to changes in several key parameters. This will help us understand exactly what is driving our outcomes. In these experiments we change only the parameter in question, and we explicitly do not recalibrate the other parameters. The results are given in Table 16.

The first set of results in column 2 examines the impact of shortening the average maturity from 2 years to 1 quarter. In both the SG and the DG versions, this shortening of the maturity sharply reduces the default rate and the average spread almost to zero. This occurs because with debt that matures in a single period, future debt issuance has no effect on the value of bonds currently being issued. With longer maturity bond this is not the case and future issuances dilutes the value of current debt. Since capital loss on outstanding bonds from new issuance of debt is not borne by the sovereign, long maturity bonds induce over-borrowing and higher default risk. Put differently, with short maturity debt,

Table 16 Comparative statistics: Stochastic and deterministic growth models

R^2 of spreads on w	0.17	0.01	0.36	0.001	0.23

the government is forced to internalize the full cost of a rise in default risk and therefore chooses to constrains its borrowing.

The second set of results concerns the impact of risk aversion on our equilibrium outcomes. In both the SG and DG cases, the frequency of default falls sharply. However, the increase in the price of risk just offsets this drop, so the average spread stays roughly unchanged. This indicates the greater discipline imposed on sovereign's borrowing behavior from a higher risk aversion on part of lenders. The greater discipline comes from the fact that the spread required per unit of default risk is higher with greater risk aversion, making default risk much more expensive for the sovereign. As a result, the sovereign optimally chooses to lower its expected future default risk. This result can also sheds light on why an increase in w raised the spread rather than lowering it. Future risk pricing can discipline future behavior. How strong that is will determine the extent to which it shows up as an increase or a decrease in the spread today. But it will increase the frequency of defaults.

The third set of results concerns the impact of making wealth shocks i.i.d. In this case, the disciplining affect of having a high future price of risk because of a low value of w today is removed. In the benchmark cases, this future discipline led to a twisting of the price schedules. When the debt-to-output is low, the future disciplinary effect dominates the static risk pricing effect and, as a result, a high w shocks lowers the price of debt. When the debt-to-output ratio is high, the static pricing effect dominates and rise in w increases the price of debt (see Fig. 5). With i.i.d. w, this twisting effect is gone and an increase in w strictly increases q where it is below the risk-free rate. In both the SG and DG models this leads to a sharp fall in the impact of wealth shocks on the spread as measured by the R^2. Consistent with this, the correlation of the wealth shock and the spread goes from 0.15 in the benchmark to 0.002 with i.i.d. w in the SG model and from 0.40 to 0.03 in the DG model.

The final set of results concerns the impact of autocorrelation of output shocks. For the SG model we reduce the correlation in the output growth rate g from 0.45 to 0, and in the DG model we reduce the correlation in the deviations from trend from 0.85 to 0.45. In both models the debt-to-output ratio goes up as the hedging motive goes up. In both models the default frequency goes down as the likelihood of a sequence of bad shocks driving a country into default goes down. In addition, in both models the incentive to borrow into a boom goes down as the likelihood of the good times continuing is reduced. As a result, the correlation of the spread and the growth rate of output is now negative in both models. At the same time spreads and default frequencies fall in both models.

5.6 Taking Stock

Our models of sovereign borrowing, default and the spread can match a number of key facts in the data. They can match the overall borrowing level, but this comes at the expense of assuming that default costs are large so that we can get the sovereign to repay, and that the sovereign is fairly myopic since borrowing and occasionally defaulting is, as we noted earlier a poor way of getting insurance.

Risk aversion on part of lenders leads to the average spread being greater than the average frequency of default, hence lenders earn a positive risk premium of about 1%.

The sovereign tends to borrow into booms, which is consistent with the boom-bust cycle we observe in many emerging economies. Also, the end of the boom is associated with a sudden shift in the price schedule for debt, which resembles the lending cutoff (sudden stops) observed in the data. This borrowing into booms depends on future optimism, which here comes through the autocorrelation in output shocks. If we make growth rates i.i.d. in the SG model or reduce the persistence of deviations from trend in the DG model, borrowing-into-booms effect largely goes away. This in turn leads to a sharp fall in the frequency of default and therefore the spread.

When we compare the spread regressions in the model simulated data with those in the data, the overall behavior is broadly consistent with that observed in the data. For both the SG and DG benchmark models, the importance of the debt-to-output ratio and the output shock is consistent with the regression results. However, the positive impact of a growth shock on the spread in the SG model is not consistent with the negative sign of the coefficient on this variable in the regression. This indicates that the reliance on a boom-bust cycle as opposed to the smoothing of consumption is excessive in this version of the model.

Global risk pricing shocks, which we model as shocks to the wealth of investors, have a surprisingly limited impact in our model. Interestingly, an increase in lenders' risk aversion that stems from a decrease in their wealth leads to a *fall* in the spread. A similar impact occurs when we increase investors' risk aversion in our comparative statics exercises. This result comes through the higher price of debt issuance, which lowers the extent to which current lenders need to worry about the dilution of the value of their claims in the future. The threat of future dilution goes away with short maturity debt. This is why we see a sharp fall in default rates and spreads when we switch to one-period debt.

The impact of persistent wealth shocks stemming from changes in borrowing discipline in the future leads to one of the surprising empirical successes of our models. In our spread regressions, a decrease in the price of risk increases the P/E ratio, but increases in the P/E ratio are associated with increases, not decreases, in the spread on emerging market sovereign bonds. This inverse relationship between the price of risk and spreads is predicted by both models. In our comparative statics exercise we saw that this correlation essentially goes away when wealth shocks become i.i.d., confirming that the inverse relationship is driven by anticipation of changes in future borrowing behavior.

The major failure of our benchmark models is with respect to the volatility of the spread. It is much too low in the model relative to the data. This indicates that the levering/delevering response to output shocks is too strong, resulting in a spread that is too smooth. This was particularly true in the initial version of our model with proportionate output costs, but is still true when we switch to nonlinear output costs of default (which improves the insurance offered by defaulting).

Increasing the variance of the output process in the DG model can substantially increase the variance of the spread, bringing it in line with the data for most countries. However, this positive result comes at a cost. First, it implies that the model cannot account for counties in our sample, such as Mexico, which have less volatile output processes. Additionally, relative to the data, higher volatility leads to too strong a dependence of spreads on output shocks.

These results suggest that what is needed is:

1. An additional shock to the pricing of debt that is not tied to country fundamentals or global risk pricing factors. This is indicated by the importance of the two common factors in the spread regressions and their lack of dependance on global asset pricing factors.
2. A reduction in the levering/delevering incentive or at least a drawing out of debt crises, which leads to high levels of the spread in response to these crises.

6. ROLLOVER CRISES

Our model was constructed to allow for rollover crises along the lines of Cole and Kehoe (2000). Here we conduct a preliminary investigation of the potential for rollover crises to add to the volatility of the spread in our models without tying this volatility too tightly to country fundamentals.

Rollover crises emerge from investors' failure to coordinate their beliefs on the good equilibrium outcome in which the government is offered a generous price schedule and therefore chooses to not default. Instead, investors adopt pessimistic beliefs about government's behavior, which leads them to offer an adverse price schedule—specifically, a zero price for new issuance of bonds—and this, in turn, induces the government to default. The government's default then validates the investors' pessimistic beliefs. What is empirically attractive about this mechanism is that while requiring that the country's fundamentals be bad enough to generate a default under the adverse price schedule, it allows relatively wide latitude in the timing of a sovereign debt crises.

In constructing a quantitative model of rollover crises, the first question is: what is a plausible process for beliefs? Beliefs, unlike, say, output, cannot be directly observed, and hence its impact and its stochastic evolution must be inferred. Aguiar et al. (2016) estimate shifts in beliefs from spreads. Another alternative is to adopt a state-space approach in which the belief process and it's realizations are estimated jointly along with other parameters of the model as in Bocola and Dovis (2015). A related alternative would be to construct belief processes that replicated the impact and time series properties of the common factors estimated in the spread regressions reported earlier. However, undertakings such as these are beyond the scope of a handbook chapter. So, instead, we follow Cole and Kehoe (2000) and its quantitative implementation in Chatterjee and Eyigungor (2012) and assume that there is a constant probability of a crisis. This limits the empirical scope of self-fulfilling rollover crises, but does allow us to partially gauge their potential impact. Also, we do not recalibrate the models so this too is a quantitative comparative statics exercise.

The results are presented in Table 17 along with our baseline results (for the nonlinear output loss from default). Here, we assume that if a country is in the crisis zone (ie, a rollover crisis can be supported in equilibrium) then a rollover crisis transpires with a 20% probability. Several results stand out. First, the possibility of rollover crises reduces

Table 17 Stochastic and deterministic growth models: Benchmark vs rollover crises

	Stochastic benchmark	**Stochastic w. RC**	**Deterministic benchmark**	**Deterministic w. RC**
Debt-to-GDP	0.66	0.63	0.66	0.65
Average default freq.	0.02	0.02	0.02	0.02
Average spread	0.03	0.04	0.03	0.04
SD of spreads	0.002	0.002	0.004	0.004
Corr of spreads with Δy or z	0.15	0.06	0.46	0.11
R^2 of spreads on w	0.26	0.18	0.17	0.09
Share of rollover defaults	0	0.70	0	0.30

the average debt-to-output ratio. This makes sense because rollover defaults are generally more costly than fundamental defaults (they can occur even when output is relatively high) and this makes the sovereign wary about borrowing too much. In contrast, the average default frequency does not change much with the addition of rollover crisis and, as a result, the impact on the average spread is fairly small (in the SG model it stays the same, while in the DG model it rises slightly). However, there is significant change in the nature of defaults since many of them are now being induced by rollover crises. This is particularly pronounced in the case of the SG model, where 70% are now rollover-induced defaults. Along with this change in the nature of the defaults comes a change in the relationship between the spread and our fundamental shocks. In both models the correlation of the spread and the output shocks falls. This is particularly pronounced in the DG model, where it falls from 0.46 to 0.11.[o] In a similar fashion, the R^2 of the regressions of our spread on our wealth shock w falls in both models. In the SG model it falls by one-third, while in the DG model it falls by one-half. At the same time, the standard deviation of the spread hardly changes with belief shocks.

The lack of increase in the spread's volatility is surprising. To understand a bit better what is going on, we plot default indifference curves for both the benchmark SG model and the SG model with rollover crises in response to belief shocks in Fig. 10. We start first with the benchmark model. The indifference condition between defaulting and not defaulting traces out combinations of the debt-to-output ratio and the current growth rate. Since growth is positively autocorrelated in this model, high growth today is good news about future output and hence reduces the incentive to default. Of course, a high debt burden encourages default. This gives us the trade-off we see in the first panel of the figure. We have also plotted the stationary debt levels (ie, the debt level where $b = a(s,b)$) as a function of the current growth rate of output. These debt levels are important because the government finds it optimal to lever/delever back to this point in response to a shock. The fact that the stationary points are positively sloped reflects the tendency to borrow into a boom discussed earlier. Defaults occur in equilibrium largely because a sufficiently low growth rate shock from a debt position close to the stationary points last period generated a current debt-to-output level that is on the wrong side of the indifference curve. In which case, the government optimally chooses to default. The fact that the gap between the indifference curve and the stationary point is increasing in g illustrates why default is closely associated with low output shocks.

In the second panel of Fig. 10, we see a similar graph for the SG model with rollover crises. Only now there are two indifference curves: one for fundamental defaults as in the

[o] Another feature of rollover defaults is that they can occur for fundamentals that are, on average, better than in the case of fundamental defaults. Thus, the correlation between defaults and fundamentals is also weakened, consistent with evidence reported in Tomz and Wright (2007). See also Yeyati and Panizza (2011) for an empirical evaluation of the timing of output losses surrounding default episodes.

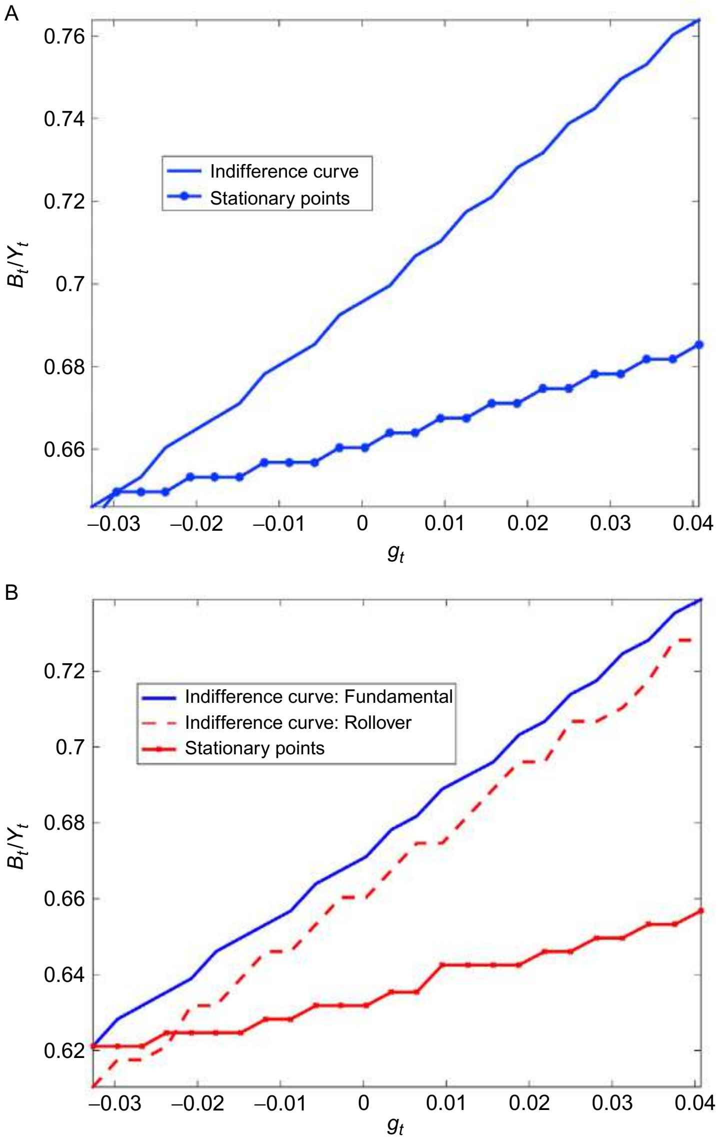

Fig. 10 Default indifference curves and stationary policy choices. (A) Benchmark. (B) w. Rollover crises.

benchmark model and one for rollover crises defaults. Since the lending terms are worse, the rollover indifference curve lies below the fundamental curve, indicating that a rollover crisis is possible for a given growth rate g_t at a strictly lower level of b_t. Note that the fundamental indifference curve is lower than in the benchmark model. This is because the future prospect of rollover crises lowers the payoff even when these crises do not occur today and this has shifted down the solvency indifference curve. As a result, defaults will occur at lower debt levels fixing g than in the benchmark model. Next, note that the stationary debt level curve has also been shifted down. This is because the increased likelihood of a default and its adverse consequences means that the optimal level of borrowing has decreased. The fact that 70% of the defaults occur under the crisis pricing schedule means that the likelihood of drawing a sufficiently bad output shock to force the government over the fundamental indifference curve has gone down substantially. In this sense the gap between the solvency indifference curve and the stationary debt levels has widened.

There is a sense in which virtually all of the defaults in the model with rollover crises are driven by beliefs. This is because, if we asked whether the states in which realized defaults are in equilibrium, very few of them are on the wrong side of the benchmark indifference schedule. It is also worth noting that if we suddenly switch from a situation in which the benchmark pricing schedule, policy function and beliefs applied, to one in which the rollover ones did, then the government would have to sharply delever in the face of a worse price schedule, even if a crisis did not formally occur in the current period. This sort of transition might be a way to generate more volatility in the spread, especially if the government could be induced to slow down the rate at which it delevered.

7. EXTENSIONS AND LITERATURE REVIEW

Beginning with Aguiar and Gopinath (2006) and Arellano (2008), there is now a substantial body of work drawing on the Eaton–Gersovitz framework. Aguiar and Amador (2014a) discuss the theoretical and conceptual issues in this area. This section provides a brief guide to the evolving quantitative literature (the reader is encouraged to consult the studies mentioned here for additional related work).

Existence and Uniqueness of Equilibrium: The existence of an equilibrium when both endowments and assets are continuous is an open question.[p] Aguiar and Amador (2014a) discuss that the operator whose fixed point characterizes the equilibrium (with permanent autarky as punishment) is monotone and note how this can be useful to compute an equilibrium. When both b and the non i.i.d. component of endowments are discrete, Chatterjee and Eyigungor (2012) establish the existence of an equilibrium for debt with arbitrary maturity and temporary or permanent autarky following default.

[p] Eaton and Gersovitz (1981) pointed out that *if* the probability of default $\mathbb{E}_s(D(s', b')$ is differentiable in b', the solution to the bond pricing equation amounts to the solution of a first-order nonlinear differential equation. However, differentiability of $\mathbb{E}_s D(s', b')$ requires everywhere differentiability of the value function, which is not true in a model with default.

The issue of uniqueness of equilibrium is more subtle. For the case where default is punished with permanent autarky, Auclert and Rognlie (2014) prove uniqueness for the Eaton–Gersovitz model with one-period debt. Passadore and Xandri (2015) study the multiplicity that arises when the state space for debt is restricted to be nonnegative (that is, no saving). Stangebye (2015a) and Aguiar and Amador (2016) discuss how multiplicity in the Eaton–Gersovitz model arises in the absence of one-period debt due to the vulnerability to dilution. More generally, one can often construct multiple equilibria with variations on the standard set up. Cole and Kehoe (2000) alter the Stackelberg nature of the government's default decision in order to generate self-fulfilling rollover crises. Chatterjee and Eyigungor (2012) exploits a similar variation to generate (investor) belief-driven rollover crises in a model that otherwise resembles the Eaton–Gersovitz setup.

The Strategic Structure of the Debt Market: In the Eaton–Gersovitz setup, the sovereign accesses the debt market at most once within a period. If the sovereign may access the market as many times within a period as it wishes, lenders at any given round of borrowing must anticipate the sovereign's future within-period borrowing decisions (Bizer and DeMarzo, 1992). As shown in Hatchondo and Martinez (undated) equilibrium implications of this is that investors will offer the sovereign a state-dependent pair of bond price and debt limit, $\{\bar{q}(y,b),\bar{x}(y,b)\}$, with the sovereign free to borrow any $b' \leq \bar{x}(y,b)$ at the price $\bar{q}(y,b)$. Interestingly, the bond *price* depends on inherited debt b (while in the standard setup the bond price *schedule* $q(y,b')$ is independent of b) and, so, borrowing history matters for the terms of credit. Lorenzoni and Werning (2014) and Ayres et al. (2015) discuss this issue in detail.

Contract Choice: In the standard setup, the structure of a unit bond is fixed and described by the pair (z,λ). At the cost of enlarging the state space, more flexible contractual structures are possible. Bai et al. (2014) define a unit bond by (T,δ), where the bond pays $(1+\delta)^{-\tau}$, $0 \leq \tau \leq T$ periods from maturity. Sanchez et al. (2015) consider the case where $\delta = 0$. Both relax the fixity of the contractual structure by letting the sovereign replace old debt each period with new debt with a different contractual structure.

Maturity Choice: Cole and Kehoe (1996) discuss the role of maturity in the presence of self-fulfilling debt crises. In the standard setup, market incompleteness is extreme in that only one type of debt contract can be issued at any time. Arellano and Ramanarayanan (2012) consider the case where the sovereign can simultaneously buy and sell bonds of different maturities and show that the average maturity shortens as fundamentals weaken. Aguiar and Amador (2014b) show that when default probabilities are high, the sovereign has an incentive to reduce its stock of one-period debt. Shorter maturity provides the sovereign the correct incentives to minimize the inefficiencies represented by default. Bocola and Dovis (2015) discuss the role of maturity choice in the presence of both fundamental and rollover crises and analyze their separate roles in the recent Eurozone debt crisis.

Exchange Rates, Default Risk, and Currency Denomination: Sovereign defaults are generally preceded by a depreciation of the country's currency, with a further sharp depreciation occurring soon after default. Asonuma (2014) documents these facts and develops a two-country model with traded and nontraded goods in which one country is the borrower and the other the lender. Negative shocks to productivity in the borrowing country can trigger a real exchange rate depreciation which, in turn, can raise the likelihood of a default on sovereign debt. Gumus (2013) examines the currency denomination of debt in a similar model with two types of debt: In one, the payoff is linked to the domestic price index (a proxy for local currency debt) and in the other to the price of the tradeable good (a proxy for foreign currency debt). Although the default risk on "local currency debt" is not uniformly lower than the default risk on "foreign currency debt," the former is found to be the better (higher welfare) arrangement.

Explicit Treatment of the Government: For some purposes, it is important to model the sovereign separately from private-sector agents. Cuadra and Sapriza (2008) analyze borrowing and default behavior when redistributive conflict and the risk of political turnover impart myopia (present-bias) *a lá* Alesina and Tabellini (1990). In their model, the sovereign discounts the future more than citizens do, which helps to partially rationalize the low discount factors often used in quantitative models. Hatchondo et al. (2009) consider two types of governments that differ in their discount factors with the goal of analyzing how political risk affects default probabilities and the volatility of spreads. Cuadra et al. (2010) model the government sector in order to give an account of the strongly procyclical nature of fiscal policy in emerging economies.[q]

Settlement Following Default: Sovereign defaults end with a settlement on the defaulted debt, wherein creditors accept a haircut and the sovereign regains (unencumbered) access to credit markets. Generally, settlement occurs after a significant amount of time has elapsed since default. In the context of one-period debt and equal treatment of all creditors in default (the so-called *pari passu* clause), Yue (2010) models settlement as the outcome of a one-shot Nash bargain between the sovereign and the representative creditor in the period of default. Following agreement, the sovereign is assumed to repay the renegotiated debt over time, with no possibility of default or access to new borrowing. This produces a theory of haircuts but not of delays. Bi (2008) assumes that defaulted debts must be settled in cash but employs the stochastic alternating-offers game developed in Merlo and Wilson (1995) to produce a theory of both haircuts and delays. Benjamin and Wright (2009) observe that settlement is typically done with new debt (rather than just cash) and allow for this possibility within the context of the stochastic

[q] Amador (2012) shows that once the equilibrium of the political game between different groups comprising the government is taken into account, it becomes possible to sustain positive levels of debt even when punishment for default is limited to exclusion from future credit (*contra*; Bulow and Rogoff, 1989)

alternating-offers game. In both models, delays arise because it is optimal for both parties to defer settlement until the sovereign's endowment is sufficiently high.[r]

Restructuring Without Default: Default and debt restructuring is a form of ex-post state contingency. Logically, and in practice, ex-post state contingency need not involve default. Hatchondo et al. (2014) point to voluntary debt exchanges as debt write-offs that occur when a sequence of bad endowment shocks places the sovereign on the wrong side of the revenue Laffer curve. Relatedly, Asonuma and Trebesch (2015) document that about a third of all restructurings in the last several decades occurred in the absence of default, termed *preemptive* restructuring. They extend the Eaton–Gersovitz model to allow for such restructurings and show that they occur when the likelihood of a future default is high. Salomao (2014) has analyzed how the presence of a credit default swap (CDS) market impacts debt renegotiation, when the outcome of the negotiation determines whether a "credit event" is triggered.

Partial Default: Default is typically modeled as a binary event on a single type of debt. In reality, sovereigns have a range of external obligations outstanding at any point in time, including trade credit, bank loans, bonds, bilateral (government-to-government) loans, loans from multilateral agencies (IMF, World Bank and other agencies) and they may choose to default on some types of loans but not on others. Thus, in the aggregate, default tends to be partial. Based on this observation, Arellano et al. (2013) develop a one-period debt model in which the sovereign can partially default on existing debt. Unpaid debts accumulate arrears and there is an output loss that is increasing in the ratio of unpaid to total debts. In their model, moderately bad output shocks trigger partial default that gets "cured" as output recovers.

Reputation: Quantitative sovereign debt models generally do not give any role to reputation in sustaining debt, although the idea that reputation matters is invoked in Eaton and Gersovitz, and, more comprehensively, in Tomz (2007). D'Erasmo (2012) extends the Eaton–Gerovitz model to the case where investors are uncertain about the sovereign's discount factor (degree of patience), which is taken to be stochastic. Investors' perception of the likelihood that the sovereign is the patient type now appears as an additional state variable in the sovereign's dynamic program. The patient type's desire to separate itself from the impatient type encourages more disciplined borrowing behavior on its part. In equilibrium, the patient type can sustain a higher level of debt on average. Generally speaking, the impatient type defaults and the patient type reaches settlement on the defaulted debt.

[r] Bai and Zhang (2012) explore the role of asymmetric information in creating delays in reaching settlement in a stylized environment. The uninformed party (the sovereign) screens creditors (who privately know their reservation value) by making successively attractive offers over time. They show that delay is shorter when the defaulted debt is traded in the secondary market because the price partially reveals the creditors' reservation value.

Sudden Stops: There is a large literature on "sudden stops" that focuses on the macroeconomic implications of a halt of capital inflows into emerging markets. This literature does not base the "sudden stop" on a rollover problem and abstracts from the possibility of sovereign default induced by the sudden stop (see, for instance, Mendoza (2010) and the references cited therein). Bianchi et al. (2014) make the connection to sovereign default by extending the Eaton–Gersovitz model to allow for an exogenous stop in capital inflows and study the role of international reserves (which cannot be grabbed by foreign investors in the event of default) as a hedge against such stops.[s]

Fiscal Rules and Default: There is a literature aimed at understanding the equilibrium implications of fiscal policy rules. Ghosh et al. (2011) analyze a model where the government adheres to some given fiscal rule as long as the deficit implied by the rule can be financed at a finite interest rate. In terms of our notation, this is a setup in which there is some function $c(y,b)$ (the fiscal policy rule) and b' is chosen each period to satisfy $q(y,b') \cdot [b' - (1 - \lambda)b] = y - (r^* + \lambda)b - c(y,b)$. Because the revenue curve $q(y,b')b'$ is an inverted U, there may be no b' that satisfies this equation in which case the sovereign defaults. Furthermore, if there is one b' that satisfies the budget constraint, there will always exist another b' on the "wrong side" of the revenue Laffer curve that will also satisfy this equation. Ghosh et al. assume that the sovereign and investors avoid the wrong side of the Laffer curve and compute the highest debt level $\bar{b}$ beyond which default is certain. Lorenzoni and Werning (2014) and Stangebye (2015b) study a similar setup but the focus is on the rise in interest rates if investors temporarily coordinate on the low price (and therefore high debt) equilibrium path. These authors focus on the recent Eurozone experience.

Debt Dilution and Alternative Trading Arrangements: In quantitative models with long-term debt, "debt-dilution" is an important force leading to excessive borrowing and default. This leads to consideration of alternative trading arrangements that mitigate the adverse effects of debt dilution. Chatterjee and Eyigungor (2015) analyze how respecting seniority during (postdefault) debt renegotiations can improve incentives and the welfare of the sovereign. Hatchondo et al. (2015) analyze how adherence to a fiscal policy rule that binds future sovereigns' borrowing decisions can improve the welfare of the current sovereign.

Decentralized Borrowing and Centralized Default: A growing portion of a country's external debt is debts incurred by private borrowers. Kim and Zhang (2012) analyze an Eaton–Gersovitz model in which private agents choose how much to borrow but the sovereign chooses whether to default. Because private borrowers act as price-takers,

[s] The accumulation of foreign reserves to mitigate rollover risk has been examined from an optimal contracting perspective in Hur and Kondo (2014). They point to the drop-off in the frequency of sudden stops following reserve accumulation by emerging markets as evidence that reserves affect the likelihood of a rollover crisis.

the equilibrium resembles one in which the sovereign can access the credit market unboundedly many times within a period.

Contagion and Correlated Defaults: Lizarazo (2009) studies how the terms of credit offered to sovereigns are affected if sovereigns share a common risk-averse lender. Correlated defaults may occur because a default by one sovereign lowers the wealth of the lender and reduces the supply of credit to all sovereigns. The reduction in supply could push another sovereign into default. Arellano and Bai (2014) study a similar environment but include renegotiation on the defaulted debt and show that bargaining protocols (independent vs coordinated bargaining with sovereigns following default) differentially affect the likelihood of correlated defaults.

Inflation and Default: The bulk of the quantitative-theoretic literature on debt and default models real economies. Two exceptions are Nuno and Thomas (2015) and Du and Schreger (2015). The former compares (in a continuous-time setting) outcomes where sovereign debt is denominated in real terms (with the possibility of outright default) to one where it is nominal and the sovereign chooses monetary and fiscal policy under discretion. The latter studies default risk on sovereign debt denominated in local currency, when private borrowers issue debt denominated in foreign currency. The existence of foreign currency private debt makes inflating away local currency sovereign debt expensive and, thus, keeps default risk on local currency sovereign debt positive (as observed in the data).

News Shocks: Sovereign defaults do not occur only when fundamentals are weak. One possible explanation of this fact could be that they occur when the sovereign and investors receive bad news about the future. Durdu et al. (2013) extend the standard Eaton–Gersovitz set up to include news shocks about future TFP. In addition to default triggered by bad news, the precision of news about future TFP is shown to have quantitatively significant effects the bond pricing schedule.

Default Costs: Quantitative-theoretic models of debt and default typically take the structure of the output costs of default as given. Two exceptions to this practice are Mendoza and Yue (2012) and Perez (2015). In the former, the default costs are grounded in producers' inability to import foreign intermediate inputs when the country is in default. The key implication of this setup is asymmetric default costs: the output costs of default are proportionally higher when TFP is high because that is when the loss of foreign intermediate inputs is proportionately more costly. In the latter, the output costs of default are grounded on the loss of net worth of financial intermediaries (who hold sovereign debt) that occurs with default and the consequent fall in the level and efficiency of financial intermediation, which then depresses output.

Investment and Default: The quantitative debt and default literature has uniformly examined endowment economies. An exception is Gordon and Guerron-Quintana (2016) who extend—both substantively and computationally—the long-term debt model of Chatterjee and Eyigungor (2012) to include capital accumulation (with costly adjustment) and labor-leisure choice. Their goals are a more complete understanding of emerging market business cycles and of the impact of phyiscal capital on debt sustainability.

8. CONCLUSION: WHERE WE'VE BEEN AND WHERE WE NEED TO GO?

This chapter has documented a number of important facts about sovereign default crises, including:

1. Average spreads, spread volatility and the frequency of spread crises vary quite a bit across developing countries.
2. Fundamentals explain only a limited share of spread movements.
3. Spreads have some common factors driving them. However, these factors do not seem tightly connected to standard measures of risk pricing, uncertainty or the risk-free rate.

We have also examined alternative versions of the standard model of sovereign borrowing and defaults. Some of these versions explain many of the main facts, such as the average spread, the default frequency and average debt-to-GDP ratios. However, all of these models struggle to simultaneously explain the volatility of spreads and its apparent lack of connection to country fundamentals. Specifically:

1. In our model countries engage in very limited borrowing and saving to smooth consumption. While this leveraging and deleveraging behavior is found in the data, it seems much less pronounced. As a result, the variation in the debt-to-output ratio is smaller in the model than in the data. This leads to much less variation in the models' implied spread.
2. Nonlinear default costs can increase the volatility of the spread in the DG model when the volatility of output is high. But this increase in the spread comes at the expense of tightly tying movements in the spread to country fundamentals.
3. The SG model is much less sensitive to including nonlinear default costs in part because the low current output realizations do not stimulate much borrowing as growth rates are modestly positively persistent and because the volatility in growth rates is small relative to volatility in the deviation from trend.

Both increases in the risk aversion of our lenders and negative shocks to their wealth did not lead to sharp increases in the spread as simple intuition might suggest. Instead the disciplinary effect of the increase in the price of default risk reduces the future incentive of the government to issue debt into the range that will generate a positive probability of default. This increase in future discipline lower creditors' anticipation of future dilution of their claims by the government and can actually reduces spreads. This negative relationship between the pricing of default risk and the equilibrium spread also appears to be an important factor in the data, thus, validating this surprising implication of our models.

The failure of our models to explain the volatility of spreads stems from the fact that the debt-to-output ratio is largely pinned down by a couple of key features. First, because the government is quite myopic, smoothing plays a limited role in it's optimal policy choice; instead, borrowing is driven by impatience that is ultimately held in check by lack of commitment. Second, because of the strong feedback effect of default risk and risk premia on the government's incentive to default, the debt price schedule is highly nonlinear in the relevant region. As a result, the location of the kink in the price schedule interacts with the sovereign's myopia to almost completely determine its borrowing behavior. In the end, this leads to sharp leveraging/deleveraging in response to positive and negative output shocks and very little variation in the spread. These forces are somewhat ameliorated in cases where the output shock is sufficiently volatile (so the nonlinearity in the default cost can play a role), but even in those cases the sovereign's behavior responds sharply to the contemporaneous shock realization and does not display the history dependance that expenditure-smoothing would have implied. As a result, only the current output shock matters for spreads and this ends up overloading its importance relative to the data.

Rollover crises are a promising way of generating debt crises, particularly since they don't imply an overly tight connection to country fundamentals. However, the sort of stationary rollover risk that we have considered here is not sufficient to produce the kind of variability in the spread that we see in the data. Instead, they seem to simply crowd out standard fundamental crises. What is needed is a more dynamic version of time-varying risks. At the same time, we need to rationalize a reduction in the speed with which the government chooses to undo the impact of negative shocks on the spread by borrowing less and yet not default on the debt.

Abstract

This essay reviews the development of neoclassical growth theory, a unified theory of aggregate economic phenomena that was first used to study business cycles and aggregate labor supply. Subsequently, the theory has been used to understand asset pricing, growth miracles and disasters, monetary economics, capital accounts, aggregate public finance, economic development, and foreign direct investment.

The focus of this essay is on real business cycle (RBC) methodology. Those who employ the discipline behind the methodology to address various quantitative questions come up with essentially the same answer—evidence that the theory has a life of its own, directing researchers to essentially the same conclusions when they apply its discipline. Deviations from the theory sometimes arise and remain open for a considerable period before they are resolved by better measurement and extensions of the theory. Elements of the discipline include selecting a model economy or sometimes a set of model economies. The model used to address a specific question or issue must have a consistent set of national accounts with all the accounting identities holding. In addition, the model assumptions must be consistent across applications and be consistent with micro as well as aggregate observations. Reality is complex, and any model economy used is necessarily an abstraction and therefore false. This does not mean, however, that model economies are not useful in drawing scientific inference.

The vast number of contributions made by many researchers who have used this methodology precludes reviewing them all in this essay. Instead, the contributions reviewed here are ones that illustrate methodological points or extend the applicability of neoclassical growth theory. Of particular interest will be important developments subsequent to the Cooley and Hansen (1995) volume, *Frontiers of Business Cycle Research*. The interaction between theory and measurement is emphasized because this is the way in which hard quantitative sciences progress.

1. INTRODUCTION

This chapter reviews the development and use of a quantitative, unified theory of aggregate variables both across time and across economies at a point in time. This theory accounts not only for traditional business cycle fluctuations but also for prosperities and depressions, as well as for the vast difference in living standards across countries. This unified quantitative dynamic general equilibrium theory accounts for the large movements in asset values relative to gross national income (GNI), the consequences of alternative monetary policies and tax systems, and the behavior of current accounts as well.

No competing quantitative theory has been developed for the study of aggregate economic behavior. This disciplined theory is unified and has been tested through successful use. The assumptions made when constructing a model economy, or in some cases a set of economies, to address a given question must be consistent with assumptions made in the previous successful applications. Deviations from this theory have arisen, which is evidence that some real theory is involved.[a] Other deviations remain to be discovered. Some of the recognized deviations or puzzles have been resolved via further development of the theory, others by better measurement. This interaction between theory and measurement is the way in which a hard quantitative science progresses.

We call this theory neoclassical growth theory. Key features of this theory are the allocation of productive time between market and household activities and the allocation of output between consumption and investment. Depending on the application, other features of reality must be included, such as sector detail, the nature of the financial system as specified by laws and regulations, and the contracting technology available. Heterogeneity of people in the model economy, with respect to age and idiosyncratic shocks, must be and has been included in models used to address issues such as the consequences of an aging population for various tax policy regimes.

The underlying theoretical framework is the theory of value, in particular the capital theory variant. This means the models used to draw scientific inference will have a recursive structure. This is a crucial feature for the model economies being used to draw scientific inference because the national account statistics can be constructed and compared with actual statistics.

To summarize, aggregate economics is now a hard quantitative science. It has been tested through successful use in all substantive fields of economics.

2. A BRIEF HISTORY OF BUSINESS CYCLES

Fluctuations in the level of business activity have long been a topic of concern. Mitchell (1913, 1927) collected many indicators of the level of economic activity. He viewed the level of economic activity as being cyclical with alternating periods of contractions and expansions. He developed the National Bureau of Economic Research (NBER) definition of recession, which is a period of contraction in the level of economic activity. This definition is still used by the NBER. He categorized his set of indicators into leading indicators, lagging indicators, and contemporaneous indicators. This was the framework he used for forecasting, and it did improve forecasting.

Mitchell called these fluctuations "business cycles." Wicksell (1918) used a rocking horse analogy to think about business cycles. Rocking horses display damped oscillations absent new shocks. This development led the profession to search for an economic structure with these properties. Frisch (1933) viewed business cycle research as the search for shocks or impulses to the economy and a damped oscillatory propagation mechanism.

[a] Trade theory is a disciplined theory. All using the discipline of trade theory come up with essentially the same findings. See Arkolakis et al. (2012).

Samuelson (1939) developed his multiplier–accelerator macroeconomic model that displayed these properties. His model had a consumption function and an investment equation. His model was also a second-order linear equation in real output with parameters that gave rise to damped oscillatory behavior.

The NBER definition of recessions is flawed along three dimensions. First, no corrections are made for trend growth or population size. With the NBER definition, the economy is in expansion 90% of the time and in recession or contraction 10% of the time. With trend-corrected real gross domestic product (GDP) per person 16 years and older, the economy is expanding approximately half of the time and contracting half of the time. Second, the NBER definition of recession is not revised subsequent to revisions in the economic time series. These revisions are sometimes large and are made years later as recent census data become available. If the revised data were used, the timing and magnitude of recessions and expansions would change. Third, the NBER definition of recession is not well defined and has a large subjective element.

The biggest problem in business cycle theory is that these so-called business cycles are not cyclical. This was established by Adelman and Adelman (1959), who found that the Klein–Goldberg model—the first econometric model to be used to forecast business cycles—displays damped nonoscillatory behavior. This finding, however, does not rule out the existence of longer cycles in the level of business activity. Kuznets's (1930) view was that there were 15- to 20-year cycles in output and prices in the United States. He labeled these fluctuations "secondary secular movements." Subsequently, they were called Kuznets cycles. Kondratieff and Stolper (1935) hypothesized even longer business fluctuations with 50- to 60-year cycles.

There are, of course, seasonal cycles, which are cycles in the true sense of the word. But they are of little interest and receive little attention in aggregate analysis. To handle them, the economic data used in aggregate analyses are seasonally adjusted.

2.1 The National Accounts: Defining Macroeconomics

A goal in the early 1930s was to come up with a measure of the performance of the business sector. Kuznets (1930) came up with one that proved to be useful. This measure is gross national product (GNP), the value of all final goods and services produced. Other researchers measured the value of the inputs to the business sector, which are the services of capital stocks. The most important category of these services is the services of different types of human capital. The aggregate value of human capital services is commonly called labor income. The services of tangible capital make up the other major category. The aggregate value of these services is called capital income. Claims against output are by definition income, and given that all businesses have a residual claimant, income equals product.

In the late 1930s, Tinbergen (1952) developed quantitative dynamic time series models and used them for forecasting. Given his background in physics, he thought in terms of empirically determined dynamic systems with instruments and targets.

On the other hand, Lawrence R. Klein, the father of macroeconometric modeling, had a theory underlying the dynamic aggregate models he developed and used for forecasting. The theory is the Hicksian IS-LM theory, later augmented with a Phillips curve. The beauty of Klein's work was that it featured a fully specified dynamic system, which had national accounts. All accounting identities held, which resulted in a consistent set of forecasts for all of the variables. Over time, these macroeconometric models grew in size as the sector detail became richer. Klein's model and other macroeconometric models in his framework came to dominate because their use dramatically improved forecasting. After World War II, for example, most economists thought the United States would experience another Great Depression. Using his model, Klein correctly forecasted that no depression would occur.

The nature of macroeconomics in the 1960s was coming up with a better equation to be included in the basic macroeconomic model. The generally held view was that the neoclassical foundations for the empirically determined aggregate dynamic system would subsequently be developed. The famous Phelps Conference at the University of Pennsylvania in 1969, entitled "Micro Foundations of Wage and Price Determination," tried to bring about the synthesis of macroeconometric models into neoclassical economics.

This neoclassical synthesis, however, was not to be. Lucas (1976a), in his paper entitled "Econometric Policy Evaluation: A Critique," found that the existence of a policy-invariant dynamic system is inconsistent with dynamic economic theory. The implication of this finding was that there was no hope for the neoclassical synthesis. The use of dynamic economic theory to evaluate policy requires that the dynamic system governing the evolution of the national accounts be an endogenous element and not a policy-invariant element, which can be empirically determined.

What happens at a point in time depends on what policy regime will be followed in the future. An implication of this fact is that economic theory cannot predict what will happen as a consequence of a possible current policy action choice. What will happen as the result of a policy action is not a well-posed question in the language of dynamic economic theory. What will happen if some policy rule or regime is followed in the future is a well-posed economic question—a point made by Lucas (1976a).

No one challenged Lucas's conclusions, and those who continued to support the use of macroeconometric models for evaluating policy took the position that a different theoretical framework was needed for the study of business cycle fluctuations. Indeed, many used the theory underlying macroeconometric models of the 1960s to confidently predict that the unemployment rate could be decreased by increasing the inflation rate. In 1969 the unemployment rate and inflation rate were both about 4%. The policy consensus based on the perceived trade-off between inflation and unemployment was that the unemployment rate should be reduced because the social gains from having a lower unemployment rate exceeded the cost of the higher inflation.

This consensus led to an attempt to exploit this trade-off in the 1970s. As Lucas and Sargent (1979) point out, this attempt failed—and failed spectacularly, as predicted by dynamic economic theory.[b] Given this failure of Keynesian macroeconomics, the question was what would replace it.

2.2 Neoclassical Growth Theory: The Theory Used in Aggregate Analysis

The development of aggregate measures of outputs and inputs to the business accounts led to the identification of a set of growth facts. Kaldor's (1957) stylized view of these facts for long-term economic growth in the United States and the United Kingdom are as follows. Roughly constant are capital and labor shares of national income, consumption and investment shares of output, the return on investment, and the capital–output ratio. Growing at the same rate over time are national income and the real wage.

Solow (1956) developed a simple, elegant model that accounted for these facts. The model has an aggregate production function with constant returns to scale, with labor and capital being paid their marginal product. All productivity change is labor augmenting. Investment is a constant share of output, and the time allocated to market production per worker is a constant. Thus, the household makes no decisions. Following Frisch (1970), I therefore refer to the model as being classical.

Around the same time, Swan (1956) developed his growth model that is also consistent with the Kaldor growth facts. The key difference between his model and Solow's model is that Swan did not require neutral technology change. Instead, he assumed a unit elasticity of substitution between the factors of production. In the Swan (1956) paper, he carries out some output accounting. The Swan model is the one that has been used for output accounting.

2.3 The Classical Growth Model and Business Cycle Fluctuations

Lucas (1976b) defined business cycles as being recurrent fluctuations of output and employment about trend and the key facts to be the nature of comovements of aggregate variables about trend. But without a definition of trend, this is not a fully specified definition of business cycle fluctuations. This led Hodrick and Prescott (1980) to develop an operational definition of trend, and they used it to represent time series as the sum of a trend component and a business cycle component. In constructing the trend, a penalty was imposed on the sum of squares of the second differences of the trend. In mathematical terms, a time series y_t is represented as the sum of a trend component g_t and a cyclical component c_t; that is,

$$y_t = g_t + c_t.$$

Given the values of the y_t, the g_t is selected to minimize

[b] Lucas (1972), in what was probably the first dynamic aggregate theory paper, developed a model that displayed an empirical Phillips curve. He predicted that if attempts were made to exploit, they would fail. This prediction was made prior to the attempts to lower the unemployment rate by increasing the inflation rate.

$$\sum_{t=1}^{T} c_t^2 + \lambda \sum_{t=-1}^{T} [(g_t - g_{t-1}) - (g_{t-1} - g_{t-2})]^2.$$

This simple operational procedure has a single smoothing parameter, $\lambda \geq 0$. This parameter is chosen to mimic the smooth curve researchers would draw through the data. The larger its value, the smoother is the trend component. For quarterly data, the first number that Hodrick and I chose and ended up using was 1600. There is no right or wrong number, and it cannot be estimated because it is part of an operational definition. What is desirable is that the same statistics are used across studies of business cycle fluctuations of this type. This uniformity permits comparisons across studies.

A feature of this procedure is that the same linear transformation of the logarithm of all the inputs and outputs to the business sector is made. Consequently, Swan's (1956) output accounting could be used for the operationally defined cyclical component of the time series.

In examining the nature of these fluctuations, researchers documented some business cycle facts for the deviations from trend for the US economy for the 1950.1 to 1979.2 period:

(i) Consumption, investment, market hours, and labor productivity all moved procyclically.

(ii) The standard deviation of fixed investment was 5.1%, and the standard deviation of consumption was only 1.3%.

(iii) Market hours and GDP per hour were roughly orthogonal, with hours having twice the variance.

(iv) The standard deviation of quarterly log output was 1.8%, and the first-order serial correlation was 0.74.

(v) Stocks of capital lagged output, with the lag increasing with the durability of the capital. Inventory stock was almost contemporaneous, producer durables stocks lagged a few quarters, and structures lagged a couple of years.

2.4 The Neoclassical Growth Model

Kydland and Prescott (1982) added an aggregate household to the classical growth model in order to endogenize two key allocation decisions. The first of these allocation decisions is the split of output between investment and consumption. The split varies cyclically. The second of these allocation decisions is how much productive time is allocated to the business sector and how much to the household sector. These allocations are endogenous elements of the neoclassical growth model and, with respect to the aggregate household, depend on both its willingness and its ability to substitute. Thus, this extension of the growth model made it neoclassical in the sense of Frisch (1970).

Kydland and I found that if there were persistent shocks to factors determining the balanced growth path *level* of the neoclassical growth model and if the aggregate household was sufficiently willing to intertemporally substitute market time, the neoclassical growth model displayed fluctuations of the business cycle variety. The aggregate utility function of the stand-in household had a high Frisch labor supply elasticity, much higher than the one labor economists estimated using a representative household construct.

If there are common homothetic convex preferences across households, the aggregated household's labor supply elasticity is the same as that of the individuals being aggregated. Empirically, however, these elasticities are not the same. Kydland and Prescott (1982) found that the aggregate labor supply elasticity must be in excess of 3 for the neoclassical growth model to predict business cycle fluctuations, whereas MaCurdy (1981), using panel data, estimated the labor supply elasticity of prime-age males working continuously to be only 0.15. The aggregate and disaggregate estimates must be consistent, and a reason for this difference is needed.

2.5 Why the Discrepancy Between Micro and Aggregate Elasticity Estimates?

Rogerson (1984) came up with the reason for the discrepancy between micro and aggregate estimates. He observed that the principal margin of adjustment in aggregate labor supply was in the number of people working in a given week and not in the hours worked per worker. Consequently, the micro estimate of the labor supply using a theoretical structure predicting just the opposite has to be dismissed as an estimate of the aggregate labor supply elasticity. The labor economist conclusion that tax rates had little consequence for aggregate labor supply was wrong. This is an important example of the failure of micro theory in drawing *aggregate* scientific inference. Aggregation matters. This was recognized by Marshall in his classic textbook first published in 1890 and by Wicksell around the same time. The aggregate production function, given that there is entry and exit of production units, is very different from the production functions of individual units.

Rogerson (1984) developed a formal theory of the aggregate utility function when there was labor indivisibility. This theory was developed in a static context. Hansen (1985) introduced it into the basic neoclassical growth model and found that the resulting model displayed business cycle fluctuations. This research resolved the puzzling discrepancy between micro and aggregate observations.

2.6 Why Is There Labor Indivisibility?

The puzzle of what could give rise to labor indivisibility was resolved by Hornstein and Prescott (1993), who found that if individuals' outputs of labor services is a function of the capital that each worker uses, the margin of adjustment is the number of people working and not the number of hours worked. The fraction working is the margin used up to the point at which all are working. This model endogenized labor indivisibility in a simple version of the optimal growth model. An important point is that it breaks the clean separation between preferences and technology in determining the aggregate elasticity of labor supply.

An alternative theory of labor indivisibility was subsequently developed by Prescott et al. (2009). The key feature of this theory is that the mapping of time allocated to the market to units of labor services supplied is not linear. The increasing mapping is initially convex. Reasons for this nonlinearity include the time needed to update information on which decisions are made and the time needed to get organized. Then the mapping becomes concave; one reason is that workers become tired and perform tasks less well or at a lower rate.

One implication of this theory is that workweeks of different lengths are different commodities. This was recognized by labor economist Rosen (1978). Hansen and Sargent (1988) have two workweek lengths in their business cycle paper: a standard workweek and an overtime workweek. The micro evidence in support of workweeks of different lengths being different commodities is strong. For example, two half-time workers on average are paid significantly less than one full-time worker with similar human capital. Additional evidence is that the normal workweek length differs across occupations. With this theory, the reason for the differences in workweek lengths across occupations is that the mapping from time allocated to the market to units of labor services produced is different across occupations. When important nonconvexities are present, the micro and aggregate elasticities are different even if all the micro units are identical.

This is true for both the household and the business sectors. At the production unit level, investment is very lumpy, yet at the aggregate level, aggregate investment is smooth. Thomas (2002) established that valuation equilibrium theory predicts that the fraction of units making discrete adjustments to production capacity will be the margin of adjustment used, as it is, and aggregate investment will be smooth.

Time series methods used to model aggregate time series use linear models. This is because there are no obvious nonlinearities in the time series. The one case in which nonlinearity was found to be significant was in the Hansen and Prescott (2005) model with a capacity utilization constraint. If capacity constraints are occasionally binding, aggregation theory leads to an aggregate production function that has a kink, which results in the labor income share falling when the capacity constraint is binding. It also implies that business cycle peaks will be flatter and smaller than troughs for the detrended data as they are. This is an improvement in theory but is of second-order importance.

2.7 A Digression on Methodology of Aggregate Analysis

Theory is a set of instructions for constructing a model economy to address a given question. The criterion for a good theory is that it is useful. Models are instruments used to draw scientific inference. What constitutes a good model depends on what question is being addressed. Reality is incredibly complex, and any model is necessarily an abstraction and therefore false.

The model economy selected in a particular application is not the one that best fits a particular set of economic statistics. It must fit along selected dimensions of reality given the question. To illustrate this idea, consider the question of how much of the higher average return on publicly traded stocks is a premium for bearing aggregate risk. The highly liquid short-term debt is called the safe asset. However, it is not a perfectly safe asset, as is the model economy's safe asset. A perfectly safe asset does not exist. Government debt is not safe because governments default fully or partially in extreme events. Therefore, the nature of the consumption process in the model economy used must not have the possibility of extreme events.

The model economy that Mehra and Prescott (1985) used to address this issue had only one type of infinitely lived households and a pure endowment process. We specified a Markov chain process on the growth rate of this endowment, which rules out extreme events. Equilibrium consumption was the output of the endowment process. The relation examined was the return on the endowment process and a security that paid one unit of consumption in the next market in the sequence with certainty in the sequence of market equilibria. Empirically, the difference in average yields on equity and short-term relatively risk-free liquid debt was over 6%. The finding was that only a small part of the difference in average yields on the two classes of securities was accounted for by a premium for bearing nondiversifiable aggregate risk.

Will a class of model economies with a richer class of processes on consumption growth rates resolve this puzzle? The answer is no because the abstraction used permits *any* stationary process on consumption growth rates. Our abstraction did rule out extreme events because truly risk-free assets do not exist.

This finding raised the question of what factors were giving rise to this big difference. McGrattan and Prescott (2005) subsequently learned that introducing taxes on distributions by corporations to owners reduced the premium by a third. Economic theory says it is after-tax distributions that should be considered in determining the return on different assets.

Another significant factor is the cost of managing assets. Pension funds have sizable costs that reduce the return on equity realized by households who are the indirect owners of the equity held by these funds. On the other hand, the cost of managing a portfolio of short-term liquid assets is small. The magnitude of the asset management and intermediation costs can be estimated using national income and product accounts. The aggregate value of the corporate equity held either directly or indirectly by the household sector can be estimated using aggregate balance sheet statistics. The annual costs are about 2% of the total value of the assets. This exercise was carried out in Mehra et al. (2011).

Most of the remainder of the difference in average yields is almost surely due to a liquidity premium for carry-out transactions. This leads to the conclusion that the equity premium puzzle is no longer a puzzle. Better measurement may identify a deviation from theory, but for the time being, theory is ahead of measurement with respect to the equity premium.

The model economy used to measure and estimate the premium for bearing nondiversifiable aggregate risk has no investment. In fact, investment is a sizable share of output. The model is not realistic along this dimension. However, this very simple model is sufficiently rich to address the question asked. The salient features of reality are incorporated into the model being used to address the given issue. The general principle is, if the question can be addressed with a simpler model, use the simpler one.

2.8 The Need for Discipline

A useful theory must have an associated discipline. Scientists, who employ the discipline and use the theory to answer a given question, reach the same conclusion as to what the theory says or does not say. Given the current state of the theory, the conclusion may state that the theory has to be extended before the question can be addressed. Or it may say that the answer depends on the magnitude of certain parameters, which have not yet been measured sufficiently accurately. The theory used in aggregate analysis is neoclassical growth theory. A crucial feature of this discipline is that when researchers extend the theory in order to resolve a deviation from theory or to expand its domain of applicability, the extended theory must be consistent with previously successful applications of the theory.

In the subsequent sections of this chapter, the development and use of neoclassical growth theory will be reviewed. This theory is applicable to virtually all substantive areas of economics including not only traditional business cycle fluctuations but also differences in per capita output levels across countries and across times. It is the theory in aggregate public finance, financial asset pricing, labor economics, monetary economics, environmental economics, and international finance.

The model economy used in an application is restricted by more disaggregated statistics. For example, the assumed time-to-build for new structures must be consistent with how long it typically takes to build a new structure. Econometricians have constructed statistical tests that rejected the Hansen (1985) model of business cycles. That model abstracted from time-to-build, because Hansen found this feature of reality to be of secondary importance in understanding business cycle fluctuations. Using data generated by the Kydland and Prescott (1982) model, which has a time-to-build technology, these statistical tests would lead to a rejection of the RBC model generating the data. It would be easy to come up with another test that would result in the rejection of the model with time-to-build. The implication is that statistical hypothesis testing is of little use in selecting a model to address some given question.

3. THE NATURE OF THE DISCIPLINE

3.1 The Back and Forth Between Theory and Measurement

The study of business cycle fluctuations led to the construction of dynamic stochastic general equilibrium models of these fluctuations. These early models had a quadratic household utility flow function and linear technology constraint. This research program did not produce models with national accounts that could be compared to the actual ones. Their use did not satisfy the Klein discipline. Examples of these early models include Sargent (1976) and Kydland and Prescott (1977). Another limitation was that using other observations in economics to restrict the choice of the model economy was difficult and, in some cases, impossible.

What turned out to be the big breakthrough was the use of growth theory to study business cycle fluctuations. A question is, why did it take so long before it was used for this purpose? The answer is that, based on micro theory reasoning, dynamic economic theory was viewed as being useless in understanding business cycle fluctuations. This view arose because, cyclically, leisure and consumption moved in opposite directions. Being that these goods are both normal goods and there is little cyclical movement in their relative price, micro reasoning leads to the conclusion that leisure should move procyclically when in fact it moves strongly countercyclically. Another fact is that labor productivity is a procyclical variable; this runs counter to the prediction of micro theory that it should be countercyclical, given the aggregate labor input to production. Micro reasoning leads to the incorrect conclusion that these aggregate observations violated the law of diminishing returns.

In order to use growth theory to study business cycle fluctuations, the investment-consumption decision and the labor-leisure decision must be endogenized. Kydland and Prescott (1982) introduced an aggregate household to accomplish this. We restricted attention to the household utility function for which the model economies had a balanced growth path, and this balanced growth path displayed the growth facts. With this extension, growth theory and business cycle theory were integrated. It turned out that the predictions of dynamic aggregate theory were consistent with the business cycle facts that ran counter to the conclusion of those using microeconomic reasoning.

That time-to-build model economy had only technology shocks, so the analysis was restricted to determining the consequences of different types of technological shock processes for the cyclical behavior of the neoclassical growth model. Kydland and Prescott (1982) found that if there are persistent technology shocks and the aggregate elasticity of labor supply is high, neoclassical growth theory can predict fluctuations of the business cycle variety. By construction, the model economy displayed the growth facts. However, the aggregate Frisch elasticity of labor supply is not tied down by the growth facts. Two questions needed to be answered before one could say that the neoclassical growth model displays business cycle fluctuations of the nature observed. The first question was whether the Frisch elasticity of the aggregate household labor supply was at least 3. The second question was whether technology shocks were highly persistent and of the right magnitude.

One criticism of Kydland's and my analysis was that empirically, cyclical labor productivity and total hours were roughly orthogonal during the period studied, whereas for the model economy, they were highly correlated. If productivity shocks were the only factor contributing to fluctuations, this would be a valid criticism, and business cycle fluctuations would be inconsistent with neoclassical growth theory. But productivity shocks were not the only factor giving rise to business cycle fluctuations during this period. To determine how much of the business cycle fluctuations were accounted for by productivity shocks, an estimate of the variance of these shocks was needed. This was provided by Prescott (1986). Given the estimate, labor productivity and aggregate hours worked should be roughly orthogonal, as they were during the period studied. The finding is that the US economy would have been 70% as volatile as it was during the period considered if productivity shocks were the only shocks.

The nature of the shock is important in the theory. If one thinks that all productivity change is due to the growth of knowledge useful in production, productivity shocks generally should be negative; in fact, however, productivity shocks are sometimes negative. One implication is that variations in the growth of the stock of useful knowledge cannot be the only reason for changes in productivity. Another factor giving rise to changes in productivity are changes in legal and regulatory constraints. Such changes can both increase and decrease productivity. The huge differences in productivity that are observed across countries provide strong evidence that the legal and regulatory systems are of great importance in determining the level of productivity.

3.2 Monopolistic Competition: Small Consequences for Business Cycle Accounting

Neoclassical growth theory assumes price taking in market transactions. Does abstracting from the fact that some businesses and groups of factor suppliers have market power and are not price takers alter the conclusions of the simple abstraction? Hornstein (1993) introduced monopolistic competition and found that for measuring the contribution of productivity shocks to business cycle fluctuations, it mattered little. He calibrated a monopolistic competitive model to the same set of statistics as those using the neoclassical growth model did. With monopolistic competition, the response to the shocks is greater, but this is offset by a smaller estimate of the variance of the underlying productivity shock. For this purpose, abstracting from market power mattered little for the estimate of the contribution of productivity shocks to business cycle fluctuations. For some other issues, this is probably not the case. This illustrates the way in which the theory progresses. A finding is successfully challenged by showing that introducing some feature of reality in a disciplined way changes the answer to the question. The results of unsuccessful challenges are of interest, for they add to the confidence in the original study.

3.3 Nonneutral Technological Change: Little Consequence in Basic Model

The relative price of the composite investment good and the composite consumption good has not been constant, as it is in the basic neoclassical growth model. Secularly, what is more or less constant is the value of investment goods produced relative to the value of all goods produced in nominal terms. A world in which the relative price of the investment good falls is one with the following aggregate production relation:

$$c_t + (1+\gamma)^{-t} x_t \leq A k_t^{\theta} h_t^{1-\theta},$$

where $\gamma > 0$. There is balanced growth with the relative price of the investment good to the consumption good falling at rate γ. Greenwood et al. (1988) show this. Another interesting finding in their paper concerns the nature of depreciation for the theory of business cycle fluctuations.

3.4 Nature of Depreciation: Matters

The standard abstraction for depreciation is the perpetual inventory assumption with a constant depreciation rate:

$$k_{t+1} = (1-\delta)k_t + x_t.$$

Greenwood et al. (1988) assume that the rate of depreciation increases with the intensity of the use of capital; that is, they assume a Taubman and Wilkinson (1970) depreciation technology. Let u_t denote the capital utilization rate. Capital services provided are $u_t k_t$. The depreciation rate is an increasing function of the utilization rate, $\delta_t = \delta(u_t)$. With this assumption, the response to productivity shocks is bigger and the aggregate elasticity of labor supply smaller for the model calibrated to the growth facts.

I am sure that this alternative theory of depreciation was considered by the national income and product accountants and found not to be important. It is true that during periods of high economic activity, some capital is utilized more intensely. However, for many capital goods, depreciation does not depend on the intensity of use. One reason is that during boom periods, machines are well maintained in order to keep them operating efficiently. Better maintenance lowers the depreciation rate. Higher occupancy rates of office buildings do not increase their depreciation rate. The national accounts stuck with the perpetual inventory method and useful life in calculating aggregate depreciation because it was consistent with the prices of used capital equipment. This is another example of micro evidence restricting the model economy being used to address an aggregate issue.

If this alternative theory of depreciation had passed the micro test, it would have introduced a number of discrepancies within the theory. Business cycle observations would imply a smaller aggregate labor supply elasticity, and this in turn would imply that the theory predictions for cross-country differences in aggregate labor supply arising from differences in the marginal tax rate on labor income would be much smaller than what they are. About the only way to resolve these discrepancies would be to assume country-specific differences in preferences that give rise to both higher marginal tax rates and lower labor supply. With this resolution, however, there would be big discrepancies between the predictions of theory for aggregate labor supply during growth miracles.

The important point is that preference and technology parameters, with the discipline reviewed here, must be consistent across applications.

3.5 Monetary Policy: Little Consequence for Business Cycle Fluctuations

The general view prior to the development of quantitative aggregate economic theory was that monetary policy had important real consequences for the behavior of real variables, in particular real output and employment. Once explicit transactions abstractions were developed that gave rise to a demand for money, it was possible to introduce them into the neoclassical growth theory and to assess their quantitative consequences for real variables. Cooley and Hansen (1995) did this and found that the real consequences were small for monetary policies that did not give rise to very high rates of inflation. This supported the empirical findings of Sargent and Sims (1977) that real movements were not the result of monetary factors in the postwar US economy.

Sticky wage and nominal staggered wage contracting arrangements were subsequently introduced into the neoclassical growth model and their quantitative consequences for real findings determined by Chari et al. (2000). The finding was that these mechanisms did not give rise to business cycle fluctuations of the nature observed.

Another bit of strong evidence for the unimportance of monetary policy is the fact that RBC models that abstract from monetary factors do not have large deviations from observations during periods with high variations in inflation rates, such as during the period 1978–82 in the United States.

3.6 Two Important Methodological Advances

In critiquing the use of neoclassical growth theory to study business cycle fluctuations, Summers (1986) asked a good question: What are these shocks? An important methodological advancement to the theory was needed before his question could be answered. The advancement was path analysis.

3.6.1 Path Analysis

Hansen and Prescott (1993) used path analysis when they addressed the question of whether technology shocks caused the 1990–91 recession. In that paper, the dynamic system for the model was used to generate time paths of the variables given the realized values of the stocks. The finding was that yes, productivity shocks did cause that recession.

That paper offered another interesting finding. A prediction of the technology-shock-only model is that the economy should have recovered in 1993–94, since productivity had returned to trend. Other factors had to be depressing the economy during this period. Subsequently, the factors were identified. They were increases in tax rates.

3.6.2 Distribution of Firms with Inventories a State Variable

A widely held view was that inventory behavior was important for understanding business cycle fluctuations given the large cyclical variability of inventory investment. The micro theory of inventory investment was developed, but introducing this feature into quantitative neoclassical growth theory was impossible given the lack of needed tools.

Fisher and Hornstein (2000) developed a way to introduce inventory investment when firms faced fixed resource costs when making an inventory investment. This made the stock of inventory a firm state variable and the distribution of firms as indexed by their inventory stock an aggregate state variable. This methodological advance was also used by Hornstein (1993) to assess the quantitative importance of monopolistic competition.

3.7 The Big Aggregate Economic Puzzle of the 1990s

A boom in output and employment in the United States began about 1994 and continued until the very end of the decade. This boom was puzzling from the perspective of what was then aggregate economic theory. In this boom, the corporate profit share of GNI was low. In other booms, this share was higher than normal. Another puzzling observation was that GDP per hour, the commonly used measure of productivity, was low in this boom. Normally, productivity accounts for about a third of the cyclical variation in GDP and market hours the other two-thirds. In this boom, the accounting was 125% due to market hours worked and negative 25% due to productivity. No changes in labor market policies or tax rates could account for these phenomena. This puzzle remained open for at least 6 years. One explanation consistent with general equilibrium theory was that Americans—as well as Europeans—experienced a contagious case of workaholism; that is, the rate at which people's willingness to substitute labor for leisure in the aggregate changed. Such explanations violate the discipline of dynamic aggregate theory reviewed in this essay.

To answer this question, two developments in quantitative aggregate theory were crucial. One was the use of an equilibrium condition for a class of economies that depend on current-period variables to account for the large differences in hours worked per working-age person across countries and across time. This equilibrium condition used was that the marginal rate of consumption and leisure is equal to the after-tax wage. A Cobb–Douglas production function was assumed, so the wage was just aggregate labor income divided by aggregate hours.[c] The elasticity of substitution between consumption and leisure for the aggregate household was the same as the one needed for the neoclassical growth model to display business cycle fluctuations.

The reason that Western Europeans now work 30% less than other advanced industrial countries is not that they are lazy or are better at making use of nonmarket productive time. It is that these countries have higher marginal tax rates on labor income and on consumption. These higher tax rates introduce a large tax wedge between the intratemporal marginal rate of substitution and the marginal rate of transformation between consumption and market time.

The second development was to use this methodology to account for the large secular movements in the value of corporations relative to GNP in the United States and the United Kingdom in the 1960–2000 period. The equilibrium relation used for the class of models considered was the following one. The market value of corporations is equal to the market value of the capital stocks owned by the firm. Given the importance of intangible capital in determining the value of corporations, this stock had to be included in the analysis. Brand names, organization capital, patents, and technology know-how embodied in the organization all contribute to the value of the business enterprise.

With these two developments, the stage was set for resolving the US hours boom of the 1990s.

4. MAJOR DEVELOPMENTS AND THEIR APPLICATIONS POST-1995

Important theoretical advancements in neoclassical growth theory have continued to occur and have expanded the theory's applicability. Also important was the development of new and better data sets that are easily accessible. These data sets are more uniform across countries, which facilitates the study of factors giving rise to international differences in economic aggregates. Increases in computing power made possible the introduction of demographics into models being used to draw scientific inference using the theory. The life cycle is crucial for understanding aggregate savings behavior as it gives rise to savings for retirement.

4.1 Clubs in the Theory and France's 35-Hour Workweek Policy

A development in valuation theory was the introduction of clubs. Clubs are arrangements that internalize externalities, whether they are positive or negative, within organizations that are small relative to the economy. One extremely important type of club is the household. In classical valuation theory, household clubs are a primitive. For each household, there is an agent that chooses an optimal point in a subset of the commodity

[c] This is the measure of wages used by Lucas and Rapping (1969) when they introduced labor supply into macroeconometric modeling.

space—that is, in that household's consumption possibility set—subject to its budget constraint. Business organizations are clubs as well. A firm is defined by its production possibility set, which is a subset of the commodity space, and the households' shares of ownership. Cole and Prescott (1997) extend valuation equilibrium theory to permit clubs.

To date, this development has been little used in quantitative aggregate analyses. To the best of my knowledge, I am aware of only one aggregate quantitative application using clubs. This application is due to Fitzgerald (1998), who uses this extension of the basic theory to predict the consequences of France's 35-hour workweek constraint. His framework has two types of households and two types of labor services: skilled and unskilled. Type 1 household can only supply unskilled labor. Type 2 household can supply either type. The important constraint is that for each firm, the work schedule of those performing the skilled and the unskilled tasks must be equal. The skilled workers' tasks include supervising, monitoring, and coordinating the unskilled workers.

The goal of the French 35-hour workweek policy was to help the unskilled and not the highly paid skilled workers. It turned out that the skilled are made better off under the 35-hour workweek and the unskilled worse off, counter to this objective. The legal constraint, which changed the technology set of a firm, had an unintended consequence. The program did have the intended consequence of increasing the employment rate of the unskilled.

4.2 Cartelization Policies and the Resolution of the US Great Depression Puzzle

Cole and Ohanian (1999) initiated a program of using the theory to study great depressions. They found a big deviation from the theory for the 1930–39 US Great Depression. This deviation was the failure of market hours per working-age person to recover to their predepression level. Throughout the 1930s, market hours per working-age person were 20–25% below their predepression level. The reasons for depressed labor supply were not financial. No financial crises occurred during the period 1934–39. The period had no deflation, and interest rates were low. This led Cole and Ohanian to rule out monetary policy as the reason for the depressed labor supply. Neither was the behavior of productivity the reason. Productivity recovered to trend in 1934 and subsequently stayed near the trend path.

These findings led Cole and Ohanian to search for an extension of the theory that would resolve this puzzling failure of the US economy to recover in the 1930s. They observed that relative wages in the cartelized industries increased relative to those in the noncartelized industries. Employment in the cartelized industries was the most depressed and did not recover. Those in the cartelized industries were the insiders and those in the competitive industries the outsiders. The problem Cole and Ohanian had to solve was to figure out how to introduce a cartelization arrangement into quantitative aggregate theory.

Eventually, Cole and Ohanian (2004) figured out a way and found that the cartelization policy was a major factor in accounting for the failure of the US economy to recover from the Great Depression subsequent to the recovery of productivity. They estimated that the cartelization policy alone accounted for over half of the depression in employment in the US Great Depression of the 1930s. It turned out that tax and wage policies can account for much of the remainder, so the Great Depression is no longer a puzzle.

McGrattan (2012) extended the theory to permit the consequences of expected future tax rate increases on the distributions from businesses to their owners. She found that they were important in accounting for the great decline in output in 1930. Businesses made large cash distributions to their owners rather than using cash to finance new investment. Fisher and Hornstein (2002) established that wage policies that set the wage above equilibrium value gave rise to the Great Depression in Germany from 1927 to 1932. The elimination of these policies late in 1932 resulted in rapid recovery from Germany's Great Depression, just as theory predicts.

4.3 Taxes and Country Labor Supply: Cross-Application Verification

The question is whether the theory used to study business cycle fluctuations accounts for the large difference in labor supply, as measured by market hours per working-age person, between Americans and Western Europeans. During the period 1993–96, Americans worked on average 40% more than did the French, Italian, and Germans. This was not always the case. In the period 1970–74, market hours per working-age person were comparable in both the United States and Western Europe and comparable to what they are now in the advanced industrial countries, with the notable exception of Western Europe.

The equilibrium relation used in Prescott (2004) to predict the difference in labor supply as a function of the effective tax rate on labor income was that the marginal rate of substitution between nonmarket productive time and consumption is equal to the after-tax real wage. A Cobb–Douglas aggregate production was assumed.

This equilibrium condition for country i can be written as

$$h_{it} = \frac{1-\theta}{1-\theta + \frac{c_{it}}{y_{it}} \frac{\alpha}{1-\tau_{it}}}.$$

Here, θ is the capital share parameter, α the value of leisure parameter, h_{it} the market hours per working-age person, τ_{it} the effective average marginal tax rate on labor income, and c_{it}/y_{it} the fraction of aggregate output consumed.

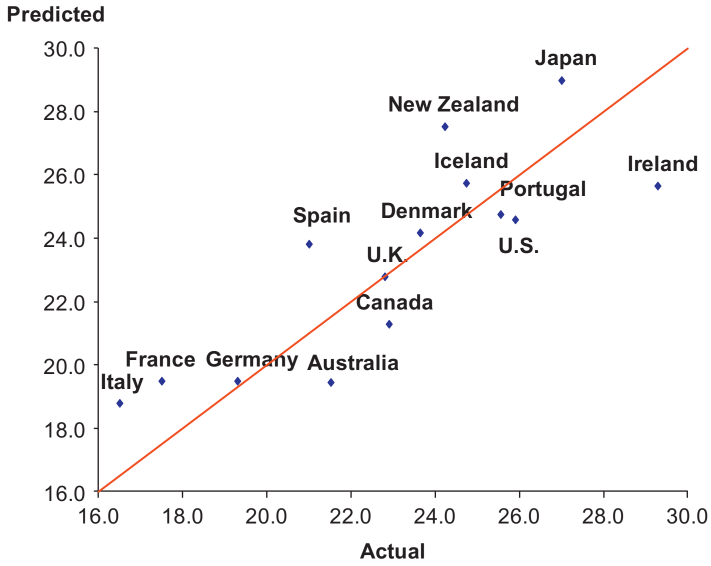

Fig. 1 Predicted and actual hours worked per working-age person, 1990–2002.

The analysis has only one free parameter, namely, the preference parameter α. This parameter is not tied down by the balanced growth facts. The capital income share parameter was nearly constant across countries and periods and was set equal to 1/3. The preference parameter α was picked so that the relation held for the United States.

The US boom in the 1990s was unlike previously studied booms and was at variance with the basic neoclassical growth model as discussed previously. Fig. 1 plots predicted and actual hours worked per working-age person for the period 1990–2002 using the model without intangible capital. It was a puzzle in the theory that remained open for 8 years. No alternative theory predicted this boom.

4.4 Use of the Overlapping Generations Abstract

For many issues, it does not matter whether the dynastic family or the overlapping generation structure is used. Before the great increase in computing capabilities, using the overlapping generation structure was not feasible. Braun et al. (2009) exploited this increase in computing capabilities and found that both the dynasty and the overlapping generation constructs are consistent with the fall in Japanese savings rates in the 1990s. However, the two constructs for aggregate households imply very different behavior for the Japanese savings rate post-2010. Because of Japan's large baby boom in the 1960s, the fraction of people who were dissaving to finance retirement would increase subsequent to 2010, and the aggregate savings rate would fall. Quantitatively, the savings rate did just what the theory with an overlapping generation structure predicted it would do.

5. INTANGIBLE CAPITAL EXPANDS THE APPLICABILITY OF THE THEORY

That intangible capital investment financed and owned by firms is big has never been in dispute. A question is why intangible capital was not incorporated into quantitative aggregate theory. The answer is that there was no disciplined way to incorporate this largely unreported component of output into the theory. The development of a consistent set of balance sheets for the household and business sectors was key to resolving this problem. Balance sheets, among other things, report the value of ownership of corporate equity.

5.1 The Value of Corporate Businesses

The price of capital good K_j is $q_j(\pi)$, where π specifies tax policy. Tax policy includes not only tax rates on corporate accounting profits but also the tax rate on distributions to owners, the nature of the capital consumption allowance, and the inflation rate. An important input to production is the services of human capital owned by the employees of the corporation. It is rivalrous and does not show up in the value of corporations. Consequently, it need not be included in the model used to determine the value of corporate businesses.

The aggregate corporate market value V, where subscript T denotes tangible capital and subscript I denotes firm-owned intangible capital, is

$$V = q_T(\pi)K_T + q_I(\pi)K_I.$$

If there were no capital income taxes, the prices of capital in units of the consumption good would be 1. But there are capital income taxes.

The price of one unit of tangible capital in terms of the consumption good, given that nearly all investment is financed through retained earnings, is

$$q_T = (1 - \tau_{\text{dist}}),$$

where τ_{dist} is the tax rate on distributions from corporations to owners. The average marginal tax rate on distributions is used. In the 1960s, virtually all distributions were in the form of dividends. The tax rate used was the average of the individual marginal tax rates weighted by the total dividends received by the group subject to that marginal tax rate. In the 1960s, this average tax rate was about 45%. Beginning in the 1980s, buybacks began to be used and permitted distributions to be deferred to when the capital gains were realized. This lowered the average tax on distributions.

Intangible capital was expensed, and as a consequence, its price to the owners of the businesses making the investment is smaller than the cost of producing it. The price of intangible capital is

$$q_I = (1 - \tau_{\text{dist}})\left(1 - \tau_{\text{corp profits}}\right).$$

In both the United States and the United Kingdom, there were large movements in V relative to annual GNI over the period studied by McGrattan and Prescott (2005) using this theory. The V/GNI number varied by a factor of 2.5 in the United States and by a factor of 3.0 in the United Kingdom during the period 1860–2000. This variation was not due to variation in the ratio of after-tax corporate income to GNI. This ratio varied little over the period. The theory found that the reason for the large secular changes was due to changes in taxes and regulations. Intangible capital was an important part of the value of corporations.

The big change in the tax system that increased the value of corporations was the deferred compensation individual savings account. These accounts permitted households to save for retirement free of capital income taxes. Insofar as the withdrawals are used to finance retirement consumption, there is no intertemporal wedge between the marginal rate of substitution between current and future consumption and the marginal rate of transformation between current and future consumption.

The added capital alone had little consequence for business cycle fluctuation accounting, so no new puzzles were created with this extension. An old puzzle that has not been resolved is the LeRoy and Porter (1981) and Shiller (1981) excess asset price volatility puzzle. Indeed, by looking at the values of the capital stocks owned by firms rather than at the present value of dividends, McGrattan and Prescott (2005) strengthened this excess volatility puzzle. These capital stocks vary smoothly, so the theory predicts their prices should as well.

In the model with intangible capital owned by business enterprises, we used an alternative aggregate production technology to the aggregate production function. There are three inputs: the services of tangible capital, the services of rival human capital, and the services of intangible capital. There are two output goods: one the composite output good less intangible capital investment and the other intangible capital investment. There were two *activities*: one producing intangible capital and one producing other final goods.

It is not a two-sector model because the services of intangible capital are not allocated between activities, as are the services of the other two inputs, but are used in both simultaneously by both activities. Otherwise, the production technology is standard. Letting Y_1 be output less intangible investment output, Y_2 intangible investment output, K_T tangible capital stock, K_I intangible capital stock, and L rival human capital services (labor), total output of the two activities is

$$\begin{aligned} Y_1 &= A_1 F_1(K_{T1}, K_I, L_1) \\ Y_2 &= A_2 F_2(K_{T2}, K_I, L_2) \\ K_T &= K_{T1} + K_{T2} \\ L &= L_1 + L_2 \end{aligned}$$

One unit of capital produces one unit of its services. All variables implicitly have a time subscript including the productivity parameters A_1 and A_2. The functions F_1 and F_2 have all the standard properties of the aggregate production function.

The important feature of the technology is that K_I has no activity subscript. A brand name can be used to produce a product sold in the market as well as in the development of a related product. The same is true of patents. The other two inputs are allocated between the activities. If productivity change is neutral in the sense that A_{1t}/A_{2t} stays constant, the implications for business cycles are the same. Thus, this technology works where the basic neoclassical growth model works. This part of the discipline is satisfied.

A problem is that most intangible capital investment made by firms and owned by firms is expensed and therefore not part of measured output. The question is how to incorporate this unobservable in a disciplined way. McGrattan developed a way (see McGrattan and Prescott, 2010b). The size of intangible capital net investment has implications for accounting profits of the corporate sector. Knowing the initial stock, the stocks can be computed from statistics reported in the national income and product accounts (NIPA).

5.2 US Hours Boom in the 1990s: A Crisis in RBC

The basic neoclassical growth theory model accurately predicted the behavior of the US economy prior to the 1990s, taking productivity taxes and demographics as exogenous. Theory was then ahead of measurement. In the 1990s it did not predict accurately. Market hours boomed while GDP per hour, the usual measure of productivity relative to trend, declined. The simple accounting was that the labor input accounted for 125% of the output and the standard measure of productivity for *minus* 25%. Typically, hours account for about two-thirds of the detrended change and productivity for the other third.

Taxes were not the answer, since the intratemporal tax wedge was, if anything, larger than before the boom. There were no major labor market reforms that improved the performance of the labor market. Economists were faced with the puzzle of why people were working so much. Fig. 2 plots the predicted and actual paths using the basic growth model without the introduction of intangible capital into the theory.

It was recognized that large investments in intangible capital were being made, and most were not reported as part of output because they were expensed. At the time, only computer software investment was reported.

Aggregate economics is not the only science with unobservable variables. A translation of a quote by Albert Einstein reads: “Not everything that counts can be counted, and not everything that can be counted counts.” The key relation is the accounting profit equation. The bigger the net unmeasured intangible investment, the smaller were these problems. This finding, along with the fact that accounting profits were a small share of GDP in this hours boom period, is consistent with intangible investment being large. Other evidence is from the National Science Foundation. The NSF provides estimates of private R&D expenditures, which are an important

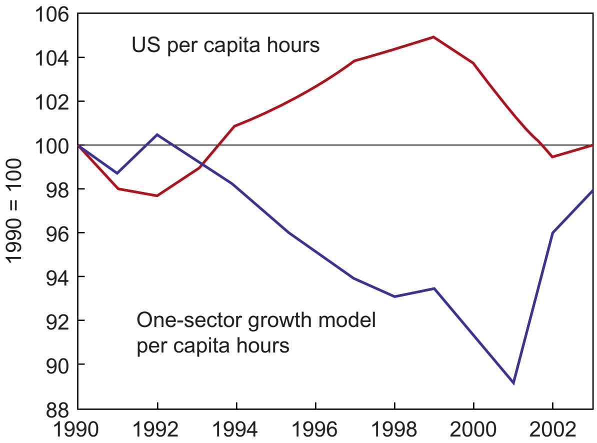

Fig. 2 Without intangible capital: big deviation from theory.

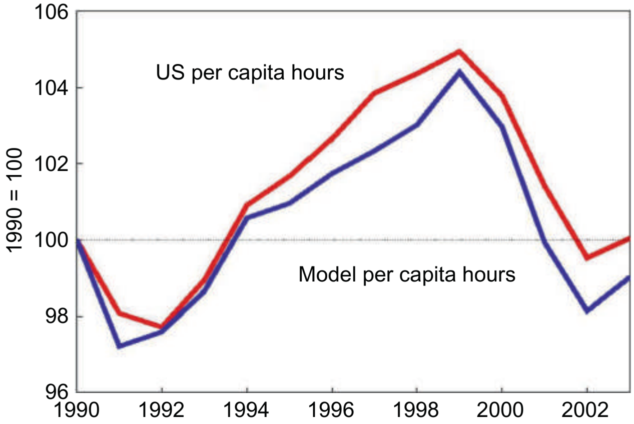

Fig. 3 With intangible capital: no deviation from theory.

component of intangible capital investment. These investment expenditures in percentage terms increased much more than measured investment expenditures during the 1990s boom.

With the introduction of intangible capital and nonneutral technology change in the production of GDP and intangible capital investment, measurement was again in conformity with theory. This is shown in Fig. 3.

The extended theory accounts for capital gains reported in the Federal Reserve System's flow of funds accounts. About half of these investments are financed by the owners of corporations subject to the corporate income tax and half by worker-owners of other businesses, which matches with micro observations.

5.3 Technology Capital

Intangible capital falls into different categories. Some are specific to the local production units and market. Some are assets with services that can be used at multiple locations. Virtually every metropolitan area in the United States has the same set of major retailers. Each of these major retailers uses the same know-how and name for all their retail outlets. The branches rely on their central headquarters for supply-side management, financial services, and advertising services. Intangible capital that can be used at multiple locations is technology capital. Investment in this type of capital is financed by location rents.

There are no increasing returns to scale, even though a closed economy with more locations will be richer than a closed economy with fewer locations, other things being equal. A production unit at a given location faces decreasing returns to scale. The production unit, being a price taker, realizes location rents. With technology capital, a reason for foreign direct investment (FDI) exists.

5.4 Use in Estimating Gains from Openness

Estimating gains from openness was originally introduced to study the role of openness in economic development (see McGrattan and Prescott, 2009). The observation was that for 50 years prior to World War II, the EU-6 GDP labor productivity was only a little more than half that of the United States, as it was in 1957 when the Treaty of Rome was signed. In the subsequent 30 years, EU-6 productivity caught up to that in the United States. This strongly suggests that openness fosters economic development. The role of trade can account for only one-ninth of the gain if the model used in the estimation is restricted to be consistent with the trade flows. Technology capital accounts for about one-third. This evidence indicates that other factors associated with openness are even more important. Two factors that have not yet been incorporated into the theory that empirically seem important are the faster diffusion of public knowledge and increasing competition reducing barriers to adopting more efficient technologies in production.

The technology extension has already permitted the theory to be used to assess China's direct foreign investment policy. Holmes et al. (2015) find that the Chinese policy of requiring access to technology capital of the foreign multinational making FDI in China in return for access to the huge Chinese market was in China's economic interest. In making these restrictions, China is violating the rules of the World Trade Organization. With the renminbi gaining reserve currency, interest in becoming more open to direct foreign investment will increase in China. This illustrates the usefulness of the theory in still another area, and, as stated earlier, usefulness is one criterion for a successful scientific theory.

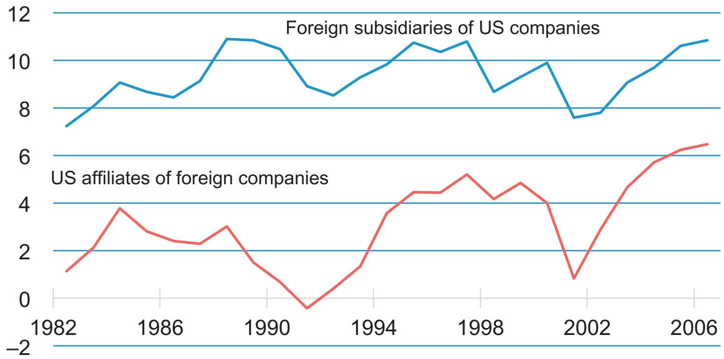

Fig. 4 BEA average FDI annual returns.

5.5 Use in Accounting for Features of US Current Accounts

A feature of US current accounts is the high reported earnings of US companies on their FDI and the low reported earnings of foreign companies' FDI in the United States. As reported by the Bureau of Economic Analysis (BEA), during the period 1982–2005, US companies earned an average return of 9.3 percentage points on their FDI, whereas foreign companies earned an average of 3.0 percentage points on their US FDI. Annual average returns for the period are plotted in Fig. 4. A question addressed by McGrattan and Prescott (2010a) naturally arises: why is the return differential so large and persistent?

The introduction of technology capital accounts for over 60% of the difference. Intangible capital investment stock is important because it increases profits but not the BEA stock of capital. It does increase the stock of capital, which lowers the economic return. US multinationals made large FDI earlier and, as a result, have relatively larger stocks of intangible capital than foreign multinationals have in their US subsidiaries. The age of the foreign subsidiaries matters because intangible investment is high and therefore BEA profits low when they are young. This micro evidence strongly supports the theory.

Using economic returns, the differential between the average return on US FDI and the average return on foreigners' FDI is reduced from 6.3 percentage points to about 2.5 percentage points. A question that naturally arises is, what accounts for the remaining 40% of the difference? Corporate tax rates differ across countries, and through transfer pricing, profits are shifted to countries where this tax rate is lower. Indeed, an important field of corporate finance is concerned with setting prices for goods and services transferred between multinationals and their foreign subsidiaries.

6. CONCLUDING COMMENTS

So much has been learned through the successful use of neoclassical growth theory and its extensions. This theory has directed the development of aggregate economics.

The availability of better data sets is fostering further development. As these better data sets become available, great progress is being made in incorporating features of the household sector,[d] which, like the business sector, is of great economic importance. In the earlier stages of the development and use of neoclassical growth theory, the household was a primitive. Now, however, its structure is becoming an endogenous element. The household sector has changed significantly over time and is not policy invariant.

In reporting household sector statistics, a household is the set of people residing at a dwelling—that is, a postal address. The size of households has changed significantly in the United States. Further, many households consist of married couples. Over time, the nature of matching has changed, as found by Greenwood et al. (2016). They find an important change is the increase in positive assortative matching. With more two-professional households, these changes have had major consequences for the distribution of household incomes.

Another important economic sector is the government sector. The question of how a group of people can set up sustainable collective government arrangements that result in outcomes preferred by the members of this group is an important one. Answering this question will require developments in pure theory.

Through the interaction of theory and measurement, the rapid development of quantitative aggregate economic theory is certain to continue. It will be interesting to see what these developments are.

Abstract

Much of macroeconomics is concerned with the allocation of physical capital, human capital, and labor over time and across people. The decisions on savings, education, and labor supply that generate these variables are made within families. Yet the family (and decision making in families) is typically ignored in macroeconomic models. In this chapter, we argue that family economics should be an integral part of macroeconomics and that accounting for the family leads to new answers to classic macro questions. Our discussion is organized around three themes. We start by focusing on short- and medium-run fluctuations and argue that changes in family structure in recent decades have important repercussions for the determination of aggregate labor supply and savings. Next, we turn to economic growth and describe how accounting for families is central for understanding differences between rich and poor countries and for the determinants of long-run development. We conclude with an analysis of the role of the family as a driver of political and institutional change.

1. INTRODUCTION

First impressions suggest that family economics and macroeconomics should be the two fields within economics at the greatest distance from each other: one looks at interactions between at most a handful of members of the same family, whereas the other considers the aggregated behavior of the millions of actors in an economy as a whole. Despite this contrast between the small and the large, we argue in this chapter that family economics and macroeconomics are in fact intimately related, and that much can be learned from making the role of the family in the macroeconomy more explicit.[a]

There are two different ways in which family economics and macroeconomics intersect. One side of the coin is to focus on questions that originate in family economics, but

[a] The basic point that family economics matters for macroeconomics was made by Becker in his AEA Presidential Address (Becker, 1988). At the time, Becker placed a challenge that inspired a sizeable amount of follow-up research. However, much of the early work at the intersection family economics and macroeconomics was focused on economic growth, whereas we argue in this chapter that family economics is equally relevant for other parts of macroeconomics.

use the methodology of dynamic macroeconomics to answer the questions. For example, macroeconomic models can be adapted to answer questions about how fertility rates, marriage rates, divorce rates, or the assortativeness of mating are determined and how they evolve over time. There is an active and exciting literature that takes this approach, but it is not the focus of this chapter.[b] Rather, our interest here is in the reverse possibility, namely that incorporating family economics into macroeconomics leads to new answers for classic macroeconomic questions. These questions concern, for example, the determination of the level and volatility of employment, the factors shaping the national savings rate, the sources of macroeconomic inequality, and the origins of economic growth.

We choose this path because, so far, it has been less traveled, yet we believe that it holds great promise. This belief is founded on the observation that many of the key decision margins in macroeconomic models, such as labor supply, consumption and saving, human capital investments, and fertility decisions, are made in large part within the family. The details of families then matter for how decisions are made; for example, the organization of families (eg, prevalence of nuclear vs extended families or monogamous vs polygynous marriage) changes the incentives to supply labor, affects motives for saving and acquiring education, and determines possibilities for risk sharing. Yet typical macroeconomic models ignore the family and instead build on representative agent modeling that abstracts from the presence of multiple family members, who may have conflicting interests, who might make separate decisions, and who may split up and form new households.

One might argue that subsuming all family details into one representative household decision maker constitutes a useful abstraction. This would perhaps be the case if the structure and behavior of families were a given constant. However, the structure of the family has changed dramatically over time and is likely to continue to do so in the future. Large changes have occurred in the size and composition of households. Fertility rates have declined, divorce risk has increased (and then decreased), the fraction of single households has grown steadily, and women have entered the labor force in large numbers. Given these trends, the nature of family interactions has changed dramatically over time, and so have the implications of family economics for macroeconomics.

There is a small, but growing, literature that opens the family black box within macro models. The goal of this chapter is to survey this literature, to summarize the main results, and to point to open questions and fruitful avenues for future research. We also aim to introduce macroeconomists to the tools of family economics.

There are multiple ways in which families can be incorporated into macroeconomics. The first generation of macroeconomists who took the family more seriously added home production to business cycle models (eg, Benhabib et al., 1991; Greenwood and Hercowitz, 1991). The insight was that home production cannot be ignored if

[b] See Greenwood et al. (2016b) for an excellent recent survey of that kind of family economics.

the cyclicality of investment and labor supply is to be understood. A large part of investment happens within the household in the form of consumer durables, a large part of time is spent on home production, and both vary over the cycle. The interaction of market time and business investment with these variables that are decided within the family is therefore important for understanding business cycles. In the home production literature, the family is a place of production, but decision making is still modeled in the then-standard way using a representative household with a single utility function.

In this chapter, we take the notion of families a step further. We emphasize that families consist of multiple members and that the interaction between these multiple members is important. We look at both horizontal interactions in the family, ie, between husband and wife, and vertical interactions, ie, between parents and children. Family members may have different interests, resources, and abilities. How potential conflicts of interests within the family are resolved has repercussions for what families do, including macrorelevant decisions on variables such as savings, education, fertility, and labor supply.

This chapter has three parts. We first consider how the family matters for short- and medium-run fluctuations. Second, we turn to economic growth. Third, we consider the role of families for understanding political and institutional change.

Our discussion of short- and medium-run fluctuations uses the US economy as an example to demonstrate how changes in family structure feed back into macroeconomics. We start by documenting how US families have changed in recent decades, including a decline in fertility rates, a large increase in the labor force participation especially of married women, and changes to marriage and divorce. We then analyze how these changes affect the evolution of aggregate labor supply over the business cycle and the determination of the savings rate. With regard to labor supply, we emphasize that couples can provide each other with insurance for labor market risk. For example, a worker may decide to increase labor supply if the worker's spouse becomes unemployed, and couples may make career and occupation choices that minimize the overall labor market risk for the family. The extent to which such insurance channels operate depends on family structure (eg, the fraction of single and married households and divorce rates) and on the relative education levels and labor force participation rates of women and men. We argue that recent changes to family structure have likely changed the volatility of aggregate labor supply and contributed to the "Great Moderation" in economic fluctuations observed between the 1980s and the Great Recession. We also discuss research that suggests that changes in female labor force participation are the main reason behind the recent phenomenon of jobless recoveries. Regarding savings rates, we emphasize how changes to divorce risk affect couples' incentives to save. We conclude this part of the chapter by discussing alternative models of the family and their use within macroeconomics. We argue that there is a need for more detailed dynamic modeling of family decision making, an area where methods widely used in macroeconomics may be fruitfully applied to family economics.

The second part of the chapter focuses on the long run, ie, economic growth. Here education, human capital accumulation, and fertility are the key choices of interest. We start by documenting sharp correlations between measures of family structure and measures of economic development in cross-country data. In a series of simple growth models, we then show how different family dimensions affect the growth rate. The first dimension is the interaction between parents and children, noting that, typically, parents make education decisions for their children. We then add fertility choice and discuss government-imposed fertility restrictions such as the one-child policy in China. Next we move from one-gender to two-gender models by first adding a second person in decision making and then adding a distinction between the two in technology. We use the framework to discuss the implications of the widely observed son preference for economic growth. We conclude the section with a discussion on the importance of nonwestern family structures (such as polygyny) and endogenous marriage.

The third part examines the role of the family in the context of political economy. We argue that the family is an important driver of political and institutional change in the course of development. Throughout the development process, all of today's rich countries (except a few countries whose wealth is built on oil) went through a similar series of reforms. Democracy was introduced, public education was initiated, child labor laws were implemented, the legal position of women was improved, and welfare and social security systems were established. Two important questions are why these reforms were implemented at a particular stage of development, and why many poorer countries failed to introduce similar reforms. We emphasize that most of these reforms concern the nature of the family. Public schooling moved the responsibility of education from the family to the public sphere, and public pension did the same for old age support. Child labor laws put constraints on the power parents have over their children. The introduction of women's rights changed the nature of the interaction between husband and wife. We discuss mechanisms linking the family and political change and the possibility of a two-way feedback between economic development and political reform. We then focus on the political economy of two specific reforms, namely the expansion of women's economic rights and the introduction of child labor laws.[c]

Throughout this chapter, we point out promising directions for future research. In line with the overall theme of the chapter, most of these research directions concern using family economics to generate new answers for questions that originate from macroeconomics. However, we also see a lot of potential for intellectual arbitrage in the opposite direction, namely using tools that are widely used in macroeconomics to build improved models of the family. In particular, a striking difference between the fields is that almost all macroeconomic models are dynamic, whereas in family economics static modeling is still

[c] The political economy of women's rights is addressed in more detail by Doepke et al. (2012).

common. In reality, dynamic considerations should be just as important in family economics as in macroeconomics. For example, if a woman decides to stay at home with her children, she will usually be aware that her absence from the labor market decreases her outside option. Similarly, when a woman and a man decide on whether to have a child, how the child will affect their future interactions will be an important consideration. There is a small literature that documents the importance of dynamics for the family. In particular, Mazzocco (2008) shows empirically that Euler equations hold at the individual but not the household level, and Mazzocco (2007) and Lise and Yamada (2015) provide evidence suggesting that bargaining power within the household evolves over time. To capture such phenomena and to better understand the link between family decisions and aggregate outcomes, more dynamic family bargaining models are needed. Tools that are widely used in macroeconomics, such as dynamic contracting under limited commitment and private information constraints, should prove useful for building such models.

In the following section, we start our analysis by considering the implications of the family for macroeconomic outcomes in the short and the medium run. In Section 3, we investigate the role of the family for economic growth, and Section 4 puts the spotlight on the family as a driver of political change. Section 5 concludes by discussing yet other dimensions in which the family matters for macroeconomics and by providing thoughts on promising directions for future research. Proofs for propositions are contained in the Appendices.

2. THE FAMILY AND THE MACROECONOMY IN THE SHORT AND MEDIUM RUN

Ever since micro-founded modeling became dominant in the 1970s and the 1980s, explicit models of household decision making have been a standard ingredient in macroeconomic models. Depending on the application, the household may face a variety of decisions, such as choosing labor supply, accumulating assets, or investing in human capital. However, within macroeconomics comparatively few attempts have been made to explicitly model families. By modeling families, we mean to account for the fact that households may contain multiple members, who may have different interests, who may make separate decisions, and who may split up in divorce or join others and form new households.

In the following sections, we argue that modeling families can make a big difference in understanding aggregate household behavior in the short and the medium run. We focus on the most basic role of the household sector in macroeconomic models, namely to provide a theory of labor supply and savings.

2.1 The Point of Departure: Representative Households

Traditional macroeconomic models used for business cycle and monetary analysis are populated by an infinitely lived, representative household, who derives utility from consumption and leisure and derives income from supplying labor and accumulating savings. A prototype household problem looks like this (eg, Cooley and Prescott, 1995):

$$\max_{\{c_t,l_t\}} E\left\{\sum_{t=0}^{\infty}\beta^t U(c_t,l_t)\right\} \tag{1}$$

subject to:

$$\begin{aligned} c_t + a_{t+1} &= w_t l_t + (1+r_t)a_t, \\ a_{t+1} &\geq -B, \\ a_0 &= 0, \\ 0 \leq l_t &\leq T. \end{aligned}$$

Here c_t is consumption, l_t is labor supply, w_t and r_t are the wage and the interest rate (taken as given by the household), β is a discount factor that satisfies $0<\beta<1$, and $B>0$ defines a slack borrowing constraint that rules out running a Ponzi scheme. The first-order conditions for the household's maximization problem are:

$$-\frac{U_l(c_t,l_t)}{U_c(c_t,l_t)} = w_t, \tag{2}$$

$$U_c(c_t,l_t) = \beta E\{(1+r_{t+1})U_c(c_{t+1},l_{t+1})\}. \tag{3}$$

Here (2) is the requirement that the marginal rate of substitution between labor and leisure is equal to the wage, and (3) is the intertemporal Euler equation for consumption. Condition (2) pins down average labor supply and the elasticity of labor supply as a function of the relative wage and overall wealth, and (3) determines savings as a function of wealth, interest rates, and expectations over future leisure and consumption.

A representative household based on a problem similar to (1) underlies most of the macroeconomic modeling in the real business cycle literature, the monetary DSGE literature, and many other subfields of macroeconomics. A theory of labor supply and savings that is build on a representative household has a number of limitations, including the obvious one that such a theory has nothing to say about questions that involve heterogeneity and inequality across households. Of course, there is nothing wrong with simplifying assumptions in principle; after all, models are intended to be simplified representations of reality. The limitations of the representative household become a bigger concern, however, when some of the driving forces the model abstracts from are subject to changes over time that substantially alter macroeconomic behavior.

There is already a sizeable literature that extends the representative-household framework in other key dimensions, in particular by accounting for heterogeneity in age (ie, allowing for the life cycle) and heterogeneity in wealth and income.[d] This literature has characterized some of the macroeconomic changes brought about by the changing economic environment in recent decades, such as the large rise in income inequality and returns to education since the 1970s, and the population aging in industrial societies that resulted from rising life expectancy and low fertility. There is much less work on the dimension that this chapter focuses on, namely allowing for the fact that many households have multiple members, ie, accounting for families.

In the following sections, we argue that accounting for families is just as important as the existing extensions of the representative-agent framework. The main reason for this is that families have changed substantially in recent decades; for example, there have been large changes to rates of marriage and divorce, to female labor force participation, and to fertility rates. We start by outlining the main facts of changing families in the United States (to the extent that they are relevant from a macroeconomic perspective), and we then outline channels for how these changes are relevant for determining aggregate labor supply and savings. We note that while there is a lot of existing work documenting and explaining the family trends, there are few papers that focus specifically on the implications of these changes for macroeconomics. In our view, this presents a high-return area for future research, with a lot of low-hanging fruit.

2.2 The Facts: Changing Families in the United States

Throughout the 20th century, the major industrialized countries underwent large changes in the composition and behavior of families. We illustrate this transformation with statistics from the US economy as an example. In the following sections, we explain the relevance of these trends for macroeconomics.

The first transformation concerns changes in fertility over time. Fig. 1 displays the number of children ever born to US women by birth cohort (ie, the horizontal axis is the year in which a mother is born; the corresponding births mostly take place 20–40 years later). As in all industrialized countries, the main trend associated with long-run development is declining fertility. In the case of the United States, fertility fell almost threefold from the cohorts born in the mid-19th century to those born in the late 20th century. The trend was not uniform, however. In the middle of the 20th century there was a phase of rising fertility: the US baby boom. In the course of the baby boom, fertility rose from about two to about three children per woman, and then sharply reversed course to fall back toward two again. These changes have led to large variations

[d] Much of this literature is surveyed by Heathcote et al. (2009) and in the chapter “Macroeconomics and household heterogeneity” by Krueger, Mitman, and Perri (in this volume).

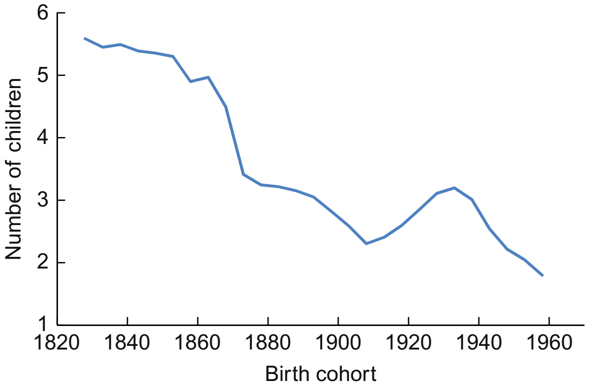

Fig. 1 Children ever born by cohort, United States (ie, average number of children for women born in a given year). *Jones, L.E., Tertilt, M., 2008. Fig. 2 Household size over time, United States. *Salcedo, A., Schoellmann, T., Tertilt, M., 2012. Families as roommates: changes in US household size from 1850 to 2000. Quant. Econ. 3 (1), 133–175 (Figure 1).*

in cohort sizes, which will affect the macroeconomy for decades to come now that the baby boom cohorts (ie, the babies, not the mothers) are reaching retirement age.

Fig. 2 displays a closely related change: a secular decline in the average size of households. Fertility decline is a main driver of this change; ie, the decline in fertility resulted in fewer children per household and thus a lower household size. However, there are additional factors because the number of adults per household also declined over time. This is in part due to fewer adults within families; ie, a smaller fraction of families include multiple generations of adults, and more families are headed by a single adult. In addition, fewer households include adults who are not related to each other.

Fig. 3 shows that there is not just a decline in the size of households but also a dramatic change in the composition of household types. As recently as 1950, most households

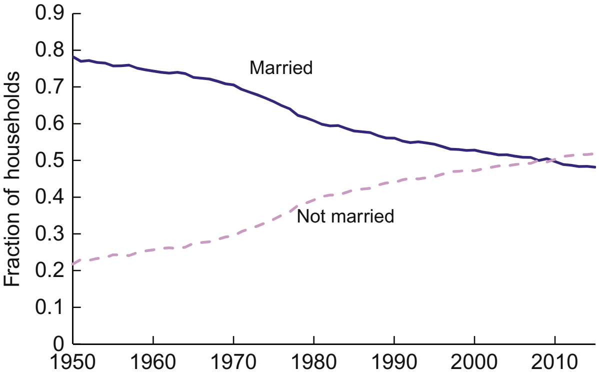

Fig. 3 Proportion of households including a married couple vs all other households over time, United States. *US Census Bureau, Historical Time Series, Current Population Survey, March and Annual Social and Economic Supplements, 2015 and earlier.*

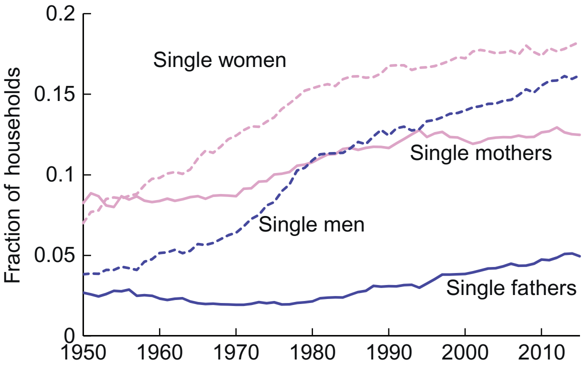

Fig. 4 Nonmarried households by type over time, United States. *US Census Bureau, Historical Time Series, Current Population Survey, March and Annual Social and Economic Supplements, 2015 and earlier.*

(about 80%) included at least one married couple. Now, married-couple households are no longer the majority. Fig. 4 breaks down the nonmarried households into further subcategories, with increases in every subcategory. The figures for single women and single men rise most, indicating primarily lower marriage rates, a higher age at first marriage, and a higher divorce rate. Single mother and single father households have also increased since the 1970s. Fig. 5 looks specifically at the role of marriage and divorce. The figure shows that the decline in the fraction of married women is due in almost equal parts to a rise in the number of never married women and a rise in the number of divorced women. Fig. 6 shows the divorce rate (defined as the number of divorces per 1000 women). Apart from the spike after World War II, the divorce rate was roughly constant from 1940 until the late 1960s and then increased sharply over the course of a decade. It has been relatively constant since the early 1980s, albeit at a much higher level.

Another key trend linking family economics and macroeconomics is the rise in female labor force participation in the postwar era. From the beginning of the 20th century until the 1950s, for married households the single male breadwinner model was the norm. Since then, female labor force participation has risen steadily over a number of decades. As Fig. 7 shows, overall female participation rose from about 30% to more than 60% of the adult population between 1950 and 1990. In the late 1990s, female participation flattened out and declined a little in the current century. Female participation still falls short of male participation, but by a small margin compared to the 1950s. As we will see later (Fig. 13), the rise in female participation is predominantly due to married women. There is also a compositional effect due to the increase in the share of single women coupled with the fact that single women are more likely to work than married women are.

A trend closely related to the rise in female labor market participation is a decline in time spent on home production by women. Figs. 8 and 9 display the average hours men

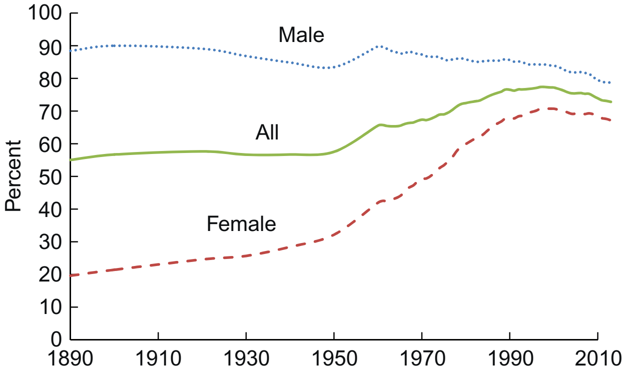

Fig. 7 Labor force participation by gender over time, all persons 16–64 years old, United States. *OECD LFS Sex and Age Indicators and US Department of Commerce, Bureau of the Census, "Historical Statistics of the United States: Colonial Times to 1970," Bicentennial Edition, Part 1, 1975, Tables A119–134 and D29–41.*

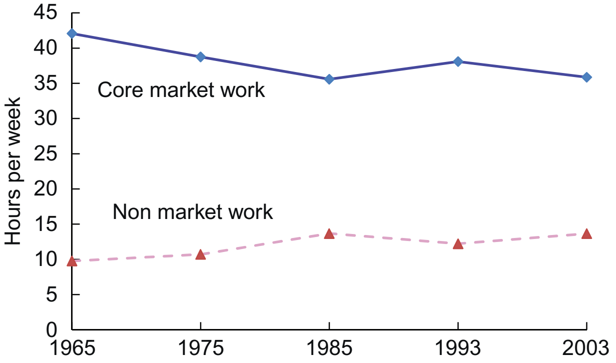

Fig. 8 Men's weekly market vs nonmarket (ie, home) work hours over time, United States. *Aguiar, M., Hurst, E., 2007. Measuring trends in leisure: the allocation of time over five decades. Q. J. Econ. 122 (3), 969–1006 (Table II).*

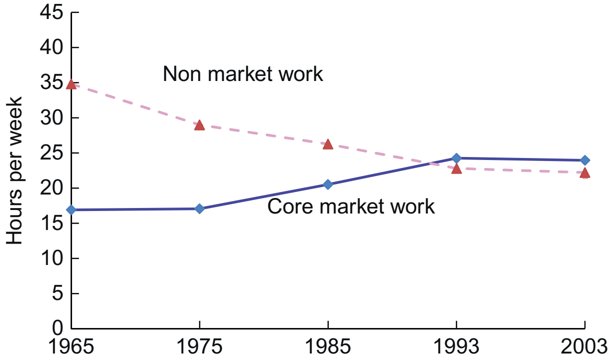

Fig. 9 Women's weekly market vs nonmarket (ie, home) work hours over time, United States. *Aguiar, M., Hurst, E., 2007. Measuring trends in leisure: the allocation of time over five decades. Q. J. Econ. 122 (3), 969–1006 (Table II).*

and women spent per week on market work vs nonmarket work, ie, home production (activities such as child care, cleaning, and preparing food). For men, there is a small decline in market work and an equally small corresponding rise in nonmarket work. For women, in contrast, since 1965 there has been a major transformation in time use: time spent on nonmarket work has dropped sharply while market work has risen, and now exceeds nonmarket time use.

Another closely related fact is the change in relative wages of men and women. Over the course of the 20th century, women have been catching up dramatically in terms of pay. Fig. 10 displays women's median earnings relative to men's earnings. In both cases only full-time, year-round workers are considered. As the figure shows, at the beginning of the 20th century, women earned less than half of what men earned. The ratio increased steadily and had reached 65% by 1955. There was a drop in the late 1960s and 1970s, but from the 1970s onward, the ratio continuously increased again. Today, female relative earnings have reached an all-time high of 80%.

While our focus here is on changes over time in the United States, an interesting pattern in cross-country data is that there is a positive correlation between the fertility rate and the female labor-force participation rate across industrialized countries (Fig. 11). That is, the OECD countries with the highest fertility rates (the United States, France, and the Scandinavian countries) all have relatively high female labor force participation rates, whereas in low fertility countries (such as Italy and Spain) fewer women work in the labor market. The pattern is important because it goes against the relationship between these variables in time-series data: within most countries, the trend through the last 100 years or so has been toward lower fertility and higher female participation. Working in the market and caring for children are alternative uses of women's time. If a single force (say, a rise in

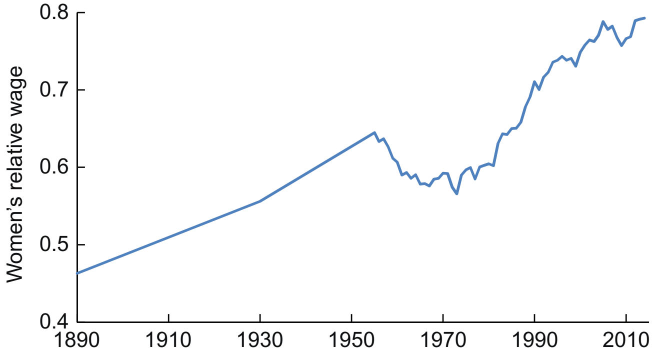

Fig. 10 Gender wage gap: median earnings of full-time, year-round, female workers 15 years and older, relative to men, United States. *US Census Bureau, Historical Income Tables. Fig. 11 Fertility vs female labor force participation across European OECD countries. *OECD LFS sex and age indicators and world development indicators.*

relative female wages) was responsible for changes to both labor force participation and fertility, we would expect these variables to always move in opposite directions. The observation in Fig. 11 that, across countries, these variables are positively correlated suggests that such a one-dimensional explanation is at odds with the data and is informative for which kind of theories can explain the family trends described here.

2.3 Explaining the Facts

There is a large literature (spanning family economics, labor economics, development economics, and macroeconomics) that provides explanations for the transformation of the family described above. We keep our discussion of this literature brief, since the goal of this chapter is not explaining these family facts but rather studying their importance for macroeconomic analysis. For a comprehensive survey of the literature on the drivers of changes in the family, we refer the reader to Greenwood et al. (2016b).

The best-known explanations for the historical fertility decline are based on the quantity–quality trade-off together with the idea that returns to education were increasing over time due to technological progress (see also Section 3.3). The more recent fertility decline that followed the baby boom is often connected to the increasing value of female time. The baby boom itself still presents a bit of a puzzle. The conventional wisdom of women catching up on their fertility after the war is clearly not the main driver, as it was young women (not of child-bearing age during the war) who had most children during the baby boom, as Fig. 1 shows. Doepke et al. (2015) suggest that the increase in labor force participation during the war was a major driver for the baby boom. The war generation of women accumulated valuable labor market experience, and after the war these women provided strong competition in the labor market for younger women who lacked that experience. Doepke, Hazan, and Maoz argue that many of these younger women were crowded out of the labor force and decided to start having children earlier instead.[e] Other papers provide a complementary explanation by attributing part of the baby boom to a decline in the cost of child bearing, for example, due to medical progress that made childbirth less risky to mothers (Albanesi and Olivetti, 2014) or improvements in household technology that lowered the time cost of children (Greenwood et al., 2005a).[f]

The causes for the secular increase in female participation have also been widely explored. Some of the explanations focus on the alternative uses of female time and argue that the time required for home production (such as child care, preparing food, or cleaning the home) fell, freeing up time for work. Greenwood et al. (2005b) attribute the reduction in time required for home production to technological progress, and in particular the introduction of time saving appliances. Even if technology had stayed as it was, home production time would have fallen because of the large reduction in the average fertility rate from the baby boom period of the 1950s to the present. Figs. 8 and 9 show that time use data indeed display a large reduction in nonmarket work (ie, home production) for women that closely mirrors the rise in market work. We also observe a small rise in home production for men, suggesting that some of the reduction in female home production arises from substitution within the household. However, the rise in male home production is quantitatively small compared to the decline in female home production. A related theory put forth by Albanesi and Olivetti (2016) is based on technological advances in health. Innovations such as infant formula made it much easier to reconcile work and motherhood and thus were an important contributor to the contemporaneous increase in fertility and female participation between 1930 and 1960.

Another factor contributing to the rise in female participation in the labor market is the decline in the gender wage gap between men and women, as shown in Fig. 10. While some of the overall rise in relative female pay is due to endogenous decisions such as education and the accumulation of work experience, other factors such as the disappearance of marriage bars can be regarded as exogenous driving forces.[g] The gender gap may also have narrowed because of technological change in the market sector that made male and female work more similar. If men have the comparative advantage in brawn and women in brain, then as knowledge becomes more important, female relative wages go up.[h] The role of the

[e] See also Goldin (1990) and Goldin and Olivetti (2013) for other perspectives on the long-run impact of World War II on the female labor market.

[f] Yet another possibility is a link between economic and demographic cycles; Jones and Schoonbroodt (2015) provide a model in which the baby boom arises due to the recovery from the Great Depression in terms of both income and fertility.

[g] Eckstein and Lifshitz (2011) decompose the effect of rising education and the decline in the gender gap conditional on education and find that rising female education accounts for a larger fraction of the increase in female participation.

[h] This idea was first formally modeled by Galor and Weil (1996). See Albanesi and Olivetti (2009) for an alternative theory of how a gender wage gap can arise from private information on work effort and specialization within the household.

declining gender gap in explaining the rise in participation is emphasized by Jones et al. (2015), who also allow for technological improvements in home production, but find them not to be quantitatively important. Attanasio et al. (2008) study the life-cycle labor supply of three cohorts of American women, born in the 1930s, 1940s, and 1950s. Their model allows for a number of potential determinants of labor supply, including changes in the gender wage gap, the number and cost of children, and changes in the returns to labor market experience. They find that for the cohorts considered, both a reduction in the costs of children and a decrease in the gender wage gap need to be allowed to explain the rise in participation. More recent contributions connect the decline in the gender wage gap explicitly with the rise of the service sector (Rendall, 2010; Ngai and Petrongolo, 2014).

Another channel that can affect relative male and female labor supply is endogenous bargaining within the household. In explicit household bargaining models (see Section 2.5), the outside options of the spouses are usually important determinants of bargaining power. Improved labor market opportunities for women (through whichever channel they occur) improve women's outside options and thus should improve women's bargaining power in marriage. Using a quantitative model, Knowles (2013) argues that an endogenous increase in female bargaining power is important in explaining the rise in female labor supply over the 1970–2000 period without implying a (counterfactual) large decline in male labor supply. Eckstein and Lifshitz (2015) estimate a labor supply model in which couples differ in how bargaining takes place (eg, cooperative vs noncooperative bargaining) and find that bargaining has a large impact on female, but not male labor supply.

The link between fertility and employment decisions is likely to have become more important throughout the last few decades. Before the 1960s, in industrialized countries most mothers were not in the labor force, so that for many the employment margin was not operative as far as decisions on additional births were concerned. Today, in the United States and other industrialized countries, most mothers are in the labor force. Hence, having children interacts with employment more directly, through margins such as deciding to work full or part time or the choice between career paths that differ in flexibility for dealing with child care needs. Recently, Adda et al. (2016) have provided a detailed study of the costs of children in terms of mother's careers based on a detailed life cycle model of female employment and fertility matched to German data. They show that the career costs of having children are substantial and that realized and expected fertility can account for a large fraction of the gender wage gap.[i] Based on the same data,

[i] See also Miller (2011) who estimates the career costs of children, using US data on biological fertility shocks as instruments. Guvenen et al. (2014) provide a recent analysis of the gender pay gap at the very top of the income distribution. They argue that a large part of the underrepresentation of women among top earners is due to the "paper floor," ie, a higher likelihood of women dropping out of the top pay percentiles, part of which may be due to fertility decisions.

Bick (2016) provides a quantitative analysis of the importance of the availability of market-based child care for fertility and female labor supply.

As discussed in Section 2.2, if a single force was responsible for both the upward trend in female labor force participation and the downward trend in fertility, we would expect these variables to always move in opposite directions. However, if we look at the cross section of industrialized countries, a positive correlation between female labor force participation and fertility emerges (see Fig. 11).[j] A number of recent studies have developed theories that are consistent with this pattern. The general intuition for these results is that many women now want to have both children and careers. In places where policies (or cultural expectations) are such that mothers can easily combine having children and careers, fertility and female labor force participation will both be high. In contrast, if there are obstacles to combing motherhood with working, many women will choose one or the other, and both fertility and participation will be lower. One of the first papers to formalize this intuition is Da Rocha and Fuster (2006), who focus on differences in labor market frictions across countries. Using a quantitative model, they find that in countries where unemployment risk is high, women both work less and are more likely to postpone births. Similarly, Erosa et al. (2010) find that more generous parental leave policies can increase both fertility and female labor force participation. Another source of variation can be cultural expectations for the roles of mothers and fathers in raising children. Doepke and Kindermann (2015) show that in European countries with exceptionally low fertility rates, women bear a disproportionately large share of the burden of caring for children. In a model of household bargaining over fertility decisions, they show that this leads to many women being opposed to having (additional) children. Hence, once again fertility will be lower, while at the same time many mothers are not able to work due to their child care duties.

The causes behind the decline in marriage, rise in divorce, and increase in single motherhood (as shown in Figs. 3–6) are likely related to the increase in female labor force participation. For a discussion of the causes behind these changes in the family structure, see Greenwood et al. (2016b).

2.4 Changing Families and Aggregate Labor Supply

We now turn to the main focus of this section, namely how changes to the family affect how labor supply and savings are determined in the aggregate. We start with aggregate labor supply, where the role of changes in female labor market behavior takes center stage.

A common thread through the studies of the rise in female participation is that the female participation decision is qualitatively different than the male participation decision. At least in part, this is due to a higher fixed cost of participation for women,

[j] A similar phenomenon has emerged recently in cross-sectional data in the United States. Hazan and Zoabi (2015a) document a U-shaped relationship between female education and fertility.

who often bear the primary responsibility for child care. The different nature of female labor supply suggests that today, aggregate labor supply is determined in a qualitatively different fashion compared to a few decades ago. We now consider a deliberately simplified model to illustrate the main channels through which the joint determination of female and male labor supply within a family affects the macroeconomic properties of labor supply.

2.4.1 Joint Labor Supply in the Family

To focus on the extensive margin, we consider a setting where an individual can either work full time or not at all.[k] The utility function of an individual of gender $g \in \{f,m\}$ is given by:

$$U_g(c_g, l_g) = \log(c_g) - \eta_g l_g,$$

where $l_g \in \{0,1\}$ is labor supply and c_g is consumption.[l] The relative weight of leisure in utility η_g varies in the population. People can live either as singles or as married (or cohabiting) couples. The budget constraint for a single individual is:

$$c_g + \psi l_g = w_g l_g + y_g,$$

where w_g is the wage for gender g, y_g is unearned income (ie, endowment or transfer income), and ψ represents the fixed cost of running a household conditional on working. The implicit assumption is that a person who does not work can replace the cost ψ through costless home production. We assume that ψ is a scalar that satisfies $0 < \psi < \min(w_f, w_m)$. The model is static, but alternatively we can interpret the decision problem as representing the labor-supply decision of a long-lived individual/household with exogenous saving in a given period, in which case y_g represents exogenous net saving/dissaving in the period.

For a married couple, the same fixed cost of running a household applies, but only if both spouses are working.[m] The joint budget constraint for a couple then is:

$$c_f + c_m + \psi \min(l_f, l_m) = w_f l_f + w_m l_m + y, \tag{4}$$

[k] We focus on the extensive margin for tractability. However, similar forces will be effective at the intensive margin as well.

[l] Here we assume that consumption is a private good. Many family models assume that consumption in the family is a public good. We consider pure public goods in Section 3. In reality, there are some private and some public elements in household consumption (see Salcedo et al., 2012 for a detailed analysis of this point).

[m] See Cho and Rogerson (1988) for an early contribution on the implications of this type of fixed cost of participation for the elasticity of labor supply.

where $y = y_f + y_m$. In this setting, the decision problem for a single person is straightforward. Comparing the utility conditional on working vs not working, an individual chooses to work if the condition,

$$\log(w_g + y_g - \psi) - \eta_g \geq \log(y_g),$$

is satisfied, or, equivalently, if the opportunity cost of working is sufficiently low:

$$\eta_g \leq \log\left(\frac{w_g + y_g - \psi}{y_g}\right).$$

For a married couple, we have to take a stand on how the inherent conflict of interest between the spouses given their different preferences is resolved. We assume cooperative bargaining, ie, the household solves a Pareto problem with welfare weights λ_f and λ_m for the wife and the husband, with $\lambda_f + \lambda_m = 1$. The problem solved by a married couple is then given by:

$$\max\{\lambda_f[\log(c_f) - \eta_f l_f] + \lambda_m[\log(c_m) - \eta_m l_m]\} \tag{5}$$

subject to the budget constraint (4). The maximization problem can be solved by using first-order conditions to characterize the consumption allocation conditional on a given pattern of labor supply, and then comparing utilities to determine optimal labor supply. To simplify notation, we focus on the case where husbands always work as long as $w_m > 0$. If the wife does not work, household income is given by $w_m + y$ and the consumption allocation is $c_f = \lambda_f(w_m + y)$, $c_m = \lambda_m(w_m + y)$. If the wife also works, household income net of the participation cost is $w_f + w_m + y - \psi$, and the consumption allocation is $c_f = \lambda_f(w_f + w_m + y - \psi)$, $c_m = \lambda_m(w_f + w_m + y - \psi)$. Denote by $V(l_f, l_m)$ the value of the objective function of the household (5) given labor supply and the optimal conditional consumption allocation. The wife will work if $V(l_f = 1, l_m = 1) \geq V(l_f = 0, l_m = 1)$, which can be written as[n]:

$$\begin{aligned}\log(w_f + w_m + y - \psi) + \lambda_f \log(\lambda_f) + \lambda_m \log(\lambda_m) - \lambda_f \eta_f - \lambda_m \eta_m \\ \geq \log(w_m + y) + \lambda_f \log(\lambda_f) + \lambda_m \log(\lambda_m) - \lambda_m \eta_m.\end{aligned}$$

Simplifying, women will work if and only if:

$$\eta_f \leq \frac{1}{\lambda_f} \log\left(\frac{w_f + w_m + y - \psi}{w_m + y}\right).$$

Hence, women are more likely to work if the participation cost ψ or male wages w_m are low, and if female wages w_f are high. A low bargaining power for women λ_f also translates into higher participation because households then place less value on the wife's leisure.

[n] For now we assume full commitment, ie, people get married before disutilities from working are realized, and they stay together even if being single would provide higher utility.

Note that the assumption of full commitment is important here. If the bargaining power of women is low, women pay the utility cost of working and consume little. Such a woman may prefer not to be a married at all. Later we endogenize the bargaining weights to ensure that participation constraints hold.

We can now consider the implications of the simple model for the variability of labor supply. Consider, first, the own-wage elasticity of labor supply. Consider the case where the only dimension of heterogeneity in the population is in leisure preference η_g, the distribution of which is described by the distribution function $F(\eta_g)$ with continuous marginal density $f(\eta_g) = F'(\eta_g)$. We assume that the density satisfies the assumptions $F(0)=0$, $F'(\eta_g)>0$ for $\eta_g > 0$, $\lim_{\eta_g \to 0} f(\eta_g) = 0$, and $\lim_{\eta_g \to \infty} f(\eta_g) = 0$. That is, all individuals place at least some value on leisure and the distribution thins out at each tail (one example is a log-normal distribution for η_g). For singles of gender g, the fraction working N_g^s given wage w_g is given by:

$$N_g^s = F\left(\log\left(\frac{w_g + y_g - \psi}{y_g}\right)\right).$$

The aggregate wage elasticity of labor supply is then given by:

$$\frac{\partial N_g^s}{\partial w_g}\frac{w_g}{N_g^s} = \frac{w_g}{w_g + y_g - \psi}\frac{F'\left(\log\left(\frac{w_g + y_g - \psi}{y_g}\right)\right)}{F\left(\log\left(\frac{w_g + y_g - \psi}{y_g}\right)\right)}.$$

Note that this elasticity focuses on the extensive margin and hence is different from what is typically measured in the micro data (eg, Pistaferri, 2003 measures only the intensive margin elasticity).[o]

Consider now married couples. By assumption, we focus on the case where married men always work if they are able to. The fraction of married women working is then given by:

$$N_f^m = F\left(\frac{1}{\lambda_f}\log\left(\frac{w_f + w_m + y - \psi}{w_m + y}\right)\right)$$

and the elasticity of their labor supply is:

$$\frac{\partial N_f^m}{\partial w_f}\frac{w_f}{N_f^m} = \frac{w_f}{\lambda_f(w_f + w_m + y - \psi)}\frac{F'\left(\frac{1}{\lambda_f}\log\left(\frac{w_f + w_m + y - \psi}{w_m + y}\right)\right)}{F\left(\frac{1}{\lambda_f}\log\left(\frac{w_f + w_m + y - \psi}{w_m + y}\right)\right)}.$$

[o] Recent contributions that explicitly consider the extensive margin include Chetty et al. (2011, 2012) and Attanasio et al. (2015).

The relative size of single and married women's labor supply elasticity cannot be unambiguously signed, because this depends on the shape of the distribution function F and the size of unearned income. However, married women's labor supply will be more elastic than the labor supply of single women if unearned income y_f is sufficiency small:

Proposition 1 (Labor Supply Elasticity of Single vs Married Women) *If unearned income* $\mathrm{y_f}$ *is sufficiently small, married women's labor supply elasticity is higher than that of unmarried women.*

Intuitively, if unearned income is small, singles have to work if they want to consume, whereas a married woman can rely in part on her spouse's income. This result is in line with the empirical observation that married women's labor supply is much more elastic than that of married men or single women at the microlevel (see, eg, the survey by Blundell and MaCurdy, 1999). Of course, if the labor supply of married men were endogenized, they would also have more scope for variability in supply compared to single men. In practice, as long as the gender wage gap was sizeable and social expectations were that women do more child care and home work, the assumption that men are the default earners was broadly realistic. But as gender roles have become more equalized over time, we can expect the labor supply behavior of men and women to converge also.

Ultimately we would like to assess the implications of changes in the family for the behavior of aggregate labor supply. The results so far may seem to suggest that a higher proportion of married households should make aggregate labor supply more variable. However, so far we have only considered the own wage elasticity of female labor supply. Another important dimension of the family is the possibility of insurance within the family. Specifically, if in a marriage the working husband experiences a negative shock such as a layoff, the wife may be able to offer insurance by starting to work. Hence, in the aggregate, the variable labor supply of married women may dampen fluctuations in total labor supply, by offsetting shocks experienced by men.[p]

To analyze the possibility of insurance within the family, consider an extension of the environment with unemployment shocks. With probability u, a given individual is unable to work, or equivalently, the potential wage is zero. The realization of the shock is independent across spouses. We can now consider how aggregate labor supply reacts to changes in u, where an increase in u can represent a recession.

As before, we start by considering singles. Their aggregate labor supply is:

$$N_g^s = (1-u)F\left(\log\left(\frac{w_g + y_g - \psi}{y_g}\right)\right).$$

[p] An early study of this insurance channel is provided by Attanasio et al. (2005).

For singles, the elasticity of labor supply with respect to the probability of employment $1 - u$ is unity:

$$\frac{\partial N_g^s}{\partial(1-u)}\frac{1-u}{N_g^s}=1.$$

For married couples, labor supply is driven by two different thresholds for the wife's leisure preference, depending on whether the husband is working or not. Denote these thresholds by:

$$\hat{\eta}_e=\frac{1}{\lambda_f}\log\left(\frac{w_f+w_m+\gamma-\psi}{w_m+\gamma}\right),$$
$$\hat{\eta}_u=\frac{1}{\lambda_f}\log\left(\frac{w_f+\gamma}{\gamma}\right).$$

The average labor supply per married couple is then:

$$N^m=(1-u)(1+(1-u)F(\hat{\eta}_e))+u(1-u)F(\hat{\eta}_u).$$

Here the first term corresponds to employed husbands, and the second term corresponds to unemployed husbands. Wives of unemployed husbands work with a strictly higher probability than wives of employed husbands, because the cost ψ does not have to be paid (a substitution effect) and overall income is lower (an income effect working in the same direction). The derivative of labor supply with respect to $1 - u$ for the married couples is:

$$\frac{\partial N^m}{\partial(1-u)}=(1+(1-u)F(\hat{\eta}_e))+(1-u)F(\hat{\eta}_e)+uF(\hat{\eta}_u)-(1-u)F(\hat{\eta}_u),$$

$$\frac{\partial N^m}{\partial(1-u)}=(1+2(1-u)F(\hat{\eta}_e))-(1-2u)F(\hat{\eta}_u).$$

The elasticity of married labor supply with respect to $1 - u$ is then:

$$\frac{\partial N^m}{\partial(1-u)}\frac{1-u}{N^m}=\frac{1+2(1-u)F(\hat{\eta}_e)-(1-2u)F(\hat{\eta}_u)}{1+(1-u)F(\hat{\eta}_e)+uF(\hat{\eta}_u)}.$$

If it were the case that $F(\hat{\eta}_u)=F(\hat{\eta}_e)$, the expression once again would yield an elasticity of unity as for the singles. However, in fact we have $\hat{\eta}_u>\hat{\eta}_e$ and hence $F(\hat{\eta}_u)>F(\hat{\eta}_e)$, so that the elasticity of labor supply by married couples is strictly smaller than one. Intuitively, there is a fraction of women (given by $F(\hat{\eta}_u)-F(\hat{\eta}_e)$) who do not work if their husband is working, but choose to enter the labor force if the husband is unemployed. Hence, there is insurance in the family that dampens fluctuations in aggregate employment. Even though married female labor supply is more elastic at the microlevel, it contributes to a dampening of the volatility of aggregate labor supply due to this intrafamily insurance effect.[q]

In the data, married female employment rose massively in the second half of the 20th century (see Fig. 7), and there were also large shifts in the composition of household types (see Figs. 3 and 4). The model suggests that these changes should affect the volatility of aggregate labor supply. The following proposition summarizes the main results.

Proposition 2 (Family Determinants of Volatility of Aggregate Labor Supply) *Consider a population of measure one consisting of* M *married households (with two members each) and 1–2*M *single households. We then have:*

1. *The elasticity of aggregate labor supply* N *with respect to* $1-\mathrm{u}$ *(the fraction of workers not affected by the unemployment shock) is equal to one if the fraction of married people is* $\mathrm{M}=0$ *and decreases with* M *for* $\mathrm{M}>0$.
2. *For a fixed* $\mathrm{M}>0$*, the elasticity of aggregate labor supply* N *with respect to* $1-\mathrm{u}$ *is strictly smaller than one, but approaches one when* $\mathrm{w_f}$ *converges to zero or to infinity.*

The first premise suggests that the large shifts in the composition of households in the past few decades may have had a marked effect on the response of aggregate labor supply to shocks. The second premise suggests that, in addition, the increase in female labor supply should also affect the behavior of aggregate labor supply, albeit in a nonmonotone way. Regarding the married households, what is at stake is the potential for insurance within the family. When conditions are such that women do not work even if their husbands are unemployed (captured here by the case of a female wage close to zero), there is no potential for insurance, and hence the labor supply of married households will be just as elastic as that of single households. Conversely, when conditions are such that all women work regardless of the employment status of their husbands (captured by the case of the female wages approaching infinity), there is no potential for insurance either. Insurance does play an important role when there is a sizeable group of women who do not work if their husbands are employed, but are willing to enter the market when the husband loses his job. Hence, the mechanism would predict the greatest role for insurance at a time when the rise in female employment is well underway, but still not close to being completed.

Fig. 12 displays how the elasticity of total labor supply by married households with respect to the unemployment shock depends on relative female wages in a computed example.[r] The male wage is normalized to one, and the source of variation is the relative

[q] There is an active debate in the literature on how micro- and macroestimates of labor supply elasticities can be reconciled (see Chetty et al., 2011, 2012; Keane and Rogerson, 2012 for recent contributions).

[r] Parameter values: $w_m=1$, $\gamma=0.1$, $\psi=0.1$, and $\lambda_f=0.5$. The distribution of leisure preferences is log-normal with $\mu=0.5$ and $\sigma=1$, and the elasticity of labor supply is evaluated at an unemployment rate of $u=0.1$.

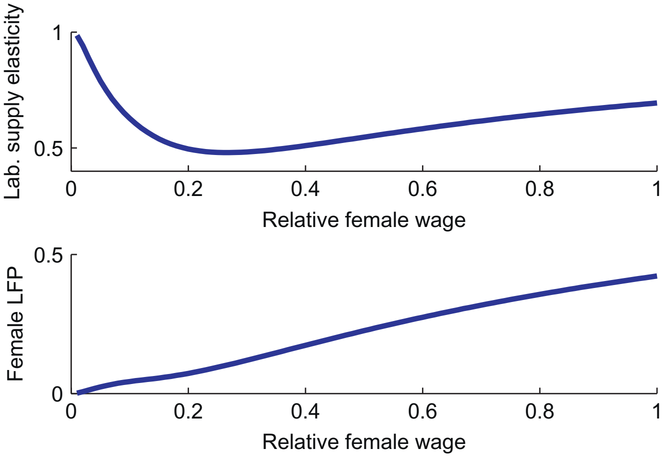

Fig. 12 Aggregate labor supply elasticity and female labor force participation (LFP) as a function of relative female wage in labor supply model.

female wage. The lower panel shows female labor supply as a function of the relative female wage. Not surprisingly, at a zero female wage, female labor supply is zero as well. However, even with very low wages some women work, namely those whose husbands are unable to work and who have a low leisure preference. The upper panel shows that this implies that the aggregate elasticity is U-shaped in relative female wages. In light of the observed decline in the gender wage gap and the increase in female labor force participation in US data (see Figs. 7 and 10), the findings suggest that the aggregate labor supply elasticity should have changed substantially in recent decades.

2.4.2 Endogenous Bargaining

The analysis of married couples' decisions has been carried out so far under the assumption of exogenous bargaining weights and full commitment. As mentioned above, if female bargaining power is low and female wages are high, women are likely to work a lot and consume little, and hence such women may prefer not to be married at all. Without full commitment, ie, if women were allowed to leave such a marriage, efficient bargaining subject to the limited commitment constraint would dictate that bargaining weights adjust to ensure that married women get at least as much utility as they would if they were single. Adjusting bargaining weights in this way is possible as long as the surplus from marriage is positive, which is guaranteed in our setting as long as $\psi > 0$ (married couples economize on the cost of running a household).[s]

[s] Other reasons for a positive marital surplus include consumption being a public good (see Section 3) and a utility benefit from being married (see Section 2.5).

Now consider how bargaining weights would adjust to changing wages w_g in this setting.[t] The utility of a single female is the maximum value between working and not working as a single:

$$U_f^s = \max\{\log(w_f + y_f - \psi) - \eta_f, \log(y_f)\}.$$

Assume that w_f is high enough (or y_f low enough) so that as a single, she always prefers to work. Comparing her utility as a single with that when married, she will prefer to be single if:

$$w_f + y_f > \frac{\lambda_f}{1-\lambda_f}(w_m + y_m) + \psi.$$

This condition will hold, for example, when her wages are high or her bargaining power is low. In such a case, the bargaining power in marriage should adjust to guarantee her at least her reservation (ie, single) utility:

$$\lambda_f = \frac{w_f + y_f - \psi}{w_m + y_m + w_f + y_f - \psi}.$$

Of course, any λ_f higher than the expression above would also guarantee that her participation constraint is satisfied.

We can use this logic to assess what would happen in a dynamic model with shocks to wages and participation cost. Suppose the couple starts out with a large marital surplus and bargaining weights such that neither participation constraint is binding. Suppose now that her wage increases unexpectedly such that, holding λ_f constant, her participation constraint would be violated. In response, her bargaining weight will increase. Similarly, a fall in the participation cost ψ may also lead to a tightening of the participation constraint and hence a shift in bargaining weights.[u] Bargaining positions will also be affected by changes in unearned income such as lottery winnings or an inheritance.

Now consider how such changes in bargaining weights affect the elasticity of labor supply. Qualitatively, the effects described in Propositions 1 and 2 rely on the possibility of insurance within the family and do not depend on the assumption of fixed bargaining weights. However, endogenous bargaining may well matter for the quantitative size of the effects. Both Knowles (2013) and Voena (2015) examine this issue, although their

[t] The model is static of course so there is no adjustment over time. Rather, one should think of bargaining weights differing across couples in an economy with heterogeneity in relative wages. However, the basic logic would carry over to a dynamic model with limited commitment where similar forces would lead to adjustments in the bargaining weights over time, see Mazzocco (2007) and Voena (2015).

[u] Since a decline in ψ affects both the male and female participation constraint, the direction of the change will depend on the details and in particular the status quo bargaining weight. Suppose her constraint is exactly binding before the shock lowering ψ is realized. Then, clearly, since he is currently reaping the entire surplus, her weight will have to go up to ensure continued participation in marriage by the female.

analyses are concerned with longer-term changes rather than with the business cycle. Nevertheless, the forces they identify should also be active at the business cycle frequency. If a higher wage increases bargaining power, it also increases the weight in the bargaining process on the leisure of the spouse who is receiving the raise. This effect lowers the response of labor supply to wage changes. Indeed, Knowles (2013) argues that the overall response of aggregate labor supply to the increase in female wages is dampened because of shifts in bargaining power. Whether such shifts in bargaining power also dampen aggregate labor volatility is less clear, as the opposite effect will apply to the other spouse. We view this as a fruitful area for future research.

2.4.3 Linking Changes in the US Labor Market to Family Labor Supply

We now relate the theoretical channels linking the family to variations in aggregate labor supply outlined above to empirical evidence on fluctuations in employment and output in the United States. We are interested in how the variability of aggregate labor supply varies between men and women and single and married individuals, and how these factors changed over time. Our analysis is based on annual data from the Current Population Survey (CPS) for the years 1962–2014. We focus on average weekly hours worked per person for the population aged 25–65.[v] Fig. 13 shows how this measure of labor supply

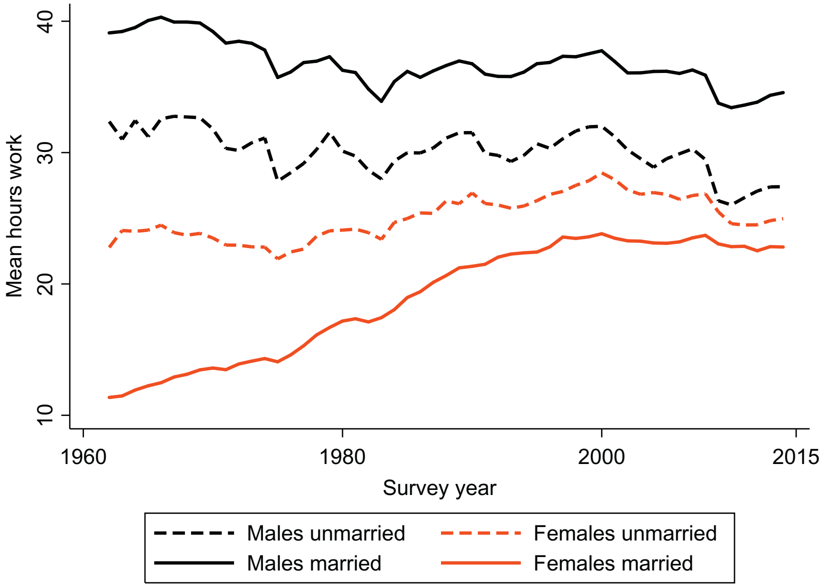

Fig. 13 Average weekly work hours by gender and marital status over time, United States. *Current Population Survey, March and Annual Social and Economic Supplements, 1962–2014.*

[v] The sample includes self-employed individuals.

evolves over time by gender and marital status. The sharp upward trend in married women's labor supply from the 1960s to the 1990s is apparent, as well as the comparatively larger drop in male labor supply since the Great Recession of 2008.

To focus on fluctuations at the business cycle frequently, we compute the cyclical component as the residual after subtracting a Hodrick–Prescott trend from the logarithm of each series (with a smoothing parameter of 6.25). The cyclical component of labor supply by gender and marital status is displayed in Fig. 14. It is immediately apparent that aggregate male labor supply is more volatile than aggregate female labor supply. Single men experience the largest fluctuations in labor supply over the cycle, whereas the smallest fluctuations are observed for married women.

The large differences in the volatility of female and male labor supply together with the large increase in female labor supply suggest that family trends may have had repercussions for the cyclical properties of aggregate labor supply over the observed period. To examine this possibility more formally, Table 1 provides detailed information on fluctuations in aggregate labor supply in the United States in relation to gender and marital status. In the table, the total volatility of a given series is the percentage standard deviation of the cyclical component of average labor supply per person in the group. Cyclical volatility is the percentage standard deviation of the predicted value from a regression of the cyclical component of employment in each group on the cyclical component of real GDP per capita (also computed using the HP filter). Cyclical volatility captures the

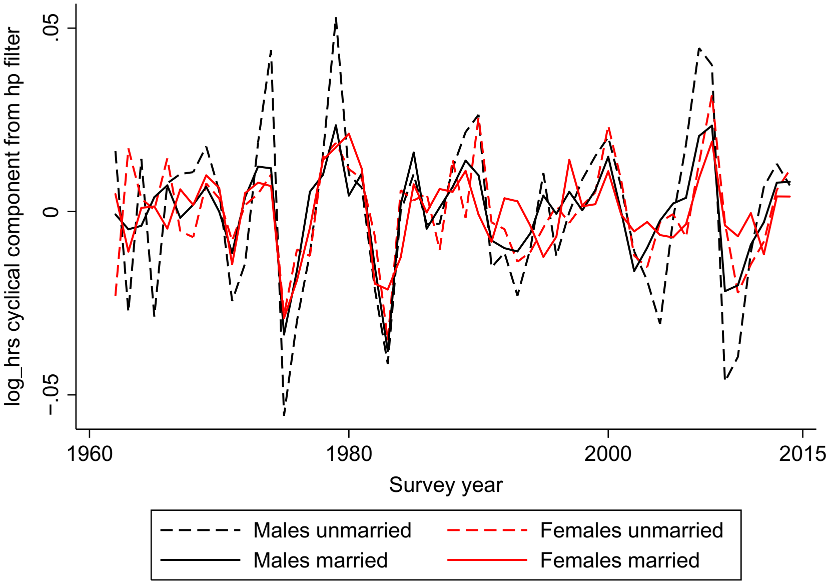

Fig. 14 Cyclical component of average weekly work hours by gender and marital status over time, United States (cyclical component is deviation from Hodrick–Prescott trend, smoothing parameter 6.25). *Current Population Survey, March and Annual Social and Economic Supplements, 1962–2014.*

Table 1 Volatility of hours worked in the United States, by gender and marital status

	All			Married		Single	
	Total	**Women**	**Men**	**Women**	**Men**	**Women**	**Men**
				1962–2014			
Total volatility	1.25	1.04	1.46	1.04	1.25	1.33	2.33
Cyclical volatility	0.99	0.72	1.18	0.67	1.01	0.74	1.68
Hours share		38.09	61.91	23.90	47.71	14.19	14.20
Volatility share		27.22	72.78	16.20	48.98	10.64	24.17
				1962–88			
Total volatility	1.35	1.19	1.48	1.26	1.36	1.37	2.44
Cyclical volatility	1.08	0.87	1.19	0.87	1.09	0.79	1.65
Hours share		33.71	66.29	21.99	55.29	11.72	11.00
Volatility share		27.14	72.86	18.02	56.29	8.67	17.02
				1989–2014			
Total volatility	1.15	0.87	1.47	0.79	1.16	1.30	2.25
Cyclical volatility	0.91	0.51	1.23	0.38	0.95	0.70	1.82
Hours share		42.64	57.36	25.89	39.83	16.75	17.53
Volatility share		23.68	76.32	10.80	41.51	12.88	34.81

Notes: All data from Current Population Survey, March and Annual Social and Economic Supplements, 1962–2014. Total volatility is the percentage standard deviation of the Hodrick-Prescott residual of average labor supply per person in each group. Cyclical volatility is the percentage deviation of the predicted value of a regression of the HP-residual on the HP-residual of GDP per capita. Hours share is the share of each component in total hours. Volatility share is share of each group in the cyclical volatility of total hours.

component of employment volatility that is related to aggregate economic fluctuations. The hours share and volatility share break down the contribution of each component to aggregate hours and to the cyclical volatility of aggregate labor supply.[w]

The first column displays the volatility of aggregate labor supply (women and men combined), and the next two columns break down labor supply between women and men. Over the entire sample, women's labor supply is less volatile than men's labor supply. Moreover, for women cyclical volatility is a smaller fraction of total volatility compared to men; ie, less of the variation in female labor supply is related to aggregate economic fluctuations. As a consequence, even though over the entire sample women contribute close to 40% of total hours, they account for less than 30% of volatility in aggregate labor supply.

A key observation is that female labor supply is less variable than male labor supply in the aggregate, even though at the microlevel women have a much higher labor supply

[w] The computation of cyclical volatility and hours and volatility shares follows the methodology used by Jaimovich and Siu (2009) and Jaimovich et al. (2013) to characterize the contributions of the young and the old to aggregate fluctuations.

elasticity than men. These facts can be reconciled if some of the microvariability in female labor supply is due to adjustments that move in the opposite direction of aggregate changes, such as women increasing labor supply in a recession. We would expect such movements to be especially likely to arise among married households, where the spouses can provide each other with some insurance. To evaluate this possibility, in the further columns the fluctuations in labor supply are further broken down into married vs single individuals. Consistent with a role for insurance, we see that, for both women and men, fluctuations are much smaller for the married than for the single individuals.

At first sight, the lower variability of married labor supply may appear to contradict Proposition 1, which states that married women should have a higher wage elasticity of labor supply than single women. However, Table 1 captures macroeconomic fluctuations rather than microelasticities, and we would expect married women to have lower aggregate volatility precisely if their higher microelasticity arises from a fraction of married women adjusting their labor supply countercyclically in response to changes in their husbands' earnings.[x]

Some of the lower variability of female labor supply is related to the fact that a larger share of women is employed in the service sector, which is less cyclical than the manufacturing sector where men dominate. However, when we compare workers employed in manufacturing and services, we find that within each sector women experience a lower cyclical volatility than men. Moreover, the link to the sector of employment does not contradict a role for insurance within the family, because the choice of sector (and also occupation) is endogenous and may be made in part precisely to offset risk encountered by a worker's spouse.[y]

The theoretical mechanisms outlined in the previous section suggest that the aggregate elasticity of labor supply should respond to changes in female labor force participation. To explore this possibility, the remainder of Table 1 compares fluctuations during the first half of our sample (1962–88), when female labor supply was rising quickly from an initially low level, to the period 1989–2014, when female labor supply had reached a

[x] A second factor driving the higher aggregate volatility of single labor supply (which is not captured in the model) is that singles tend to be younger than married people, and the young generally have more variable labor supply for other reasons (such as a more important education margin, see Jaimovich et al., 2013). We can control for the effect of age by considering narrower age brackets. For example, among people aged 25–30, the total volatility of the labor supply of married and single women is about the same.

[y] The special role of the service sector in the rise of female employment is analyzed by Buera et al. (2013), Ngai and Petrongolo (2014), and Rendall (2015). Olivetti and Petrongolo (2016) provide an empirical study of the role of industry structure for trends in female employment, working hours, and relative wages in a cross-section of developed economies, and argue that the rise of the service sector accounts for at least half of the long-term variation in female hours. Albanesi and Şahin (2013) study the role of industry composition for male-female differences in cyclical fluctuations in employment in the United States, and show that that industry composition was not important for pre-1990 recessions, but mattered more once female participation flattened out in the 1990s.

higher plateau. The most important observation here is that whereas the volatility of male labor supply is essentially unchanged, the volatility of female labor supply has substantially decreased, and particularly so the cyclical volatility. The breakdown by marital status shows that this change is driven primarily by married women. Married women already have a low total volatility of about 0.8% in the second half of the sample, and less than half of this total volatility is accounted for by cyclical volatility. These numbers suggest, as predicted by the simple theoretical model in the previous section, that the rise in female labor force participation had a substantial dampening effect on the volatility of total labor supply. In contrast, there are no substantial changes in the cyclical volatility of the labor supply of singles, with a small decrease in volatility for single women and a small increase for single men.

The overall result of the changes is that at the same time women increased their share of total hours (from 34% to 43%), they accounted for a smaller share of total volatility (24% in 1989–2014 compared to 27% in 1962–88). As a consequence, the total volatility and cyclical volatility of aggregate labor supply fell substantially (see first column), even though the volatility of male labor supply slightly increased over the period. Hence, the rise in female participation dampened the volatility of aggregate labor supply over the cycle, in line with Proposition 2 and the declining portion of the aggregate elasticity in Fig. 12. Rising female participation may thus have been one of the driving forces of the "Great Moderation" in US aggregate fluctuations observed from the mid-1980s to the onset of the Great Recession in 2007.[z] Of course, the Great Recession appears to have brought the Great Moderation to an end, and hence one may wonder whether this dampening effect is still operative. The data suggest that female labor supply continues to partially offset aggregate fluctuations. A division of the sample into three periods shows that the most recent era displays the lowest volatility of female labor supply, with a cyclical volatility for married women of only 0.37%. The dampening role of married women's labor supply was particularly pronounced during the Great Recession itself. From 2007 to 2010, the average labor supply by married men declined by more than 8%, whereas the decrease was less than 3% for married women.

If the trend toward more gender equality continues, according to Proposition 2 the volatility of female and male labor supply should ultimately become more similar again (see also Fig. 12). In part, as married women become even more strongly attached to the labor force (eg, in the sense of more women being the main breadwinner for their family), their labor supply will become less elastic (this can already be observed at the

[z] See Galí and Gambetti (2009) for an overview of the discussion on the Great Moderation, and Jaimovich and Siu (2009) for an explanation that focuses on changes in the age composition of the labor force. Mennuni (2015) also considers the impact of demographic trends on the Great Moderation (although without considering the distinction of single and married individuals), and finds that demographics (including the rise in female participation) account for about 20% of the Great Moderation in the United States.

microlevel, eg, Heim, 2007). Conversely, men will become more able to rely on their wives' incomes, which should make their labor supply more elastic at the microlevel but also less cyclical in the aggregate. Hence, family trends will continue to play a role in shaping aggregate fluctuations.

2.4.4 Jobless Recoveries

A phenomenon that has received a lot of attention recently in business cycle research is the so-called jobless recoveries. This term refers to a recent change in the employment response to recessions in the United States. Before the 1990s, most postwar recessions were characterized by a strong rise in employment from the trough of the recession. In contrast, since the 1990s the increase in employment during the recovery has been anemic.

A variety of explanations have been proposed for the recent jobless recoveries, including structural change (Groshen and Potter, 2003), an increase in "job polarization" (the disappearance of jobs in the middle of the skill distribution in recessions; see Jaimovich and Siu, 2014), and fixed costs of labor adjustment (Bachmann, 2012). However, in recent work, Albanesi (2014) makes a strong case for jobless recoveries at least in part being due to changes within families, and more specifically to changes in female labor force participation. In a nutshell, Albanesi argues that employment differed in the aftermath of pre-1990 and post-1990 recessions because the earlier recessions took place in the context of a strong secular upward trend in female labor force participation, whereas the more recent ones did not. As Fig. 7 shows, female labor force participation in the United States followed a sharp upward trend, but participation leveled out after about 1990, and even declined somewhat in the last 15 years.

Table 2 summarizes the employment response to recent recessions and breaks them down by male vs female employment. Each entry in the table is a percentage change in the employment to population ratio (E/P) in the 4 years following the trough of the recession. The first column reproduces the basic fact of jobless recoveries. In the pre-1990 recessions, employment had fully recovered (and even increased a little) 4 years after the downturn, whereas for the post-1990 recessions the E/P ratio is on average close to 3% lower at that point of the recovery (1.35% if the Great Recession is excluded). Hence, it appears that recoveries after 1990 are qualitatively different from earlier recoveries. The next two columns break down the overall employment change into changes in the E/P ratio for women and men. The main message from these data is that, statistically, the jobless recoveries are due to changes in the behavior of female but not male employment. For men, recoveries have been "jobless" even before 1990, in the sense that the E/P ratio is down by 2.62% on average 4 years after the trough. The decline in E/P after 1990 is of a similar order of magnitude, and in fact a little smaller when the Great Recession is excluded. In contrast, we see a dramatic change for women. In the pre-1990 recessions, the female E/P ratio recovers strongly after each recession, with an average increase of

Table 2 Jobless recoveries: change in employment/population ratio in 4 years after peak in unemployment rate, in percentage points, by gender (includes three pre-1990 and tree post-1990 recessions)

	Change in E/P		
Period	**Total**	**Men**	**Women**
Pre-1990	0.65	−2.62	5.85
Post-1990	−2.78	−3.94	−1.41
Post-1990, excl. Great Recession	−1.35	−2.47	−0.07

Notes: Pre-1990 recessions include the 1969, 1973, and 1981 recessions. Post-1990 recessions include the 1990, 2001, and 2007 recessions.

close to 6% after 4 years. In contrast, in the post-1990 downturns female employment declines and now follows a pattern similar to that of male employment.

Table 2 suggests that, in a statistical sense, the change in the trend in female labor supply is responsible for jobless recoveries. Specifically, for men recoveries have always been jobless, whereas for women, before 1990 recession-related job losses were quickly made up by the secular upward trend in female participation. Of course, the empirical findings alone are not conclusive evidence in favor of such an explanation. For example, it is conceivable that if in the pre-1990s recessions female employment had risen more slowly, male employment would have suffered fewer losses. To fully evaluate the role of the changing trend in female labor supply for explaining jobless recoveries, one needs to spell out an economic model. Albanesi (2014) considers a model in which the increase in female participation is driven by gender-biased technological change, ie, tasks at which women have a comparative advantage become more important compared to those that favor men (such as those relying on physical strength). Albanesi shows that the model can reproduce both the long-run trend in female participation and the occurrence of jobless recoveries after female employment levels out.

2.4.5 Additional Notes on Related Literature

Whereas few papers explicitly consider how family trends change business cycle dynamics, there is a larger literature that incorporates at least some of the features of the family labor supply model described above into business cycle research. An early example is the literature on home production in macroeconomics (see Greenwood et al., 1995 for an early overview of this work). The first models did not explicitly distinguish between male and female labor supply, but by incorporating the possibility of working in the home (on child care, food production, and so on), the literature took implicit account of the different nature of female labor supply. Benhabib et al. (1991) is an early contribution focusing on the importance of home production for explaining business cycle facts. In their model, households derive utility from home and market consumption and supply both home and market hours. They find that the model with home production is much better at matching various volatilities and correlations over the business cycle than standard macro models. Closely related arguments are made by Greenwood and Hercowitz (1991) and Ríos-Rull (1993).

The role of family labor supply in the context of search models of the labor market has been analyzed by Guler et al. (2012). Spouses who are both in the labor force can provide each other insurance in the case of unemployment. They find that the possibility of insurance lowers the search effort of unemployed workers and also provides higher welfare compared to a setting where all workers are singles. Ortigueira and Siassi (2013) use a quantitative model to assess the importance of risk sharing within the family, and find that insurance through spousal labor supply is particularly important for wealth-poor households who lack access to other insurance mechanisms.

Family labor supply also plays a central role in a recent macroeconomic literature on the effects of tax reform. Using a quantitative life-cycle model with single and married households calibrated to US data, Guner et al. (2012a) explore the economic consequences of revenue-neutral tax reforms that adopt either a flat income tax or separate taxation of married couples (ie, separate filing). In either case, the reform generates a large increase in labor supply, which is mostly driven by married women (see also Guner et al., 2012b). Guner et al. (2014) extend this work to consider the effects of child care subsidies. They find that such subsidies have large effects on female labor supply, in particular at the bottom of the skill distribution. Bick and Fuchs-Schündeln (2014) document differences in labor supply of married couples across 18 OECD countries, and find that variation in tax systems (in particular joint vs separate taxation) can account for most of the differences.[aa]

In the labor literature, the phenomenon of a wife entering the labor market in response to her husband's unemployment that partly underlies Proposition 2 is known as the "added worker effect" (Lundberg, 1985). Empirical studies using data from the early 1980s or earlier have generally only found weak evidence in favor of the added worker effect. Using CPS data over a long time period, Juhn and Potter (2007) find evidence in support of the added worker effect but also argue that it has diminished in strength recently, in part because assortative mating has led to a higher intrahousehold correlation of the labor market shocks faced by wives and husbands.

The large differences in the cyclical volatility of the labor supply of single and married women and men documented above suggest that insurance within the family goes beyond a narrow added worker affect (which specifically concerns wives entering the labor force *after* their husbands become unemployed). Other forms of insurance include entering employment already in response to higher unemployment risk for the spouse (rather than the actual realization of unemployment, when entering the labor force quickly may be difficult), and adjustments on the intensive margin when both spouses

[aa] See also Chade and Ventura (2005) for an analysis of the welfare consequences of different tax treatments for married couples.

are in the labor force. Hyslop (2001) and Shore (2010, 2015) provide evidence in favor of a more general sharing of labor market risk in terms of the correlation of earnings within couples. Using a structural model of life cycle decisions, Blundell et al. (2016) similarly find strong evidence in favor of insurance within the family. Using CPS data, Mankart and Oikonomou (2015) document a substantial response of female labor force participation to spousal unemployment, where the response is more drawn out over time compared to early tests of the added worker effect. Moreover, Shore (2010) provides evidence that intrahousehold risk sharing is particularly strong within recessions. Our findings of a shift over time in the aggregate behavior of labor supply by gender and marital status suggest that it would be productive to expand on these findings by examining whether insurance within the family has undergone similar shifts at the microlevel.[ab]

Our analysis of family labor supply has focused on the interaction between husbands and wives. Another dimension of insurance within the family concerns the interaction between young and old family members. Quantitative studies that focus on this dimension include Jaimovich et al. (2013), who aim to explain age differences in the volatility of labor supply, and Kaplan (2012), who quantifies the role of the option of moving in and out of the parental home as an insurance mechanism for young workers. Building on this work, Dyrda et al. (2016) develop a business cycle model that allows for the option of young people moving in with their parents. They find that living arrangements matter a lot for labor supply elasticities: the elasticity is three times larger for young people who live with their parents compared to those who live alone. Accounting for household formation also implies that the aggregate labor supply elasticity is much larger than the microelasticity for stable households.

2.5 Changing Families and Aggregate Savings

In addition to providing a theory of labor supply, the representative household that populates baseline macroeconomic models also provides a theory of savings. In this section, we argue that models that go beyond representative households by explicitly modeling families have important implications for the determination of savings in the macroeconomy.

There are a few different channels through which families matter for savings; they relate to the life cycle savings motive and the precautionary savings motive. First, changes in the size of the household over time (eg, through marriage, divorce, and having children) imply that consumption needs vary over the life cycle, which is reflected in the optimal level of saving. Second, the precautionary savings motive also plays an important role in macroeconomic models (at least since Aiyagari, 1994). The strength of the precautionary motive depends on the insurance mechanisms people have access to. Similar to our analysis of labor supply above, we will argue that insurance within the family plays

[ab] Some evidence in this direction is provided by Blau and Kahn (2007), who show that married women's labor supply has become less responsive to their husbands' wages since the 1980s.

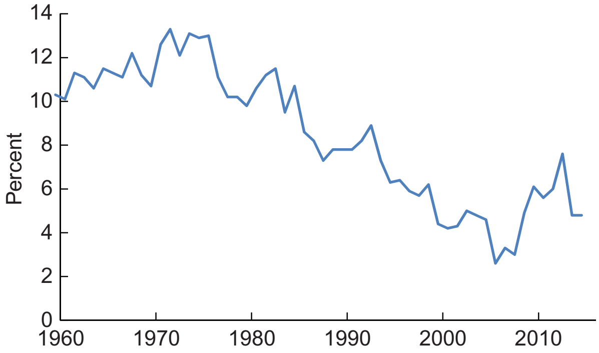

Fig. 15 Personal savings rate, United States. *Bureau of Economic Analysis, retrieved from FRED, St. Louis Fed.*

an important role in the sharing of income risk and hence in the determination of savings. Third, not only do families affect the sharing of existing sources of risk, but accounting for families also introduces new sources of risk. Getting married and having children can lead to (sometimes large) additional expenses, and to the extent that people face uncertainty over marriage and fertility, this should affect their precautionary savings. Equally important is the probability that a family dissolves: divorce is common and in many cases represents a sizeable financial risk.

The large shifts in fertility, marriage, and divorce over the last few decades suggest that the family determinants of savings may have been responsible for some of the changes in aggregate savings behavior over time. In particular, in the United States the personal savings rate has declined steadily from more than 10% in the late 1970s to less than 5% in the mid-2000s (see Fig. 15). Various explanations have been proposed for this change, although no single explanation is widely accepted (see Guidolin and Jeunesse, 2007 for an overview and discussion). In this section, we examine the possibility that changes at the family level may have played a role.

As far as the life cycle savings motive is concerned, there is a substantial literature within macroeconomics that accounts for the life cycle using a unitary model of the household, ie, without making an explicit distinction between the interests of different household members. Life cycle models were first introduced to modern business cycle research by Attanasio and Browning (1995) and Ríos-Rull (1996). In such models, the varying consumption needs due to changes in family composition over the life cycle can be incorporated through consumption equivalence scales.[ac] There is a small literature that uses life cycle models to quantify the impact of population aging on savings (Miles, 1999; Ríos-Rull, 2001). Depending on future population growth, these effects on the

[ac] See, for example, Fernández-Villaverde and Krueger (2007) and Fernández-Villaverde and Krueger (2011).

savings rate can be large, although they generally occur too slowly to explain much of the rapid decline in the savings rate in recent decades.

Given that there is already a sizeable literature on the life-cycle motive for saving, our discussion here is focused primarily on the implications of marriage and divorce for aggregate savings, a topic on which relatively few papers exist.

2.5.1 Savings and Divorce

In the models discussed in Section 2.4, we examined differences in the behavior of single and married households, while taking the existence of these different types of households as given. In reality, most adults start out as singles, marry at some point in their life, and many return to being single, eg, due to divorce. We now consider the implications for savings of the possibility of divorce. We start by taking marital bargaining power as given and by modeling divorce as an exogenous shock; endogenous bargaining and endogenous divorce will be considered below.

We consider a married couple whose life extends over two periods. The couple is married in the first period, and in the second period the union continues with probability $1-\pi$, whereas with probability π a divorce occurs. The divorce regime is that in the case of a divorce the wife retains fraction κ_f of assets, and the husbands receives $\kappa_m = 1 - \kappa_f$.

We focus on implications for savings and take as given that both spouses work in both periods.[ad] Let d' denote savings. The couple bargains cooperatively with bargaining weights given by λ_f and $\lambda_m = 1 - \lambda_f$. The couple's decision problem in the first period can be formulated as follows:

$$\max_{c_f, c_m, d'} \Big\{\lambda_f \log(c_f) + \lambda_m \log(c_m) \\ + \beta[\lambda_f(\pi V_f^D(d') + (1-\pi)V_f(d')) + \lambda_m(\pi V_m^D(d') + (1-\pi)V_m(d'))]\Big\}$$

subject to the budget constraint:

$$c_f + c_m + d' = w_f + w_m.$$

Here $V_g(d')$ is the second period value function for spouse $g \in \{f,m\}$ if the union continues, and $V_g^D(d')$ is the value function in the case of divorce.

In the case of divorce, in the second period each spouse simply consumes earnings and savings, which earn interest at rate r. We therefore have:

$$V_g^D(d') = \log(w_g' + (1+r)\kappa_g d').$$

[ad] Clearly, the possibility of divorce also affects the incentive to work, in part by altering the marginal utility of wealth, and in more complex environments also through the accumulation of individual-specific labor market experience.

In contrast, if the marriage continues, consumption shares are given by bargaining weights:

$$V_g(a') = \log(\lambda_g(w'_f + w'_m + (1+r)a')).$$

We can now consider the savings problem in the first period. The first-order condition for a' is given by:

$$\begin{aligned}\frac{1}{w_f + w_m - a'} = \beta\pi &\left[\frac{\lambda_f(1+r)\kappa_f}{w'_f + (1+r)\kappa_f a'} + \frac{\lambda_m(1+r)\kappa_m}{w'_m + (1+r)\kappa_m a'}\right] \\ &+ \beta(1-\pi)\frac{1+r}{w'_f + w'_m + (1+r)a'}.\end{aligned} \tag{6}$$

The optimal savings in the case of no divorce risk ($\pi = 0$) are:

$$\tilde{a} = \frac{\beta(1+r)(w_f + w_m) - w'_f - w'_m}{(1+\beta)(1+r)}.$$

Now consider the case $\pi > 0$. The optimal savings will be unchanged at $\tilde{a}$ if the following condition is satisfied:

$$\frac{w'_g + (1+r)\kappa_g\tilde{a}}{\lambda_g} = w'_f + w'_m + (1+r)\tilde{a}$$

for $g \in \{f, m\}$, or:

$$\kappa_f = \widetilde{\kappa f} \equiv \frac{-\lambda_m w'_f + \lambda_f w'_m + \lambda_f(1+r)\tilde{a}}{(1+r)\tilde{a}},$$

$$\kappa_m = \widetilde{\kappa m} \equiv \frac{\lambda_m w'_f - \lambda_f w'_m + \lambda_m(1+r)\tilde{a}}{(1+r)\tilde{a}},$$

where we have $\widetilde{\kappa}_f + \widetilde{\kappa}_m = 1$ as required. Intuitively, this specific divorce regime recreates the same consumption allocation that would have been obtained had the marriage continued, and hence savings incentives are unchanged. What happens when κ_f does not equal $\widetilde{\kappa}_f$ depends on relative female and male bargaining power. The derivative of the right-hand side of (6) with respect to κ_f is given by:

$$\beta\pi(1+r)\left(\frac{\lambda_f w'_f}{(w'_f + (1+r)\kappa_f a')^2} - \frac{\lambda_m w'_m}{(w'_m + (1+r)\kappa_m a')^2}\right)$$

Evaluating this expression at $a' = \tilde{a}$, $\kappa_f = \widetilde{\kappa}_f$, and $\kappa_m = \widetilde{\kappa}_m$ gives:

$$\frac{\beta\pi(1+r)}{\left(w'_f + w'_m + (1+r)\tilde{a}\right)^2}\left(\frac{w'_f}{\lambda_f} - \frac{w'_m}{\lambda_m}\right).$$

Hence, the derivative is positive if $w'_f/\lambda_f > w'_m/\lambda_m$, which is equivalent to $\widetilde{\kappa}_f < \lambda_f$. A positive derivative, in turn, implies that when $\kappa_f > \widetilde{\kappa}_f$, the optimal savings a' satisfy

$a' > \tilde{a}$, ie, the presence of divorce risk increases savings. More generally, divorce risk increases savings if for the spouse who is made worse off by divorce the asset share in divorce exceeds the relative bargaining power in marriage. Intuitively, under this condition increasing savings lowers the additional inequality across spouses brought about by divorce, which generates a precautionary demand for savings.[ae] If the couple starts out with equal bargaining power and there is an equal division divorce regime $\lambda_f = \lambda_m = \kappa_f = \kappa_m = 0.5$, the possibility of divorce always leads to precautionary savings, except in the knife edge case where the divorce regime that exactly reproduces the married allocation. The intuition is the same as for the usual motive for precautionary savings with preferences that display prudence. Under divorce, one spouse ends up with less consumption and the other one with more consumption compared to the married state. Due to the curvature in utility, the outcome of the less fortunate spouse receives higher weight when savings are determined in the first period, leading to an increase in precautionary savings.

We derived these results under the assumption that the divorce leaves the consumption possibilities of the couple unchanged. Realistically, there are also direct costs of divorce and forgone returns to scale from having a joint household. Hence, the possibility of divorce would also induce a negative income effect, which further increases desired savings.

To summarize the results, the effect of divorce risk on savings depends on the divorce regime (ie, the property division rule in divorce) and also on the relative bargaining power of the spouses. In practice, the most common divorce regimes in the data are the title-based regime and the equitable distribution regime.[af] Under the title-based regime, each spouse gets to keep the marital assets that are already in her or his name; ie, real estate goes to the owner listed in the title, bank accounts go to the account owner, and so on. Under the equitable distribution regime, judges have discretion in dividing assets in divorce. Often an equal division of marital assets is a starting point, but judges can make allowances for different needs (eg, the spouse with custody for children may receive more assets). When men are the main breadwinners and also hold title to major assets such as real estate, cars, and bank accounts, we would expect divorce under the title-based regime to lead to a precautionary demand for savings, because the wife is likely to be worse off in divorce compared to marriage. However, the precautionary demand only arises if the wife is able to save in her own name, because otherwise she would not be able to increase her outcome in divorce. Predictions are more ambiguous under the equitable distribution regime, because in this regime the wife may obtain more consumption in divorce compared to marriage. Comparing across regimes for a given divorce rate, as long as equitable distribution is more advantageous for the spouse with less power than the title-based system (as seems likely), a switch to equitable distribution (which occurred

[ae] This is a local result close to the marriage allocation.

[af] Additional possibilities include an equal division regime, and a regime where the division of assets is set through enforced prenuptial agreements.

in most US states in the 1970s) will weaken the precautionary motive and hence lead to lower savings.

What is more, individual labor earnings are likely to make up a large fraction of income in divorce. The rise in married women's earnings over time also implies that women are better able to support themselves after divorce (under either divorce regime). Hence, for a given divorce risk, the rise in married women's labor force participation and the decline in the gender pay gap are likely to have lowered the precautionary demand for savings associated with divorce over time.

2.5.2 Savings and Divorce with Endogenous Bargaining Power

The analysis so far suggests that divorce may have a substantial impact on a country's personal savings rate. Divorce is one of the largest and most common risks people face today (along with unemployment and ill health). Moreover, changes in the divorce rate, the divorce regime, and female labor force participation all affect how much precautionary saving arises from divorce risk, and thus may be in part responsible for changes in the savings rate over time.

In the preceding analysis, we introduced divorce as an exogenous shock, and the impact of divorce risk on couples' behavior was proportional to the probability with which this shock occurred. In this setting, the possibility of divorce has large effects only if the divorce rate is high. We now extend our analysis by endogenizing the divorce decision and the evolution of bargaining power within the marriage. We will see that in this extended model, the mere possibility of divorce can affect household behavior, so that large impacts on behavior can arise even if few couples divorce in equilibrium. Hence, the extension further amplifies the potential role of divorce for explaining how a country's savings rate is determined.

We consider a variant of the model above in which bargaining and divorce are endogenous. The ability of the spouses to commit to future allocations is limited by the ability to divorce, so that divorce functions as a threat point that informs bargaining during the marriage. In the first period, the couple is married and starts out with initial bargaining power $\lambda_f$and λ_m, where $\lambda_f + \lambda_m = 1$. In the second period, the couple experience marriage quality shocks ξ_f, ξ_m, which can be positive or negative. There is a unilateral divorce regime; that is, the marriage continues in the second period only if both spouses are at least as well off married compared to being divorced.

In the first period, the couple's decision problem can be written as:

$$\max\left\{\lambda_f \log(c_f) + \lambda_m \log(c_m) + \beta\left[\lambda_f E(V_f(a', \xi_f, \xi_m)) + \lambda_m E(V_m(a', \xi_f, \xi_m))\right]\right\},$$

subject to the budget constraint:

$$c_f + c_m + a' = w_f + w_m.$$

Here $V_g(d', \xi_f, \xi_m))$ is the expected utility of spouse g in the second period as a function of the state variables d', ξ_f, and ξ_m.

In the second period, the decision problem of the couple is constrained by the possibility of divorce. If a divorce takes place, existing property is divided with share κ_f for the wife and $\kappa_m = 1 - \kappa_f$ for the husband. Utilities conditional on divorce are therefore given by:

$$V_g^D(d') = \log(w_g' + (1+r)\kappa_g d').$$

The full decision problem in the second period can then be written as:

$$\max_{D \in \{0,1\},\, c_f,\, c_m} \Big\{\lambda_f \Big[(1-D)\big(\log(c_f) + \xi_f\big) + DV_f^D(d')\Big] + \lambda_m\big[(1-D)(\log(c_m) + \xi_m) + DV_m^D(d')\big]\Big\} \tag{7}$$

subject to:

$$c_f + c_m = w_f' + w_m' + (1+r)d', \tag{8}$$

$$(1-D)\big(\log(c_f) + \xi_f\big) + DV_f^D(d') \geq V_f^D(d'), \tag{9}$$

$$(1-D)(\log(c_m) + \xi_m) + DV_m^D(d') \geq V_m^D(d'). \tag{10}$$

Here $D \in \{0,1\}$ denotes the endogenous divorce decision and c_f, c_m is the consumption allocation conditional on staying married. Clearly, by setting $D = 1$ (divorce) the constraints (9) and (10) can always be met. However, divorcing is optimal only if there is no consumption allocation that leaves both spouses at least as well off married compared to divorced.

The decision problem in the second period can be solved by first considering a spouse who ends up just indifferent between divorce and staying married. Let $\tilde{\lambda}_g$ denote the consumption share that would make spouse g indifferent between these options, for a given ξ_g. The indifference condition is:

$$\log\Big(\tilde{\lambda}_g\Big(w_f' + w_m' + (1+r)d'\Big)\Big) + \xi_g = \log\Big(w_g' + (1+r)\kappa_g d'\Big),$$

which can be solved to give:

$$\tilde{\lambda}_g = \frac{w_g' + (1+r)\kappa_g d'}{\exp(\xi_g)\Big(w_f' + w_m' + (1+r)d'\Big)}.$$

The second period outcome can now be determined by comparing the implicit bargaining weights $\tilde{\lambda}_f$ and $\tilde{\lambda}_m$ to the actual ex ante bargaining weights λ_f and λ_m. In particular:

Proposition 3 (Divorce and Bargaining Power in Limited Commitment Model)

The outcome of the couple's decision problem in the second period can be characterized as follows:

- *If $\widetilde{\lambda}_f \leq \lambda_f$ and $\widetilde{\lambda}_m \leq \lambda_m$, the couple stays married (D = 0), and consumption is:*

$$c_f = \lambda_f \left(w'_f + w'_m + (1+r)d' \right),$$
$$c_m = \lambda_m \left(w'_f + w'_m + (1+r)d' \right).$$

- *If $\widetilde{\lambda}_f > \lambda_f$ and $\widetilde{\lambda}_f + \widetilde{\lambda}_m \leq 1$, the couple stays married (D = 0), but the wife's consumption share is increased to satisfy her participation constraint. Consumption is:*

$$c_f = \widetilde{\lambda}_f \left(w'_f + w'_m + (1+r)d' \right),$$
$$c_m = w'_f + w'_m + (1+r)d' - c_f.$$

- *If $\widetilde{\lambda}_m > \lambda_m$ and $\widetilde{\lambda}_f + \widetilde{\lambda}_m \leq 1$, the couple stays married (D = 0), but the husband's consumption share is increased to satisfy his participation constraint. Consumption is:*

$$c_m = \widetilde{\lambda}_m \left(w'_f + w'_m + (1+r)d' \right),$$
$$c_f = w'_f + w'_m + (1+r)d' - c_m.$$

- *If $\widetilde{\lambda}_f + \widetilde{\lambda}_m > 1$, the couple divorces (D = 1), and consumption is:*

$$c_f = w'_f + (1+r)\kappa_f d',$$
$$c_m = w'_m + (1+r)\kappa_m d'.$$

The implications of the possibility of divorce for savings are similar to those of the exogenous-divorce model above, but savings are affected already when one of the spouses' participation constraints is binding, even if the marriage continues.

Fig. 16 presents a computed example to show how the trend toward higher labor market participation of married women would affect divorce and the savings rate in the model with endogenous bargaining and divorce.[ag] Male earnings are normalized to $w_m = 1$, and the equilibrium savings rate and divorce rate are shown for female earnings varying from $w_f = 0.1$ to $w_f = 0.8$. The divorce regime is unilateral divorce with an equal division of marital assets upon divorce. Given that total earnings are constant and the interest rate equals the inverse of the discount factor, if there was no possibility of divorce, the savings rate would be equal to zero regardless of female earnings. Hence, any positive savings are due to the precautionary motive generated by the possibility of divorce.

[ag] The parameter values used are $\lambda_f = 0.4$, $\lambda_m = 0.6$, $r = 0.05$, and $\beta = 1/(1 + r)$. The divorce regime features equal division of assets, $\kappa_f = \kappa_m = 0.5$, and the marriage quality shocks ξ_f and ξ_m are uniformly distributed on the interval [−0.2, 1] and are independent across the spouses.

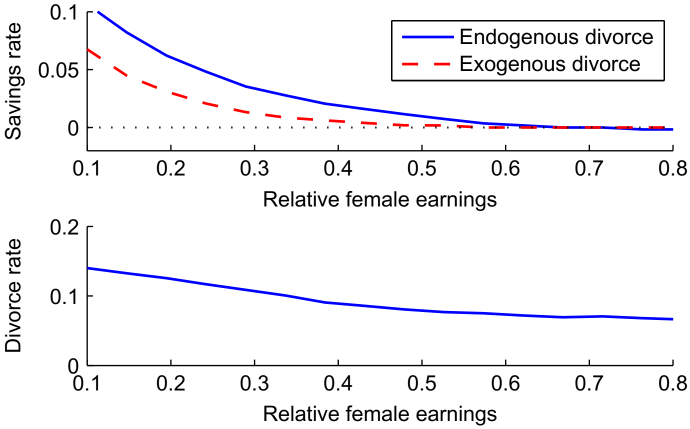

Fig. 16 Savings rate and divorce rate as a function of relative female earnings.

With endogenous bargaining and divorce, we see that the savings rate and divorce rate are both positive, and sharply decreasing in relative female earnings. Once female earnings are above 60% of male earnings, the savings rate approaches zero (the value that would be obtained without the possibility of divorce). The intuition for these findings is that for low female earnings, divorce leaves women much worse off compared to marriage. The equal division of assets only provides limited insurance, because most of the second period income of the couple is due to the husband's earnings. Thus, the possibility of divorce leads to a precautionary demand for savings primarily to insure women against the possibility of divorce. Own earnings provide an alternative route of insurance and also increase the overall share of income that women can claim in divorce. Hence, as earnings rise, precautionary savings are much reduced and ultimately disappear.

The picture also displays the savings rate in the exogenous divorce model when the equilibrium divorce rate (displayed in the lower panel) is fed as an exogenous variable into the model of the previous section (ie, the exogenous divorce rate varies together with female earnings). The exogenous divorce model generates qualitatively similar findings, but the impact on savings is much smaller in size. In the exogenous divorce model, as long as the couple stays married, bargaining power stays at the initial value. In contrast, in the endogenous divorce model, there are couples where, say, the husband is at the participation constraint (the realization of ξ_m is low), so that the wife has to offer additional compensation to the husband for the husband to stay. This need to compensate the other spouse generates an additional need for precautionary savings. Hence, the endogenous divorce model generally leads to a larger impact on the savings rate and can generate a feedback from the possibility of divorce on aggregate variables even if the realized divorce rate is low.

2.5.3 Additional Notes on Related Literature

There are only a few papers that use models of the type outlined here to address macroeconomic questions. Dynamic models of marriage under limited commitment with the possibility of divorce have been introduced by Mazzocco (2007), Mazzocco et al. (2013), and Voena (2015). In these models, the shifts in bargaining power that are necessary when one of the spouses' participation constraint is binding have persistent effects on the marital allocation. By specifically addressing how divorce law affects incentives for saving, Voena (2015) is the closest to the questions addressed here. Voena finds (using an estimated structural model) that the introduction of unilateral divorce (in states with an equal division of property) leads to higher savings and lower female employment. Intuitively, the introduction of unilateral divorce removes spouses' veto power in the divorce decision, which reduces risk sharing and increases precautionary savings. To our knowledge, there are no studies that analyze how the possibility of divorce (in a given divorce regime) affects the private savings rate (and other aggregate variables) in light of other observed changes to the family, such as the rise in female labor force participation and relative female earnings and the decline in fertility.

An early study that considers the role of divorce as an exogenous shock is Cubeddu and Ríos-Rull (2003). They assess the potential role of divorce for asset accumulation by comparing counterfactuals that differ in when (or if) people marry and divorce, and in how costly divorce is. Unlike in the model outlined above, consumption within marriage is constrained to be equal across spouses. They find that the impact of marriage and divorce can be large in their setting, but they do not directly relate this finding to observed changes in macro variables.[ah]

Love (2010) documents empirically (and analyzes in a quantitative model) how asset allocations change with marital-status transitions. As in Cubeddu and Ríos-Rull (2003) and Hong and Rios-Rull (2012), changes in marital status are modeled as exogenous shocks, and there is only public consumption in marriage. The theoretical model predicts that portfolio shares (ie, the fraction of wealth invested in stocks vs bonds) should react sharply to fertility, marriage, and divorce. Empirical results based on the Health and Retirement Study and the Panel Study on Income Dynamics are supportive of some of the predictions of the model, although not for all groups of households.

Fernández and Wong (2014a,b) use a quantitative life cycle model with exogenous divorce to study the importance of the likelihood of divorce for explaining the rise in female labor force participation from the 1960s to the 1990s. They argue that the increase in divorce risk accounts for a substantial fraction of the increase in female labor force participation. The main reason for this finding is that women (who often have lower wages

[ah] A similar framework is used by Hong and Rios-Rull (2012) in a setting that also accounts for the arrival of children, stochastic survival, and bequest motives, and uses information on life insurance holdings to infer how the utilities of different household members interact.

than their husbands and need to provide for their children) face lower consumption possibilities after a divorce, which increases desired savings. One way of increasing savings is to work more during marriage, which raises the total resources of the household and facilitates the smoothing of consumption between the married and divorced states. In Fernández and Wong (2014c) this analysis is extended to a setting with endogenous divorce.

In addition to increasing savings and increasing labor supply, another insurance mechanism that is likely to be relevant in the data is education. In Guvenen and Rendall (2015), women acquire education in part as insurance against a bad marriage. Guvenen and Rendall argue that the introduction of unilateral divorce increases this insurance motive, accounting for a sizeable fraction of the increase in female education and helping rationalize the observation that women now obtain more higher education than do men.[ai]

2.6 Private Information in the Household

Throughout Section 2, we have used a number of different approaches for modeling husband–wife interactions. We now step back from the applied questions to discuss the relative advantages of different models of the family and their uses within macroeconomics. The pioneering work of Gary Becker was largely based on the so-called unitary model of the family. A unitary model distinguishes between, say, male and female labor supply, but does so in the context of a single household utility function rather than allowing for separate preferences for each spouse. This approach is also how the family was first introduced into macroeconomics in the literature on home production and the business cycle (eg, Benhabib et al., 1991; Greenwood and Hercowitz, 1991). The limitation of the unitary approach is that since it does not distinguish individual utility functions, it does not allow for conflict of interest between spouses. This restricts the range of questions that can be addressed by the unitary model. Moreover, there is a sizeable literature in family economics that empirically tests the unitary model against richer alternatives that allow for bargaining, and finds strong evidence against the unitary model.[aj]

To go beyond the unitary model, one needs to start with women and men (characterized by separate utility functions) as primitives and then analyze how they act either together as couples or as singles. Within couples, one has to specify some form of bargaining process that determines how the couple resolves the conflict of interest between the spouses. Two broad classes of bargaining models that can be used for this purpose are

[ai] Another perspective on higher premarital investments by women is provided by Iyigun and Walsh (2007a), who focus on the impact of investments both on sorting of spouses and on bargaining power within marriage (see also Iyigun and Walsh, 2007b; Chiappori et al., 2009).

[aj] See Alderman et al. (1995) for an early summary of the evidence, and Attanasio and Lechene (2002) for an influential contribution based on Progresa data from Mexico.

noncooperative bargaining models (where the interaction between the spouses is modeled as a noncooperative game, using standard game theory tools) and cooperative bargaining models (where the spouses are able to achieve an outcome that is at least statically efficient). A common argument in favor of cooperative bargaining is that marriage is usually a sustained long-term relationship, which suggests that the spouses should be able to avoid major inefficiencies. However, while the majority of recent work in family economics uses a cooperative approach, other authors provide evidence in favor of inefficient bargaining outcomes within the family,[ak] and noncooperative models have been used by Lundberg and Pollak (1994), Konrad and Lommerud (1995), and Doepke and Tertilt (2014), among others.

Within the literature on cooperative bargaining in the family, many papers use explicit bargaining models such as Nash bargaining subject to divorce as the outside option.[al] Another popular approach, introduced by Chiappori (1988; 1992), is to only impose that the couple reaches a statically efficient outcome, but to remain agnostic about the details of the bargaining process. Empirical implementations of this approach often allow bargaining power to be a function of observables (called "distribution factors") such as the relative education or the relative age of the spouses, without specifying the mechanism through which these variables matter.[am] The advantage of this approach, labeled the "collective model," is its generality, because all (static) efficient allocations can be characterized in this way. The labor supply model employed in Section 2.4 is an example of a collective model (albeit with fixed bargaining power).

The collective approach is less suitable for dynamic contexts, because it does not provide an explicit theory for how bargaining within a couple evolves. This would perhaps not matter much if bargaining weights were constant over time, which would also imply ex-ante efficiency, ie, full insurance in the household. Yet there is plenty of empirical evidence of limited risk sharing in couples. For example, based on data from Kenya, Robinson (2012) documents that private expenditures increase in own labor income. Duflo and Udry (2004) use data from the Ivory Coast to show that the composition of household expenditure is sensitive to the gender of the recipient of a rainfall shock that affects male and female income differentially. The evidence is not exclusive to developing countries. Cesarini et al. (2015) document a larger fall in labor earnings after winning a lottery for the winners relative to their spouses in Sweden. One could rationalize such findings in a collective model where the bargaining weights move due to shifts in relative income, wages, or lottery winnings. However, this approach has the downside of

[ak] See, eg, Udry (1996), Duflo and Udry (2004), and Goldstein and Udry (2008).

[al] The classic papers are Manser and Brown (1980) and McElroy and Horney (1981). Another classic is the "separate spheres" bargaining model of Lundberg and Pollak (1993), which is an interesting hybrid between a cooperative and a noncooperative model.

[am] See, for example, Attanasio and Lechene (2014).

violating ex-ante efficiency without being explicit about the underlying bargaining friction. Moreover, the approach precludes transitions to a (presumably) noncooperative state such as divorce, which is an important limitation given that divorce is commonplace (see Fig. 6).

A more fruitful avenue in our view is to take a stand on the friction that prevents couples from achieving full insurance and model it explicitly. One obvious friction is limited commitment. Since spouses usually have the option to walk away from each other (ie, divorce or separation), at any point in time each spouse should get at least as much utility as his or her outside option. This is what we alluded to at the end of Section 2.4 and modeled more explicitly in the endogenous bargaining model of Section 2.5. A limited literature on dynamic household decisions pursues this avenue.[an] A model based on limited commitment will lead to endogenous shifts in bargaining power over time, namely whenever the commitment constraint becomes binding. When divorce is the outside option, limited commitment implies shifts in bargaining power only when a couple is close to divorce. An alternative is to consider an outside option of noncooperation within marriage as in Lundberg and Pollak (1993). Doepke and Kindermann (2015) is a recent example of a dynamic bargaining model with such an outside option. Such limited commitment models are consistent with the empirical evidence on continuously shifting bargaining power within couples provided by Lise and Yamada (2015).

An alternative friction that so far has received much less attention is private information within the household. Before showing how this friction can be modeled, let us discuss some indications that private information may indeed be relevant for bargaining between spouses. There are many things that spouses may not precisely know about each other, such as income, assets, consumption, work effort, or preferences. Contrary to the belief that love and altruism will lead to perfect information sharing between spouses, the evidence suggests otherwise. The most obvious example may be that people do not typically tell their partner when they are having an extramarital affair. Relatedly, some people do not disclose that they have HIV or other sexually transmitted diseases to their partner. Women sometimes hide from their partners that they are using birth control (or, depending on the context, that they are not using birth control).[ao] More directly related to the context of this chapter is that people do not always disclose income, spending, and savings behavior to their spouse. de Laat (2014) shows that husbands in split-migrant couples in Kenya invest significant resources into monitoring the spending behavior of their wives. When given the option, people often prefer to put money into private (and possibly secret) accounts.[ap]Hoel (2015) finds in Kenyan data that 31% of people say their spouse was not aware of any income they had received the preceding week.

[an] See in particular Mazzocco (2007) and Voena (2015).

[ao] For example, Ashraf et al. (2014) show that women in Zambia hide the use of birth control from their husbands when given the chance.

[ap] See Anderson and Baland (2002), Ashraf (2009), and Schaner (2015).

Further, evidence from lab and field experiments suggests that information treatments affect intrahousehold allocations, suggesting that information frictions are important.[aq] Most of this evidence is from developing countries and in some dimensions (such as uncertainty about a spouse's income) couples in industrialized countries with joint checking accounts and tax filings may be less affected by information frictions. However, private information about preferences and hidden effort is likely to be equally relevant all around the world.

In sum, there is ample evidence that private information plays an important role in household bargaining. Nevertheless, hardly any work has been done on this issue in terms of explicit models of the bargaining process. We believe this is an important area for future work. While most of this chapter concerns applying family economics to macroeconomics, the issue of information frictions presents an opportunity for intellectual arbitrage in the opposite direction: while in family economics static models are still common, in macroeconomics dynamic contracting models that make the underlying frictions explicit have been widespread for many years. In particular, it should be possible to apply some of the tools to analyze informational frictions currently used in theoretical macroeconomics and public finance to issues in family economics.[ar] Some work of this kind exists in development economics (eg, Townsend, 2010; Karaivanov and Townsend, 2014; Kinnan, 2014), but the question is a different one as the degree of insurance within a village—as opposed to within a couple—is analyzed.

We currently explore how to account for information frictions in household bargaining in ongoing work (Doepke and Tertilt, 2015). As a simple example for modeling such a friction, consider a variant of the model analyzed above under private information about each spouse's labor income w_g. To simplify the exposition, we assume that there is a private income realization only in the first period, whereas there is no income in the second period, $w'_f = w'_m = 0$. Bargaining is assumed to be efficient subject to the constraints imposed by private information, with initial welfare weights λ_f and λ_m. The constrained efficient allocation can be computed as a mechanism design problem. The revelation principle can be applied and implies that we can restrict attention to truth-telling mechanisms with truth-telling constraints imposed. Hence, the spouses will simultaneously report their income w_f and w_m to each other, and consumption is given by functions $c_g(w_f, w_m)$ and $c'_g(w_f, w_m)$, which depend on the reports. For simplicity, we

[aq] When income is private information in dictator games, less is transferred to the partner Hoel (2015). Migrants send home less cash to family members when their choice is not revealed to the recipients (Ambler, 2015). More is spent on goods that are hard to monitor or difficult to reverse and less on household public goods when a transfer is given privately to one spouse relative to a full information transfer (Castilla and Walker, 2013).

[ar] See Atkeson and Lucas (1992) and the follow-up literature for applications of models with information frictions in macroeconomics. For a survey of the literature incorporating information frictions into public finance, see Golosov et al. (2006).

assume that each income is drawn from a finite set $w_g \in W_g$ with independent probability distributions denoted by $p(w_g)$.

With these preliminaries, the optimization problem faced by the household can be written as follows:

$$\begin{aligned}\max E \quad \{&\lambda_f[\log(c_f(w_f,w_m)) + \beta \log(c_f'(w_f,w_m))]. \\ &+ \lambda_m[\log(c_m(w_f,w_m)) + \beta \log(c_m'(w_f,w_m))]\},\end{aligned}$$

subject to the budget constraints:

$$\begin{aligned} c_f + c_m + a' &= w_f + w_m, \\ c_f' + c_m' &= (1+r)a. \end{aligned}$$

The maximization problem is also subject to truth-telling constraints. Consider first the wife. For each w_f and each alternative $\widetilde{w}_f \in W_f$, we impose:

$$\begin{aligned}&\sum_{w_m} p(w_m)[\log(c_f(w_f,w_m)) + \beta \log(c_f'(w_f,w_g))] \\ &\qquad \geq \sum_{w_m} p(w_m)[\log(c_f(\widetilde{w}_f,w_m) + w_f - \widetilde{w}_f) + \beta \log(c_f'(\widetilde{w}_f,w_m))].\end{aligned}$$

Similarly, for the husband we have:

$$\begin{aligned}&\sum_{w_f} p(w_f)\left[\log(c_m(w_f,w_m)) + \beta \log(c_m'(w_f,w_g))\right] \\ &\qquad \geq \sum_{w_f} p(w_f)\left[\log(c_m(w_f,\widetilde{w}_m) + w_m - \widetilde{w}_m) + \beta \log(c_m'(w_m,\widetilde{w}_m))\right].\end{aligned}$$

A direct implication of this model is that consumption is more responsive to a change in own income than to a change in the spouse's income. The reason is that incentives need to be provided to tell the truth about own income shocks. Other frictions (such as unobservable effort or unobservable preference shocks) can be modeled along similar lines.

Models of bargaining with limited commitment frictions and private information frictions have distinct implications for how consumption and leisure depend on bargaining power. Consider, for example, a limited commitment model where the outside option responds to income shocks. In such a setting, a positive income shock for a given spouse increases this spouse's bargaining weight, which (all else equal) tends to increase leisure and lower labor supply. In contrast, in a hidden effort model it is costly to distort the effort of a productive spouse; hence, a more productive spouse may be provided more incentives to work and end up working more. This example shows that the underlying friction matters for how household bargaining reacts to family trends such as the increase in women's labor market attachment. We believe that further work on incorporating methods for dealing with dynamic contracting frictions into family economics will be productive for improving our understanding of these issues.

3. THE FAMILY AND ECONOMIC GROWTH

The most fundamental questions in macroeconomics concern economic growth. As Robert Lucas put it, once one starts to think about the determinants of cross-country income differences and policies that may allow poor countries to catch up with rich ones, "it is hard to think about anything else" (Lucas, 1988, p. 5).

Early theorizing on the sources of economic growth was focused on firms rather than families. The Solow model, for example, puts investment in physical capital by the business sector into the spotlight, coupled with exogenous improvements in productivity. To be sure, even in a model driven by capital accumulation families matter for growth; after all, investment has to be financed by savings, and savings are determined within the family. Both husband-wife and parent-child interactions are relevant for savings. First, as already shown in Section 2.5, a couple's savings rate responds to the possibility of divorce. More generally, if husbands and wives disagree about the consumption-savings trade-off (eg, because they differ in their degree of patience), then how spouses negotiate affects the savings rate. Second, a large part of long-run wealth accumulation is due to bequests, for which interactions between parents and children are crucial.

Family decisions have become even more central to growth theory with more recent developments that emphasize the importance of human capital accumulation and endogenous population growth. The importance of human capital accumulation for growth has been well recognized since the work of Lucas (1988). To fix ideas, consider a simple endogenous growth model based on accumulation of human capital H and physical capital K. Final output is produced using physical capital and effective units of labor as inputs. Effective units of labor depend both on time spent working u and the stock of human capital. Assuming a simple Cobb–Douglas production function, output is:

$$Y = K^{\alpha}(uH)^{1-\alpha}.$$

Human capital is accumulated by spending time studying. The higher the level of human capital and the more time spent in school $(1 - u)$, the higher is tomorrow's human capital,

$$H' = B(1-u)H, \tag{11}$$

where B is a technology parameter. In the simplest model, the fraction of time spent in school is given exogenously. Then, the growth rate of output in the balanced growth path is simply $B(1-u)$. Growth thus depends not only on technology but also on the time spent in school.

So far we have taken u to be an exogenous parameter. But clearly the time spent on education is a choice. Who makes the choice? A large part of education happens during childhood and hence, leaving mandatory schooling laws aside, it is parents who make education decisions for their children. In other words, education is a family decision. Note also that the formulation of the human capital production function above assumes past human capital enters into next period's human capital. Intuitively, the initial human capital stock of a new member in society is proportional to the level already attained by older members of the family. As Lucas put it, "human capital accumulation is a social activity, involving groups of people in a way that has no counterpart in the accumulation of physical capital" (Lucas, 1988, p. 19). Much of the time, the group in which the accumulation happens is the family, where children learn from parents both by imitating them and by being actively taught.

Understanding the human capital accumulation process is an active research area. Many open questions remain, but what is understood by now is that education and skill formation are complex processes that involve many ingredients. Inputs both in forms of time (own time, teacher time, parental time) and goods (textbooks, school buildings) are important, as is the age at which specific investments take place. For example, Jim Heckman and coauthors have emphasized the importance of early childhood education for long-run outcomes (Heckman, 2008). Citing Cunha and Heckmann (2007), "The family plays a powerful role […] through parental investments and through choice of childhood environments." Recent research captures such links in formal models of human capital investments within families (eg, Caucutt and Lochner, 2012; Aizer and Cunha, 2012). Del Boca et al. (2014) find that both paternal and maternal time input are essential inputs into child development.

So far, we have motivated the importance of families for growth based on the intuitive argument that human capital and savings decisions are made in the family. An equally compelling argument for the importance of families can be made on the basis of empirical findings. As we will document in the next section, cross-country data show strong correlations between development indicators such as GDP per capita and measures of family structure. While such findings constitute no proof of causality, they suggest a close link between family structure and development. After documenting these facts, we will show in a sequence of simple growth models how modeling increasingly complex family interactions can affect economic growth in an economy. While the most straightforward link from families to growth concerns fertility decisions, we emphasize that there are many dimensions to families, their role in producing new people being only one of them. Families typically consist of many family members (husband, wife, sons, daughters), who may differ in preferences and skills. When preferences differ, the exact nature of the decision process in the family becomes important. When skills differ, ie, when men and women are not perfect substitutes in production, then the details of how they enter differently into the human capital and goods production functions will also matter for growth. Further, families may have different attitudes toward sons and daughters, affecting human capital investment, and institutions such as polygyny may also affect incentives for investing in human and physical capital.

3.1 Cross-Country Family Facts

In this section, we report strong correlations between indicators of economic development and measures of family structure. Perhaps the most well-known example is the close link between the fertility rate and development. Fig. 17 displays a strong negative relationship between the total fertility rate and GDP per capita across countries.[as] Fertility, in turn, is strongly negatively correlated with measures of schooling (Fig. 18).

Many other measures of family structure are related to development as well. Fig. 19 displays the fraction of teenage girls (15–19 years) that has ever been married. The figure reveals a striking negative relationship between GDP per capita and early marriage. In poor countries, such as Ghana and Malawi, almost 50% of 15–19 year old girls are

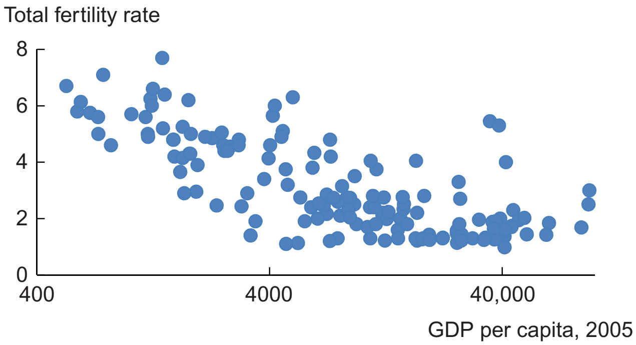

Fig. 17 TFR and GDP per capita across countries. *GID 2006 and World Development Indicators 2005.*

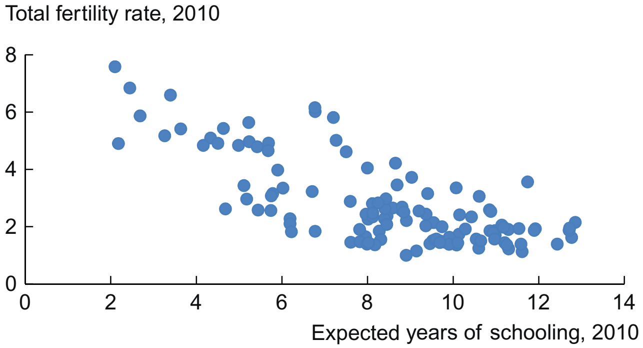

Fig. 18 Schooling and TFR across countries. *World Development Indicators.*

[as] A similar relationship can be observed over time within countries: in most cases, the demographic transition took place during times of rapid economic growth. For the United States, the decline in children ever born by birth cohort of mothers is shown in Fig. 1.

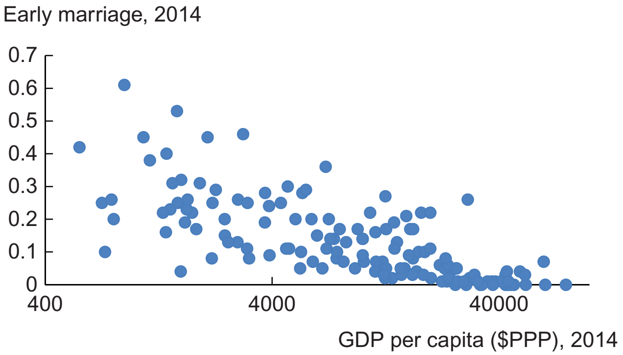

Fig. 19 Early marriage and GDP per capita across countries. *OECD Gender Statistics 2014 and World Development Indicators.*

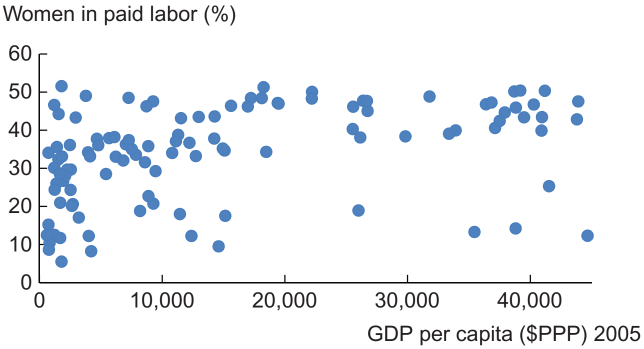

Fig. 20 Women in paid labor and GDP per capita across countries. *OECD Gender Statistics 2006 and World Development Indicators.*

married, compared to less than 5% in countries with a GDP per capita of more than $25,000 (in 2005 PPP terms). Fig. 20 plots the relationship between female labor force participation and GDP per capita. Since rates of formal employment are low for women and men alike in many poor countries, rather than plotting the absolute participation rate, Fig. 20 depicts the fraction of formal employment accounted for by women. In virtually all countries with a GDP per capita higher than $20,000, women make up 40% or more percent of the paid labor force, while in many poor countries women account for less than 20%.[at]

The figures discussed so far were chosen to highlight a few particularly interesting and pronounced relationships between family structure and development. Yet, essentially all indicators of family structure are related to development, including both measures of outcomes and measures of legal differences between men and women. Table 3 gives

[at] The few rich countries with low female labor force participation are oil-rich countries such as Saudi Arabia and the United Arab Emirates.

correlations of family variables with two measures of economic development, GDP per capita and the share of the agricultural sector in GDP (which is typically low in developed countries). The first three rows are about children: Fertility rates are high, child mortality is high, and schooling is low in poor countries. The next two rows show that a preference for sons is systematically related to development. First, people in poor countries are more likely to state that when resources are scarce, educating boys is more important than educating girls. Second, inheritance laws favor sons over daughters. The next three rows are about the education and work of women relative to men. Women are more likely to be illiterate than men in poor countries. They work less in the market and provide a larger burden of unpaid family care work, such as taking care of children and the elderly. The next set of indicators show that the legal position of women is negatively related to development. Women obtained access to politics (through representation in national parliaments) earlier in today's rich countries. They also have better access to land ownership and usage. There is also a tight relationship between the United Nations' Gender Empowerment Measure and GDP per capita. The last set of indicators show that the position specifically of married women is weaker in poor countries. Women in poor countries marry earlier than in rich countries and wife beating is more accepted. The legal position also favors men in poor countries: inheritance laws are more likely to favor

Table 3 Correlations between family variables and GDP per capita and share of agriculture across countries

Notes: Data are from OECD gender, institutions, and development data base (GID 2006 and 2014), the world development indicators (WDI 2003, 2005, and 2014), and the UN Development Report 2004. Correlations are computed with GDP per capita and percentage of value-added in agriculture from the WDI in two different years: 2005 and 2014. See the Appendices for variable definitions and further details.

Table 4 Differences between polygynous countries and monogamous countries close to the equator

	Polygynous	Monogamous
Total fertility rate	6.8	4.6
Husband–wife age gap	6.4	2.8
Aggregate capital–output ratio	1.1	1.9
GDP per capita (dollars)	975	2798
Number of countries	28	58

Notes: Data are either from 1980 or an average for the 1960–85 time period. Details and sources are given in Tertilt (2005). Polygynous countries defined as countries with at least 10% of men in polygamous unions. Monogamous countries are all other countries within 20 degrees of latitude from the equator, to control for the fact that most polygynous countries are in sub-Saharan Africa.

widowers over widows, and laws against domestic violence (if they exist in the first place) are less strict compared to developed countries.

A family structure that has long been illegal in most developed countries but is still practiced in many poorer countries is polygyny, which is the practice of men being married to multiple wives. Table 4 shows that polygynous countries are among the poorest in the world, display extremely high fertility rates, invest little, and are characterized by large age gaps between husbands and wives.

3.2 Parents and Children

The strong empirical association between economic development and measures of family structure suggests that changes to the family are an integral part of the growth process. We now analyze a series of simple growth models to highlight a number of specific channels that tie development and families together.

We start with a simple view of the family. In this first version of the model, each family consists of a parent and a child. Parents care about children in a warm-glow fashion. Specifically, they derive utility from their children's full income.[au] Fertility is exogenous. In other words, we start with a single sex model where each parent has exactly one child. Since the children themselves will have children again, the model is an overlapping generations model. The difference to the standard OLG setup is that generations are explicitly linked through parent-child relationships.

Preferences are given by the utility function

$$u(c)+\delta u(y'),$$

where c is the parent's consumption and y' is the child's full income (as an adult in the next period). For simplicity, we assume consumption goods are produced at home with a

[au] Models with true altruism would yield qualitatively similar results, but are less tractable.

production function that uses effective units of time as the only input.[av] Let H denote the human capital of the parent and ℓ the units of time the parent devotes to production. Then consumption, or equivalently GDP (per adult), is given by:

$$c = A\ell H,$$

where A is a technology parameter. We define full income as the income that would be obtained if the parent was working full time:

$$y = AH.$$

Not all time will be devoted to production, because the parent will also spend some time educating the child. Let e denote this education time. Human capital of the child is given by the following production function:

$$H' = (Be)^{\theta} H,$$

where B and θ are technology parameters. Here θ is an especially important parameter as it captures the returns to education. Each parent is endowed with one unit of time. Thus, the parent faces the following time constraint: $\ell + e \leq 1$. Assuming log utility, we can write the objective function of the parent as follows:

$$\max \log(c) + \delta\theta \log(e).$$

The equilibrium is characterized by the optimal education choice $e^* = \dfrac{\delta\theta}{1+\delta\theta}$. The equilibrium growth rate (for both human capital and consumption) is:

$$\frac{H'}{H} = \left(B\frac{\delta\theta}{1+\delta\theta}\right)^{\theta}. \tag{12}$$

As in the simple Lucas model at the beginning of this section (Eq. 11), the human capital accumulation technology in part determines the growth rate. What is different from the Lucas model is that how much parents care about their children's well-being also enters. In contrast, in standard growth models that abstract from intergenerational links, it is the individual's discount factor that matters. There is no reason for the rate of time preference across periods for a given person to coincide with the intergenerational discount factor. A related point is that the intergenerational elasticity of substitution may differ from the intertemporal elasticity of substitution (IES). In other words, estimates of the IES in the business cycle context are not necessarily relevant for calibrating growth models based on trade-offs across generations.[aw] There is a need for empirical research in this

[av] This is isomorphic to a model with market production. The home production formulation has the advantage that we do not need notation for wages and, later, interest rates.

[aw] See Cordoba and Ripoll (2014) for a formal treatment of this point.

area, as good estimates of the intergenerational discount factor and the intergenerational elasticity of substitution are currently not available.

The model as written assumes that all families accumulate human capital independently from each other. An alternative vision of the process of human capital accumulation is that much of the increase in people's productivity over time is due to the dissemination of productive ideas, implying that exchange of knowledge between different families is crucial for growth. In a setting that makes this engine of growth explicit, de la Croix et al. (2016) examine the role of institutions that organize the exchange of knowledge for growth. They compare both family-based institutions (knowledge exchange within nuclear families or families/clans) and market-based institutions, and argue that institutions that facilitated the exchange of ideas across families were crucial for the economic ascendency of Western Europe in the centuries leading up to industrialization.

3.3 Adding Fertility Choice

Next, we enrich the model by endogenizing fertility choice. The analysis of fertility choices in explicit dynamic growth models was pioneered by Becker and Barro (1988) and Barro and Becker (1989). These papers assume an altruistic utility function (ie, the children's utility enters the parent's utility), whereas we will stick to the warm-glow motive for investing in children. This distinction makes no difference for most qualitative results and allows more closed form solutions. In contrast to Barro and Becker (1989), which features exogenous technological progress, our focus is on human capital as the engine of growth.

For simplicity (and in line with the majority of existing analyses of fertility in dynamic models), we stick with one-parent families. However, conceptually it is straightforward to consider fertility decisions in a two-parent model (see Doepke and Tertilt, 2009 for an example).[ax]

To give the parent a reason to want children, we modify the utility function as follows:

$$u(c) + \delta^n u(n) + \delta u(y'),$$

where n is the number of children chosen by the parent. It takes ϕ units of time to raise a child in addition to the e units of education time devoted to each child. Note that ϕ is a fixed cost, while e is a choice variable. The time constraint is thus

[ax] Doepke and Kindermann (2015) document empirically that spouses often disagree about whether to have another child and present a bargaining model of fertility decisions to analyze the implications of this fact.

$$\ell + (\phi + e)n \leq 1.$$

We keep everything else (ie, production and human capital accumulation) as before. Assuming log utility, the objective function can be written as

$$\max \log(c) + \delta^n \log(n) + \delta\theta \log(e).$$

To guarantee that the problem is well defined, we assume $\delta^n > \delta\theta$.

The equilibrium is characterized by the following education and fertility choices:

$$e^* = \frac{\delta\theta}{\delta^n - \delta\theta}\phi,$$

$$n^* = \frac{(\delta^n - \delta\theta)}{\phi(1 + \delta^n)}.$$

The equilibrium growth rate is:

$$\frac{H'}{H} = \left(B\frac{\delta\theta\phi}{\delta^n - \delta\theta}\right)^{\theta}. \tag{13}$$

Comparing the expression for n^* and the equilibrium growth factor given in (13), it becomes apparent that many of the same features leading to high fertility, such as a low cost of children and low returns to education, also lead to a low growth rate. The negative dependence of fertility on growth was already a feature in Barro and Becker (1989), albeit in a model of exogenous growth. The importance of human capital as an engine for growth in a model with endogenous fertility was first analyzed by Becker et al. (1990). While the exact expression is different, they also derive a growth rate that depends positively on the returns to education, the fixed cost of children, and an altruism parameter.

Comparing the growth rate given in (13) with the growth rate in the model without fertility choice (12), two points emerge. First, two types of intergenerational preference parameters appear now: δ and δ^n. In other words, how much parents care about the quality vs the quantity of children is a determinant of the growth rate. Second, the return to human capital enters positively into the optimal education choice and negatively into the optimal fertility choice.

These results may help in understanding some empirical regularities, such as the negative relationship between fertility and schooling, on the one hand, and fertility and GDP per capita, on the other hand (Figs. 17 and 18). In the model, these relationships would arise if countries differ in the return to skill θ or the cost of children ϕ. Similarly, within most countries fertility decreased, while education increased over time. The model can generate this pattern if the return to education increases gradually from generation to generation. The resulting theory interprets the demographic transition to low fertility as driven by a move from investing in child quantity to emphasizing child quality (ie, education).

There is a substantial literature aiming to account for the historical relationship between fertility and growth based on this mechanism. Before the onset of industrialization in the 18th century, living standards around the world were stagnant, and fertility rates were high. In most countries, this "Malthusian" stage was followed by a transition to growing incomes and declining fertility rates. The first theory to fully account for such a transition is Galor and Weil (2000), which is based on the quantity–quality trade-off, a Malthusian constraint due to the role of land in agriculture, and human capital as an engine for growth. The role of structural change in the transition is highlighted by Hansen and Prescott (2002), who model the endogenous transition from a stagnant land-intensive technology to a capital-intensive growth technology. Population growth changes with growing incomes in their model. However, rather than explicitly modeling fertility choice, the authors assume a particular dependence of population growth on consumption. Greenwood and Seshadri (2002) introduce explicit fertility preferences when analyzing a similar transition from an agricultural to a manufacturing society. Doepke (2004) also models fertility preferences explicitly to analyze the importance of education and child labor policies for the transition from stagnation to growth. Some authors argue that the transition was triggered by declines in mortality, which increased the incentive to educate children. Soares (2005) provides a model where gains in life expectancy lead to reductions in fertility and increases in human capital accumulation, leading to an endogenous transition from a Malthusian to a long-run growth equilibrium.[ay] However, Hazan and Zoabi (2006) show that the impact of increasing longevity on human capital investment is mitigated by the fact that higher longevity also raises the incentive to have more children, which works against human capital investment through the quantity–quality trade-off.

One could also use variants of this setup to understand cross-country fertility differences today. For example, Manuelli and Seshadri (2009) study international fertility differences using a life-cycle version of the Barro–Becker model with human and health capital. They find that differences in productivity, social security, and taxes can go a long way in explaining the observed differences.

The empirical regularities that characterize differences across countries are also visible across families. There is a sizeable empirical literature documenting that in the cross section of families in a given country, quantity and quality of children are negatively related.[az] An augmented version of the model with heterogeneity across families in δ^n (or, similarly, δ) would deliver this empirical regularity. The overall economy-wide

[ay] The importance of changes in mortality for development is also analyzed in Cervellati and Sunde (2005).

[az] See, for example, Rosenzweig and Wolpin (1980) and Bleakley and Lange (2009). Vogl (2016) argues that the negative relationship of quantity and quality may be a relatively recent phenomenon. He documents that in many developing countries there was a reversal in the education-fertility relationship from positive to negative. Baudin et al. (2015) provide an analysis that also allows for the possibility of childlessness, and argue that childlessness is U-shaped as economies develop.

growth rate would then depend on how many parents of each type exist, and also on whether such preferences are passed on from parents to children or randomly distributed in the population.[ba] de la Croix and Doepke (2003) explore the association between inequality and growth based on the differential fertility channel and argue that it explains a large part of the observed relationship between inequality and growth across countries.[bb]

3.3.1 Fertility Restrictions

The link between fertility and human capital accumulation suggests that countries may be able to speed up economic development by limiting fertility rates. Out of the many policies that can affect a country's fertility rate, the most direct is a hard limit on how many children a couple can have. Several countries have implemented such fertility restrictions, the most famous example of which is the one-child policy of China. Another examples are forced sterilization policies implemented by the Indian government in the 1980s. Other countries have used more subtle family planning policies, either through monetary incentive schemes or in the form of media campaigns, often advocating a two-child norm.

We can incorporate such policies into the model by adding a fertility limit $\bar{n}$. Whenever the constraint is binding, the optimal education decision is:

$$e^* = \frac{\delta\theta[\frac{1}{\bar{n}} - \phi]}{1 + \delta\theta}.$$

Education increases with a tighter fertility restriction. Thus, fertility restrictions do speed up economic growth in our model. Yet, they are not the panacea one might have hoped for, as fertility restrictions also come with a cost. Fig. 21 illustrates these effects in a computed example of our model.[bc] The top panels show how fertility and education change with different levels of fertility restrictions, while the bottom panels depict the growth rate and steady state utility as a function of the restrictions. The optimal (unrestricted) fertility rate in the example is 3. Thus, only restrictions below 3 are binding. Tighter restrictions lead to higher levels of education and higher growth rates, but they lower equilibrium utility. In our simple model, this negative effect on utility comes from parents being deprived of (part of) the enjoyment they

[ba] Thus, whether differential fertility increases or decreases the growth rate depends on many factors. See Vogl (2016) for an analysis of this point. The specific role of preference transmission in the context of the British Industrial Revolution is analyzed by Doepke and Zilibotti (2008).

[bb] de la Croix and Doepke (2004, 2009) analyze the importance of this mechanism in the context of education policies.

[bc] The parameters in the example are: $\delta^n = 0.8$, $\delta = 0.5$, $\phi = 0.1$, $B = 1$, $\theta = 0.5$, $A = 10$. The initial level of human capital is normalized at $H = 1$ and the fertility restriction ranges from 1 to 5.

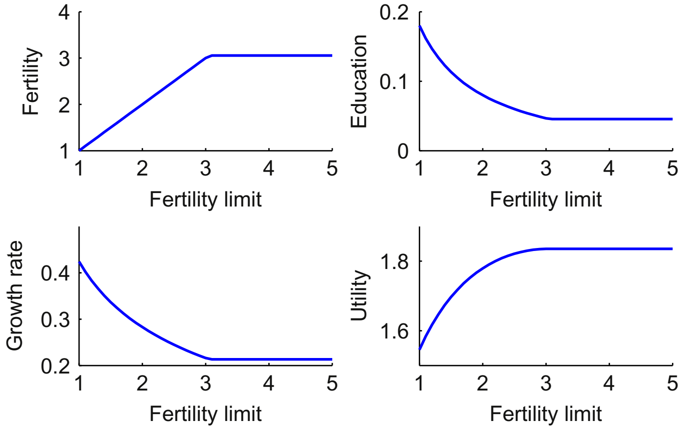

Fig. 21 Fertility restrictions.

obtain from children.[bd] In more elaborate settings, such negative effects can also arise from the differential effect of the fertility constraint on a heterogeneous population. Also, with a public social security system, lower fertility depresses future payouts, ie, the demographic dividend declines, a problem that is starting to become pressing in China right now.

These issues are analyzed in a small emerging literature. Liao (2013) analyzes how the one-child policy in China increased human capital and output. She simulates counterfactual experiments to analyze the effects of a relaxation of the policy. The main findings are that results differ across generations and skill groups. In particular, the initial old would benefit from a sudden unexpected relaxation of the policy, but future generations would be hurt. Moreover, such a policy would hurt unskilled people more than skilled people. Choukhmane et al. (2014) conduct a richer analysis using a life-cycle model and more detailed micro data. They argue that a large part of the rise in aggregate savings in China can be attributed to the one-child policy. The focus in Banerjee et al. (2014) is on the importance of general equilibrium effects when estimating how fertility restrictions (and their removal) would impact savings. These authors argue that appropriately taking general equilibrium effects into account reduces the size of such estimates. Coeurdacier et al. (2014) focus on the interaction between fertility policies and social security reform.[be] Since an expansion of social security lowers the incentives to have children (and thereby lowers the number of contributors to the system), the relaxation of the one child policy is likely to have smaller effects than typically anticipated. The authors find that this effect is quantitatively important for China.

[bd] The mechanism that lower fertility decreases utility is analyzed in Cordoba (2015), who finds that, during the 1970–2005 period, world growth in well-being was lower than the growth rate in per capita consumption precisely because fertility fell so dramatically during that period.

[be] Song et al. (2015) also analyze the consequences of low fertility for pension reform in China, albeit in a model with exogenous fertility.

3.4 Two-Parent Families: Decision Making

The vast majority of the literature on fertility and growth focuses on the interaction between parents and children in one-gender models. In other words, reproduction is asexual and differences between men and women in technology and preferences are abstracted from. We now expand our analysis by introducing two-gender families. In this version of our growth model, children have two parents: a mother and a father. For simplicity we return to exogenous fertility for now and assume that each couple has two children. Thus, families now consist of a husband, a wife, a son, and a daughter. Suppose men and women disagree about how much they care about their children's well-being.[bf] As in Section 2.4, suppose that the couple solves a Pareto problem with fixed bargaining weights, where $\lambda_f$is the bargaining weight of the woman, and λ_m is the weight of the man. Then the objective function is:

$$\lambda_f[u(c)+\delta_f u(y')]+(1-\lambda_f)[u(c)+\delta_m u(y')].$$

To keep the rest of the model comparable to the previous section, we assume that all consumption in marriage is public and the total time endowment (of the couple) is still one. We also make no distinction between sons and daughters in the parent's objective function. We will relax these assumptions further below. Assuming log utility, the objective function can be written as:

$$\max \lambda[\log(c)+\delta_f\theta \log(e)]+(1-\lambda)[\log(c)+\delta_m\theta \log(e)].$$

Equilibrium education now is

$$e^* = \frac{\tilde{\delta}\theta}{1+\tilde{\delta}\theta},$$

where $\tilde{\delta} \equiv \lambda_f \delta_f + (1-\lambda_f)\delta_m$. Thus, the equilibrium growth rate is:

$$\frac{H'}{H} = \left(B\frac{\tilde{\delta}\theta}{1+\tilde{\delta}\theta}\right)^{\theta}. \tag{14}$$

A comparison of Eqs. (12) and (14) shows not only that gender preference gaps matter for the growth rate, but also how such preferences make their way into decisions within the family. Specifically, assuming mothers care more about children than fathers do ($\delta_f > \delta_m$), the economy grows faster, the larger the bargaining power of women. Doepke and

[bf] There could be many reasons for such a disagreement, ranging from biological/evolutionary arguments to cultural factors. See Alger and Cox (2013) for a survey.

Tertilt (2009) explore the endogenous evolution of women's rights based on such a mechanism (details will be discussed in Section 4). However, whether female empowerment enhances growth depends on the details of the bargaining process within the household. Doepke and Tertilt (2014) use a noncooperative model to show that what looks like gender differences in preferences may ultimately be due to specialization in tasks within the household. Based on this mechanism, Doepke and Tertilt (2014) show that monetary transfers to women may reduce growth, even if women are more likely to spend transfers on children. The reason is that the equilibrium is characterized by a division of labor in which women are in charge of time-intensive tasks such as education, while men provide money-intensive goods and hence are in charge of savings and physical capital accumulation. In such a world, exogenous transfers to women (financed by a tax on men) increase human capital accumulation but reduce physical capital accumulation. Depending on the production function, such a reallocation may increase or decrease growth. Specifically, when returns to physical capital relative to human capital are high, then such a policy would lower growth. To assess whether this is an issue in reality, more empirical research is needed. The current literature on the effects of transfers to women largely focuses on child expenditures, but there is little work analyzing effects on savings and investment.

3.5 Two-Parent Families: Technology

Empirical research (eg, Del Boca et al., 2014) has shown that mothers and fathers are both important factors in the human capital formation process of their children. In most families, both mothers and fathers spend a significant amount of time with children (Schoonbroodt, 2016). Further, men and women may not be perfect substitutes in market production.[bg] To address these issues, we now extend our view of the family to include fathers and mothers explicitly in the human capital formation process and also men and women as entering separately into production. To isolate the role of women in technology (vs their role as decision makers), we assume again that all consumption in families is public and that men and women have the same preferences regarding their children. In other words, we ignore here the additional complication that arises if fathers and mothers disagree (which we analyzed in Section 3.4). We also focus on the education decision (rather than fertility choice); however, it would be straightforward to include both margins in the same model.

[bg] Large and persistent gender wage differentials exist (see Blau and Kahn, 2000 for a survey). There is an extensive empirical literature trying to analyze their causes. We do not take a stand here on what the ultimate cause is, but rather explore the implications of men and women being imperfect substitutes in production. Whether the gap is due to different innate skills, different preferences, or cultural factors leading to differences in skill acquisition is largely irrelevant for our analysis.

In contrast to the previous versions of the model, men and women enter differently into technology. The consumption good is produced with a Cobb-Douglas production function using both male and female efficiency units of time as inputs,

$$c = A(\ell_f H_f)^{\alpha}(H_m)^{1-\alpha},$$

where $\alpha \in (0,1)$. For simplicity, we assume that only women raise children, while men work full time. The female time constraint is $\ell_f + e_f + e_m \leq 1$, where e_f is the time invested in educating daughters, and e_m is time devoted to the education of sons. Full income is defined as the production function evaluated at $\ell_f = 1$ and is therefore given by:

$$y = AH_f^{\alpha}H_m^{1-\alpha}.$$

Each couple has two children: a daughter and a son. Both mothers and fathers are essential for their children's human capital accumulation:

$$H_f' = (Be_f)^{\theta}H_f^{\beta}H_m^{1-\beta}, \tag{15}$$

$$H_m' = (Be_m)^{\theta}H_f^{\beta}H_m^{1-\beta}, \tag{16}$$

with $\beta \in (0,1)$. In summary, there are two gender differences in this setup: the relative importance of women vs men in transmitting own human capital to children (β) and the relative importance of women vs men in production (α).[bh]

Assuming log utility, the objective function can be written as:

$$\max \log(c) + \delta[\alpha\theta \log(e_f) + (1-\alpha)\theta \log(e_m)].$$

The equilibrium allocation is:

$$\ell_f^* = \frac{\alpha}{\alpha + (1-\alpha)\delta\theta + \alpha\delta\theta},$$

$$e_m^* = \frac{(1-\alpha)\delta\theta}{\alpha + (1-\alpha)\delta\theta + \alpha\delta\theta},$$

$$e_f^* = \frac{\alpha\delta\theta}{\alpha + (1-\alpha)\delta\theta + \alpha\delta\theta}.$$

The equilibrium ratio of female to male human capital is given by:

$$\frac{H_f}{H_m} = \left(\frac{e_f}{e_m}\right)^{\theta} = \left(\frac{\alpha}{1-\alpha}\right)^{\theta}.$$

Note that the asymmetry between mothers and fathers in the human capital production function captured by β does not appear in this expression. This is not a fundamental

[bh] A third asymmetry is that we have assumed that only women can spend time educating children. But this asymmetry is made for tractability and is not essential for the qualitative results.

result, but rather a feature of our warm-glow altruism. In an altruistic model, parents would take into account that educating their children will turn the children themselves into better parents, and hence enable them to provide grandchildren with more education. In such a formulation, the relative importance of fathers vs mothers in child development will also enter the relative human capital of men and women in equilibrium.

This model features a gender education gap and accordingly a gender wage gap.[bi] Specifically, the wage ratio per unit of time is $\frac{w_f}{w_m} = \frac{\alpha}{1-\alpha}$. The more productive women are in production (higher α), the smaller is the gender education gap. Higher female wage increase the opportunity cost of time and hence make children more costly. In a variant of the model with endogenous fertility, this logic would lead to fertility decline in response to rising female productivity. This mechanism is analyzed by Galor and Weil (1996), who explore how this channel contributed to the demographic transition.

In a fully altruistic model, parents would further take into account that their sons and daughters will be working different hours in the market (because of the child-bearing obligations of mothers) and accordingly invest less in daughters.[bj] This amplification channel is explored by Echevarria and Merlo (1999). Lagerlöf (2003) further explores the effect of the marriage market in this context and stresses the importance of multiple equilibria. If all families invest more into sons, then daughters on average expect high spousal income, which lowers the incentive for each individual family to educate daughters. However, complete gender equality is also an equilibrium in his model.

Plugging the ratio of human capital back into the human capital production function, we get the following equilibrium growth rate (for both male and female human capital, and hence also output and consumption):

$$\frac{H'}{H} = B^{\theta}(e_m)^{(1-\beta)\theta}(e_f)^{\theta\beta} = \left\{\frac{B\delta\theta}{\alpha+\delta\theta}(1-\alpha)^{1-\beta}\alpha^{\beta}\right\}^{\theta}. \tag{17}$$

Eq. (17) shows that the growth rate depends on many features of the family. As before, the more parents care about their children, the higher the growth rate. What is new is that gender differences in technology also matter for growth. This is true for both the role women play in production (as captured by α) and the relative importance of fathers and mothers in human capital transmission (captured by β). Moreover, the two dimensions of technology interact. For example, in a world where men and women enter symmetrically into production ($\alpha = 0.5$), the relative importance of mothers and fathers in human capital transmission becomes irrelevant. On the other hand, α always enters,

[bi] Strictly speaking there are no wages in our formulation with home production. However, the model can be reinterpreted as one with market production and wages given by marginal products.

[bj] Our warm-glow altruism does not capture this channel, because parents care about the full income of their children and do not take into account the time daughters will spend on child-bearing.

even in a world where mothers and fathers are equally important in human capital transmission ($\beta = 0.5$). Closer inspection of (17) shows that the growth rate is hump-shaped in α. Thus, whether an increase in α increases or decreases the growth depends on the starting point. Starting from a low role of women in production, an increase in α will lead to a reduction in the gender education gap, an increase in relative female wages, an increase in female labor force participation, and an acceleration of economic growth. This mechanism may well have been historically relevant: recall that Fig. 20 displays a strong positive relationship between GDP per capita and the role of women in paid labor. Similarly, recall that Table 3 showed a negative correlation between the gender education gap and development.

Since World War II, all developed countries went through a period of increasing female labor force participation and declining gender wage gaps. How women's role for production evolved over longer historical time periods is less clear. Humphries and Weisdorf (2015) construct measures of relative male and female wages in England dating back to 1270 and find large swings over the centuries. They also try to measure the wages of married and single women separately, using the distinction between casual work (more relevant for married women) and annual contracts (mostly used for unmarried women). Using their data and accepting their interpretation, we find that the relative wages of married vs single women over time have sometimes moved in the opposite directions (Fig. 22). There is also evidence suggesting that in the long run, the relationship between development and female market work is not always monotonic. Specifically, based on cross-country data, Goldin (1995) argues that female labor supply is U-shaped in development.[bk] A similar point is made by Costa (2000), who argues

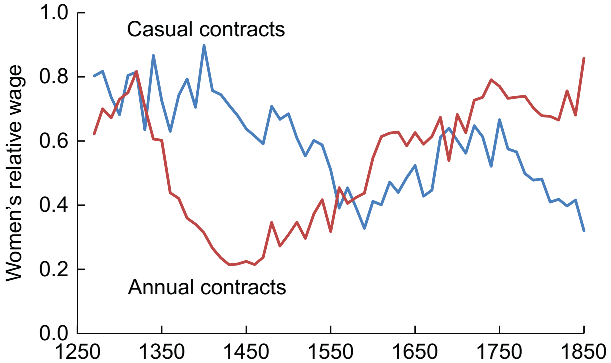

Fig. 22 Historical wage gap in England. *Humphries, J., Weisdorf, J., 2015. The wages of women in England, 1260–1850. J. Econ. Hist. 75 (2), 405–447 (Table A1).*

[bk] See also Olivetti (2014) for evidence of a U-shape in time series data of 16 developed countries (including the United States) and Mammen and Paxson (2000) for evidence from India and Thailand.

that female labor force participation is N-shaped if one goes back far enough in time. Establishing such historical facts is difficult not only due to lack of reliable data but also because of the lack of a sharp distinction between market and home production in agricultural economies.[bl]

A further complication arises when market production is made up of different tasks. If individuals differ in their ability to perform different tasks, then the allocation of talent to activities becomes important. Norms about gender roles (or other barriers) can then be an obstacle to the optimal allocation of talent to tasks. Hsieh et al. (2013) analyze the importance of this channel in the United States. They find that an improved allocation of talent across genders (and also ethnic groups) accounts for 15–20% of US growth during the 1960–2008 period. Lee (2015) explores the importance of misallocation of female talent for cross-country income differences. The paper finds that entry barriers for women in the nonagricultural sector play a large role for the observed low agricultural productivity in poor countries.

3.6 Two-Parent Families: Endogenous Bargaining

In Section 3.4, we have seen that who makes decisions in the household matters for growth. Hence, an important question is what determines bargaining power in marriage.[bm] Here we are interested in what changes bargaining weights across generations, which is distinct from the analysis of endogenous bargaining over time for a given couple (which we considered in Section 2). Initial bargaining power should be determined at time of marriage, which we do not model here. It is often assumed that relative educational attainments matter in the marriage market and hence for bargaining power. Relative education between men and women may itself be endogenous as we have seen in Section 3.5. In this section, we connect these two forces. To do so, we impose that the bargaining weight is a function of the gender education gap, which is itself chosen in the family. This assumption allows us to analyze the feedback from a gender education gap to bargaining power in the family.[bn]

We use a model that combines the setup with a gender preference gap in Section 3.4 with gender differences in technology as explored in Section 3.5. First, consider such a

[bl] For example, Goldin (1995) includes unpaid farm and family firm workers, while our Fig. 20 includes only paid workers.

[bm] There is a sizeable literature estimating models of household decision making. Key for identification is typically the existence of so-called distribution factors that affect bargaining weights but are exogenous to the bargaining process (see, for example, Blundell et al., 2005).

[bn] Basu (2006) also explores the implications of endogenous bargaining power, albeit in a different context. We are interested in how bargaining power changes across generations, while Basu (2006) analyzes the dynamic implications for a given couple. By adjusting labor supply, and thus income, spouses may affect their bargaining power in the household.

setup with exogenous bargaining power. Combining the features of the two models, the couple solves the following maximization problem:

$$\max_{c,\, e_f,\, e_m} u(c) + \widetilde{\delta}\left\{\alpha\theta \log(e_f) + (1-\alpha)\theta \log(e_m)\right\}$$

subject to:

$$1 = \ell_f + e_m + e_f,$$
$$c = A(\ell_f H_f)^{\alpha} H_m^{1-\alpha},$$

where $\widetilde{\delta} \equiv \lambda_f \delta_f + (1-\lambda_f)\delta_m$. As before, human capital evolves according to (15) and (16). This is the same problem as in Section 3.5, but with a modified δ. Thus, the equilibrium growth rate is:

$$1 + g^{exog} = \left\{\frac{B\widetilde{\delta}\theta}{\alpha + \widetilde{\delta}\theta}(1-\alpha)^{1-\beta}\alpha^{\beta}\right\}^{\theta}.$$

Now we can explore how endogenous bargaining differs from exogenous bargaining in this setup by assuming that λ is a function of relative education. A simple functional form assumption that captures this dependence and at the same time guarantees a bargaining weight between zero and one is $\lambda(e_f, e_m) = \frac{e_f}{e_f + e_m}$. Recall that relative education is a function of the relative importance of female labor in the market: $\frac{e_f}{e_f + e_m} = \alpha$. Thus, we can replace λ_f by α and write the growth rate as[bo]:

$$1 + g^{end} = \left\{\frac{B[\alpha\delta_f + (1-\alpha)\delta_m]\theta}{\alpha + [\alpha\delta_f + (1-\alpha)\delta_m]\theta}(1-\alpha)^{1-\beta}\alpha^{\beta}\right\}^{\theta}. \tag{18}$$

Proposition 4 *Assume* $\delta_f > \delta_m$. *If* $\lambda_f < \alpha$, *then the growth rate is higher in the endogenous bargaining model, while* $\lambda_f > \alpha$ *implies a higher growth rate in the exogenous bargaining model.* This result relates women's role in technology to women's role in decision making. Specifically when women's power in decision making is low relative to their importance for production, then endogenizing the link from education to bargaining power increases the growth rate. The opposite is true when women have a lot of bargaining power relative to their importance in production.

[bo] Note that with our warm-glow altruism, parents do not take into account that when increasing their daughter's education, they also increase the daughter's bargaining weight. de la Croix and Vander Donckt (2010) analyze a model with altruism where parents explicitly consider the impact of education choices on their children's future bargaining power.

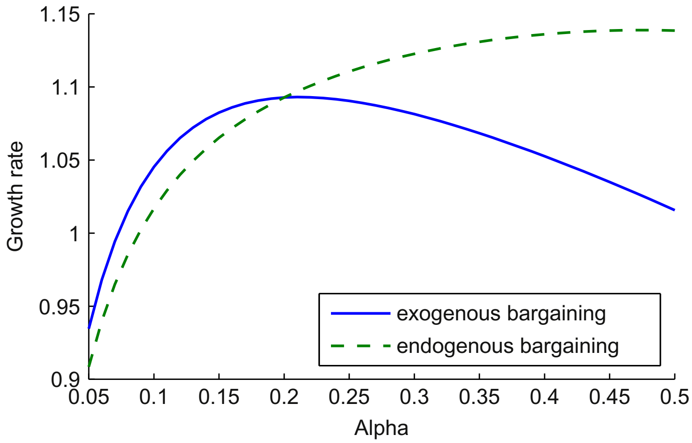

Fig. 23 Growth rate as a function of α, exogenous vs endogenous bargaining.

This result is illustrated in Fig. 23 with a numerical example.[bp] As was discussed in Section 3.5, the growth rate of the exogenous bargaining model is hump-shaped in α. This is not necessarily true in the endogenous bargaining model. In the example, growth monotonically increases in α. With fixed bargaining weights, an increase in women's role in production can lower growth because the resulting rise in female labor force participation decreases education time with children and thereby slows down human capital accumulation. This effect is mitigated in the endogenous bargaining model, where the resulting increase in bargaining power pushes toward more education (given that in the model women care more about children's education than men do). This example shows that the details of decision making in the family matter for growth and that asymmetries between men and women in decision making interact with asymmetries in technology.

3.7 Son Preferences

Many cultures are characterized by a preference for sons. This preference typically has effects on fertility behavior, where families that have only daughters are more likely to have another child (eg, Anukriti, 2014). Recently, sex-selective abortion has also been a concern (Ebenstein, 2010). Son preferences also manifest themselves in boys being treated better than girls. For example, Jayachandran and Kuziemko (2011) document gender differences in breast-feeding rates and Tarozzi and Mahajan (2007) document better nutritional status for boys in India. Further, such a preference is more pronounced in poorer countries (see Table 3).

[bp] The parameters in the example are: $\beta = 0.7, \theta = 0.5, B = 10, \delta_f = 0.5, \delta_m = 0.2, \lambda = 0.2$.

We now investigate the growth consequences of such a son preference in an extension of our model.[bq] First, consider an economy with physical capital in which parents leave bequests to sons and daughters. As before, consumption in marriage is public, fertility is exogenous, and each couple has one son and one daughter. Also as before, parents care about their children in a warm-glow fashion. In this case, parents derive utility from the bequest they give to their children. Output is produced using a linear technology in capital, ie, output is given by $y = AK$, where A is a parameter. All sons and daughters will be married. Without heterogeneity, it is irrelevant who marries whom. The capital of any given couple is made up of the sum of the bequests they each got, ie, $k = b_s + b_d$, where s denotes sons and d daughters.

Preferences are given by:

$$u(c) + \delta_s u(b_s) + \delta_d u(b_d),$$

where $\delta_s > \delta_d$ would capture a son preference. The budget constraint is $c + b_s + b_d \leq y$.

Assuming log utility, equilibrium bequests are

$$b_s = \frac{\delta_s}{1 + \delta_s + \delta_d} y,$$
$$b_d = \frac{\delta_d}{1 + \delta_s + \delta_d} y.$$

The equilibrium growth rate of income is:

$$\frac{y'}{y} = \frac{A(\delta_s + \delta_d)}{1 + \delta_s + \delta_d}.$$

The key result here is that the son preference is irrelevant for the growth rate. The only thing that matters is how much parents care on average about their children, ie, only the sum $\delta_s + \delta_d$ appears.

The finding changes if human capital accumulation is considered, as long as there are decreasing returns to educating a given person. In contrast to physical capital (where ownership does not matter for growth), it is plausible that total knowledge in an economy will be larger if knowledge is shared by more people. We now show how a son preference will interact with such decreasing returns in individual human capital.

The technologies for producing output and human capital are the same as in Section 3.5. Parents care only about their own children and hence they do not take into account that educating their daughter/son will also benefit the future son-in-law/daughter-in-law. Rather, they anticipate that their son-in-law will be endowed with the average male human capital in the economy, which we denote by $\bar{H}'_m$, and daughters-in-law are

[bq] Hazan and Zoabi (2015b) analyze endogenous son preferences in a related model with endogenous fertility.

anticipated to have human capital $\bar{H}'_f$. The optimization problem of a couple endowed with human capital (H_f, H_m) is thus given by:

$$\max_{e_f,\, e_m,\, \ell_f} u(c) + \delta_d u(y'_d) + \delta_s u(y'_s)$$

subject to:

$$\begin{aligned} c &= A(\ell_f H_f)^{\alpha} H_m^{1-\alpha}, \\ 1 &\geq \ell_f + e_f + e_m, \\ y'_d &= A(H'_f)^{\alpha}(\bar{H}'_m)^{1-\alpha}, \\ y'_s &= A(\bar{H}'_f)^{\alpha}(H'_m)^{1-\alpha}, \\ H'_f &= (Be_f)^{\theta} H_f^{\beta} H_m^{1-\beta}, \\ H'_m &= (Be_m)^{\theta} H_f^{\beta} H_m^{1-\beta}, \end{aligned}$$

where $\bar{H}'_f$ and $\bar{H}'_m$ are taken as given.

Assuming log utility, the maximization problem reduces to

$$\max_{\ell_f,\, e_f,\, e_m} \alpha \log(\ell_f) + \delta_d \alpha\theta \log(e_f) + \delta_s(1-\alpha)\theta \log(e_m)$$

subject to:

$$\ell_f + e_f + e_m \leq 1.$$

The resulting optimal education choices are

$$\begin{aligned} e_m^* &= \frac{\delta_s(1-\alpha)\theta}{\alpha + \delta_s(1-\alpha)\theta + \alpha\delta_d\theta}, \\ e_f^* &= \frac{\delta_d \alpha\theta}{\alpha + \delta_s(1-\alpha)\theta + \alpha\delta_d\theta}. \end{aligned}$$

As before, human capital, income, and consumption all grow at the same rate on the balanced growth path. The equilibrium growth rate is:

$$\left\{ \frac{B\theta}{\alpha + [\delta_d\alpha + \delta_s(1-\alpha)]\theta} (\delta_s[1-\alpha])^{1-\beta} (\delta_d \alpha)^{\beta} \right\}^{\theta}.$$

This expression shows how the effect of a son preference on the growth rate depends on the technology for goods production and human capital accumulation. First, consider the symmetric case where men and women are equally important in production (by setting $\beta = \alpha = 0.5$). Fix the total weight parents put on children: $\delta_s + \delta_d = 1$. In this case, the growth rate is maximized at $\delta_s = \delta_d = 0.5$. In other words, a son preference lowers growth. This is in contrast to the economy with only physical capital, where a son preference is irrelevant. Hence, a son preference is only growth-reducing when knowledge is the engine of growth. But even in a knowledge economy a son preference is not always disadvantageous. If men have the comparative advantage in knowledge production ($\beta < 0.5$), the growth-maximizing weight on children will display a son preference, the strength of which depends on the extent of men's comparative advantage.

On the other hand, in a world where men have a comparative advantage in goods production ($\alpha < 0.5$), but we have $\beta = 0.5$, a slight daughter preference enhances growth. The reason is that human capital is the engine of growth, implying that educating sons and daughters equally is the growth-maximizing strategy. Parents, on the other hand, do not maximize the growth rate, but rather output in the next period, where sons have the comparative advantage in production. Thus, parents overinvest in sons (compared to growth-maximizing solution). A son preference amplifies this problem.

Empirical evidence also links son preferences to the increasingly asymmetric sex ratios in some countries. In China, for example, in 2005 over 120 boys were born for each 100 girls (Wei and Zhang, 2011). Such asymmetries may have important aggregate consequences, which are largely unexplored in the literature. A notable exception is Wei and Zhang (2011), who find that rising sex ratios are an important determinant of the high Chinese savings rate. Du and Wei (2010) take this idea a step further and show in a calibrated model that this channel explains more than 50% of the current account surplus in China.

3.8 Polygyny

The role model for the family considered in most of this chapter is the Western nuclear family. The dominance of the nuclear family consisting of a husband, a wife, and the couple's own children is a relatively recent phenomenon, and even today typical families in some parts of the world do not follow this norm. Historically, the extended family (with multiple generations living together) was more prevalent than it is today.[br] Moreover, many families today no longer include married couples, as single parents are on the rise and many individuals no longer live in families at all (see Figs. 3 and 4 in Section 2.2).

Another important type of family structure is polygamy. In many parts of Africa men marrying multiple wives (polygyny) is common to the present day.[bs] Does such a family structure matter for macroeconomic outcomes? Tertilt (2005) suggests it does. The paper builds a model of polygynous families in which men buy brides and sell daughters to future husbands. The family structure reduces output (relative to enforced monogamy) through two channels. The market for daughters turns women into a valuable asset. This has two implications. First, the revenues from selling daughters become a useful way of financing old age, which depresses savings and thus physical capital. Second, it increases fertility as men want many daughters. This results in higher population growth rates,

[br] Although, because of shorter life spans, perhaps not as prevalent as one might think. See Ruggles (1994) for an extensive historical account of changing household structures in the United States over the last 150 years.

[bs] Polyandry (women having multiple husbands) is extremely rare, but a few societies exist as well.

which depresses capital per person and thus GDP per capita. The paper uses a calibrated general equilibrium model to show that this effect is quantitatively important, and shows that the mechanism can account for a large part of the observed differences between polygynous and monogamous countries shown in Table 4.

Polygyny matters for growth through its effect on brideprices. Thus, the marriage market is essential for the mechanism. It is not the case that an individual polygynous couple would save less than a monogamous couple living in the same country. Rather, if a large fraction of households is polygynous, the equilibrium price of women is high, which changes incentives for all families. In other words, polygyny lowers output precisely because of the general equilibrium effects in the marriage market. We thus turn to the importance of marriage markets for growth in the next section.

A few papers attempt to understand why polygyny exists in some cultures and not in others. Gould et al. (2008) and Lagerlöf (2005) relate the disappearance of polygyny to economic development. Heterogeneity plays a key role in both papers. Gould, Moav, and Simhon argue that the increasing skill premium has led men to want fewer, higher quality children. To educate their children, they accordingly demand higher quality wives, but fewer of them, which naturally leads to fewer wives per men. Lagerlöf relates the disappearance of polygyny to the decline in male inequality over time. Primitive societies are arguably more unequal, which allows wealthy men to marry more wives and have more children. Over time, this dilutes their wealth, making societies more equal, which eventually leads to a more equal distribution of wives across men. In both papers, the decline in polygyny goes hand in hand with fertility decline and economic growth. Both papers explain the decline in polygyny prevalence, but are silent on the introduction of formal restrictions.

Two recent papers analyze the political economy of the introduction of monogamy. Lagerlöf (2010) proposes a theory related to inequality of wives across men. When polygyny is allowed, the elites have many wives, while poor men have none. This may lead to revolutions and thus creates an incentive for the elites to impose a formal ban on polygyny. de la Croix and Mariani (2015) provide a comprehensive political economy analysis of the switch from polygyny to monogamy and then to serial monogamy. The theory is based on the voting behavior of the entire population (including women), rather than the incentives of the elites. The transition between regimes is endogenously generated by human capital accumulation that changes the coalitions that stand to gain from a change in the marriage regime.

3.9 The Marriage Market

While there is a substantial literature on marriage choices within family economics, incorporating a marriage market into macroeconomic models is no trivial undertaking. One approach was proposed by Tertilt (2005), who models a competitive market for brides featuring an equilibrium brideprice that clears the market. However, such a formulation works only if there is no heterogeneity; if potential spouses vary in "quality," it matters who marries whom.

A number of recent contributions analyze marriage formation with heterogeneous agents within macro models. This allows the analysis of questions such as the impact of changes in the assortativeness of mating on income inequality. An early example is Fernández et al. (2005).[bt] The paper investigates the relationship between inequality, assortative mating, human capital accumulation, and per capita GDP. Mating is modeled through a search model with random matching. The model also features an intergenerational transmission mechanism, because parental income is used as collateral that children need when investing in education. One main finding is that such a model can generate multiple steady states that differ in wage inequality. Across steady states, marital sorting and wage inequality are positively related, while marital sorting and GDP per capita are negatively related.

Eika et al. (2014) document empirically the importance of assortative mating for income inequality in the United States. While assortative mating is found to be an important determinant of inequality, the study finds that changes in inequality cannot be attributed to changes in sorting patterns. Greenwood et al. (2016a) analyze such a link in a structural quantitative model.

Beyond these few contributions, the importance of marriage for growth is largely unexplored. In part, this may be due to the computational complexity of models that feature sorting with heterogeneous agents. However, with recent advances in computational power allowing increasingly complex models to be analyzed, we expect this to be an active research area in the near future.

4. THE FAMILY AND THE POLITICAL ECONOMY OF INSTITUTIONAL CHANGE

Long-run economic development is characterized not just by economic transformations but also by a set of striking regularities in terms of political change. During the development process, almost all of today's rich countries went through a series of similar policy reforms: for instance, democracy spread, public education systems were built, and public pension systems were introduced. The only exception to this pattern are countries that are rich primarily because of endowments with natural resources such as oil. Among countries who owe their wealth to the productivity of their citizens, these political transformations are a universal characteristic of the development process.

The tight link between economic and political transformations raises the question of how the causality runs between the two realms. Does economic growth trigger political

[bt] Fernández and Rogerson (2001), Choo and Siow (2006), and Greenwood et al. (2014, 2016a) also analyze the relationship between marital sorting and income inequality, but do not consider broader macroeconomic implications.

change, or is political change a precondition for growth? Can today's poor countries, many of which have implemented only a subset of the political reforms that characterize rich countries, foster faster economic development by adopting rich-country political institutions and reforms?

In this section, we argue that in answering such questions the family once again plays a central role. Many of the political reforms that go along with development are directly about the family (such as the introduction of child labor laws and the expansion of women's rights). In other cases (such as education and pension reforms), the political changes concern areas that originally were organized within families but in which, over time, the state played an increasing role. We provide a brief overview of the facts of political change during the development process. We then discuss some of the political economy literature analyzing the causes and consequences of political change, arguing that in many cases changes in family life were driving reform. We illustrate the role of the family by zooming in on two specific reforms—the expansion of women's rights and the introduction of child labor laws.

4.1 Political Economy Facts

The main political transformations that go along with the development process are the introduction of democracy, public and compulsory schooling, and child labor regulation; the gradual expansion of women's rights; and more generally the creation of large welfare states that raise a significant fraction of GDP in tax revenue to provide welfare benefits and old-age pensions. Before the onset of modern economic growth (say, in 1750), no country in the world had any of these institutions. Most poor countries today have some but not all of these features.

There is considerable variation across countries in the timing of reforms. For some countries, the first transformation was the introduction of democracy, starting with the founding of the United States in 1776 and then followed by a series of franchise extensions in Britain. Other countries adopted other reforms first and achieved democracy later. Some European countries democratized after World War I, and others had to wait until after the fall of the Iron Curtain in the early 1990s. In some countries (such as South Korea and Taiwan), democracy was introduced only after most other political reforms had been implemented and after rapid economic growth had been achieved.

Initially, democracy generally meant that men, but not women, obtained the right to vote and run for office. In the United States, the first state to give women the right to vote was Wyoming in 1869, and most other states had followed by World War I.[bu] At the federal level, universal suffrage was introduced with the Nineteenth Amendment in

[bu] See Doepke et al. (2012) for a detailed timeline of the introduction of women's rights in the United States.

1920. In many European countries women were able to vote after World War I, but once again there is a lot of variation across countries. For example, in Switzerland women received the right to vote in federal elections only in 1972, and the last canton to allow women to vote was Appenzell Innerrhoden in 1990.[bv]

Compared to the spread of political rights, the timing of education reforms is more uniform across countries. In the United States, Canada, and the industrializing Western European countries, public and compulsory education was widely introduced in the late 19th and early 20th centuries. In many cases, these reforms went along with significant restrictions of child labor.

The first country to introduce a public pension system was Germany in 1891. Mandatory health and accident insurance for workers were introduced around the same time. Most other European countries, Canada, and the United States had followed these steps before the middle of the 20th century. The first unemployment benefit scheme was introduced in the United Kingdom with the National Insurance Act 1911. In the midst of the Great Depression, the US Congress passed the Social Security Act, which contained provisions for old age insurance, welfare, and unemployment insurance. Most European countries and Canada introduced similar provisions during the first half of the 20th century.

The timing of political reforms that affected families most directly (in particular the regulation of child labor, the public provision of education, and the spread of women's rights) is closely associated with a major transformation of families themselves. As discussed in Section 3, as countries transition from a preindustrial society to modern growth, they universally undergo a demographic transition from high to low fertility. In North America and Western Europe, the main phase of fertility decline took place between the middle of the 19th century and World War I. Access to primary education became near-universal during the same period. Given that formal schooling moved children from the family home (where many had been working from a young age) to schools, the rise of mass education implied a transformation of family life on its own.

4.2 The Family as a Driver of Political Change

To understand the political economy of reforms, one needs to understand who the winners and losers of a reform are. Political reforms happen if there is a constituency that stands to gain from the reform, and if this constituency has sufficient political power to implement the desired policy. The trigger for a reform can either be a change in how a policy affects specific groups, or an increase in the political power of a group that

[bv] In fact, the last canton to voluntarily introduce the right to vote for women was Appenzell Aussenrhoden in 1989. In Appenzell Innerrhoden women's suffrage was mandated by a Supreme Court decision in 1990.

stands to gain from a reform. One might expect that democratization, which increased the political power of broad parts of the population at the expense of established elites, should be a major engine for political change. While there are examples of democratization triggering reform, the introduction of the major reforms associated with economic development described above is not closely correlated with expansions in political rights. We therefore focus on mechanisms that change who gains and who loses from reforms, and take as given that the relevant groups have sufficient political power to be heard.[bw]

We argue that for most of the major political reforms associated with economic development, the reorganization of families is a key reason for why political incentives changed. Technological and structural change affects fertility choices, education choices, and the division of labor in the family, all of which determine how people are affected by reforms. For example, reforms such as mandatory schooling laws and public pensions move responsibilities from the family to the public sphere and affect the relationship between parents and children. How people feel about such changes will depend in part on how many children they have, on whether they plan to educate their children, and on whether they anticipate living with their children in old age. Other reforms—such as the expansion of women's rights—affect the interaction between spouses. How people are affected by such reforms depend in part on the division of labor in the household and on women's labor force participation, both of which vary with development.

Consider the introduction of public schooling systems. Before public schooling, most children were working with their parents from a young age. Hence, the spread of public and compulsory education implied a major change of parent-child relations. Galor and Moav (2006) provide a theory that explains the public provision of education as a consequence of the rising importance of human capital in the economy. They consider a model economy populated by capitalists and workers. The model features heterogeneity in wealth, and initially only capitalists are accumulating capital through bequests to their children. However, the model features complementary between physical and human capital, and as the stock of physical capital rises, over time the capitalists stand to gain from higher education among the workers. Ultimately, both workers and capitalists support a tax on capitalists to support public education. The accumulation of physical and human capital within families is central to this mechanism. The public provision of schooling was often followed by mandatory schooling laws. Such laws affect the family even more directly by forcing parents to send their children to school. A closely related policy is a child labor ban, which we will analyze in Section 4.4.

In the case of schooling and child labor bans, who is a winner and who is a loser from reform depends on people's factor endowments (physical capital and human capital) and

[bw] Key contributions examining the causes of expansions of political rights include Acemoglu and Robinson (2000) and Lizzeri and Persico (2004).

also on fertility. Thus, potential conflicts arise between capitalists and skilled workers on the one hand, and unskilled workers with large families and no desire to educate their children on the other hand. For other types of reforms, gender and marital status are the dividing lines. This point is emphasized in Edlund and Pande (2002), who analyze the importance of women as voters. The paper shows that the political gender gap in the United States—women are more likely to vote Democrat than men—is a relatively recent phenomenon. Up until the mid-1960s, women voted more conservative than men on average. The paper argues that the change in political preferences (which in turn may have impacted other reforms) was due to a specific change in the family, namely the increase in divorce. A large increase in divorce rates during the 1960s and 1970s (see Fig. 6) increased the fraction of relatively poor single women. These women tend to benefit from redistribution, which is typically favored by Democrats. The paper provides evidence in support of the hypothesis by showing that marriage tends to make a woman more Republican, while divorce tends to make her more Democrat.

There are also a few papers that emphasize the importance of women as policymakers. Chattopadhyay and Duflo (2004) use gender quotas in India to empirically analyze which public projects are implemented at the village level depending on the gender of the leader. While the paper is not specifically about reforms, it shows that the gender of the leader affects the types of public goods that are provided. A related point is made by Washington (2008) and Oswald and Powdthavee (2010), who show that the gender composition of children affects the voting behavior of (male) legislators in both the United States and the United Kingdom: having more daughters makes politicians take more liberal positions.

Another important reform is the introduction of public pension systems.[bx] Social security programs transfer resources from young and middle-aged workers to the elderly. Without public systems, such transfers typically happen within the family, with altruistic children voluntarily taking care of elderly parents. Because of the dramatic fertility decline during the 19th century (see Fig. 1), more people ended up without children caring for them during old age, increasing the risk of poverty. This fact probably played an important role in the introduction of public pension systems. At the same time, the existence of such systems further decreases the incentive to have children, which leads to a two-way interaction between the structure of the family and political reforms.

Finally, a large class of reforms affected the legal position of women. These include reforms affecting ownership rights of women (such as the Married Women's Property Act of 1870 in England), reforms affecting child custody laws, the introduction of suffrage for women, and laws banning labor market discrimination and removing occupational

[bx] There is a large literature on social security systems (see, for example, Cooley and Soares, 1996; Boldrin and Montes, 2005; Caucutt et al., 2013).

restrictions (such as allowing women to become judges and soldiers). Reforming the legal position of women also impacts the position of women in the household, eg, by changing their outside options. And conversely, changes in family structure (such as the decline in fertility and the increase in female labor force participation) affected the gains from such reforms. We will discuss the political economy of women's economic rights (such as married women's property rights) in Section 4.3. Other types of women's rights, such as suffrage or labor rights, imply different political economy trade-offs. While there is some empirical work on these other rights, there is a lack of work that formally analyzes the political economy of other types of rights for women.[by] We believe that this is an important issue to be addressed by future research.

4.3 Voting for Women's Rights

Throughout the course of development, all industrialized countries implemented reforms that changed the legal position of women. Doepke and Tertilt (2009) propose a mechanism that provides a causal link between women's rights and economic growth. The mechanism is based on women's role in nurturing children. In contrast, Geddes and Lueck (2002) argue that the initial expansion of women's rights was related to women's role in the labor market. Given that the main phase of expanding women's economic rights was in the 19th century, a time when female labor force participation was low, we argue that a mechanism related to a women's role in the family is more plausible.

We now illustrate the basic mechanism of Doepke and Tertilt (2009) in a simplified framework. The setup is similar to that in Section 3.4 with a modified utility function. We now assume that consumption is a private good, which allows for a stronger conflict of interest between husbands and wives. We also introduce grandchildren and assume that people derive utility from the human capital of children and grandchildren. This assumption introduces a conflict across generations: men want their grandchildren to have as much human capital as possible, but it is the next generation that makes the decision. Since the next generation also cares about their own consumption, fathers will not invest as much in their children's education as desired by the grandfathers. We will now show how this conflict across generations may induce men to vote for female empowerment.

Let the utility function of spouse of gender g be

$$\log(c_g) + \delta_g \log(H') + \delta_g^G \log(H'),$$

where δ_g is the weight spouse g attaches to the human capital of own children, while δ_g^G is the weight on grandchildren. As in Section 3.4, we assume that $\delta_f > \delta_m$.[bz] Given the private goods assumption, the budget constraint is

[by] See Duflo (2012) and Doepke et al. (2012) for two surveys.

[bz] While it may seem natural to assume the same for grandchildren, $\delta_f^G > \delta_m^G$, this assumption is not needed for the analysis.

$$c_m + c_f = A\ell H,$$

where ℓ is total working time of the couple. Assuming that each spouse has a time endowment of 1, the family time constraint is

$$\ell + 2e \leq 2,$$

where e is education time for each of two children.

We now consider two political regimes. In the first one—*patriarchy*—only men make decisions. In the second regime—*empowerment*—men and women make decisions jointly, ie, they solve a collective bargaining problem with equal weights. To find the equilibrium allocation under patriarchy, one can solve the following maximization problem:

$$\max_{\ell, e} \log(c_g) + \delta_g \log(H') + \delta_g^G \log(H')$$

subject to:

$$\ell + 2e \leq 2,$$

$$H' = (Be)^\theta,$$

$$c_m + c_f = A\ell H,$$

$$c_m, c_f \geq 0.$$

Note that $H'' = (Be')^\theta$, where e' is determined by the next generation and is taken as given by the grandparent. Given the technology, the choice of education for own children e will not affect H'', ie, there is no interdependence between the choices of different generations. Further, since a man does not derive utility from his wife's consumption, women's consumption will be zero, and hence male consumption equals production.[ca] The equilibrium allocation under patriarchy is:

$$e^P = \frac{\delta_m \theta}{1 + \delta_m \theta},$$

$$\ell^P = \frac{2}{1 + \delta_m \theta},$$

$$c_m^P = \frac{2AH}{1 + \delta_m \theta}.$$

[ca] This counterfactual result can be easily modified by introducing altruism, as we do in Doepke and Tertilt (2009).

In contrast, under empowerment, couples solve a joint maximization problem with equal bargaining weights. The objective function then is

$$\frac{1}{2}\log(c_m) + \frac{1}{2}\log(c_f) + \tilde{\delta}\log(H') + \tilde{\delta}^G\log(H''),$$

where $\tilde{\delta} = \frac{\delta_f + \delta_m}{2}$ and $\tilde{\delta}^G = \frac{\delta_f^G + \delta_m^G}{2}$. Given the objective function, women and men consume equal amounts, $c_f^E = c_m^E$. The optimal education and labor choices are:

$$e^E = \frac{\tilde{\delta}\theta}{1 + \tilde{\delta}\theta},$$

$$\ell^E = \frac{2}{1 + \tilde{\delta}\theta}.$$

Consumption is equalized and depends on the initial human capital:

$$c_m^E = c_f^E = \frac{AH}{1 + \tilde{\delta}\theta}.$$

We are interested in understanding under what conditions men prefer to live in a patriarchal world and when they prefer empowering women. We focus on men's preferences because women's economic rights were expanded long before women gained the right to vote. Hence, the expansion of women's right can be viewed as a voluntary sharing of power by men. To understand men's political preferences, we compare the indirect utility function of a man in both regimes starting from the same initial human capital. Denote the indirect utility functions by U^E and U^P. Plugging in the equilibrium allocations and simplifying, we see that $U^E > U^P$ if and only if:

$$(\delta_m + \delta_m^G)\theta\log\left(\frac{\tilde{\delta}}{\delta_m}\frac{1 + \delta_m\theta}{1 + \tilde{\delta}\theta}\right) > \log\left(\frac{2(1 + \tilde{\delta}\theta)}{1 + \delta_m\theta}\right). \tag{19}$$

From a man's perspective, there is a trade-off. Patriarchy implies strictly higher own consumption, since resources do not need to be shared with one's wife. On the other hand, from the grandfather's perspective, the son will underinvest in the education of the grandchild. Empowering women will lead the future daughter in law to have more bargaining power, and, given that women care more about children than men do ($\delta_f > \delta_m$), this will increase the education of the grandchildren.

We will now show how this trade-off changes with development. Assume that the human capital technology improves over time, ie, θ increases. When the returns to education are zero, ie, $\theta = 0$, men strictly prefer to live under patriarchy (this follows from

Eq. 19). The intuition is that with $\theta = 0$, there is no reason to educate children. With zero education, from a man's perspective empowering women imposes a cost in terms of lost consumption, but does not bring any benefits. However, as θ increases, the concern about the grandchildren's education becomes increasingly important. The next proposition shows that as long as the concern about grandchildren is above a threshold, when θ becomes large enough, the grandchild effect dominates and hence men gain from switching to the empowerment regime.

Proposition 5 *If the weight δ_m^G men attach to grandchildren is above a threshold (given in the proof), there is a threshold $\overline{\theta}$ such that men prefer empowerment if $\theta > \overline{\theta}$.*

Fig. 24 illustrates the result with a numerical example.[cb] The equilibrium education choice e increases with θ in both regimes. Initially, for low levels of θ, men prefer to live under patriarchy. However, as θ increases, patriarchy becomes too costly for men. By introducing women's empowerment, men gain because of the positive effect on grandchildren.

The result is in line with what was observed during the 19th century in both the United States and England. Primary education expanded rapidly at the same time when male legislators passed laws to grant property and other economic rights to married women. Fertility rates also decreased quickly and economic growth increased. These features can be incorporated by adding fertility choice and assuming that parental human capital is an input in children's human capital. In Doepke and Tertilt (2009), we analyze such an augmented model in a fully dynamic context. The main result of the model is also in line with cross-country data. Fig. 25 shows that the position

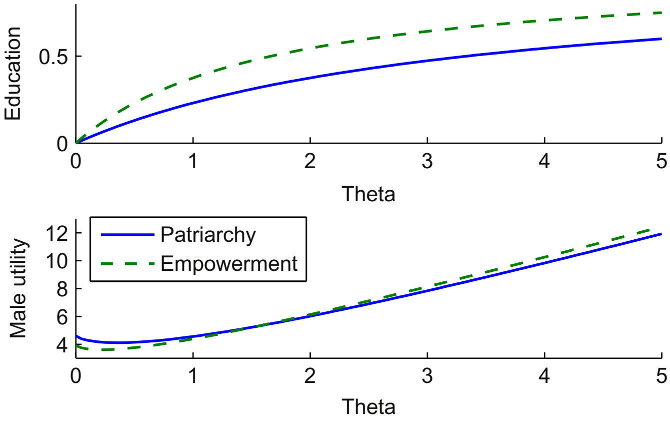

Fig. 24 Education and male utility as a function of θ, patriarchy vs empowerment.

[cb] The parameters used in the example are $\delta_m = 0.3, \delta_f = 0.9, \delta_m^G = 1.2, A = B = 5$. The initial level of human capital is set to $H_0 = 10$. The return to education θ varies between 0 and 5.

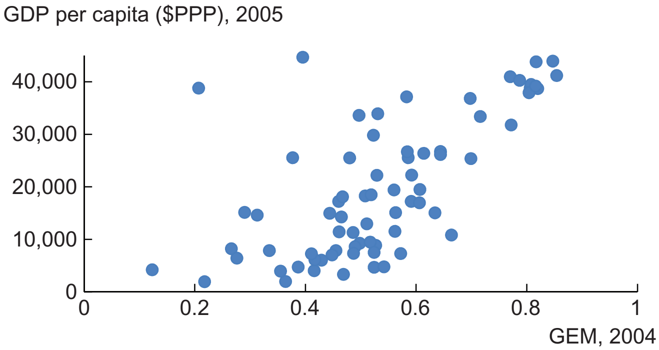

Fig. 25 Gender empowerment measure (GEM) and GDP per capita across countries. *GEM is an index constructed by the UN (Human Development Report, 2004), and GDP numbers are from the World Development Indicators.*

of women, as measured by the gender empowerment measure (GEM) constructed by the United Nations, is strongly positively correlated with GDP per capita. Assuming that returns to education differ systematically across countries, the model reproduces the same relationship.

A complementary theory is proposed by Fernández (2014). As in Doepke and Tertilt (2009), father's concern for their children is a central element. However, the key issue is not investment in education, but fathers preferring a more equal outcome between sons and daughters than what is produced under patriarchy. Economic growth widens disparities between sons and daughters in the patriarchy regime, which ultimately induces fathers to vote for empowerment. Fernández (2014) also provides empirical evidence based on the variation in extensions of women's economic rights across US states, showing that per capita wealth is positively associated with reform, whereas the association with fertility rates is negative (which is in line with the theories of both Doepke and Tertilt, 2009 and Fernández, 2014).

4.4 Voting for Children's Rights

Another near-universal policy reform associated with long-run development is the restriction of child labor. In preindustrial societies, child labor was the norm. In Western Europe and the United States, concern about child labor increased with industrialization, and ultimately industrializing countries introduced a variety of child labor restrictions such as minimum age laws and laws against working in hazardous occupations. A closely related policy reform that often coincided with child labor legislation is the introduction of compulsory schooling. This policy is usually the most effective constraint on child labor (in part because enforcement is straightforward). The close link between child labor and schooling is also part of the reason why child labor reforms matter for growth, as rising educational attainment is one engine of long-run development.

Whereas child labor bans are now in place in all industrial countries, in many developing countries child labor continues to be widespread. Child labor is especially common among poorer families who depend on the additional income. In these countries, public support for introducing restrictions is low.

What explains the passing of child labor reform in some countries, and persistent failure to do so in others? These questions are addressed in Doepke and Zilibotti (2005a), who present an analysis of the political economy of child labor legislation within a dynamic framework that endogenizes skill premia as well as fertility and education decisions.[cc] Here we use a simpler, static framework to highlight the main trade-offs. To understand the political support for and opposition to child labor laws, it is necessary to identify which groups stand to gain or lose from the introduction of regulation. Doepke and Zilibotti argue that the group that stands to gain most from banning child labor consists of unskilled adult workers. To the extent that these workers compete with children in the labor market, by banning child labor they can reduce competition and potentially raise their own wages.[cd] However, the situation is complicated by the fact that the same workers may also have working children themselves, so that the potential wage gains have to be traded off against the loss of child-labor income. A family's fertility and education choices therefore also matter.

To analyze these trade-offs more formally, consider an economy with N_S skilled and N_U unskilled workers. We start under the assumption that each worker has n children, but that only the children of the unskilled workers are working. This is consistent with the observation that child labor is generally more prevalent among poorer families, whereas richer, more highly educated families tend to send their children to school rather than to work. The production technology is:

$$Y = AX_S^{\alpha}X_U^{1-\alpha},$$

where X_S is skilled labor and X_U is unskilled labor. Each working child supplies λ units of unskilled labor, where $\lambda < 1$, reflecting that children are less productive than adult workers. If child labor is legal (the *laissez faire* policy), labor supply is given by:

$$X_S^{\text{laissez faire}} = N_S,$$

$$X_U^{\text{laissez faire}} = N_U + \lambda n N_U,$$

[cc] An analysis of the welfare implications of banning child labor is contained in Doepke and Krueger (2008).

[cd] The feedback from regulation to wages is also central to the seminal analysis of Basu and Van (1998), which focuses on the possibility of multiple equilibria.

and, under the assumption of competitive production, wages are given by:

$$w_S^{\text{laissez faire}} = A\alpha\left(\frac{(1+\lambda n)N_U}{N_S}\right)^{1-\alpha},$$

$$w_U^{\text{laissez faire}} = A(1-\alpha)\left(\frac{N_S}{(1+\lambda n)N_U}\right)^{\alpha}.$$

Workers seek to maximize their total income (ie, consumption). Adding adult and child-labor income, total family income for the two types of workers is given by:

$$I_S^{\text{laissez faire}} = w_S = A\alpha\left(\frac{(1+\lambda n)N_U}{N_S}\right)^{1-\alpha},$$

$$I_U^{\text{laissez faire}} = (1+\lambda n)w_U = (1+\lambda n)^{1-\alpha}A(1-\alpha)\left(\frac{N_S}{N_U}\right)^{\alpha}.$$

Let us now see who would gain or lose if child labor were to be banned. Under a child labor ban, no children are working, so that labor supply is simply $X_S^{\text{Ban}} = N_S$ and $X_U^{\text{Ban}} = N_U$, and wages are:

$$w_S^{\text{Ban}} = A\alpha\left(\frac{N_U}{N_S}\right)^{1-\alpha},$$

$$w_U^{\text{Ban}} = A(1-\alpha)\left(\frac{N_S}{N_U}\right)^{\alpha}.$$

The ratios of wages under the two policies are:

$$\frac{w_S^{\text{Ban}}}{w_S^{\text{laissez faire}}} = \left(\frac{1}{1+\lambda n}\right)^{1-\alpha} < 1,$$

$$\frac{w_U^{\text{Ban}}}{w_U^{\text{laissez faire}}} = (1+\lambda n)^{\alpha} > 1.$$

Thus, the skilled wage falls and the unskilled wage increases. This happens because child labor is a substitute for unskilled but a complement for skilled adult labor. The result suggests that unskilled workers may be in favor of banning child labor. However, this is no longer clear when we look at what happens to total family income:

$$I_S^{\text{Ban}} = w_S^{\text{Ban}} = A\alpha\left(\frac{N_U}{N_S}\right)^{1-\alpha},$$

$$I_U^{\text{Ban}} = w_U^{\text{Ban}} = A(1-\alpha)\left(\frac{N_S}{N_U}\right)^{\alpha}.$$

The income ratios are:

$$\frac{I_S^{\text{Ban}}}{I_S^{\text{laissez faire}}} = \left(\frac{1}{1+\lambda n}\right)^{1-\alpha} < 1,$$

$$\frac{I_U^{\text{Ban}}}{I_U^{\text{laissez faire}}} = \left(\frac{1}{1+\lambda n}\right)^{1-\alpha} < 1.$$

We see that, in fact, income falls for both groups, including the unskilled. The reason is that the unskilled workers' gain in terms of higher wages is more than offset by the loss of child labor income. Intuitively, the loss of child labor income is proportional to the total reduction in the supply of unskilled labor, whereas the increase in the unskilled wage is less than proportional to the decline in labor supply.

The analysis suggests that in a country where unskilled workers' children are working as well, public support for introducing child-labor restrictions should be low. The support for child labor restrictions should rise, however, if there is a group of unskilled workers whose children are not working (say, because they send their children to school). Assume that fraction s of unskilled workers send their children to school, while only fraction $(1 - s)$ has working children. The wages then become:

$$w_S^{\text{laissez faire}} = A\alpha\left(\frac{(1+\lambda(1-s)n)N_U}{N_S}\right)^{1-\alpha},$$

$$w_U^{\text{laissez faire}} = A(1-\alpha)\left(\frac{N_S}{(1+\lambda(1-s)n)N_U}\right)^{\alpha}$$

Income is now given by:

$$I_S^{\text{laissez faire}} = w_S = A\alpha\left(\frac{(1+\lambda(1-s)n)N_U}{N_S}\right)^{1-\alpha},$$

$$I_U^{\text{laissez faire}}(\text{working children}) = (1+\lambda n)w_U = (1+\lambda n)A(1-\alpha)\left(\frac{N_S}{(1+\lambda(1-s)n)N_U}\right)^{\alpha},$$

$$I_U^{\text{laissez faire}}(\text{children in school}) = w_U = A(1-\alpha)\left(\frac{N_S}{(1+\lambda(1-s)n)N_U}\right)^{\alpha}.$$

If child labor is now banned, incomes are:

$$I_S^{\text{Ban}} = w_S^{\text{Ban}} = A\alpha\left(\frac{N_U}{N_S}\right)^{1-\alpha},$$

$$I_U^{\text{Ban}}(\text{working children}) = I_U^{\text{Ban}}(\text{children in school}) = A(1-\alpha)\left(\frac{N_S}{N_U}\right)^{\alpha}.$$

Thus, for the unskilled workers with children in school, the introduction of a child labor ban unambiguously increases income. This result explains why child labor reform tends to happen in times when child labor is already declining for other reasons, such as an increased demand for human capital and a higher propensity among unskilled workers to send children to school. It is unskilled workers who do not depend on child labor themselves who should be the strongest advocates of reform.

Notice that the basic mechanism outlined so far is similar to our analysis of the political economy of women's rights in Section 4.3. First, technological change (not modeled explicitly here) increases the demand for human capital; next, the higher demand for human capital induces families to start educating their children; and finally, the families who now send their children to school become supporters of a child labor ban, triggering reform.

So far, we have focused on the case of a country in which child labor is initially legal. Our results show that as long as child labor is widespread among unskilled workers, support for introducing a child-labor ban will remain low. In cross-country data, we observe that differences in child-labor regulations are highly persistent over time, which suggests the existence of a status-quo bias. To examine whether such a bias can arise in our model, let us now consider the opposite situation of a country where a child labor ban is already in place. Are there any reasons why people might be more supportive of banning child labor if a child labor ban is already in place? As we will see, a status-quo bias can indeed arise in our theory, but only if fertility decisions are endogenous and depend on the current political regime.

We would like to find conditions under which the electorate would be willing to abandon an already existing child-labor ban. Consider first the case where fertility is independent of the policy, ie, every household continues to have n children as before. In this case, the trade-off that arises from abandoning an existing ban is exactly the reverse of the trade-off following from introducing a ban described above. In particular, if all unskilled households would actually send their children to work once the ban is abandoned, they would stand to gain from introducing child labor and abandoning the ban. In other words, the preferred policy is independent of the current policy, and a status-quo bias does not arise.

The situation is different, however, if the number of children depends on the current state of the law. It is a common observation that parents face a quantity–quality trade-off in their decisions on children: Parents who invest a lot in their children in terms of education tend to have fewer children than parents who send their children to work. We would therefore expect that once a child labor ban is in place (which effectively makes children more expensive), fertility would be lower. For concreteness, assume that fraction o of unskilled workers have already chosen their number of children under the assumption that the child-labor ban will stay in place, and that their fertility rate is $n^{\text{Ban}} < n$. The remaining families choose their family size later; in particular, if the ban is abandoned, they will optimally choose the larger fertility size n to maximize child labor income. What are now the relevant trade-offs? As above, in the presence of a ban, workers' incomes are $I_S^{\text{Ban}} = A\alpha(N_U/N_S)^{1-\alpha}$ and $I_U^{\text{Ban}} = A(1-\alpha)(N_S/N_U)^{\alpha}$, respectively. If the ban is now abandoned, income is:

$$I_S^{\text{laissez faire}} = A\alpha\left(\frac{(1+\lambda(on^{\text{Ban}}+(1-o)n))N_U}{N_S}\right)^{1-\alpha}$$

for the skilled,

$$I_U^{\text{laissez faire}}(\text{old}) = (1+\lambda n^{\text{Ban}})A(1-\alpha)\left(\frac{N_S}{(1+\lambda(on^{\text{Ban}}+(1-o)n))N_U}\right)^{\alpha}$$

for the "old" unskilled with small families, and:

$$I_U^{\text{laissez faire}}(\text{young}) = (1+\lambda n)A(1-\alpha)\left(\frac{N_S}{(1+\lambda(on^{\text{Ban}}+(1-o)n))N_U}\right)^{\alpha}$$

for the "young" unskilled with larger families. Comparing incomes, we can see that the old unskilled can now lose from the introduction of child labor. Their income ratio is:

$$\frac{I_U^{\text{laissez faire}}(\text{old})}{I_U^{\text{Ban}}(\text{old})} = \frac{1+\lambda n^{\text{Ban}}}{(1+\lambda(on^{\text{Ban}}+(1-o)n))^{\alpha}},$$

which is smaller than one if n^{Ban} is sufficiently small relative to n. These families made their low fertility choice under the assumption that child labor would not be an option. Given that they cannot change fertility ex-post, they have little to gain from making their own children work, but lose from the lower wages due to other families' children entering the labor force.

This mechanism induces policy persistence: Once a ban is in place, families start to make decisions that in the future increase political support for maintaining the ban. This mechanism can explain why differences in child labor and its regulations can be highly persistent across countries. In particular, the theory predicts that some countries can get locked into steady state equilibria featuring high fertility, high incidence of child labor, and little political support for the introduction of child labor regulation. In contrast, other countries with otherwise identical economic fundamentals have low fertility, no child labor, and widespread support for the ban of child labor.

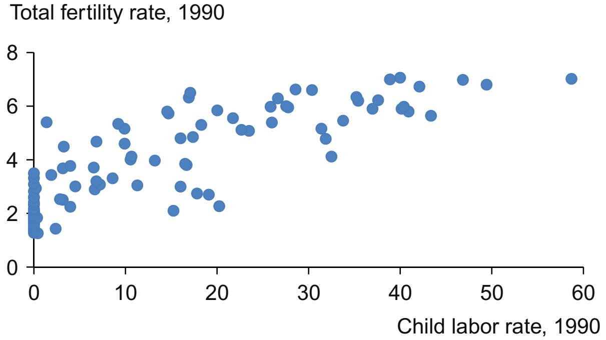

Fig. 26 The child labor rate (percentage of children aged 10–14 economically active) and total fertility rate across countries. *World Bank Development Indicators*.

Consistent with these predictions, we observe large cross-country differences in child labor rates, even among today's developing countries that are at similar levels of income per capita. The theory also predicts a positive correlation between fertility and child labor rates, even after controlling for other variables that might affect child labor or fertility. As Fig. 26 shows, there is a strong positive relationship between fertility rates and child labor rates across countries in contemporary data. Doepke and Zilibotti (2005a) examine the prediction more formally using an international panel of 125 countries from 1960 to 1990. They regress child labor rates on fertility rates, controlling for time dummies, GDP per capita, the Gini coefficient, and the share of agriculture in employment (arguably an independent factor affecting child labor) and find a positive and highly significant coefficient on the fertility rate, implying that a one standard deviation increase in fertility is associated with an increase in the child labor rate of 2.5 percentage points. The results are robust to the inclusion of country fixed effects.

The preceding analysis shows that the key feature of the political economy of child-labor regulation is that the group that most stands to gain from banning child labor (unskilled workers) is often simultaneously economically invested in child labor (because their own children are working). This observation leads to an explanation of why child labor was banned only after an increasing share of parents sent their children to school instead of work, and why differences in child labor and child-labor regulation across countries can be highly persistent over time. The analysis can also be used to help in designing policies that facilitate the passing of child labor regulations in developing countries today. Doepke and Zilibotti (2009, 2010) examine interventions such as international labor standards and trade restrictions aimed at reducing child labor from this perspective and argue that such well-intentioned policies can backfire and reduce the likelihood of comprehensive action of child labor within developing countries.

5. CONCLUSION

In this chapter, we have argued that accounting for the family should be an integral part of macroeconomics. The family is where many of the key decisions that are relevant for macroeconomics are made. Since families have been changing, with fewer marriages, more single households, lower fertility, and higher female labor supply, the answers to standard macroeconomic questions concerning, say, how labor supply and savings react to the business cycle have likely changed, too. Family structure also differs across countries. Developing countries are characterized by higher fertility, more traditional gender roles, often a son preference, and sometimes polygyny. These differences matter for the decisions that families make, and hence for the size and age structure of the population, for the accumulation of human and physical capital, and ultimately for the rate of economic growth.

The family matters not just for its role in household-level decisions but also through its effect on the evolution of institutions. Long-run economic development is characterized by a strikingly universal process of political change. Almost all of today's rich countries went through a series of similar reforms: democracy spread, public education systems were built, women and children gained rights, and public pension systems and the welfare state were introduced. We argue that many of these reforms transfer responsibility from the household to the public sphere, and that the ultimate triggers behind the reforms were often related to changes in the family.

There are additional ways in which the family matters for macroeconomics which we did not cover in this chapter. For example, the issues we discussed here are largely positive in nature. We touched only briefly on normative questions in a few places, for example, the discussion of the one child policy. We purposely did not talk about efficiency in this context, since this is not straightforward to do. The regular notion of Pareto efficiency is not defined in models where population size is endogenous, which includes all models with endogenous fertility. To evaluate policies that may affect fertility—such as education policies, child labor laws, policies banning abortion, or subsidies for single mothers—new concepts are required. Golosov et al. (2007) propose two new notions—$\mathcal{A}$- and $\mathcal{P}$-efficiency—and show how they can be used in standard fertility models. Schoonbroodt and Tertilt (2014) use the concepts to explore under what conditions fertility choice may be inefficiently low and hence pronatalist policies may be desired.

There is also a burgeoning literature on the role of the family for the transmission of preferences, cultural values, and attitudes, which can also feed back into macroeconomic outcomes. Theoretical models of the transmission of preferences and values in the family are developed by Bisin and Verdier (2001) and Doepke and Zilibotti (2005b, 2008). Empirical evidence for the intergenerational transmission of risk attitudes is provided by Dohmen et al. (2012). In Fernández et al. (2004), men's preferences for working vs stay-at-home wives are formed in childhood by the work behavior of their mothers. This leads to a dynamic process affecting female labor supply over time. Cultural transmission may also occur in society more generally. For example, in Fogli and Veldkamp (2011) and Fernández (2013), women learn from others about the costs of working. Both papers argue that a reduction in the perceived cost of working through this learning process is key to understanding the increase in female labor supply. The cultural transmission of fertility and female labor supply decisions is established empirically using data from second-generation immigrants to the United States by Fernández and Fogli (2006). Alesina and Giuliano (2010, 2014) argue that the strength of family ties varies across countries, and that these differences matter for cultural attitudes and macroeconomic outcomes. Alesina et al. (2013) take a historical perspective and trace unequal gender norms back to plough agriculture (and ultimately to soil type).[ce] Doepke and Zilibotti (2015) expand theories of preference transmission in the family to account for different parenting styles and link changes in parenting to macroeconomic trends such as increasing demand for human capital and increasing occupational differentiation in society.

Another important research area focuses on the importance of the family for understanding inequality. For example, de Nardi (2004) emphasizes the importance of bequest motives for the wealth distribution. Scholz and Seshadri (2009) build on this insight by investigating more generally the importance of children and fertility choice for the US wealth distribution. The interaction between parents and children is also analyzed for insights into the causes of intergenerational persistence of earnings.[cf] For example, parental inputs may amplify persistence if high-skill parents spend more resources and time on their children than low-skill parents. Other authors have emphasized the role of differences between women and men (and their interactions as couples) for understanding the distribution of earnings (and changes in earnings inequality over time). For example, Heathcote et al. (2010b) explicitly include male and female labor supply in their analysis of the US rising wage inequality. Other authors take this a step further and analyze how sorting and changes in sorting pattern have impacted inequality.[cg] Recent research also makes an explicit distinction between individual and household inequality.[ch] True consumption inequality may be lower than what is measured based on individual income data if the family plays a role in providing insurance (Blundell et al., 2008). Conversely, if family members do not provide full insurance

[ce] This hypothesis was first put forth by Boserup (1970), but had not been tested empirically until recently.

[cf] See, for example, Restuccia and Urrutia (2004), Lee and Seshadri (2015), and Yum (2015).

[cg] See, for example, Fernández and Rogerson (2001), Fernández et al. (2005), Choo and Siow (2006), and Greenwood et al. (2014, 2016a).

[ch] See Heathcote et al. (2010a).

to each other, true consumption inequality may be higher than what is measured based on household expenditure data (Lise and Seitz, 2011). Further, the mapping between individual and household inequality may change over time if the structure of the family is changing.

In our view, the intersection of family economics and macroeconomics offers many promising avenues for future research. Throughout this chapter, we have pointed out a number of particular questions that are in need of answers, and which could be addressed with the data, models, and methods available today. There is also a need to push out the frontier of theoretical modeling; in particular, we see a strong potential for intellectual arbitrage by applying methods of dynamic modeling that are common in macroeconomics to better understand the dynamics of household bargaining under commitment and private information frictions. Finally, there are promising applied topics that have barely been explored yet. For example, an important topic in recent macroeconomics concerns house price dynamics (see the chapter "Housing and macroeconomics" by Piazzesi and Schneider). Changes in family structure—such as the rise in single households—have a direct impact on housing demand. Further, singles are more eager to live in cities (where they can meet other singles) compared to families, who place higher value on space. Hence, changes in family formation and family structure should matter for the housing market. We hope that this and other research topics will be picked up by more researchers as family economics continues to become an integral part of macroeconomics.

APPENDICES

A Proofs for Propositions

Proof of Proposition 1 *As y_f approaches zero, the density $f(\eta_g) = F'(\eta_g)$ approaches zero, so that the elasticity of labor supply approaches zero also. In contrast, for married women, the fact that $w_m > 0$ guarantees that the elasticity of labor supply is bounded away from zero.* □

Proof of Proposition 2 *The first part follows from the fact that aggregate labor supply elasticity for single households equals one, whereas for married households, it is strictly smaller than one.*

For the second part, for any $w_f > 0$, we have $\hat{\eta}_u > \hat{\eta}_e$, which implies that the elasticity is smaller than one. As w_f converges to zero, $\hat{\eta}_e$ and $\hat{\eta}_u$ both converge to zero. Since $F(0) = 0$ and F is continuous, we then have that $F(\hat{\eta}_e)$ and $F(\hat{\eta}_u)$ both converge to zero, which implies that the elasticity of labor supply converges to one. Conversely, as w_f converges to infinity, $\hat{\eta}_e$ and $\hat{\eta}_u$ both converge to infinity, implying that $F(\hat{\eta}_e)$ and $F(\hat{\eta}_u)$ both converge to one and once again resulting in an elasticity of one. □

Proof of Proposition 3 *If $\widetilde{\lambda}_f \leq \lambda_f$ and $\widetilde{\lambda}_m \leq \lambda_m$, neither participation constraint (9) and (10) is binding. Hence, it is optimal to stay married, $D = 0$, and the consumption allocation follows from maximizing (7) subject to the budget constraint (8). If $\widetilde{\lambda}_f > \lambda_f$ and $\widetilde{\lambda}_f + \widetilde{\lambda}_m \leq 1$, the wife's* *participation constraint is binding. Staying married* ($D = 0$) *continues to be optimal, however, because it is possible to increase the wife's consumption share to make her indifferent between marriage and divorce, with the husband continuing to be better off married. The wife's consumption can then be solved from solving for* c_f *in her participation constraint (9) (imposed as an equality) while setting* $D = 0$. *The husband's consumption then follows from the budget constraint (8). The case where the husband's participation constraint is binding is parallel. Finally, when there is no allocation of ex-post bargaining power that keeps both spouses at least as well off married compared to being divorced, divorce* ($D = 1$) *is the optimal choice, and consumption follows from the individual budget constraints in the divorced state.* □

Proof of Proposition 4 *The ratio of the growth factors is*

$$\frac{1+g^{end}}{1+g^{exog}} = \left\{ \left(\frac{\alpha\delta_f + (1-\alpha)\delta_m}{\lambda_f\delta_f + (1-\lambda_f)\delta_m} \right) \left(\frac{\alpha + [\lambda_f\delta_f + (1-\lambda_f)\delta_m]\theta}{\alpha + [\alpha\delta_f + (1-\alpha)\delta_m]\theta} \right) \right\}^{\theta}.$$

Thus the result follows trivially, given the assumption $\delta_f > \delta_m$ *and* $\theta < 1$. □

Proof of Proposition 5 *Take the limit as* $\theta \to \infty$ *on both sides of Eq. (19) separately. The limit of the left-hand side can be written as:*

$$\lim_{\theta\to\infty} (\delta_m + \delta_m^G) \lim_{\theta\to\infty} \frac{\log\left(\frac{\tilde{\delta}}{\delta_m} \frac{1+\delta_m\theta}{1+\tilde{\delta}\theta} \right)}{\frac{1}{\theta}}.$$

Note that both numerator and denominator converge to zero. Applying L'Hopital's Rule, canceling terms and rearranging, the limit can be written as:

$$(\delta_m + \delta_m^G) \lim_{\theta\to\infty} \left(\frac{(\tilde{\delta} - \delta_m)}{\left(\frac{1}{\theta} + \tilde{\delta}\right)\left(\frac{1}{\theta} + \delta_m\right)} \right).$$

From this expression, we can see that the limit exits and is equal to:

$$(\delta_m + \delta_m^G) \left(\frac{\tilde{\delta} - \delta_m}{\tilde{\delta}\delta_m} \right).$$

The limit of the right hand side of (19) is $\log\left(\frac{2\tilde{\delta}}{\delta_m}\right)$. *Thus, in the limit* $U^E > U^P$ *if and only if* $(\delta_m + \delta_m^G)\left(\frac{\tilde{\delta} - \delta_m}{\tilde{\delta}\delta_m}\right) > \log\left(\frac{2\tilde{\delta}}{\delta_m}\right)$. *Using the definition of* $\tilde{\delta}$ *and rearranging, this can be expressed as:*

$$\delta_m^G > \log\left(\frac{\delta_f + \delta_m}{\delta_m}\right)\left(\frac{(\delta_f + \delta_m)\delta_m}{\delta_f - \delta_m}\right) - \delta_m.$$

Hence, as long as δ_m^G *is large enough, the equation is satisfied.* □

B Data Definitions and Sources

The data used in Table 3 are from two different editions of the OECD Gender, Institutions and Development Data Base (GID 2006 and 2014), the World Development Indicators (WDI 2003, 2005, and WDI 2014) and the United Nations Human Development Report 2004. Here we give the definition of each variable and its source.

GDP per capita: GDP data were used from two different years. The variables from GID 2014 and WDI 2014 were correlated with GDP p.c. from the WDI 2014. The variables from WDI 2003, UN 2004, and GID 2006 were correlated with GDP p.c. from the WDI 2005.

Share of agriculture: Measured as the value-added share of agriculture in GDP. Data were used from two different years. The variables from GID 2014 and WDI 2014 were correlated with percent agriculture from the WDI 2014. The variables from WDI 2003, UN 2004, and GID 2006 were correlated with percent agriculture from the WDI 2005.

Total fertility rate: Source: GID 2006.

Child mortality rate: Under-five mortality rate. Source: WDI 2014.

Average years of schooling: Source: WDI 2003.

Boy/girl sex ratio at birth: Measured as boys born per girl. Source: GID 2006.

Son preference in education: Percentage of people agreeing that university is more important for boys than for girls. GID 2014.

Inheritance discrimination against daughters: Whether daughters have the same inheritance rights as sons. Reported in three categories between 0 ("equal") and 1 ("unequal"). Source: GID 2014.

Female literacy relative to male: Female literacy as percentage of male literacy. Source: GID 2006.

Percent females in paid labor force: Percentage of women among wage and salaried workers. Source: GID 2006.

Unpaid care work by women: Female to male ratio of time devoted to unpaid care work. Source: GID 2014.

Year first woman in parliament: Source: Human Development Report 2004.

Women's access to land: Whether women and men have equal and secure access to land use, control and ownership. Categorical (three categories = 0, 0.5, 1), where 1 ("full") and 0 ("impossible"). Source: GID 2014.

Gender empowerment measure: Measures inequality between men's and women's opportunities, combining measures of inequality in political participation and decision making, in economic participation and decision making, and in power over economic resources. The level is between 1 ("full equality") and 0 ("no equality"). Source: UN 2004.

Early marriage: Share of female population between ages 15 and 19 ever married. GID 2014.

Agreement with wife beating: Percentage of women who agree that a husband/partner is justified in beating his wife/partner under certain circumstances. Source: GID 2014.

Inheritance discrimination against widows: Whether a widow has the same inheritance rights as a widower. Reported in three categories (0, 0.5, 1), where 0 means equal rights. Source: GID 2014.

Laws on domestic violence: Whether the legal framework offers women legal protection from domestic violence. Reported in five categories = 0, 0.25, 0.5, 0.75, 1, where 1 means no protection and 0 full protection. Source: GID 2014.

ACKNOWLEDGMENTS

We thank Stefania Albanesi, Raquel Fernández, Moshe Hazan, Claudia Olivetti, Víctor Ríos-Rull, John Taylor, Harald Uhlig, and Alessandra Voena for comments that helped to greatly improve the manuscript. Titan Alon, Florian Exler, Xue Zhang, Tim Hildebrand, Katarina Kuske, and Clara Schäper provided excellent research assistance. Financial support from the National Science Foundation (Grant SES-1260961) and the European Research Council (Grant SH1-313719) is gratefully acknowledged

Abstract

We discuss climate change and resource scarcity from the perspective of macroeconomic modeling and quantitative evaluation. Our focus is on climate change: we build a very simple “integrated assessment model,” ie, a model that integrates the global economy and the climate in a unified framework. Such a model has three key modules: the climate, the carbon cycle, and the economy. We provide a description of how to build tractable and yet realistic modules of the climate and the carbon cycle. The baseline economic model, then, is static but has a macroeconomic structure, ie, it has the standard features of modern macroeconomic analysis. Thus, it is quantitatively specified and can be calibrated to obtain an approximate social cost of carbon. The static model is then used to illustrate a number of points that have been made in the broad literature on climate change. Our chapter begins, however, with a short discussion of resource scarcity—also from the perspective of standard macroeconomic modeling—offering a dynamic framework of analysis and stating the key challenges. Our last section combines resource scarcity and the integrated assessment setup within a fully dynamic general equilibrium model with uncertainty. That model delivers positive and normative quantitative implications and can be viewed as a platform for macroeconomic analysis of climate change and sustainability issues more broadly.

1. INTRODUCTION

In this chapter we discuss climate change and resource scarcity from the perspective of macroeconomic modeling and quantitative evaluation. Our focus is to build toward an "integrated assessment model," (IAM) ie, a model that integrates the global economy and the climate in a unified framework. The chapter is not meant to be a survey of the rather broad field defined by interconnections between climate and economics. Rather, it has a sharp focus on the use of microeconomics-based macroeconomic models in this area, parameterized to match historical data and used for positive and normative work. Our understanding of the literature is that this approach, which is now standard macroeconomic in analyses (rather broadly defined), has not been dominant in the literature focused on developing IAMs, let alone anywhere else in the climate literature. We consider it a very promising approach also for climate-economy work, however, having contributed to it recently; in fact, the treatment we offer here is naturally built up around some of our own models and substantive contributions. Although there is a risk that this fact will be interpreted as undue marketing of our own work, it is rather that our climate-economy work from the very beginning made an effort precisely to formulate the IAM, and all the issues that can be discussed with an IAM, in terms of a standard macroeconomic settings and in such a way that calibration and model evaluation could be conducted with standard methods. Ex-post, then, one can say that our work grew out of an effort to write something akin to a climate-economy handbook for macroeconomists, even though the kind offer to write an actual such a chapter arrived much later. At this point, with this work, we are simply hopeful that macroeconomists with modern training will find our exposition useful as a quick introduction to a host of issues and perhaps also as inspiration for doing research on climate change and sustainability. We do find the area of great importance and, at the same time, rather undeveloped in many ways.

One exception to our claim that IAMs are not microeconomics-based macroeconomic models is Nordhaus's work, which started in the late 1970s and which led to the industry standards DICE and RIce: dynamic integrated models of climate and the economy, DICE depicting a one-region world and RICE a multiregion world. However, these models remain the nearest thing to the kind of setting we have in mind, and even the DICE and RICE models are closer to pure planning problems. That is, they do not fully specify market structures and, hence, do not allow a full analysis of typical policies such as a carbon tax or a quota system. Most of the models in the literature—to the extent they are fully specified models—are simply planning problems, so a question such as "What happens if we pursue a suboptimal policy?" cannot be addressed. This came as a surprise to us when we began to study the literature. Our subsequent research and the present chapter thus simply reflect this view: some more focus on the approach used in modern macroeconomics is a useful one.

So as a means of abstract introduction, consider a growth economy inhabited by a representative agent with utility function $\sum_{t=0}^{\infty}\beta^t u(C_t, S_t)$ with a resource constraint $C_t + K_{t+1} = (1-\delta)K_t + F(K_t,\ E_t,\ S_t)$ and with a law of motion $S_{t+1} = H(S_t,\ E_t)$. The new variables, relative to a standard macroeconomic setting, are S and E. S, a stock, represents something that is affects utility directly and/or affects production, whereas E, a flow, represents an activity that influences the stock. To a social planner, this would be nothing but an augmented growth model, with (interrelated) Euler equations both for K and S. In fact, standard models of human capital accumulation map into this setup, with H increasing in both arguments and F increasing in S but decreasing in E.[a] However, here we are interested in issues relating to environmental management—from a macroeconomic perspective—and then the same setup can be thought of, at least in abstract, with different labels: we could identify S with, say, clean air or biodiversity, and E with an activity that raises output but lowers the stock S. Our main interest will be in the connections between the economy and the climate. Then, S_t can be thought of as the climate at t, or a key variable that influences it, namely, the stock of carbon in the atmosphere; and E_t would be emissions of carbon dioxide caused by the use of fossil fuel in production. The carbon stock S then hurts both utility (perhaps because a warmer climate makes people suffer more in various ways) and output. Thus, $u_2 < 0$, $F_2 > 0$, $F_3 < 0$, $H_1 > 0$, and $H_2 > 0$. The setting still does not appear fully adequate for looking at the climate issue, because there ought to be another stock: that of the available amounts of fossil fuel (oil, coal, and natural gas), which are depletable resources in finite supply. Indeed, many of our settings below do include such stocks, but as we will argue even the setting without an additional stock is quite useful for analyzing the climate issue.

[a] See, eg, Lucas, 1988.

Furthermore, one would also think that technology, and technological change of different sorts, must play a role, and indeed we agree. Technology can enhance the production possibilities in a neutral manner but also amount to specific forms of innovation aimed at developing nonfossil energy sources or more generally saving on fossil-based energy. We will discuss these issues in the chapter too, including endogenous technology, but the exposition covers a lot of ground and therefore only devotes limited attention to technology endogeneity.

Now so far the abstract setting just described simply describes preferences and technology. So how would markets handle the evolution of the two stocks K and S? The key approach here is that it is reasonable to assume, in the climate case, that the evolution of S is simply a byproduct of economic activity: an externality. Thus, tracing out the difference between an optimal path for K and S and a laissez-faire market path becomes important, as does thinking about what policies could be used to move the market outcome toward the optimum as well as what intermediate cases would imply. Thus, the modern macroeconomist approach would be to (i) define a dynamic competitive equilibrium with policy (say, a unit tax on E), with firms, consumers, and markets clearly spelled out, then (ii) look for insights about optimal policy both qualitatively and quantitatively (based on, say, calibration), and perhaps (iii) characterize outcomes for the future for different (optimal and suboptimal) policy scenarios. This is the overall approach we will follow here.

We proceed in three steps. In the first step, contained in Section 2, we discuss a setting with resource scarcity alone—such as an economy with a limited amount of oil. How will markets then price the resource, and how will it be used up over time? Thus, in this section we touch on the broader area of "sustainability," whereby the question is how the economy manages a set of depletable resources. It appears to be a common view in the public debate that markets do not carry this task out properly, and our view is that it really is an open question whether they do or not; indeed, we find this issue intriguing in itself, quite aside from any interest in the specific area of climate change. The basic market mechanisms we go through involve the Hotelling rule for pricing and then, coupled with a representative agent with preferences defined over time as in our abstract setting above and a specific demand for the resource (say, from its use in production), a dynamic path for resource use. As a preliminary exploration into whether our market-based analysis works, one can compare the models implications for prices and quantities and we briefly do. As a rough summary, it is far from clear that Hotelling-based pricing can explain our past data for depletable resources (like fossil fuel or metals). Similarly, it is challenging to account for the historical patterns of resource use, though here the predictions of the theory are arguably less sharp. Taken together, this suggests that it is not obvious that at least our benchmark theories of markets match the data, so it seems fruitful to at least consider alternatives. In Section 2 we also look at the case of fossil fuel in more detail and, in this context, look at (endogenous) technical change: we look at how markets could potentially react to resource scarcity by saving on the scarce resource instead of saving on other inputs. Thus, we apply the notion of "directed technical change" in this context and propose it as an interesting avenue for conducting further macroeconomic research within the area of sustainability more broadly. Finally, Section 2 should be viewed as a delivering a building block for the IAMs to be discussed later in the chapter, in particular that in Section 5.

In Section 4, we take our second step and develop a very simple, static integrated assessment model of climate change and the global economy. Despite its being simple and stylized, this baseline model does have a macroeconomic structure, ie, it makes assumptions that are standard in modern macroeconomic analysis. Many of its key parameters are therefore straightforwardly calibrated to observables and thus, with the additional calibration necessary to introduce climate into the model, it can be used to obtain an approximate social cost of carbon. The static model is then used to illustrate a number of points that have been made in broad literature on climate change. None of these applications do full justice to the literature, of course, since our main purpose is to introduce the macroeconomic analyst to it. At the same time, we do offer a setting that is quantitatively oriented and one can imagine embedding each application in a fully dynamic and calibrated model; in fact, as far as we are aware, only a (minority) subset of these applications exist as full quantitative studies in the literature.

In our last section, Section 5, which is also the third and final step of the chapter, we describe a fully dynamic, stochastic IAM setting. With it, we show how to derive a robust formula for the (optimal) marginal cost of carbon and, hence, the appropriate Pigou tax. We show how to assign parameter values and compute the size of the optimal tax. The model can also be used as a complete setting for predicting the climate in the future—along with the paths for consumption, output, etc.—for different policy paths. We conclude that although the optimal-tax formula is quite robust, the positive side of the model involves rather strong sensitivity to some parameters, such as those involving different sources for energy generation and, of course, the total sizes of the stocks of fossil fuels.

Before transiting from discussing sustainability in Section 2 to climate modeling in Section 4, we offer a rather comprehensive introduction to the natural-science aspects of climate change. Section 3 is important for explaining what we perceive as the basic and (among expert natural scientists) broadly agreed upon mechanisms behind global warming: how the climate is influenced by the carbon concentration in the atmosphere (the climate model) and how the carbon concentration evolves over time as a function of the time path for emissions (the model of the carbon cycle). This presentation thus offers two "modules" that are crucial elements in IAMs. These modules are extremely simplified versions of what actual climate models and carbon-cycle models in use look like. However, they are, we argue, decent approximations of up-to-date models. The reason why simplifications are necessary is that our economic models have forward-looking agents and it is well known that such models are much more difficult to analyze, given any complexity in the laws of motions of stocks given flows: they involve finding dynamic fixed points, unlike any natural-science model where particles behave mechanically.[b]

Finally, although it should be clear already, let us reiterate that this chapter fails to discuss many environmental issues that are of general as well as macroeconomic interest. For example, the section on sustainability does not discuss, either empirically or theoretically, the possible existence of a "pollution Kuznets curve": the notion that over the course of economic development, pollution (of some or all forms) first increases and then decreases.[c] That section also does not offer any theoretical discussion of other common-pool problems than that associated with our climate (such as overfishing or pollution). The sections on IAMs, moreover, does not contain a listing/discussion of the different such models in the literature; such a treatment would require a full survey in itself.

2. LIMITED NATURAL RESOURCES AND SUSTAINABILITY CONCERNS

Climate change is a leading example within environmental economics where global macroeconomic analysis is called for. It involves a global externality that arises from the release of carbon dioxide into the atmosphere. This release is a byproduct of our economies' burning of fossil fuel, and it increases the carbon dioxide concentration worldwide and thus causes warming not just where the emission occurs. In two ways, climate change makes contact with the broader area of *sustainability*: it involves two stocks that are important for humans and that are affected by human activity. The first stock is the carbon concentration in the atmosphere. It exerts an influence on the global climate; to the extent warming causes damages on net, it is a stock whose size negatively impacts human welfare. The second stock is that of fossil fuels, ie, coal, oil, and natural gas. These stocks are not harmful per se but thus can be to the extent they are burnt.

More generally, sustainability concerns can be thought of in terms of the existence of stocks in finite supply with two properties: (i) their size is affected by economic activity and (ii) they influence human welfare.[d] Obvious stocks are natural resources in finite supply, and these are often traded in markets. Other stocks are "commons," such as air quality, the atmosphere, oceans, ecosystems, and biodiversity. Furthermore, recently, the term "planetary boundaries" has appeared (Rockström et al., 2009). These boundaries represent other limits that may be exceeded with sufficient economic growth (and therefore, according to the authors, growth should be limited). This specific *Nature* article lists

[b] The statement about the complexity of economic models does not rely on fully rational expectations, which we do assume here, but at least on some amount of forward-looking because any forward-looking will involve a dynamic fixed-point problem.

[c] See, eg, Grossman and Krueger, 1991 and Stokey, 1998.

[d] Relatedly, but less relevant from the perspective taken in this section, there is theoretical work on sustainability, defining, based on a utility-function representation, what the term means: roughly, an allocation is sustainable if the indirect utility function of generation t is not be below that of generation $t-k$.

nine boundaries, among them climate change; the remaining items are (i) stratospheric ozone depletion, (ii) loss of biosphere integrity (biodiversity loss and extinctions), (iii) chemical pollution and the release of novel entities, (iv) ocean acidification, (v) freshwater consumption and the global hydrological cycle, (vi) land system change, (vii) nitrogen and phosphorus flows to the biosphere and oceans, and (viii) atmospheric aerosol loading. Thus, these are other examples of commons.

Aside from in the work on climate change, the macroeconomic literature has had relatively little to say on the effects and management of global stocks. The Club of Rome (that started in the late 1960s) was concerned with population growth and a lack of food and energy. The oil crisis in the 1970s prompted a discussion about the finiteness of oil (see, eg, the 1974 *Review of Economic Studies* issue on this topic), but new discoveries and a rather large fall in the oil price in the 1980s appeared to have eliminated the concern about oil among macroeconomists. Similarly, technology advances in agriculture seemed to make limited food supply less of an issue. Nordhaus (1973, 1974) discussed a limited number of metals in finite supply, along with their prices, and concluded that the available stocks were so large at that point that there was no cause for alarm in the near to medium-run future. Thus, the concerns of these decades did not have a long-lasting impact on macroeconomics. Perhaps relatedly, so-called green accounting, where the idea is to measure the relevant stocks and count their increases or decreases as part of an extended notion of national economic product, was proposed but has been implemented and used in relatively few countries.[e] Limited resources and sustainability are typically not even mentioned in introductory or intermediate undergraduate textbooks in macroeconomics, let alone in PhD texts. In PhD texts specifically on growth, there is also very little: Aghion and Howitt's (2008) growth book has a very short, theoretical chapter on the subject, Jones (2001) has a chapter in his growth book which mentions some data; Acemoglu's (2009) growth book has nothing.[f]

The purpose here is not to review the literature but to point to this broad area as one of at least potential relevance and as one where we think that more macroeconomic research could be productive. To this end, we will discuss the basic theory and its confrontation with data. This discussion will lay bare some challenges and illustrate the need for more work.

We will focus on finite resources that are traded in markets and hence abstract from commons, mainly because these have not been subject to much economic macroeconomic analysis (with the exception of the atmosphere and climate change, which we will

[e] For example, in the United States, the BEA started such an endeavor in the 1990s but it was discontinued.

[f] The area of *ecological economics* is arguably further removed from standard economic analysis and certainly from macroeconomics. It is concerned precisely with limited resources but appears, at least in some of its versions, to have close connections Marx's labor theory of value, but with "labor" replaced by "limited resources" more broadly and, in specific cases, "energy" or "fossil fuel".

discuss in detail later). Thus, our discussion begins with price formation and quantity determination in markets for finite resources and then moves on to briefly discuss endogenous technological change in the form of resource saving.

2.1 Prices and Quantities in Markets for Finite Resources

To begin with, let us consider the simplest of all cases: a resource e in finite supply R that is costless to extract and that has economic value. Let us suppose the economic value is given by an inverse demand function $p_t = D(e_t)$, which we assume is time-invariant and negatively sloped. In a macroeconomic context we can derive such a function assuming, say, that e is an input into production. Abstracting from capital formation, suppose $y_t = F(n_t, e_t) = An_t^{1-\nu}e_t^{\nu}$, with inelastic labor supply $n_t = 1$, that $c_t = y_t$, and that utility is $\sum_{t=0}^{\infty}\beta^t \log c_t$.[g] Let time be $t = 0, \ldots, T$, with T possibly infinite. Here, the demand function would be derived from the firm's input decision: $p_t = \nu A e_t^{\nu-1}$.

2.1.1 The Hotelling Result: The Price Equation in a Baseline Case

The key notion now is that the resource can be saved. We assume initially that extraction/use of the resource is costless. The decision to save is therefore a dynamic one: should the resource be sold today or in the future? For a comparison, an interest rate is needed, so let r_t denote the interest rate between $t-1$ and t. If the resource is sold in two consecutive periods, it would then have to be that on the margin, the owner of the resource is indifferent between selling at t and at $t+1$:

$$p_t = \frac{1}{1+r_{t+1}} p_{t+1}.$$

This is the *Hotelling equation*, presented in Hotelling (1931). The price of the finite resource, thus, grows at the real rate of interest. The equation can also be turned around, using the inverse demand function, to deliver predictions for how the quantity sold will develop; for now, however, let us focus on the price. Thus, we notice that an arbitrage condition delivers a sharp prediction for the dynamics of the price that is independent of the demand. For the *price dynamics*, the demand is only relevant to the extent it may be such that the resource is not demanded at all at some point in time. For the *price level(s)*, however, demand is of course key: one needs to solve the difference equation along with the inverse demand function and the constraint on the resource to arrive at a value for p_0 (and, consequently, all its subsequent values). Here, p_t would be denoted the *Hotelling rent* accruing to the owner: as it is costless to extract it, the price is a pure rent. Thus, to the extent the demand is higher, the price/rent path will be at a higher level. Similarly, if there is more of the resource, the price/rent path will be lower, since more will be used at each point in time.

[g] In all of this section, we use logarithmic utility. More general CRRA preferences would only slightly change the analysis and all the key insights remain the same in this more general case.

2.1.2 Prices and Quantities in Equilibrium: Using a Planning Problem

Let us consider the planning problem implicit in the earlier discussion and let us for simplicity assume that $T=\infty$. Thus the planner would maximize $\nu\sum_{t=0}^{T}\beta^t \log c_t$ subject to $c_t = Ae_t^{\nu}$ for all t and $\sum_{t=0}^{T} e_t = R$.[h] This delivers the condition $\nu\beta^t/e_t = \mu$, where μ is the multiplier on the resource constraint, and hence $e_{t+1} = \beta e_t$. Inserting this into the resource constraint, one obtains $e_0(1+\beta+\ldots) = e_0/(1-\beta) = R$. Hence, $e_0 = (1-\beta)R$ and the initial price of the resource in terms of consumption (which can be derived from the decentralization) will be $p_0 = A\nu((1-\beta)R)^{\nu-1}$. Furthermore, $p_t = A\nu((1-\beta)R)^{\nu-1}\beta^{(\nu-1)t}$; notice that the gross interest rate here is constant over time and equal to $\beta^{\nu-1}$.[i] We see that a more abundant resource translates into a lower price/rent. In particular, as R goes to infinity, the price approaches 0: marginal cost. Similarly, higher demand (eg, through a higher A or higher weight on future consumption, β, so that the resource is demanded in more periods and will thus not experience as much diminishing returns per period), delivers a higher price/rent. Consider also the extension where the demand parameter A is time varying. Then the extraction path is not affected at all, due to income and substitution effects canceling. The consumption interest rates will change, since the relative price between consumption and the resource must change. The equation for price dynamics applies just as before, however, so price growth is affected only to the extent the interest rate changes. The price level, of course, is also affected by overall demand shifts.

2.1.3 Extraction Costs

More generally, suppose that the marginal cost of extraction of the resource is c_t in period t, and let us for simplicity assume that these marginal costs are exogenous (more generally it would depend on the amount extracted and the total remaining amount of the resource). The Hotelling formula for price dynamics becomes

$$p_t - c_t = \frac{1}{1+r_{t+1}}(p_{t+1} - c_{t+1}).$$

Put differently, the Hotelling rent, which is now the marginal profit per unit, $p-c$, grows at the real rate of interest. This is thus the more general formula that applies. It is robust in a number of ways; eg, allowing endogenous extraction costs delivers the same formula and the consideration of uncertainty reproduces the formula in expectation).[j] The discussion of determinants of prices and quantities above thus still applies, though the

[h] For $\nu=1$ this is a standard cake-eating problem.

[i] The Euler equation of the consumer delivers $1+r_{t+1} = c_{t+1}/(c_t\beta) = e_{t+1}^{\nu}/(e_t^{\nu}\beta) = \beta^{\nu}/\beta = \beta^{\nu-1}$.

[j] The case where the natural resource is owned by a monopolist produces a more complicated formula, as one has to consider marginal revenue instead of price and as the interest rate possibly becomes endogenous. However, the case of monopoly does not appear so relevant, at least not today. In the case of oil, Saudi oil production is currently only about 10% of world production.

key object now becomes the marginal profit per unit. First, the general idea that more of the resource (higher R) lowers the price survives: more of the resource moves the price toward marginal cost, thus gradually eliminating the rent. Second, regarding the effects of costs, let us consider three key cases: one where marginal costs are constant (and positive), one where they are declining, and one where they are increasing. We assume, for simplicity, that there is a constant interest rate. A constant positive marginal cost thus implies that the price is rising at a somewhat lower rate initially than when extraction is costless, since early on the price is a smaller fraction of the rent (early on, there is more left of the resource). If the marginal cost of extraction rises over time—a case that would apply in the absence of technological change if the easy-to-extract sources are exploited first—the price will rise at a higher rate; and under the assumption of a falling marginal extraction cost, typically reflecting productivity improvements in extraction, prices rise more slowly. Quantity paths change accordingly, when we use an invariant demand function. With a faster price rise, quantities fall faster, and vice versa. In particular, when the future promises lower (higher) extraction costs, extraction is postponed (slowed down) and so falls less (more) rapidly.

2.2 Confronting Theory with Data

The Hotelling predictions are, in principle, straightforwardly compared with data. The ambition here is not to review all the empirical work evaluating the Hotelling equation for finite resources but merely to mention some stylized facts and make some general points.[k] As for prices, it is well known that (real) prices of metals fall at a modest rate over the "long run," measured as one hundred years or more; see, eg, Harvey et al. (2010). The prices of fossil fuels (oil, coal, and natural gas) have been stable, with a slight net increase over the last 40 or so years. The volatilities of all these time series are high, on the order of magnitude of those for typical stock-market indices.[l] When it comes to quantities, these time series have been increasing steadily, and with lower fluctuations than displayed by the corresponding prices. Are these observations broadly consistent with Hotelling's theory?

To answer this question, note that Hotelling's theory is mainly an arbitrage-based theory of prices and that quantity predictions involve more assumptions on supply and demand, such as those invoked in our planning problem above. To evaluate Hotelling's rule, we first need to have an idea of the path for extraction costs, as they figure prominently in the more general version of the theory. The situation is somewhat complicated by the fact that extraction occurs on multiple sites. For oil at least, it is also clear that the marginal costs differ greatly between active oil wells, for example with much lower costs in Saudi Arabia than in the North Sea. This in itself appears inefficient, as the less

[k] For excellent discussions, see, eg, Krautkraemer, 1998 and Cuddington and Nülle, 2014.

[l] There are also attempts to identify long-run cycles; see, eg, Erten and Ocampo, 2012.

expensive oil ought to be extracted first in order to minimize overall present-value costs. We know of no study that has good measurements of marginal extraction costs going far back in time. Suppose, however, that productivity growth in the mining/extraction sector was commensurate with that in the rest of our economies. Then it would be reasonable to assume that the *relative* cost of extracting natural resources—and that is the relevant price given that we are referring to evidence on real prices—does not have any sharp movements upward or downward. Hence, the Hotelling formula, given a known total depletable stock of the resource, would imply an increasing price series, at a rate of a few percent per year, with a slightly lower growth rate early on, as explained earlier. This is clearly not what we see. It is, alternatively, possible that extraction costs have developed unevenly. Pindyck (1978) argues, for the case of oil, that lower and lower extraction costs explained a stable price path initially but that later extraction costs stabilized (or even increased), hence pushing prices up. In retrospect, however, although prices rose again in 1979 they did not continue increasing after that and rather fell overall; today, the oil price is back at a real price that is not terribly far from the pre-1973 level.

An proposed explanation for the lack of price growth in the data is a gradual finding of new deposits (of oil, metals, and so on). As explained earlier, the theory does predict lower prices for higher total deposits of the resource. However, it would then have to be that markets systematically underpredicted the successes of new explorations, and over very long periods of time.

Relatedly, it is possible that markets expect technological change in the form of the appearance of close substitutes to the resource in question. Consider a very simple case with a costless-to-extract raw material as in the baseline Hotelling model but where next period a perfect substitute, in infinite supply and with a constant marginal cost $\bar{p}$, appears with some probability. Then the arbitrage equation reads $p_t = \frac{1}{1+r_{t+1}}(\pi_{t+1}p_{t+1} + (1-\pi_{t+1})\bar{p})$, where π_{t+1} is the probability of the perfect substitute appearing. Clearly, such uncertainty and potential price competition will influence price dynamics and will lead to richer predictions. However, we know of no systematic study evaluating a quantitative version of this kind of hypothesis and comparing it to data.

A different view of the prices of natural resources (and commodities more generally) is the Prebisch (1962) and Singer (1950) hypothesis: that commodities have lower demand elasticities, so that when income rises, prices fall. Their hypothesis, thus, is in contrast with Hotelling's rule, since scarcity is abstracted from. Clearly, if one formulated a model with the Prebisch–Singer assumption and scarcity, as discussed earlier, the Hotelling formula would survive, and any demand effects would merely affect the level of the price path and not its dynamics.

In sum, although many authors claim that richer versions of the Hotelling model take its predictions closer to data, it seems safe to say that there is no full resolution of the contrast between the model's prediction of rising prices/profits per unit (at the rate of interest) and the data showing a stable or declining real price of the typical resource.

Some would argue that markets are not fully rational, or not forward-looking enough: the power of the scarcity argument in Hotelling's seminal work is very powerful but relies crucially on forward-looking with a long horizon, to the extent there is a relatively large amount of the resource left in ground. It seems to us that this hypothesis deserves some attention, though it is a challenge even to formulate it.[m]

To evaluate quantities, as underlined earlier, a fuller theory needs to be specified. This leads to challenges as well, as we shall see. Here, we will simply look at an application, albeit a well-known one and one that is relevant to the climate context. In the context of this application, we will also discuss technological change as a means toward saving on a scarce resource.

2.3 An Application: Fossil Energy

On a broad level, when a resource is in scarce supply, a key question is its substitutability with alternative resources. In this section, we look at fossil energy and provide an outline of how one could go about looking at one aspect of scarcity in this market: the response of energy saving, ie, one of the ways in which markets can respond to a shortage. This analysis, like the rest of this chapter (that addresses climate change), is built on a quantitatively oriented macroeconomic model. It can also be regarded as one of the building blocks in the climate-economy model; indeed, the exhaustible-resource formulation in Section 5 coincides with the core formulation entertained here.

The starting point is the extension of basic growth theory to include energy; the standard reference is Dasgupta and Heal (1974), but noteworthy other contributions include those by Solow (1974) and Stiglitz (1974). One of the main concerns here was precisely sustainability, ie, whether production functions (or various sorts) would allow future generations to be as well off as current generations. The Cobb–Douglas function was found to be an in-between case here; with more substitutability between energy and the other inputs, sustainability was possible. This line of work did not much address technical change, neither quantitatively nor theoretically. Clearly, much of the literature on scarce resources was written shortly after the oil-price hikes in the 1970s and it was not until the late 1980s that the theoretical developments allowed technological change to be endogenized in market-based environments.

We build a similar framework to that in Dasgupta and Heal's work and formulate an aggregate production function with three inputs—capital, labor, and fossil energy—and we use it to account for postwar US data. This analysis follows Hassler et al. (2015) closely. We allow technical change in this production function in the form of capital/labor saving and energy saving and we consider three broad issues: (i) what substitution elasticity (between a capital-labor composite, on the one hand, and energy, on the other) fits the data best; (ii) measurement of the series for input saving and to what extent they appear to respond to price movements (ie, does energy-saving appear to respond to the price of fossil fuel?); and (iii) the model's predictions for future input saving and fossil-fuel

[m] See, eg, Spiro (2014).

dependence. The model focuses on energy demand, as derived from an aggregate production function, and all of the discussion can be carried out without modeling supply.

So consider an aggregate production function of the nested CES form

$$y = \left[(1-\nu)\left[Ak^{\alpha}l^{1-\alpha}\right]^{\frac{\varepsilon-1}{\varepsilon}} + \left[A^{e}e\right]^{\frac{\varepsilon-1}{\varepsilon}} \right]^{\frac{\varepsilon}{\varepsilon-1}},$$

with the obvious notation.[n] Here, we see that $\varepsilon \in [0, \infty]$ expresses the substitutability between capital/labor and energy. A is the technology parameter describing capital/labor saving and A^{e} correspondingly describes energy saving. If there is perfect competition for inputs, firms set the marginal product of each input equal to its price, delivering—expressed in terms of shares—the equations

$$\frac{wl}{y} = (1-\alpha)(1-\gamma)\left[\frac{Ak^{\alpha}l^{1-\alpha}}{y}\right]^{\frac{\varepsilon-1}{\varepsilon}} \tag{1}$$

and

$$\frac{pe}{y} = \gamma\left[\frac{A^{e}e}{y}\right]^{\frac{\varepsilon-1}{\varepsilon}}. \tag{2}$$

2.3.1 Accounting for Input Saving Using US Data

Eqs. (1) and (2) can be rearranged and solved directly for the two technology trends A and A^{E}. This means that it is possible, as do Hassler et al., to use data on output and inputs and their prices to generate time paths for the input-saving technology series. This is parallel with Solow's growth-accounting exercise, only using a specific functional form. In particular, A^{e} can be examined over the postwar period, when the price of fossil fuel—oil in particular—has moved around significantly, as shown in Fig. 1.

The authors use this setting and these data to back out series for A^{e} and A, conditional on a value for ε. With the view that the A and A^{e} series are technology series mainly, one can then examine the extent to which the backed-out series for different ε look like technology series: are fairly smooth and mostly nondecreasing. It turns out that ε has to be close to zero for the A^{e} series to look like a technology series at all; if ε is higher than 0.2 or so, the implied up-and-down swings in A^{e} are too high to be plausible. On the other hand, for a range of ε values between 0 (implying that production is Leontief) and 0.1, the series is rather smooth and looks like it could be a technology series. Fig. 2 plots both the A and A^{e} series. We see that A^{e} grows very slowly until prices rise; then it starts

[n] This production function introduces a key elasticity, along with input-specific technology levels, in the most tightly parameterized way. Extensions beyond this functional class, eg, to the translog case, would be interesting not only for further generality but because it would introduce a number of additional technology shifters; see, eg, Berndt and Christensen, 1973.

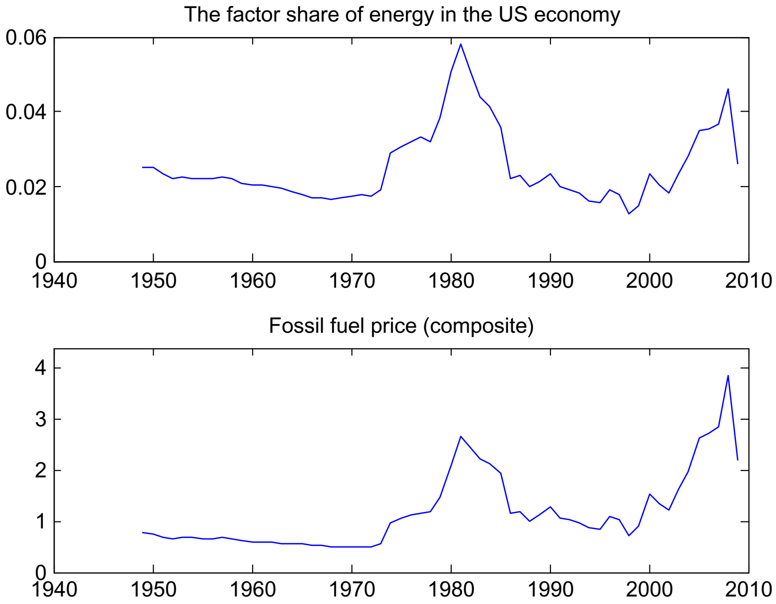

Fig. 1 Fossil energy share and its price.

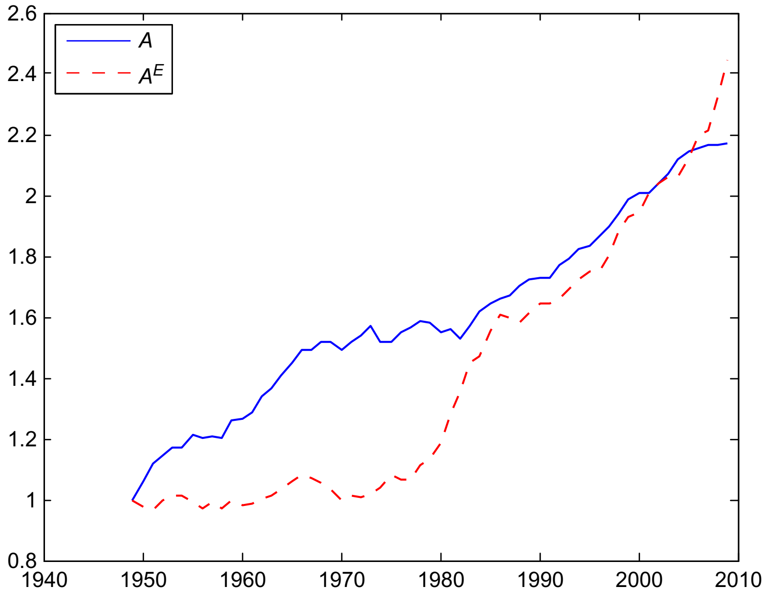

Fig. 2 Energy- and capital/labor-saving technologies compared.

growing significantly. Hence, the figure does suggest that the scarcity mechanism is operative in a quantitatively important way. It is also informative to look at how the two series compare. A it looks like TFP overall, but more importantly it does seem to covary negatively in the medium run with A^e, thus suggesting that the concept of *directed technical change* may be at play. In other words, when the oil price rose, the incentives to save on oil and improve oil efficiency went up, and to the extent these efforts compete for a scarce resource that could alternatively be used for saving on/improving the efficiency of capital and labor, as a result the latter efforts would have fallen.

Hassler et al. (2015) go on to suggest a formal model for this phenomenon and use it, with a calibration of the technology parameters in R&D based on the negative historical association between A and A^E, to also predict the future paths of technology and of energy dependence. We will briefly summarize this research later, but first it is necessary to formulate a quantitatively oriented dynamic macroeconomic model with energy demand and supply included explicitly.

2.3.2 A Positive Model of Energy Supply and Demand with a Finite Resource

Using the simple production function above and logarithmic preferences, it is straightforward to formulate a planner's problem, assuming that energy comes from a finite stock. We will first illustrate with a production function that is in the specified class and that is often used but that does not (as argued earlier) fit the macroeconomic data: the Cobb–Douglas case, where $F(Ak^\alpha, A^e e) = k^\alpha e^\nu$, where a constant labor supply (with a share $1-\alpha-\nu$) is implicit and we have normalized overall TFP including labor to 1. We also assume, to simplify matters, that (i) there is 100% depreciation of capital between periods (which fits a period of, say, 20 years or more) and that (ii) the extraction of energy is costless (which fits oil rather well, as its marginal cost is much lower than its price, at least for much of the available oil). For now, we abstract from technological change; we will revisit it later. Thus, the planner would maximize

$$\sum_{t=0}^{\infty} \log c_t$$

subject to

$$c_t + k_{t+1} = k_t^\alpha e_t^\nu$$

and $\sum_{t=0}^{\infty} e_t = R$, with R being the total available stock. It is straightforward to verify that we obtain a closed-form solution here: consumption is a constant fraction $1-\alpha\beta$ of output and $e_t = (1-\beta)\beta^t R$, ie, energy use falls at the rate of discount. As energy falls, so does capital, consumption, and output. In fact, this model asymptotically delivers balanced (negative) growth at a gross rate g satisfying (from the resource constraint) $g = g^\alpha \beta^\nu = \beta^{\overline{1-\alpha}}$ with ν over the bar: $g = g^\alpha\beta^\nu = \beta^{\frac{\nu}{1-\alpha}}$. Capital is not on the balanced path at all times, unless its initial value is in the proper relation to initial energy use.[o] This model of course also generates the Hotelling result: p_{t+1} must equal $p_t(1+r_{t+1})$, where $1+r$ is the marginal product of capital and $1+r$ hence the gross real interest rate. Notice, thus, that the interest rate will be constant on the balanced growth path but that it obeys transition dynamics. Hence, even though energy use falls at a constant rate at all times, the energy price will not grow at a constant rate at all times (unless the initial capital stock is at its balanced-growth level): it will grow either faster or slower. Consumption, along with output and capital, goes to zero here along a balanced growth path, but when there is sufficient growth in technology (which is easily added in the model), there will be positive balanced growth. The striking fall in energy use over time would of course be mitigated by an assumption that marginal extraction costs are positive and decreasing over time, as discussed earlier, but it is not obvious that such an assumption is warranted.

Fig. 3, which is borrowed from Hassler et al. (2015), shows that, in the data, energy (defined as a fossil composite) rises significantly over time. In contrast, as we have just shown, the simple Cobb–Douglas model predicts falling energy use, at a rate equaling the discount rate. Suppose instead one adopts the model Hassler et al. (2015) argue fit the data better, ie, a function that is near Leontief in k^α and e. Let us first assume that the technology coefficients A and A^e are constant over time. Then, there will be transition

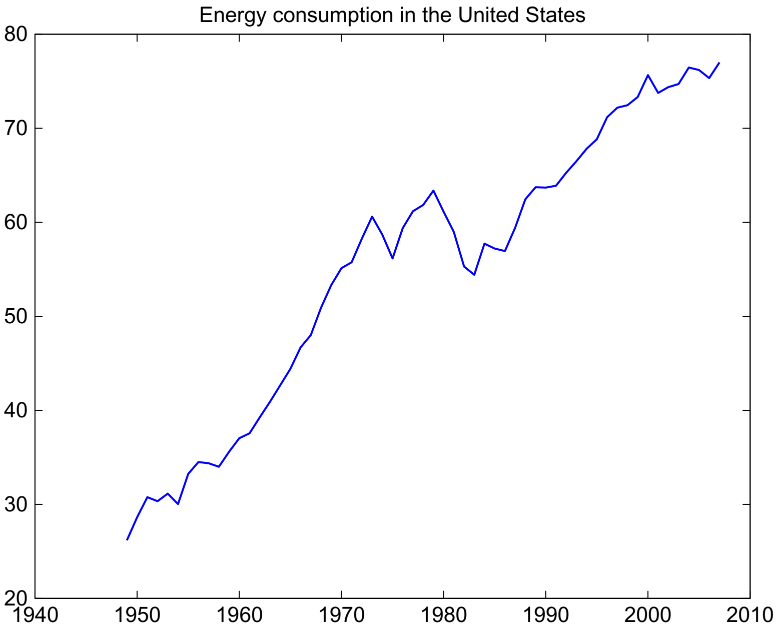

Fig. 3 US energy use.

[o] Initial capital then has to equal $(\alpha(R(1-\beta))^\nu)^{\frac{1}{1-\alpha}}\beta^{\frac{1-\alpha-\nu}{1-\alpha}}$.

dynamics in energy use, for Ak^α has to equal $A^e e$ at all points in time. Thus, the initial value of capital and R may not admit balanced growth in e at all times, given A and A^e. Intuitively, if Ak_0^α is too low, e will be held back initially and grow over time as capital catches up to its balanced path. Thus, it is possible to obtain an increasing path for energy use over a period of time. Eventually, of course, energy use has to fall. There is no exact balanced growth path in this case. Instead, the saving rate has to go to zero since any positive long-run saving rate would imply a positive capital stock.[p] Hence, the asymptotic economy will be like one without capital and in this sense behave like in a cake-eating problem: consumption and energy will fall at rate β. In sum, this model can deliver *peak oil*, ie, a path for oil use with a maximum later than at time 0. As already pointed out, increasing oil use can also be produced from other assumptions, such as a decreasing sequence of marginal extraction costs for oil; these explanations are complementary.

With exogenous technology growth in A and A^e it is possible that very different long-run extraction behavior results.[q] In particular, it appears that a balanced growth path with the property that $g_A g^\alpha = g_{A^e} g_e = g$ is at least feasible. Here, the first equality follows from the two arguments of the production function growing at the same rate—given that the production function F is homogeneous of degree one in the two arguments Ak^α and $A^e e$—and the second equality says that output and capital have to grow at that same rate. Clearly, if the planner chooses such asymptotic behavior, g_e can be solved for from the two equations to equal $g_A^{\frac{1}{1-\alpha}}/g_{A^e}$, a number that of course needs to be less than 1. Thus, in such a case, g_e will not generally equal β. A more general study of these cases is beyond the scope of the present chapter.

2.3.3 Endogenous Energy-Saving Technical Change

Given the backed-out series for A and A^e, which showed negative covariation in the medium run, let us consider the model of technology choice Hassler et al. (2015) propose. In it, there is an explicit tradeoff between raising A and raising A^e. Such a tradeoff arguably offers one of the economy's key behavioral responses to scarcity. That is, growth in A^e can be thought of as energy-saving technological change. In line with the authors' treatment, we consider a setup with directed technological change in the form of a planning problem, thus interpreting the outcome as one where the government has used policy optimally to internalize any spillovers in the research sector. It would be straightforward, along the lines of the endogenous-growth literature following Romer (1990), to consider market mechanisms based on variety expansion or quality improvements,

[p] If the saving rate asymptotically stayed above $_s > 0$, then $k_{t+1} \geq_s Ak_t^\alpha$. This would imply that capital would remain uniformly bounded below from zero. However, here, it does have to go to zero as its complement energy has to go to zero.

[q] An exception is the Cobb–Douglas case for which it is easy to show that the result above generalizes: e falls at rate β.

monopoly power, possibly with Schumpeterian elements, and an explicit market sector for R&D. Such an analysis would be interesting and would allow interesting policy questions to be analyzed. For example, is the market mechanism not allowing enough technical change in response to scarcity, and does the answer depend on whether there are also other market failures such as a climate externality? We leave these interesting questions for future research and merely focus here on efficient outcomes. The key mechanism we build in rests on the following simple structure: we introduce one resource, a measure one of "researchers." Researchers can direct their efforts to the advancement of A and A^e. We look at a very simple formulation:

$$A_{t+1} = A_t f(n_t) \quad \text{and} \quad A^e_{t+1} = A^e_t f_e(1 - n_t),$$

where $n_t \in [0,1]$ summarizes the R&D choice at time t and where f and f_e are both strictly increasing and strictly concave; these functions thus jointly demarcate the frontier for technologies at $t+1$ given their positions at t. Hence, at a point in time t, A_t and A^e_t are fixed. In the case of a Leontief technology, there would be absolutely no substitutability at all between capital and energy ex-post, ie, at time t when A_t and A^e_t have been chosen, but there is substitutability ex-ante, by varying n_s for $s < t$. With a less extreme production function there would be substitutability ex-post too but less so than ex-ante.[r] Relatedly, whereas the share of income in this economy that accrues to each of the inputs is endogenous and, typically, varies with the state of the economy, on a balanced growth path the share settles down. As we shall see, in fact, the share is determined in a relatively simple manner.

The analysis proceeds by adding these two equations to the above planning problem. Taking first-order conditions and focusing on a balanced-growth outcome, this model rather surprisingly delivers the result that the extraction rate must be equal to β, regardless of the values of all the other primitives.[s] This means, in turn, that two equations jointly determining the long-run growth rates of A and A_e can be derived. One captures the technology tradeoff and follows directly from the equations above stating that these growth rates, respectively, are $g_A = f(n)$ and $g_{A^e} = f^e(1-n)$. The other equation comes from the balanced-growth condition that $A_t k^\alpha_t = A^e_t e_t$, given that F is homogeneous of degree one; from this equality the growth rates of A and A^e are positively related. In fact, given that e_t falls at rate β, we obtain n from $g_A^{\frac{1}{1-\alpha}} = g_{A^e}\beta$.

[r] The Cobb–Douglas case is easy to analyze. It leads to an interior choice for n that is constant over time, regardless of initial conditions and hence looks like the case above where the two technology factors are exogenous.

[s] The proof is straightforward; for details, see Hassler et al. (2015). It is thus the endogeneity of the technology levels in the CES formulation that makes energy fall at rate β; when they grow exogenously, we saw that energy does not have to go to zero at rate β.

One can also show, quite surprisingly as well, that the long run share of energy s_e in output is determined by $(1-s_e)/s_e = -\partial \log g_A / \partial \log g_{A^e}$.[t] In steady state, this expression is a function of n only, and as we saw above it is determined straightforwardly knowing β, α, f, and f^e. How, then, can these primitives be calibrated? One way to proceed is to look at historical data to obtain information about the tradeoff relation between g_A and g_{A^e}. If this relation is approximately log-linear (ie, the net rates are related linearly), the observed slope is all that is needed, since it then gives $\partial \log g_A / \partial \log g_{A^e}$ directly. The postwar behaviors of A and A^e reported above imply a slope of -0.235 and hence a predicted long-run value of s_e of around 0.19, which is significantly above its current value, which is well below 0.1.

2.3.4 Takeaway from the Fossil-Energy Application

The fossil-energy application shows that standard macroeconomic modeling with the inclusion of an exhaustible resource can be used to derive predictions for the time paths for quantities and compare them to data. Moreover, the same kind of framework augmented with endogenous directed technical change can be used to look at optimal/market responses to scarcity. It even appears possible to use historical data reflecting past technological tradeoffs in input saving to make predictions for the future. The presentation here has been very stylized and many important real-world features have largely been abstracted from, such as the nature of extraction technologies over time and space. The focus has also been restricted to the long-run behaviors of the prices and quantities of the resources in limited supply, but there are other striking facts as well, such as the high volatilities in most of these markets. Natural resources in limited supply can become increasingly limiting for economic activity in the future and more macroeconomic research may need to be directed to these issues. Hopefully the analysis herein can give some insights into fruitful avenues for such research.

3. CLIMATE CHANGE: THE NATURAL-SCIENCE BACKGROUND

An economic model of climate change needs to describe three phenomena and their dynamic interactions. These are (i) economic activity; (ii) carbon circulation; and (iii) the climate. From a conceptual as well as a modeling point of view it is convenient to view the three phenomena as distinct sub-subsystems. We begin with a very brief description of the three subsystems and then focus this section on the two latter.

The economy consists of individuals that act as consumers, producers and perhaps as politicians. Their actions are drivers of the economy. In particular, the actions are determinants of emissions and other factors behind climate change. The actions are also

[t] The authors show that this result follows rather generally in the model: utility is allowed to be any power function and production any function with constant returns to scale.

responses to current and expected changes in the climate by adaptation. Specifically, when fossil fuel is burned, carbon dioxide (CO_2) is released and spreads very quickly in the atmosphere. The atmosphere is part of the carbon circulation subsystem where carbon is transported between different reservoirs; the atmosphere is thus one such reservoir. The biosphere (plants, and to a much smaller extent, animals including humans) and the soil are other reservoirs. The oceans constitute the largest carbon reservoir.

The climate is a system that determines the distribution of weather events over time and space and is, in particular, affected by the carbon dioxide concentration in the atmosphere. Due to its molecular structure, carbon dioxide more easily lets through short-wave radiation, like sun-light, than long-wave, infrared radiation. Relative to the energy outflow from earth, the inflow consists of more short-wave radiation. Therefore, an increase in the atmospheric CO_2 concentration affects the difference between energy inflow and outflow. This is the *greenhouse effect*.

It is straightforward to see that we need at minimum the three subsystems to construct a climate-economy model. The economy is needed to model emissions and economic effects of climate change. The carbon circulation model is needed to specify how emissions over time translate into a path of CO_2 concentration. Finally, the climate model is needed to specify the link between the atmospheric CO_2 concentration and the climate.

3.1 The Climate

3.1.1 The Energy Budget

We will now present the simplest possible climate model. As described earlier, the purpose of the climate model is to determine how the (path of) CO_2 concentration determines the (path of the) climate. A minimal description of the climate is the global mean atmospheric temperature near the surface. Thus, at minimum we need a relationship between the path of the CO_2 concentration and the global mean temperature. We start the discussion by describing the *energy budget* concept.

Suppose that the earth is in a radiative steady state where the incoming flow of short-wave radiation from the sun light is equal to the outgoing flow of largely infrared radiation.[u] The energy budget of the earth is then balanced, implying that the earth's heat content and the global mean temperature is constant.[v] Now consider a perturbation of this equilibrium that makes the net inflow positive by an amount F. Such an increase could be caused by an increase in the incoming flow and/or a reduction in the outgoing flow. Regardless of how this is achieved, the earth's energy budget is now in surplus

[u] We neglect the additional outflow due to the nuclear process in the interior of the earth, which is in the order of one to ten thousands in relative terms when compared to the incoming flux from the sun; see the Kam et al. (2011).

[v] We disregard the obvious fact that energy flows vary with latitude and over the year producing differences in temperatures over space and time. Since the outflow of energy is a nonlinear (convex) function of the temperature, the distribution of temperature affects the average outflow.

causing an accumulation of heat in the earth and thus a higher temperature. The speed at which the temperature increases is higher the larger is the difference between the inflow and outflow of energy, ie, the larger the surplus in the energy budget.

As the temperature rises, the outgoing energy flow increases since all else equal, a hotter object radiates more energy. Sometimes this simple mechanism is referred to as the 'Planck feedback'. As an approximation, let this increase be proportional to the increase in temperature over its initial value. Denoting the temperature perturbation relative to the initial steady state at time t by T_t and the proportionality factor between energy flows and temperature by κ, we can summarize these relations in the following equation:

$$\frac{dT_t}{dt} = \sigma(F - \kappa T_t). \tag{3}$$

The left-hand side of the equation is the speed of change of the temperature at time t. The term in parenthesis on the right-hand side is the net energy flow, ie, the difference in incoming and outgoing flows. The equation is labeled the energy budget and we note that it should be thought of as a flow budget with an analogy to how the difference between income and spending determines the speed of change of assets.

When the right-hand side of (3) is positive, the energy budget is in surplus, heat is accumulated, and the temperature increases. Vice versa, if the energy budget has a deficit, heat is lost, and the temperature falls. When discussing climate change, the variable F is typically called *forcing* and it is then defined as the change in the energy budget caused by human activities. The parameter σ is (inversely) related to the heat capacity of the system for which the energy budget is defined and determines how fast the temperature changes for a given imbalance of the energy budget.[w]

We can use Eq. (3) to find how much the temperature needs to rise before the system reaches a new steady state, ie, when the temperature has settled down to a constant. Such an equilibrium requires that the energy budget has become balanced, so that the term in parenthesis in (3) again has become zero. Let the steady-state temperature associated with a forcing F be denoted $T(F)$. At $T(F)$, the temperature is constant, which requires that the energy budget is balanced, ie, that $F - \kappa T(F) = 0$. Thus,

$$T(F) = \frac{F}{\kappa}. \tag{4}$$

Furthermore, the path of the temperature is given by

$$T_t = e^{-\sigma\kappa t}\left(T_0 - \frac{F}{\kappa}\right) + \frac{F}{\kappa}.$$

[w] The heat capacity of the atmosphere is much lower than that of the oceans, an issue we will return to below.

Measuring temperature in Kelvin (K), and F in Watt per square meter, the unit of κ is $\frac{W/m^2}{K}$.[x] If the earth were a blackbody without an atmosphere, we could calculate the exact value of κ from laws of physics. In fact, at the earth's current mean temperature $\frac{1}{\kappa}$ would be approximately 0.3, ie, an increase in forcing by 1 W/m^2 would lead to an increase in the global temperature of 0.3 K (an equal amount in degrees Celsius).[y] In reality, various feedback mechanisms make it difficult to assess the true value of κ. One of the important feedbacks is that a higher temperature increases the concentration of water vapor, which is also is a greenhouse gas; another is that the polar ice sheets melt, which decreases direct reflection of sun light and changes the cloud formation. We will return to this issue below but note that the value of κ is likely to be substantially smaller than the blackbody value of 0.3^{-1}, leading to a higher steady-state temperature for a given forcing.

Now consider how a given concentration of CO_2 determines F. This relationship can be well approximated by a logarithmic function. Thus, F, the change in the energy budget relative to preindustrial times, can be written as a logarithmic function of the increase in CO_2 concentration relative to the preindustrial level or, equivalently, as a logarithmic function of the amount of carbon in the atmosphere relative to the amount in preindustrial times. Let S_t and $\bar{S}$, respectively, denote the current and preindustrial amounts of carbon in the atmosphere. Then, forcing can be well approximated by the following equation.[z]

$$F_t = \frac{\eta}{\log 2} \log\left(\frac{S_t}{\bar{S}}\right). \tag{5}$$

The parameter η has a straightforward interpretation: if the amount of carbon in the atmosphere in period t has doubled relative to preindustrial times, forcing is η. If it quadruples, it is 2η, and so forth. An approximate value for η is 3.7, implying that a doubling of the amount of carbon in the atmosphere leads to a forcing of 3.7 watts per square meter on earth.[aa]

[x] Formally, a flow rate per area unit is denoted flux. However, since we deal with systems with constant areas, flows and fluxes are proportional and the terms are used interchangeably.

[y] See Schwartz et al. (2010) who report that if earth were a blackbody radiator with a temperature of $288K \approx 15°C$, an increase in the temperature of 1.1 K would increase the outflow by 3.7 W/m^2, implying $\kappa^{-1} = 1.1/3.7 \approx 0.3$.

[z] This relation was first demonstrated by the Swedish physicist and chemist and 1903 Nobel Prize winner in Chemistry, Svante Arrhenius. Therefore, the relation is often referred to as the *Arrhenius's Greenhouse Law*. See Arrhenius (1896).

[aa] See Schwartz et al. (2014). The value 3.7 is, however, not undisputed. Otto et al. (2013) use a value of 3.44 in their calculations.

We are now ready to present a relation between the long-run change in the earth's average temperature as a function of the carbon concentration in the atmosphere. Combining Eqs. (4) and (5) we obtain

$$T(F_t) = \frac{\eta}{\kappa}\frac{1}{\log 2}\log\left(\frac{S_t}{\bar{S}}\right). \tag{6}$$

As we can see, a doubling of the carbon concentration in the atmosphere leads to an increase in temperature given by $\frac{\eta}{\kappa}$. Using the Planck feedback, $\eta/\kappa \approx 1.1$°C. This is a modest sensitivity, and as already noted very likely too low an estimate of the overall sensitivity of the global climate due to the existence of positive feedbacks.

A straightforward way of including feedbacks in the energy budget is by adding a term to the energy budget. Suppose initially that feedbacks can be approximated by a linear term xT_t, where x captures the marginal impact on the energy budget due to feedbacks. The energy budget now becomes

$$\frac{dT_t}{dt} = \sigma(F + xT_t - \kappa T_t), \tag{7}$$

where we think of κ as solely determined by the Planck feedback. The steady-state temperature is now given by

$$T(F) = \frac{\eta}{\kappa - x}\frac{1}{\ln 2}\ \ln\left(\frac{S}{\bar{S}}\right). \tag{8}$$

Since the ratio $\eta/(\kappa - x)$ has such an important interpretation, it is often labeled the*Equilibrium Climate Sensitivity (ECS)* and we will use the notation λ for it.[ab] Some feedbacks are positive but not necessarily all of them; theoretically, we cannot rule out either $x < 0$ or $x \geq \kappa$. In the latter case, the dynamics would be explosive, which appears inconsistent with historical reactions to natural variations in the energy budget. Also $x < 0$ is difficult to reconcile with the observation that relatively small changes in forcing in the earth's history have had substantial impact on the climate. However, within these bands a large degree of uncertainty remains.

According to the IPCC, the ECS is "likely in the range 1.5–4.5°C," "extremely unlikely less than 1°C," and "very unlikely greater than 6° C."[ac] Another concept, taking some account of the shorter run dynamics, is the *Transient Climate Response (TCR)*. This is the defined as the increase in global mean temperature at the time the CO_2 concentration

[ab] Note that equilibrium here refers to the energy budget. For an economist, it might have been more natural to call λ the *steady-state climate sensitivity*.

[ac] See IPCC (2013, page 81 and Technical Summary). The report states that "likely" should be taken to mean a probability of 66–100%, "extremely unlikely" 0–5%, and "very unlikely" 0–10%.

has doubled following a 70-year period of annual increases of 1%.[ad] IPCC et al. (2013b, Box 12.1) states that the TCR is "likely in the range 1°C–2.5°C" and "extremely unlikely greater than 3°C."

3.1.2 Nonlinearities and Uncertainty

It is important to note that the fact that $\frac{1}{\kappa - x}$ is a nonlinear transformation of x has important consequences for how uncertainty about the strength of feedbacks translate into uncertainty about the equilibrium climate sensitivity.[ae] Suppose, for example, that the uncertainty about the strength in the feedback mechanism can be represented by a symmetric triangular density function with mode 2.1 and endpoints at 1.35 and 2.85. This is represented by the upper panel of Fig. 4. The mean, and most likely, value of x translates into a climate sensitivity of 3. However, the implied distribution of climate sensitivities is severely skewed to the right.[af] This is illustrated in the lower panel, where $\frac{\eta}{\kappa - x}$ is plotted with $\eta = 3.7$ and $\kappa = 0.3^{-1}$.

The models have so far assumed linearity. There are obvious arguments in favor of relaxing this linearity. Changes in the albedo due to shrinking ice sheets and abrupt weaking of the Gulf are possible examples.[ag] Such effects could simply be introduced by making x in (7) depend on temperature. This could for example, introduce dynamics with so-called *tipping points*. Suppose, for example, that

$$x = \begin{cases} 2.1 \text{ if } T < 3^{o}C \\ 2.72 \text{ else} \end{cases}$$

Using the same parameters as earlier, this leads to a discontinuity in the climate sensitivity. For CO_2, concentrations below $2 \times \bar{S}$ corresponding to a global mean temperature deviation of 3 degrees, the climate sensitivity is 3. Above that tipping point, the climate sensitivity is 6. The mapping between $\frac{S_t}{\bar{S}}$ and the global mean temperature using Eq. (6) is shown in Fig. 5.

[ad] This is about twice as fast as the current increases in the CO_2 concentration. Over the 5, 10, and 20 year-periods ending in 2014, the average increases in the CO_2 concentration have been 0.54%, 0.54%, and 0.48% per year, respectively. However, note that also other greenhouse gases, in particular methane, affect climate change. For data, see the Global Monitor Division of the Earth System Research Labroratory at the US Department of Commerce.

[ae] The presentation follows Roe and Baker (2007).

[af] The policy implications of the possibility of a very large climate sensitivity is discussed in Weitzman (2011).

[ag] Many state-of-the-art climate models feature regional tipping points; see Drijfhouta et al. (2015) for a list. Currently, there is, however, no consensus on the existence of specific global tipping points at particular threshold levels; see Lenton et al. (2008), Levitan (2013), and IPCC (2013, Technical Summary page 70).

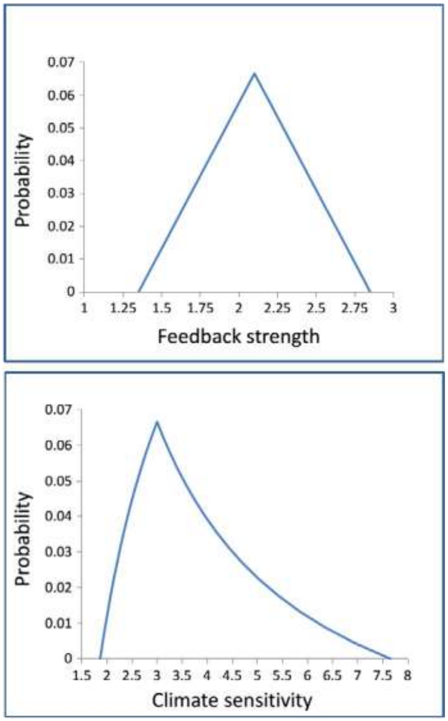

Fig. 4 Example of symmetric uncertainty of feedbacks producing right-skewed climate sensitivity.

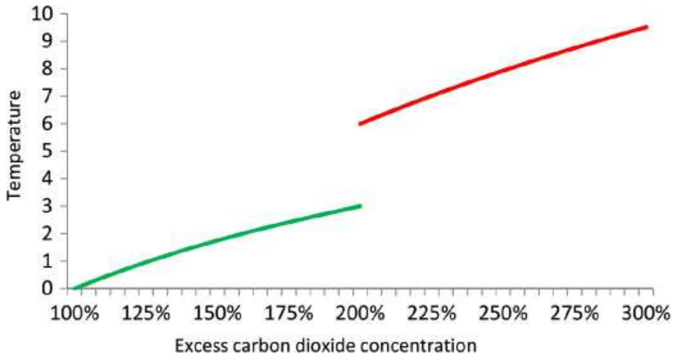

Fig. 5 Tipping point at 3 K due to stronger feedback.

It is also straightforward to introduce irreversibilities, for example by assuming that feedbacks are stronger (higher x) if a state variable like temperature or CO_2 concentration has ever been above some threshold value.

3.1.3 Ocean Drag

We have presented the simplest possible model of how the CO_2 concentration determines climate change. There are of course endless possibilities of extending this simplest framework. An example is to include another energy-budget equation. In Eqs. (3) and (7), we described *laws of motion* for the atmospheric temperature, which heats much faster than the oceans. During the adjustment to a steady state, there will be net energy flows between the ocean and the atmosphere. Let T_t and T_t^L, respectively, denote the atmospheric and ocean temperatures in period t, both measured as deviations from the initial (preindustrial) steady state. With two temperatures, we can define energy budgets separately for the atmosphere and for the oceans. Furthermore, allow for a variation in forcing over time and let F_t denote the forcing at time t. We then arrive at an extended version of Eq. (7) given by

$$\frac{dT_t}{dt} = \sigma_1\left(F_t + xT_t - \kappa T_t - \sigma_2\left(T_t - T_t^L\right)\right). \tag{9}$$

Comparing (9) to (7), we see that the term $\sigma_2\left(T_t - T_t^L\right)$ is added. This term represents a new flow in the energy budget (now defined specifically for the atmosphere), namely the net energy flow from the atmosphere to the ocean. To understand this term, note that if the ocean is cooler than the atmosphere, energy flows from the atmosphere to the ocean. This flow is captured in the energy budget by the term $-\sigma_2\left(T_t - T_t^L\right)$. If $T_t > T_t^L$, this flow has a negative impact on the atmosphere's energy budget and likewise on the rate of change in temperature in the atmosphere (the LHS). The cooler is the ocean relative to the atmosphere, the larger is the negative impact on the energy budget.

To complete this dynamic model, we need to specify how the ocean temperature evolves by using the energy budget of the ocean. If the temperature is higher in the atmosphere than in the oceans, energy will flow to the oceans, thus causing an increase in the ocean temperature. Expressing this as a linear equation delivers

$$\frac{dT_t^L}{dt} = \sigma_3\left(T_t - T_t^L\right). \tag{10}$$

Eqs. (9) and (10) together complete the specification of how the temperatures of the atmosphere and the oceans are affected by a change in forcing.

We can simulate the behavior of the system once we specify the parameters of the system (σ_1, σ_2, σ_3, and κ all positive) and feed in a sequence of forcing levels F_t. Nordhaus and Boyer (2000) use $\sigma_1 = 0.226$, $\sigma_2 = 0.44$, and $\sigma_3 = 0.02$ for a discrete-time version of (9) and (10) defined as the analogous difference equations with a 10-year step. In (6) we show the dynamic response of this model to a constant forcing of $1\,W/m^2$ for $(\kappa - x)^{-1} = 0.81$. The lower curve represents the ocean temperature T_t^L, which increases quite slowly. The middle curve is the atmospheric temperature, T_t, which increases more quickly (Fig. 6).

Clearly, the long-run increase in both temperatures is given by $\frac{1}{\kappa}$ times the increase in forcing, ie, by 0.81°C. Most of the adjustment to the long-run equilibrium is achieved after a few decades for the atmosphere but takes several hundred years for the ocean temperature. Without the dragging effect of the oceans, the temperature increases faster, as

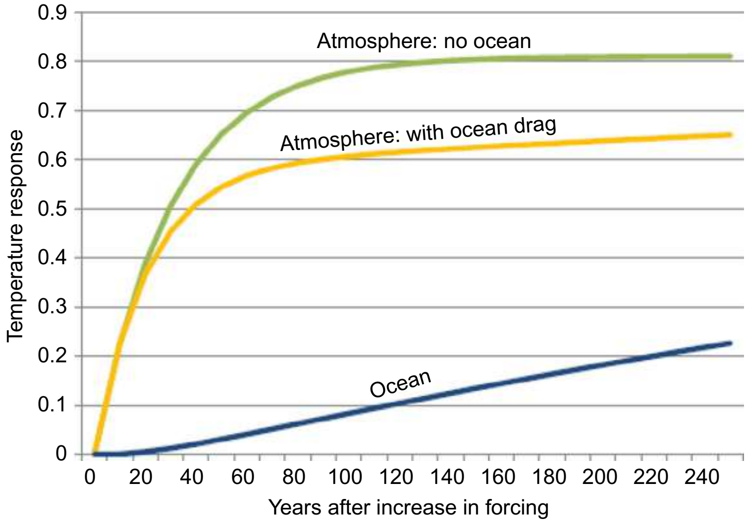

Fig. 6 Increase in atmospheric and ocean temperatures after a permanent forcing of $1W/m^2$.

shown by the top curve where we have set $\sigma_2 = 0$, which shuts down the effect of the slower warming of the ocean. However, we see that the time until half of the adjustment is achieved is not very different in the two cases.

3.1.4 Global Circulation Models

The climate models discussed so far are extremely limited in scope from the perspective of a climate scientist. In particular, they are based on the concept of an energy budget. Such models are by construction incapable of predicting the large disparity in climates over the world. For this, substantially more complex general circulation models (GCMs) need to be used. Such models are based on the fact that the energy flow to earth is unevenly spread over the globe both over time and space. This leads to movements in air and water that are the drivers of weather events and the climate. These models exist in various degrees of complexity, often with an extremely large number of state variables.[ah]

The complexity of general circulation models make them difficult to use in economics. In contrast to systems without human agents, such models do not contain any forward-looking agents. Thus, causality runs in one time direction only and the evolution of the system does not depend on expectations about the future. Therefore, solving such a complex climate model with a very large set of state variables may pose difficulties—in practice, because they are highly nonlinear and often feature chaotic behavior—but not the kind of difficulties economists face when solving their dynamic models.

[ah] See IPCC (2013, chapter 9) for a list and discussion of GCMs.

One way of modeling a heterogeneous world climate that does not require a combination of a very large state space and forward-looking behavior builds on *statistical downscaling*.[ai] The output of large-scale dynamic circulation models or historical data is then used to derive a *statistical* relation between aggregate and disaggregated variables. This is in contrast to the actual nonlinear high-dimensional models because they do not feature randomness; the model output only looks random due to the nonlinearities. The basic idea in statistical downscaling is thus to treat a small number of state variables as sufficient statistics for a more detailed description of the climate. This works well due in part to the fact that climate change is ultimately driven by a global phenomenon: the disruption of the energy balance due to the release of green house gases, where CO_2 plays the most prominent role.

Let $T_{i,\,t}$ denote a particular measure of the climate, eg, the yearly average temperature, in region i in period t. We can then estimate a model like

$$\begin{aligned} T_{i,t} &= \bar{T}_i + f(l_i, \psi_1) T_t + z_{i,t} \\ z_{i,t} &= \rho z_{i,t-1} + \nu_{i,t} \\ \mathrm{var}(\nu_{i,t}) &= g(l_i, \psi_2) \\ \mathrm{corr}\left(\nu_{i,t}, \nu_{j,t}\right) &= h\left(d\left(l_i, l_j\right), \psi_3\right). \end{aligned}$$

This very simple system, used for illustration mainly, explains downscaling conceptually. Here, $\bar{T}_i$ is the baseline temperature in region i. f, g, and h are specified functions parameterized by ψ_1, ψ_2, and ψ_3. $z_{i,t}$ is the prediction error and it is assumed to follow an AR(1) process. l_i is some observed characteristic of the region, eg, latitude, and $d\left(l_i, l_j\right)$ is a distance measure. Krusell and Smith (2014) estimate such a model on historical data. The upper panel in Fig. 7 shows the estimated function f with l_i denoting latitude. We see that an increase in the global mean temperature T_t has an effect on regional temperature levels that depends strongly on the latitude. The effect of a 1°C increase in the global temperature ranges from 0.25°C to 3.6°C. The lower panel in the figure shows the correlation pattern of prediction errors using d to measure Euclidian distance.

Now consider a dynamic economic model (where agents are forward-looking) with a small enough number of state variables that the model can be solved numerically. With one of these state variables playing the role of global temperature in the above equation system, one can imagine adding a large amount of heterogeneity without losing tractability, so long as the heterogeneous climate outcomes (eg, the realization of the local temperature distribution) do not feed back into global temperature. This is the approach featured in Krusell and Smith (2015), whose model can be viewed as otherwise building directly on the models (static and dynamic) presented in the sections later in this chapter.[aj]

[ai] See IPCC (2013, chapter 9) for a discussion of statistical downscaling.

[aj] Krusell and Smith (2015) actually allow some feedback, through economic variables, from the temperature distribution on global temperature but develop numerical methods that nevertheless allow the model to be solved.

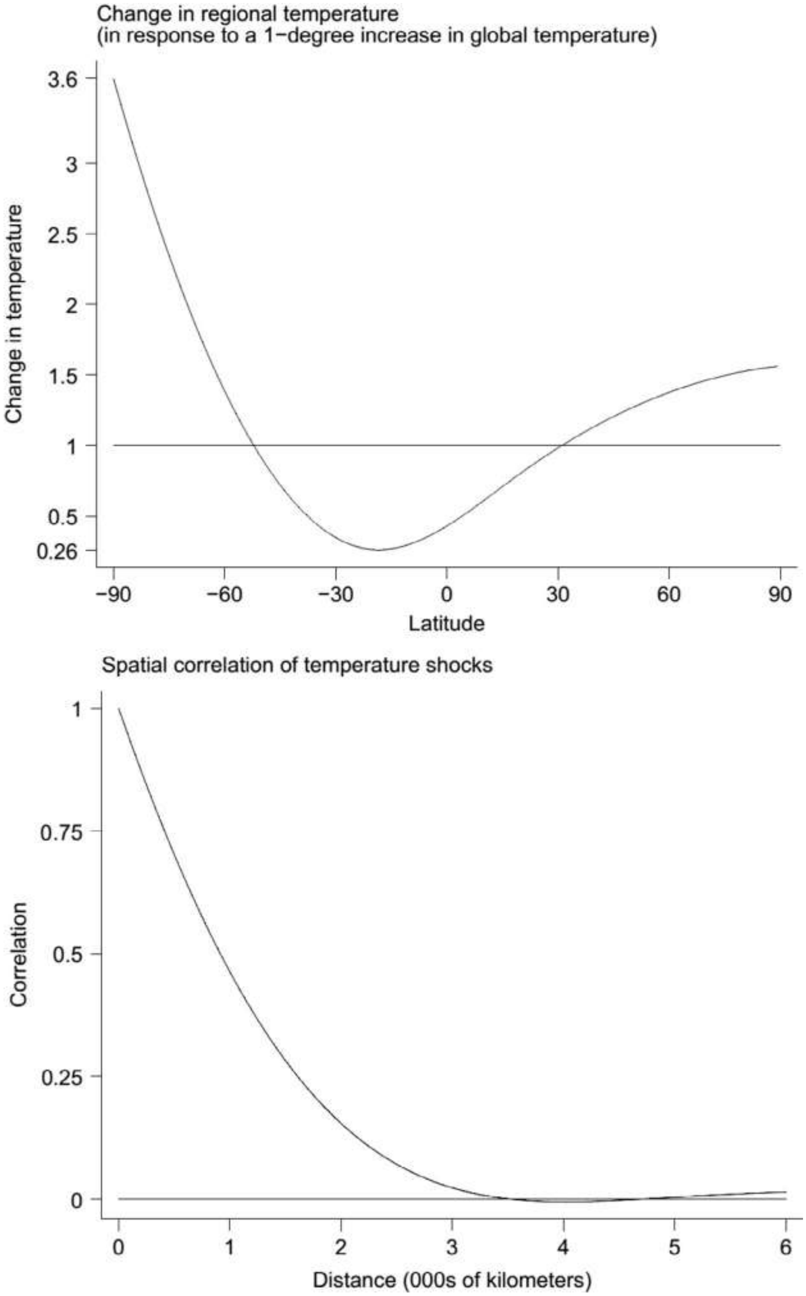

Fig. 7 Statistical downscaling: regional climate responses to global temperature.

3.2 Carbon Circulation

We now turn to carbon circulation (also called the carbon cycle). The purpose of the modeling here is to produce a mapping between emissions of CO_2 and the path of the CO_2 concentration in the atmosphere. The focus on CO_2 is due to the fact that while other gases emitted by human activities, in particular methane, are also important contributors to the greenhouse effect, CO_2 leaves the atmosphere much more slowly. The half-life of methane is on the order of 10 years, while as we will see, a sizeable share of emitted CO_2 remains in the atmosphere for thousands of years.[ak]

3.2.1 Carbon Sinks and Stores

The burning of fossil fuel leads to emissions of carbon dioxide into the atmosphere. The carbon then enters into a circulation system between different global reservoirs of carbon (carbon sinks) of which the atmosphere is one. In Fig. 8, the carbon reservoirs are represented by boxes. The number in black in each box indicates the size of the reservoir in GtC, ie, billions of tons of carbon. As we can see, the biggest reservoir by far is the intermediate/deep ocean, with more than 37,000 GtC. The vegetation and the atmosphere are of about the same size, around 600 GtC, although the uncertainty about the former is substantial. Soils represent a larger stock as does carbon embedded in the permafrost. Black arrows in the figure indicate preindustrial flows between the stocks measured in GtC per year. The flows between the atmosphere and the ocean were almost balanced, implying a constant atmospheric CO_2 concentration.

By transforming carbon dioxide into organic substances, vegetation in the earth's biosphere induces a flow of carbon from the atmosphere to the biosphere. This is the photosynthesis. The reverse process, respiration, is also taking place in plants' fungi, bacteria, and animals. This, together with oxidation, fires, and other physical processes in the soil, leads to the release of carbon in the form of CO_2 to the atmosphere. A similar process is taking place in the sea, where carbon is taken up by phytoplankton through photosynthesis and released back into the surface ocean. When phytoplankton sink into deeper layers they take carbon with them. A small fraction of the carbon that is sinking into the deep oceans is eventually buried in the sediments of the ocean floor, but most of the carbon remains in the circulation system between lower and higher ocean water. Between the atmosphere and the upper ocean, CO_2 is exchanged directly. Carbon dioxide reacts with water and forms dissolved inorganic carbon that is stored in the water. When the CO_2-rich surface water cools down in the winter, it falls to the deeper ocean and a similar exchange occurs in the other direction. From the figure, we also note that there are large flows of carbon between the upper layers of the ocean and the atmosphere via gas exchange. These flows are smaller than, but of the same order of magnitude as, the photosynthesis and respiration.

[ak] Prather et al. (2012) derive a half-life of methane of 9.1 years with a range of uncertainty of 0.9 years.

3.2.2 Human Influence on Carbon Circulation

Before the industrial revolution, human influence on carbon circulation was small. However, atmospheric CO_2 concentration started to rise from the mid-18th century and onwards, mainly due to the burning of fossil fuels and deforestation but also as a result of rising cement production.

In Fig. 8, the red figures denote changes in the reservoirs and flows over and above preindustrial values. The figures for reservoirs refer to 2011 while flows are yearly averages during the period 2000–09. At the bottom of the picture, we see that the stock of fossil fuel in the ground has been depleted by 365 ± 30 GtC since the beginning of industrialization. The flow to the atmosphere due to fossil-fuel use and cement production is reported to be 7.8 ± 0.6 GtC per year. In addition, changed land use adds 1.1 ± 0.8 GtC per year to the flow of carbon to the atmosphere. In the other direction, the net flows from the atmosphere to the terrestrial biosphere and to the oceans have increased. All in all, we note that while the fossil reserves have shrunk, the amount of carbon in the atmosphere has gone from close to 600 to around 840 GtC and currently increases at a rate of 4 GtC per year. A sizeable but somewhat smaller increase has taken place in the oceans while the amount of carbon in the vegetation has remained largely constant.

We see that the gross flows of carbon are large relative to the additions due to fossil-fuel burning. Furthermore, the flows may be indirectly affected by climate change, creating feedback mechanism. For example, the ability of the biosphere to store carbon is affected by temperature and precipitation. Similarly, the ability of the oceans to store carbon is affected by the temperature. Deposits of carbon in the soil may also be affected by climate change. We will return to these mechanisms below.

3.2.3 The Reserves of Fossil Fuel

The extent to which burning of fossil fuel is a problem from the perspective of climate change obviously depends on how much fossil fuel remains to (potentially) be burnt. This amount is not known and the available estimates depends on definitions. The amount of fossil resources that eventually can be used depends on estimates of future findings as well as on forecasts about technological developments and relative prices. Often, reserves are defined in successively wider classes. For example, the US Energy Information Agency defines four classes for oil and gas. The smallest is *proved reserves*, which are reserves that geologic and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions. As technology and prices change, this stock normally increases over time. Successively larger ones are *economically recoverable resources*, *technically recoverable resources*, and *remaining oil and natural gas in place*.

Given different definitions and estimation procedures the estimated stocks differ and will change over time. Therefore, the numbers in this section can only be taken as indications. Furthermore, reserves of different types of fossil fuels are measured in different units, often barrels for oil, cubic meters or cubic feet for gas, and tons for coal. However, for our purpose, it is convenient to express all stocks in terms of their carbon content. Therefore nontrivial conversion must be undertaken. Given these caveats, we calculate from BP (2015) global proved reserves of oil and natural gas to be approximately 200 GtC and 100 GtC, respectively.[al] At current extraction rates, both these stocks would last approximately 50 years. Putting these numbers in perspective, we note that the

[al] BP (2015) reports proved oil reserves to 239,8 Gt. For conversion, we use IPCC (2006, table 1.2 and 1.3). From these, we calculate a carbon content of 0.846 GtC per Gt of oil. BP (2015) reports proved natural gas reserves to be 187.1 trillion m^3. The same source states an energy content of 35.7 trillion BtU per trillion m^3 equal to 35.9 trillion kJ. IPCC (2006) reports 15.3 kgC/GJ for natural gas. This means that 1 trillion m^3 natural gas contains 0.546 GtC. For coal, we use the IPCC (2006) numbers for antracite, giving 0.716 GtC per Gt of coal. For all these conversions, it should be noted that there is substantial variation in carbon content depending on the quality of the fuel and the numbers used must therefore be used with caution.

atmosphere currently contains over 800 GtC. Given the results in the previous sections, we note that burning all proved reserves of oil and natural gas would have fairly modest effects on the climate.[am] Again using BP (2015), we calculate proved reserves of coal to around 600 GtC, providing more potential dangers for the climate.

Using wider definitions of reserves, stocks are much larger. Specifically, using data from McGlade and Ekins (2015) we calculate ultimately recoverable reserves of oil, natural gas and coal to close to 600 GtC, 400 GtC and 3000 GtC.[an] Rogner (1997) estimates coal reserves to be 3500 GtC with a marginal extraction cost curve that is fairly flat. Clearly, if all these reserves are used, climate change can hardly be called modest.

3.2.4 A Linear Carbon Circulation Model

A natural starting point is a linear carbon circulation model. Let us begin with a two-stock model as in Nordhaus and Boyer (2000). We let the variables S_t and S_t^L denote the amount of carbon in the two reservoirs, respectively: S_t for the atmosphere and S_t^L for the ocean. Emissions, denoted E_t, enter into the atmosphere. Under the linearity assumption, we assume that a constant share ϕ_1 of S_t flows to S_t^L per unit of time and, conversely, a share ϕ_2 of S_t^L flows in the other direction implying

$$\begin{aligned} \frac{dS_t}{dt} &= -\phi_1 S_t + \phi_2 S_t^L + E_t, \\ \frac{dS_t^L}{dt} &= \phi_1 S_t - \phi_2 S_t^L. \end{aligned} \tag{11}$$

Eq. (11) form a linear system of differential equations, similar to Eqs. (9) and (10). However, there is a key difference: additions of carbon to this system through emissions get "trapped" in the sense that there is no outflow from the system as a whole, reflecting the fact that one of the characteristic roots of the system in (11) is zero.[ao] This implies that if E settles down to a positive constant, the sizes of the reservoirs S and S^L will not approach a steady state, but will grow forever. If emissions eventually stop and remain zero, the sizes of the reservoirs will settle down to some steady-state values, but these values will depend on the amount of emissions accumulated before that. This steady state satisfies a zero net flow as per

$$0 = -\phi_1 S + \phi_2 S^L, \tag{12}$$

[am] As we will soon see, a substantial share of burned fossil fuel quickly leaves the atmosphere.

[an] See footnote al for conversions.

[ao] If we were to also define a stock of fossil fuel in the ground from which emissions are taken, total net flows would be zero. Since it is safe to assume that flows into the stock of fossil fuel are negligible, we could simply add an equation $\frac{dR_t}{dt} = -E_t$ to the other equations, which would thus capture the depletion of fossil reserves.

implying that

$$\frac{S}{S^L} = \frac{\phi_2}{\phi_1}$$

and that the rate of convergence is determined by the nonzero root $-(\phi_1 + \phi_2)$.

As we have seen above, CO_2 is mixed very quickly into the atmosphere. CO_2 also passes quickly through the ocean surface implying that a new balance between the amount of carbon in the atmosphere and the shallow ocean water is reached quickly.[ap] The further transport of carbon to the deep oceans is much slower, motivating a third model reservoir: the deep oceans. This is the choice made in recent versions of the DICE and RICE models (Nordhaus and Sztorc, 2013), which use a three-reservoir linear system similar to (11).

3.2.5 Reduced-Form Depreciation Models

Although the stock-flow model has a great deal of theoretical and intuitive appeal, it runs the risk of simplifying complicated processes too much. For example, the ability of the terrestrial biosphere to store carbon depends on temperature and precipitation. Therefore, changes in the climate may have an effect on the flows to and from the biosphere not captured in the model described earlier. Similarly, the storage capacity of the oceans depends (negatively) on the temperature. These shortcomings could possibly be addressed by including temperature and precipitation as separate variables in the system. Furthermore, also the processes involved in the deep oceans are substantially more complicated than what is expressed in the linear model. In particular, the fact that carbon in the oceans exists in different chemical forms and that the balance between these has an important role for the dynamics of the carbon circulation is ignored but can potentially be of importance.

An important problem with the linear specification (see, Archer, 2005 and Archer et al., 2009) is due to the so-called Revelle buffer factor (Revelle and Suess, 1957). As CO_2 is accumulated in the oceans, the water is acidified. This dramatically limits its capacity to absorb more CO_2, making the effective "size" of the oceans as a carbon reservoir decrease by approximately a factor of 15 (Archer, 2005). Very slowly, the acidity decreases and the preindustrial equilibrium can be restored. This process is so slow, however, that it can be ignored in economic models. IPCC (2007, p. 25, Technical Summary), take account of the Revelle buffer factor and conclude that "About half of a CO_2 pulse to the atmosphere is removed over a time scale of 30 years; a further 30% is removed within a few centuries; and the remaining 20% will typically stay in the atmosphere for many thousands of years." The conclusion of Archer (2005) is that

[ap] This takes 1–2 years IPCC (2013).

a good approximation is that 75% of an excess atmospheric carbon concentration has a mean lifetime of 300 years and the remaining 25% remain several thousands of years.[aq]

A way of representing this is to define a depreciation model. Golosov et al. (2014) define a carbon depreciation function. Let $1-d(s)$ represent the amount of a marginal unit of emitted carbon that remains in the atmosphere after s periods. Then postulate that

$$1-d(s)=\varphi_L+(1-\varphi_L)\varphi_0(1-\varphi)^s. \tag{13}$$

The three parameters in (13) are easily calibrated to match the three facts in the earlier IPCC quote; we do this in Section 5. A similar approach is described in IPCC (2007a, table 2.14). There,

$$1-d(s)=a_0+\sum_{i=1}^{3}\left(a_i e^{-\frac{s}{\tau_i}}\right), \tag{14}$$

with $a_0=0.217$, $a_1=0.259$, $a_2=0.338$, $a_3=0.186$, $\tau_1=172.9$, $\tau_2=18.51$, and $\tau_3=1.186$, where s and the τ_is are measured in years. With this parametrization, 50% of an emitted unit of carbon has left the atmosphere after 30 years, 75% after 356 years, and 21.7% stays forever. It is important to note that this depreciation model is appropriate for a marginal emission at an initial CO_2 concentration equal to the current one (around 800 GtC). The parameters of the depreciation function should be allowed to depend on initial conditions and inframarginal future emissions. If emissions are very large, a larger share will remain in the atmosphere for a long time. To provide a measure for how sensitive the parameters are, note that of an extremely large emission pulse of 5000 GtC, which is more than 1 × the current accumulated emissions, around 40% remains after a thousand years, as opposed to half as much for a much smaller pulse.[ar]

3.2.6 A Linear Relation Between Emissions and Temperature

As discussed earlier, it may be too simplistic to analyze the carbon circulation in isolation. The storage capacity of the various carbon sinks depends on how the climate develops. One might think that including these interactions would make the model more complicated. However, this does not have to be the case. In fact, there is evidence that various feedbacks and nonlinearity in the climate and carbon-cycle systems tend to cancel each other out, making the combined system behave in a much simpler and, in fact, linear way.[as] In order to briefly discuss this, let us defined the variable CCR_m (Carbon-Climate Response) as the change in the global mean temperature over some specified time interval m per unit of emissions of fossil carbon into the atmosphere over that same time interval

[aq] Similar findings are reported in IPCC (2013, Box 6.1).

[ar] See IPCC (2013, Box 6.1).

[as] This subsection is based on Matthews et al. (2009).

$$CCR_m \equiv \frac{T_{t+m} - T_t}{\int_t^m E_s ds}.$$

Given our previous discussions in this and the previous sections, one would think that this variable is far from a constant: the dynamic behavior of the climate and the carbon cycle will in general make the CCR_m depend on the length of the time interval considered. For example, since it takes time to heat the oceans, the temperature response could depend on whether the time interval is a decade or a century. Similarly, since also the carbon dynamics are slow, the extra CO_2 concentration induced by a unit of emission tends to be lower the longer the time interval considered. Furthermore, the CCR_m might depend on how much emissions have already occurred; higher previous emissions can reduce the effectiveness of carbon sinks and even turn them into net contributors. The marginal effect on temperature from an increase in the CO_2 concentration also depends on the level of CO_2 concentration due to the logarithmic relation between CO_2 concentration and the greenhouse effect.

Quite surprisingly, Matthews et al. (2009) show that the dynamic and nonlinear effects tend to cancel, making it a quite good approximation to consider the CCR_m as a constant, CCR, independent of both the time interval considered and the amount of previous emissions. Of course, knowledge about the value of CCR is incomplete but Matthews et al. (2012) quantify this knowledge gap and argue that a 90% confidence interval is between 1 and 2.5°C per 1000 GtC.[at] This means that we can write the (approximate) linear relationship

$$T_{t+m} = T_t + CCR \int_t^m E_s ds.$$

To get some understanding for this surprising result, first consider the time independence. We have shown in the previous chapter that when the ocean is included in the analysis, there is a substantial delay in the temperature response of a given forcing. Thus, if the CO_2 concentration permanently jumps to a higher level, it takes many decades before even half the final change in temperature has taken place. On the other hand, if carbon is released into the atmosphere, a large share of it is removed quite slowly from the atmosphere. It happens to be the case that these dynamics cancel each other, at least if the time scale is from a decade up to a millennium. Thus, in the shorter run, the CO_2 concentration and thus forcing is higher but this is balanced by the cooling effect of the oceans.

Second, for the independence of CCR with respect to previous emissions note that the Arrhenius law discussed in the previous chapter implies a logarithmic relation

[at] IPCC (2013) defines the very similar concept, the Transient Climate Response to cumulative carbon Emissions (TCRE), and states that it is likely between 0.8 and 2.5°C per 1000 GtC for cumulative emissions below 2000 GtC.

between CO_2 concentration and the temperature. Thus, at higher CO_2 concentrations, an increase in the CO_2 concentration has a smaller effect on the temperature. On the other hand, existing carbon cycle models tend to have the property that the storage capacity of the sinks diminishes as more CO_2 is released into the atmosphere. These effects also balance—at higher levels of CO_2 concentration, an additional unit of emissions increases the CO_2 concentration more but the effect of CO_2 concentration on temperature is lower by roughly the same proportion.

Given a value of CCR, it is immediate to calculate how much more emissions can be allowed in order to limit global warning to a particular value. Suppose, for example, we use a value of $CCR = 1.75$. Then, to limit global warming to 2°C, we cannot emit more than $(2/1.75) \times 1000 = 1140$ GtC, implying that only around 600 GtC can be emitted in the future. If, on the other hand, we use the upper limit of the 95% confidence interval ($CCR = 2.5$) and aim to reduce global warming to 2°C, accumulated emissions cannot be more than a total of 800 GtC of which most is already emitted.

3.3 Damages

In this section, we discuss how the economy is affected by climate change. Since economic analysis of climate change tends to rely on cost-benefit calculation, it is not only a necessary cornerstone of the analysis but arguably also a key challenge for climate economics. For several reasons, this is a very complicated area, however. First, there is an almost infinite number of ways in which climate change can affect the economy. Second, carbon emissions are likely to affect the climate for a very long time: for thousands of years. This implies that the quantitative issue of what weight to attach to the welfare of future generations becomes of key importance for the valuation. Third, global climate change can potentially be much larger than experienced during the modern history of mankind. Historical relations between climate change and the economy must therefore be extrapolated significantly if they are to be used to infer the consequences of future climate change. Fourth, many potential costs are to goods and services without market prices.

The idea that the climate affect the economy is probably as old as the economy itself, or rather as old as mankind. That the distribution of weather outcomes—the climate—affects agricultural output must have been obvious for humans since the Neolithic revolution. The literature on how the climate affects agriculture is vast and not reviewed here. It is also well known that in a cross-country setting, a hotter climate is strongly associated with less income per capita. Also within countries, such a negative relation between temperature and income per capita can be found (Nordhaus, 2006). However, Nordhaus (2006) also finds a hump-shaped relation between output density, ie, output per unit of land area, and average temperature. This suggests that a method of adaptation is geographic mobility. An overview is provided in Tol (2009). A more recent economic literature using modern methods emphasizing identification is now rapidly expanding. The focus is broad and climate change is allowed to have many different effects, including a heterogeneous effect on the economic productivity of different production sectors, effects on health, mortality, social unrest, conflicts, and much more. Dell et al. (2014) provide an overview of this newer literature.

Climate change thus likely has extremely diverse effects, involving a large number of different mechanisms affecting different activities differently. The effects are spatially heterogeneous and have different dynamics. Despite this, it appears important to aggregate the effects to a level that can be handled by macroeconomic models.[au]

3.3.1 Nordhaus's Approach

Early attempts to aggregate the economic impacts of climate change were carried out in Nordhaus (1991).[av] Nordhaus (1992, 1993) constructed the path-breaking integrated assessment model named DICE, ie, a model with the three interlinked systems—the climate, the carbon cycle, and the economy.[aw] This is a global growth model with carbon circulation, and climate module, and a damage function. This very early incarnation of the damage function assumed that the economic losses from global warming were proportional to GDP and a function of the global mean temperature, measured as a deviation from the preindustrial average temperature. Nordhaus's assumption in the first version of DICE was that the fraction of output lost was

$$D(T) = 0.0133\left(\frac{T}{3}\right)^2.$$

Nordhaus underlines the very limited knowledge that supported this specification. His own study (Nordhaus, 1991) studies a number of activities in the United States and concludes that these would contribute to a loss of output of 0.25% of US GDP for a temperature deviation of 3°C. He argues that a reasonable guess is that the this estimate omits important factors and that the United States losses rather are on the order of 1% of GDP and that the global losses are somewhat larger. Nordhaus (1992) cites Cline (1992) for an estimate of the power on temperature in the damage function but chooses 2 rather than the cited 1.3.

Later work (Nordhaus and Boyer, 2000) provided more detailed sectorial estimates of the damage function. Here, the aggregation includes both damages that accrue to market activities and those that could affect goods, services, and other values that are not traded.

[au] Macroeconomic modeling with large degrees of heterogeneity is developing rapidly, however. In the context of climate economy modeling, see eg, Krusell and Smith (2015) for a model with nearly 20,000 regions.

[av] Other early examples are Cline (1992), Fankhauser (1994), and Titus (1992).

[aw] DICE stands for Dynamic Integrated Climate-Economy model.

An attempt to value the risk of catastrophic consequences of climate change is also included. Obviously, this is an almost impossible task, given the little quantitative knowledge about tail risks. Nordhaus and Boyer use a survey, where climate experts are asked to assess the probability of permanent and dramatic losses of output at different increases in the global mean temperature.

The latest version of DICE (Nordhaus and Sztorc, 2013) instead goes back to a more ad-hoc calibration of the damage function. Based on results in a survey in Tol (2009) and IPCC (2007b) depicted in Fig. 9, they postulate a damage function given by

$$D(T) = 1 - \frac{1}{1 + 0.00267T^2}. \tag{15}$$

The functional form in (15) is chosen so that damages are necessarily smaller than 1 but for the intended ranges of temperature, it may be noted that $1 - \frac{1}{1+0.00267T^2} \approx 0.023\left(\frac{T}{3}\right)^2$.[ax] Thus, the functional form remains similar to the first version of DICE but the estimated damages at three degrees have increased from 1.3% to 2.3% of global GDP.

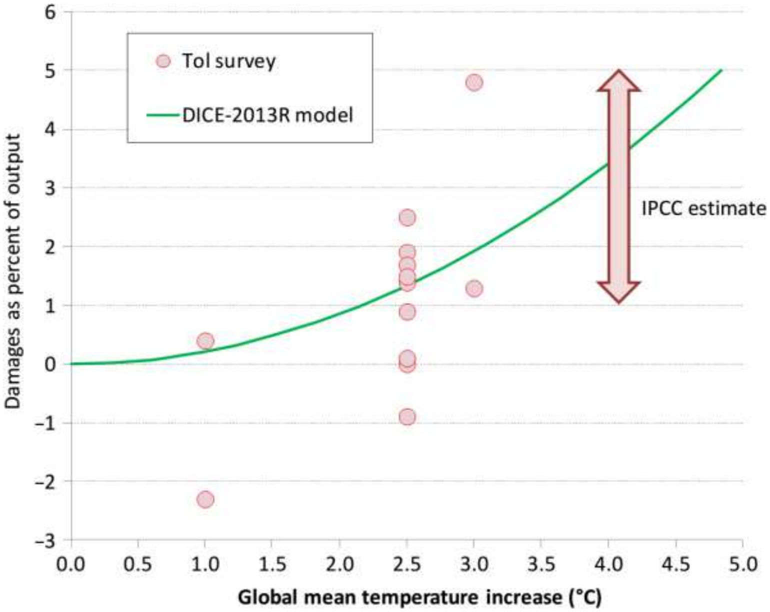

Fig. 9 Global damage estimates. Dots are from Tol (2009). The solid line is the estimate from the DICE-2013R model. The arrow is from the IPCC (2007b, page 17). *Reprinted from Nordhaus, W.D., Sztorc, P., 2013. DICE 2013R: introduction and users manual. Mimeo, Yale University.*

[ax] It is important to note that Nordhaus and Sztorc (2013) warn against using their damage function for temperature deviations over 3°C.

Nordhaus has also developed models with multiple regions, RICE (Regional Integrated Climate-Economy model). The later versions of this model have different damage functions defined for 12 regions. Here, the linear-quadratic function of the global mean temperature is appended with a threshold effect at a four-degree temperature deviation: at this level, the exponent on the temperature is increased to six. Separate account is also taken for sea-level rise, whose damages are described using a linear-quadratic function.

Similar aggregate damage functions are used in other global integrated assessment models; prominent examples are WITCH, FUND, and PAGE.[ay]. Specifically, WITCH has quadratic, region-specific damage functions for eight global regions. FUND uses eight different sectorial damage functions defined for each of 16 regions. PAGE, which was used in the highly influential Stern report (Stern, 2007), uses four separate damage functions for different types of damages in each of eight regions. A special feature of the damage functions in FUND is that the exponent on the global mean temperature is assumed to be a random variable in the interval [1.5–3].

3.3.2 Explicit Damage Aggregation

The damage functions described so far has only been derived to a limited degree from a "bottom-up approach" where explicit damages to particular regions and economic sectors are defined and aggregated. To the extent that such an approach has been used, the final results have been adjusted in an ad-hoc manner, often in the direction of postulating substantially larger damages than found in the explicit aggregation. Furthermore, the work has abstracted from general-equilibrium effects and simply added estimated damages sector by sector and region by region. Obviously this is problematic as the welfare consequences of productivity losses to a particular sector in a particular region depend on the extent to which production can move to other regions or be substituted for by other goods.

An example of a detailed high-resolution modeling of climate damages where (regional) general equilibrium effects are taken into account is the PESETA project, initiated by the European Commission.[az] Damages estimated are for coastal damages, flooding, agriculture, tourism, and health in the European Union. A reference scenario there is a 3.1°C increase in the temperature in the EU by the end of this century relative to the average over 1961–90. The resulting damages imply an EU-wide loss of 1.8% of GDP. The largest part of this loss is due to higher premature mortality in particular in south-central EU.[ba] In the northern parts of the EU, welfare gains associated mainly with lower energy expenditures are approximately balanced by negative impacts in

[ay] See Bosetti et al. (2006), Tol (1995), and Chris et al. (1993) for descriptions of WITCH, FUND, and PAGE, respectively.

[az] See Ciscar et al. (2011) for a short description.

[ba] France, Austria, Czech Republic, Slovakia, Hungary, Slovenia, and Romania.

human health and coastal area damages.[bb] Clearly, these effects are small relative to the expectations for economic growth over this period as well as compared to fears of dramatic impacts often expressed in the policy debate about climate change.

3.3.3 Top-Down Approaches

An alternative approach to the bottom-up approach is to estimate a reduced-form relation between aggregate measures like GDP, consumption, and investments and climate. The idea here is to associate natural historical variation in climate to changes in the aggregate variables of interest. Most of this work thus focuses on short-run changes in temperature as opposed to climate change. Examples of this approach are Dell et al. (2012) who examine how natural year-to-year variation in a country's temperature affects its GDP. Using data from 1950–2003, they find strong and persistent effects of a temporary deviation in temperature, with a point estimate of 1.4% of GDP per degrees Celsius—*but only in poor countries*. A similar result, but using global variation in the temperature, is reported by Bansal and Ochoa (2011). Krusell and Smith (2015), however, find that positive temperature shocks affect the level of GDP but not its rate of growth, and they do not find evidence of a difference between rich and poor countries.

Another approach is taken in Mendelsohn et al. (1994). Instead of attempting to measure a direct relation between climate and output, ie, estimating a production function with climate as an input, the focus is here on agricultural land prices. They label this a *Ricardian approach*.The advantage of this is that adaptation, for example changed crops, can be taken into account. The finding is that higher temperature, except in the fall, is associated with lower land prices. However, the strength in this relation is lower than what is suggested by estimates based on traditional production function analysis. This indicates that the latter underestimates the potential for adaptation.

Burke et al. (2015) estimate empirical relations between economic activity and climate by assuming that local damages are a function not of global temperature but of local temperature. That is, heterogeneity here is built in not in terms of differences in responses to global temperature changes but simply through how local climates are very different to start with. If a region is very cold, warming can be beneficial, and if a region is very warm, further warming will likely be particularly detrimental. In line with Nordhaus (2006), a hump-shaped relation between economic activity and average yearly temperature is then estimated, with a maximum around 12–13°C. If this relation is taken as a causal relation from climate to productivity, it can be used to measure the long-run consequences of climate change. However, the use of the relation to evaluate long-run consequences precludes a study of short- and medium-run costs. This holds in particular for the costs of geographic reallocation of people, an area where little is known. In line with Burke et al. (2015) and Krusell and Smith (2015) postulate a unique damage function of local

[bb] This area is defined by Sweden, Finland, Estonia, Lithuania, Latvia, and Denmark.

temperature for a large number of regions and impose the condition that this function generate Nordhaus's estimated aggregate damages for warming of 1°C, 2.5°C, and 5°C. They find a somewhat lower ideal temperature than do Burke et al. but that the losses from having local temperatures far from the ideal value can be very large.

3.3.4 Remarks

The section on damage measurements in this chapter is short and does not do full justice to the literature. However, even a very ambitious survey would make clear that the research area of damage measurement is at a very early stage and provides frustratingly little guidance for cost-benefit analysis. On the one hand, most of the evidence points to rather limited aggregate global damages, at last for moderate degrees of climate change. On the other hand, it is not possible to rule out large damages, at least if climate change is more than moderate. After all, if the damages from climate change cannot be measured and quantified, how can we arrive at policy recommendations? There is no quick answer; much more research on this is clearly needed. In the absence of more solid evidence there is unfortunately ample room for extreme views—on both sides of the climate debate—to make claims about damage functions that support any desired action. We therefore prefer to proceed cautiously and to base our calibrations of damage functions on the evidence that, after all, has been gathered and put together. But before moving on to a description of the approach we take here, let us make some remarks about some mechanisms we will be abstracting from and that could nevertheless prove to be important.

One aspect of damages concerns the long run: is it possible that a warmer climate hurts (or helps?) long-run economic development, and might it even affect the growth rate of output? The work by Dell et al. (2012) as well as Burke et al. (2015) suggest such effects might be present on the local level, though without providing evidence on mechanisms. For an overall growth-rate effect on world GDP, there is as far as we know no evidence. Clearly, any growth effects—by naturally adding effects over time—will lead to large total effects, and that regions at different ends of the distribution would diverge in their levels of production and welfare, and it is not clear that our growth data support this conclusion. At the same time, the large implied effects make it all the more important to dig deeper and understand whether growth effects could actually be present. To be clear, our null hypothesis is that there are no effects on long-run growth rates of climate change.

Relatedly, it is common—following Nordhaus's lead—to describe damages as essentially proportional to GDP. This formulation, which to an important extent appears to be untested, has some important implications. One is that higher GDP ceteris paribus leads to higher damages. Another is that, since lower GDP means less to consume and consumption (typically, in macroeconomic models) is assumed to be associated with diminishing marginal utility, the welfare losses from a unit of damage measured in consumption units are lower the higher is GDP. Thus, if future generations will have higher GDP than we have today, there are two opposing forces: the total damages in consumption units will be higher but each of those units will hurt future generations less. As we shall see, under reasonable assumptions on utility, those two forces cancel, or roughly cancel. However, there are various ways to depart from Nordhaus approach. One is to assume that damages occur in consumption units but are not (linearly) proportional to GDP (eg, our capital stock could be damaged). Another is to think of damages as occurring to specific consumption bundles that may not display the same degree of diminishing returns as consumption as a whole (examples include effects on leisure, health, or longevity). Damages can also occur in the form of changes in the distribution of resources and in other ways that are not easily thought of in terms of an aggregate damage function proportional to GDP.

Climate change can also lead to social conflict, as it changes the values of different activities and, more generally, "endowments." One channel occurs via migration: if a region is hit hard by a changed climate and people migrate out, history tells us that the probability of conflict in the transition/destination areas will rise (see eg, Miguel et al., 2004, Burke et al., 2009, Jia, 2014, Harari and La Ferrara, 2014, and Burke et al., 2015, for an overview). At the same time, migration is also one of the main ways humans have to adapt to a changing climate. In fact, one view is that "populations can simply move toward the poles a bit" and hence drastically limit any damages from warmer weather; see Desmet and Rossi-Hansberg (2015) for an analysis that takes the migration mechanism seriously (see also Brock et al., 2014). A related aspect is that climate change will have very diverse effects. It may be true that aggregated damages are small as a share of GDP and that those who lose a lot could be compensated by other, losing less or nothing at all. However, such global insurance schemes do not exist, at least not presently. The extent to which there are compensating transfers will likely to greatly impact any reasonable cost-benefit analysis of climate change and policies against it.

Tipping points are often mentioned in the climate-economy area and earlier we discussed some possible tipping points in the natural-science sections. Damages can also have tipping points in various ways and on some level a tipping point is simply a highly nonlinear damage function. One example leading to tipping points is the case of rising sea levels due to the melting of the ice caps. Clearly, some areas may become flooded and uninhabitable if the sea level rises enough, and the outcome is thus highly nonlinear. This argument speaks clearly in favor of using highly nonlinear damage functions on the local level, at least when it comes to some aspects of higher global temperatures. However, the sea-level rise equally clearly does not necessarily amount to a global nonlinearity in damages. Suffice it to say here that very little is known on the topic of global tipping points in damages. We will proceed with the null that a smooth convex aggregate damage function is a good starting point: we follow Nordhaus in this respect as well.

On an even broader level, let us be clear that different approaches are needed in this area. Bottom-up structural approaches like the PESETA project are very explicit and allow extrapolation, but they are limited to a certain number of factors and may miss important other mechanisms. Reduced-form micro-based approaches allow credible identification but may also miss important factors and general-equilibrium effects. Reduced-form aggregate approaches are less likely to miss mechanisms or general-equilibrium effects but necessarily involve a small number of observables and are much harder to interpret and extrapolate from. There is, we believe, no alternative at this point other than proceeding forward on all fronts in this important part of the climate-economy research area.

3.3.5 The Operational Approach: A Direct Relation

We now discuss a very convenient tool for the rest of the analysis in this chapter: a way of incorporating the existing damage estimates into our structural integrated-assessment models. In Section 3.1.1, we have noted that the relation between the CO_2 concentration and the greenhouse effect is concave (it is approximately logarithmic). The existence of feedbacks is likely to imply an amplification of the direct effect, but in the absence of known global threshold effects, the logarithmic relation is likely to survive. Above we have also noted that that modelers so far typically have chosen a convex relation between temperature and damages: at least for moderate degrees of heating, a linear-quadratic formulation is often chosen. Golosov et al. (2014) show that the combination of a concave mapping from CO_2 concentrations to temperature and a convex mapping from temperature to damages for standard parameterizations imply an approximately constant marginal effect of higher CO_2 concentration on damages as a share of GDP. Therefore, they postulate

$$D(T(S)) = 1 - e^{-\gamma(S-\bar{S})}, \tag{16}$$

where S is the amount of carbon in the atmosphere at a point in time and $\bar{S}$ is its preindustrial level. This formulation disregards the dynamic relation between CO_2 concentration and temperature. It also disregards the possibility of abrupt increases in the convexity of the damage mapping and threshold effects in the climate system. These are important considerations, in particular when large increases in temperature are considered. However, the approximation provides a very convenient benchmark by implying that the marginal damage measured as a share of GDP per marginal unit of carbon in the atmosphere is constant and given by γ.[bc] Measuring S in billions of tons of carbon (GtC), Golosov et al. (2014) show that a good approximation to the damages used to derive the damage function in DICE (Nordhaus, 2007) is given by (16) with $\gamma = 5.3 \cdot 10^{-5}$.

In Fig. 10, we show an exponential damage function with this parameter. Specifically, the figure shows the implied damage function plotted against temperature using the relationship $T(S) = 3\frac{\ln S - \ln S_0}{\ln 2}$, ie, using a climate sensitivity of 3 degrees. Comparing this damage function to the Nordhaus function as depicted in Fig. 9, we see that the former is

[bc] Output net of damages is $e^{-\gamma(S-S_0)}Y$. Marginal damages as a share of net-of-damage output then become $[d((1-e^{-\gamma(S-S_0)})Y)/dS]/e^{-\gamma(S-S_0)}Y = \gamma$.

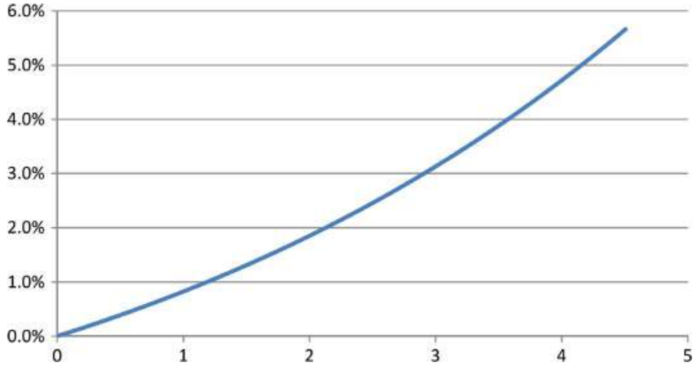

Fig. 10 Damage function using $T(S) = 3\frac{\ln S - \ln S_0}{\ln 2}$ and $D(T(S)) = 1 - e^{-\gamma(S-\bar{S})}$.

slightly less convex.[bd] While the exponential damage function implies a constant marginal loss of 0.0053% per GtC, the quadratic formulation implies increasing marginal loss up to approximately 4°C. However, in the important range 2.5–5.0°C, the marginal loss is fairly constant within the range 0.0053% and 0.0059% per GtC.

4. A STATIC GLOBAL ECONOMY-CLIMATE MODEL

Our discussion of integrated assessment models comes in two parts. The first part—in the present section—introduces an essentially static and highly stylized model, whereas the second part presents a fully dynamic and quantitatively oriented setup. The simple model in the present section can be viewed as a first step and an organizational tool: we can use it to formally discuss a large number of topics that have been studied in the literature. Moreover, for some of these topics we can actually use the model for a quantitative assessment, since it has most of the features of the macroeconomic structure in the later section. The model is thus a static version of Golosov et al. (2014) and it is also very similar to Nordhaus's DICE model.

We consider a world economy where the production of output—a consumption good—is given by

$$c = A(S)k^{\alpha}n^{1-\alpha-\nu}E^{\nu} - \zeta E.$$

Here, $A(S)$ denotes global TFP, which we take to be a function of the amount of carbon in the atmosphere, S. Moreover, we normalize so that S measures the excess carbon concentration, relative to a preindustrial average, $\bar{S}$. That is, the actual concentration is $S + \bar{S}$, whereas we will only need to use S in our modeling. The discussion in Section 3.3 allows us to use this notation and, moreover, to use a simple functional form that we argue is a

[bd] Reducing the exponent on temperature to 1.5 and increasing the constant in front of temperature to 0.0061 in (15) produces a damage function very close to the exponential one.

decent approximation to the complex system mapping the amount of carbon in the atmosphere to temperature and then mapping temperature, with its negative impacts on the economy, to TFP. We will thus use

$$A(S) = e^{-\gamma S},$$

with $\gamma > 0$. Recall from the previous discussions that the map from S to T is logarithmic, so it features decreasing marginal impacts of increased atmospheric carbon concentration on temperature. The estimated mapping from T to TFP, on the other hand, is usually convex, so that the combined mapping actually can be described with the negative exponential function. Thus, damages are $(1 - e^{-\gamma S})k^{\alpha}n^{1-\alpha-\nu}E^{\nu}$, which is increasing and concave in S. (Note that we let energy, E, be capitalized henceforth, to distinguish it from Euler's number, e, used in the exponential damage function.) Though we argue above that this form for the damage function is a good one, it is straightforward to change it in this simple model, as we will below in one of our model applications. The exponential function is also useful because it simplifies the algebra and thus helps us in our illustrations. We will occasionally refer to γ as the *damage elasticity of output*.

The inputs in production include capital and labor, which we take to be exogenously supplied in the static model. The production function is Cobb–Douglas in the three inputs. As for capital and labor entering this way, we just use the standard macroeconomic formulation. The substitution elasticity between the capital-labor composite and energy is also unitary here, which is not far from available estimates of long-run elasticities, and we think of the static model as a short-cut representation of a long-run model. The short-run elasticity is estimated to be far lower, as discussed in Section 2.3.

We also see that the generation of output involves a cost ζE of producing energy. We will discuss in detail below how energy is generated but the simple linear form here is useful because it allows us to illustrate with some main cases. One of these cases is that when energy is only produced from oil. Much of the oil (say, the Saudi oil) is very cheap to produce relative to its market price, so in fact we can think of this case as characterized by $\zeta = 0$. Oil exists in finite supply, so this case comes along with an upper bound on energy: $E \leq \bar{E}$.

A second case is that when energy comes from coal. Coal is very different because its market price is close to its marginal cost, so here we can think of ζ as a positive deep parameter representing a constant marginal cost in terms of output units (and hence the cost of producing energy in terms of capital and labor, and energy itself, has the same characteristics as does the final-output good). Coal is also only available in a finite amount but the available amount here is so large that we can think of it as infinite; in fact, if we were to use up all the coal within, say, the next 500 years, the implied global warming will be so high that most analysts would regard the outcome as disastrous, and hence the presumption in this case is that not all of the amount will be used up (and hence considering the available amount to be infinite is not restrictive). In reality, the supply of fossil fuel is of course not dichotomous: a range of fuels with intermediate extraction costs exists (see the discussion earlier in Section 3.2.3).

A third case is that with "green energy," where a constant marginal cost in terms of output is also a reasonable assumption. Finally, we can imagine a combination of these three assumptions and we will indeed discuss such possibilities below, but it is useful to consider coal and oil first separately first.

Turning to the mapping between energy use and atmospheric carbon concentration, the different energy sources correspond to different cases. In the case of oil and coal, we will simply assume that $S = \phi E + \bar{S}$, where $\bar{S}$ is the part of carbon concentration that is not of anthropogenic origin. As constants in TFP do not influence any outcomes here, we normalize $\bar{S}$ to equal zero. The equation thus states that carbon concentration is increased by the amount of emissions times ϕ. The constant ϕ represents the role of the carbon cycle over the course of a model period—which we will later calibrate to 100 years—and captures the fraction of the emissions during a period that end up in the atmosphere. A explained in Section 3.2, the depreciation structure of carbon in the atmosphere, though nontrivial in nature, can be rather well approximated linearly. Emissions, in turn, are proportional to the amount of fossil fuel used.[be]

We consider a consumer's utility function that, for now, only has consumption as an argument. Hence, so long as it is strictly increasing in consumption the model is complete.

We will discuss outcomes in a market economy of this sort where the consumer owns the capital and supplies labor under price taking, just like in standard macroeconomic models. Firms buy inputs, including energy, in competitive markets and energy is produced competitively. Formally, we can think of there being two sectors where isoquants have the same shape but where in the consumption-goods sector firms solve

$$\max_{k,l,E} e^{-\gamma S} k^{\alpha} n^{1-\alpha-\nu} E^{\nu} - wn - rk - pE,$$

where we denote wages and rental rates by w and r, respectively, and where p is the price of energy; the consumption good is the numéraire. In the energy sector the firms thus solve

$$\max_{k,l,E} p \frac{e^{-\gamma S}}{\zeta} k^{\alpha} n^{1-\alpha-\nu} E^{\nu} - wn - rk - pE.$$

It is straightforward to show, because the Cobb–Douglas share parameters are the same in the two sectors and inputs can be moved across sectors without cost, that this delivers

[be] Constants of proportion are omitted and are inconsequential in this simple model. In a more general framework one must take into account how oil and coal differ in the transformation between the basic carbon content and the resulting emissions as well as how they differ in productive use. We discuss these issues below when we consider coal and oil jointly.

$p=\zeta$ (whenever energy is nontrivially produced, so in the coal and green-energy cases, $1/\zeta$ becomes the TFP in the energy sector relative to that in the final-goods sector). Note also that GDP, y, equals the production of the consumption good, since energy here is an intermediate input.[bf]

Note that in both of the above profit maximization problems firms do not choose S, ie, they do not perceive an effect on TFP in their choice, even though $S=\phi E$ in equilibrium. This is as it should be: the climate damage from emissions are a pure, and global, externality. Markets fail to take this effect into account and optimal policy should be designed to steer markets in the right direction.

The associated planning problem thus reads

$$\max_E e^{-\gamma\phi E}k^\alpha n^{1-\alpha-\nu}E^\nu-\zeta E;$$

here, clearly, the externality is taken into account. In the case of oil, for which $\zeta=0$ is assumed, there is an additional constraint for the planner, namely that $E\leq\bar{E}$.

We will now discuss the solution to this problem for the different cases, starting with the case of oil.

4.1 The Case of Oil

Here, $\zeta=0$ and the energy-producing sector is trivial. Under laissez-faire, all of the oil is supplied to the market and its price will be given by its marginal product: $p\equiv\bar{p}=\nu e^{-\gamma\phi\bar{E}}k^\alpha n^{1-\alpha-\nu}\bar{E}^{\nu-1}$. To the extent $\bar{E}$ and $\gamma\phi$ are large, this will involve an allocation with large damages to welfare.

The planner, on the other hand, may not use up all the oil. It is straightforward to see that the solution to the planner's problem is a corner solution whenever $\bar{E}<\nu/(\gamma\phi)$: the planner would then, like the markets, use up all the available oil. Thus, there is a negative by-product of emissions but it is not, at its maximal use, so bad as to suggest that its use should be limited. (In fact, as we shall argue below, this is not an unreasonable conclusion for oil given a more general, calibrated structure.) If, on the other hand, $\bar{E}\geq\nu/(\gamma\phi)$, the solution is interior at an E that solves $E=\nu/(\gamma\phi)$.

4.1.1 Optimal Taxes

What are the policy implications of this model? For a range of parameter values—for $\bar{E}<\nu/(\gamma\phi)$—no policy is needed. At the same time, taxes are not necessarily harmful: if we think of a unit tax on the use of oil (the firms, whose maximization problems are displayed earlier), so that users of oil pay $p+\tau$ per unit instead of p, all tax rates on

[bf] We do not explicitly have a home sector demanding energy. We take GDP to include housing services and to the extent they can be thought of as produced according to the market production function, these energy needs are included, but other home energy needs (such as gasoline for cars) are simply abstracted from.

oil less than $\bar{p}$ will deliver the optimal outcome (recall that the price of oil is a pure rent and the tax will therefore not affect the allocation). If the unit tax is exactly equal to $\bar{p}$, the market price of oil will be zero and oil producers are indifferent between producing or not. At this level there is still an equilibrium which delivers the optimal amount of oil, namely, when all producers choose to produce; otherwise, not enough oil is used.

So suppose instead that $\bar{E} > \nu/(\gamma\phi)$. Now a tax is needed, and the tax should be set so that $p=0$; the price is zero at the socially optimal use of oil. Otherwise, no oil producer would restrict its production and the outcome would be $\bar{E}$. With a tax that is high enough that the price oil producers receive is zero, ie,

$$\tau = \nu e^{-\nu} k^{\alpha} n^{1-\alpha-\nu} \left(\frac{\nu}{\gamma\phi}\right)^{\nu-1},$$

there exists an equilibrium where precisely oil output is equal to $\nu/(\gamma\phi) < \bar{E}$.

4.1.2 Pigou and the Social Cost of Carbon: A Simple Formula

A different way of getting at optimal policy here is to directly compute the optimal tax of carbon to be that direct damage cost of a unit of emission that is not taken into account by markets. This "marginal externality damage" is referred to in the literature as the *social cost of carbon*.[bg] Moreover, the concept needs to be sharpened as the marginal externality damage can be computed at different allocations. We thus refer to the *optimal social cost of carbon* (OSCC) as the marginal externality damage of a unit of carbon emission evaluated at the optimal allocation. Let the optimal carbon amount be denoted E^*. Given Pigou's principle (Pigou, 1920), the OSCC is the way to think about optimal tax policy, so the tax to be applied is

$$\tau^* = \gamma\phi e^{-\gamma\phi E^*} k^{\alpha} n^{1-\alpha-\nu} (E^*)^{\nu},$$

since this is the derivative of the production function with respect to E where it appears as an externality, evaluated at E^*. The idea here is that this tax always allows the government to achieve the optimal outcome as a competitive equilibrium with taxes. To check that this is consistent with the brute-force analysis earlier, note first that for the case where $E^* = \bar{E}$, $\tau^* = \gamma\phi y^* < \nu y^*/\bar{E}$, where y^* is the optimal level of output. Thus, in equilibrium $p = \nu y^*/\bar{E} - \gamma\phi y^* > 0$, which is consistent with all oil being sold. For the case where $\bar{E} > \nu/(\gamma\phi)$, the optimal tax formula $\tau^* = \gamma\phi y^*$ implies, at the interior solution $E^* = \nu/(\gamma\phi)$, that $p + \tau^* = \nu y^*/E^* = \gamma\phi y^*$ so that $p = 0$. In other words, oil producers are indifferent between producing or not and E^* is therefore an optimal choice.

[bg] The terminology is perhaps a little misleading since one might be led to think that the social cost is the sum of the private and the externality cost, ie, the total cost. Instead "social" just refers to the part not taken into account by the market.

More generally, it is important to understand that Pigou pricing proceeds in two steps: (i) work out the optimal allocation, by solving the planning problem; and (ii) find the OSCC at this allocation and impose that tax. The first step is straightforward in principle but can be challenging if the planning problem is not convex, eg, because the damage function is highly nonlinear; in such a case, there may in particular be multiple solutions to the planner's first-order conditions. The second step has a potential difficulty if for a given tax there are multiple market equilibria. The simple baseline model here does not admit multiple equilibria for a given tax rate but such models are not inconceivable. One important case may be where there are coordination problems in which technology a society chooses—perhaps between a fossil and a green technology. We discuss such cases later.

The OSCC formula that we derived says that the optimal unit tax on carbon is proportional to the value of GDP at the optimal allocation, with a constant of proportionality given by $\gamma\phi$. This result is an adaptation of the finding in Golosov et al. (2014) who derive the OSCC to be proportional to GDP in a much more general setting—a dynamic model that is calibrated to long-run data. The constant of proportionality in that model is also a function of other parameters relating to intertemporal preferences and the carbon cycle, both elements of which are dynamic modeling aspects. They also find this result to be very robust to a number of modeling changes. We shall review these results later but it is important to note already at this point that the core of the proportionality of the OSCC to output can be explained within the structure of the simple static model here.

4.1.3 Costs of Carbon When Taxes are not Optimally Set

Let us emphasize what the OSCC formula says and does not say. It tells us what the marginal externality cost of carbon is, provided we are in an optimal allocation. However, as there appear to be damages from global warming on net and very few countries have carbon taxes, the real world is not at an optimal allocation with respect to carbon use, and this fact suggests that there is another measure that might be relevant: what the marginal externality cost of carbon is today, in the suboptimal allocation. So let SCC, the *social cost of carbon*, be a concept that can be evaluated at any allocation, and suppose we look at the laissez-faire allocation.

One can, conceptually, define a SCC in more than one way. We will define it here as the marginal externality damage of carbon emissions *keeping constant behavior in the given allocation*. This is an important qualification, because if an additional unit of carbon is emitted into the atmosphere, equilibrium decisions will change—whether we are in an optimal allocation or not—and if the given allocation is not optimal, the induced changes in behavior will, in general, have a first-order effect on utility. Hence, an alternative definition would, somehow, take the induced changes in decisions into account. (If the allocation is optimal, these effects can be ignored based on an envelope-theorem argument.)

Let us thus compute the SCC for the case of our static model. Let us assume $\bar{E} > \nu/(\gamma\phi)$, so that there is excessive carbon use. Then the SCC, $\gamma\phi y$, is lower than the OSCC, $\gamma\phi y^*$. This is of course true since $y^* > y$ by definition: the planner's aim is precisely to maximize GDP in this simple model and laissez-faire markets fail to. Note also that the percentage difference between the two measures here is only a function of $\bar{E}$ and E^* and not of other indicators of the "size" of the economy, such as the amount of capital or labor.

Depending on the allocation we are looking at, the SCC may in general be higher or lower than the OSCC. There is also no presumption that the laissez-faire SCC have to be higher than the OSCC, which one might imagine if the marginal damages of emissions rise with the level of emissions. In the simple static model we just looked at here, however, the SCC is always be below the OSCC, because damages appear in TFP and are of a form that implies proportionality to output; the OSCC is chosen to maximize output in this setting, so the OSCC must then be higher than the SCC. In contrast, in our dynamic model in Section 5, although the SCC will be proportional to current output there too, the SCC will typically be above the OSCC. The reason there is that current output tends to be rising with higher current fossil use—it is primarily future output that will fall with current emissions, due to the incurred damages—implying that the SCC will be higher for higher levels of current emissions, and in particular the SCC will be higher than the OSCC since the latter dictates lower emissions. The comparison between the SCC and the OSCC is of practical importance: suppose we are in a laissez-faire allocation today, and that econometricians have measured SCC, ie, damages from emissions based on our current allocation. Then this SCC measure is not of direct relevance for taxation; in fact, for the calibrated dynamic model, we would conclude that the optimal tax is below the econometricians' laissez-faire SCC estimates.

Most of the integrated-assessment literature on the social cost of carbon computes the cost as is indicated above, ie, as a marginal cost at an optimal allocation and, more generally, comparisons between suboptimal and optimal allocations are rather unusual. The simple model here does allow such comparisons (as does the dynamic benchmark model described later). Thus define the *percentage consumption equivalent* as the value λ such that $u(c^*(1-\lambda)) = u(c)$, where c^* is the optimal consumption level and c any suboptimal level. Thus we can compute the laissez-faire value for λ in the simple model (i) to be 0, in the case where there is little enough carbon that all of it should be used ($\bar{E} > \nu/(\gamma\phi)$); and (ii), in the case where too much carbon is available, to satisfy

$$1-\lambda = \frac{e^{-\gamma\phi\bar{E}} k^{\alpha} n^{1-\alpha-\nu} \bar{E}^{\nu}}{e^{-\gamma\phi E^*} k^{\alpha} n^{1-\alpha-\nu} (E^*)^{\nu}}$$
$$= e^{-\gamma\phi(\bar{E}-\frac{\nu}{\gamma\phi})} \left(\frac{\gamma\phi\bar{E}}{\nu}\right)^{\nu}.$$

It is straightforward to verify that λ is increasing in $\bar{E}$ here. Note, however, that variables such as capital or labor do not enter, nor would the size of the population if it were introduced as a separate variable. So the "size" of the economy is not important for this measure.

4.2 The Case of Coal

Here, $\zeta > 0$ and we interpret E as coal. Laissez faire now always involves an interior solution for E and it is such that its (private) benefit equals its (private) cost $p = \zeta = \nu e^{-\gamma\phi E} k^{\alpha} n^{1-\alpha-\nu} E^{\nu-1}$. The planner chooses a lower amount of E: E^* is chosen so that the private benefit of coal minus its social cost equals its private cost:

$$-\gamma\phi e^{-\gamma\phi E^*} k^{\alpha} n^{1-\alpha-\nu} (E^*)^{\nu} + \nu e^{-\gamma\phi E^*} k^{\alpha} n^{1-\alpha-\nu} (E^*)^{\nu-1} = \zeta.$$

Notice here that when coal production becomes more productive (ζ falls), markets use more coal. The same is true for the planner, since the left-hand side of the above equation must be decreasing at an optimum level E^* (so that the second-order condition is satisfied): if ζ falls, the left-hand side must fall, requiring E^* to rise. Thus, technical improvements in coal production imply higher emissions.

4.2.1 Optimal Taxes and the Optimal Social Cost of Carbon

Recall that, in the benchmark model, we think of coal as produced at a constant marginal cost in terms of output goods. Given that GDP, y, equals consumption or $e^{-\gamma\phi E} k^{\alpha} n^{1-\alpha-\nu} (E)^{\nu} - \zeta E$, we can write the equation determining the optimal coal use as

$$-\gamma\phi(y^* + \zeta E^*) + \nu(y^* + \zeta E^*)/E^* = \zeta.$$

Hence, the optimal social cost of carbon, OSCC, is now $\gamma\phi y^*(1 + \zeta E^*/Y^*) = \gamma\phi y^*(1 + \frac{pE^*}{y^*})$. So it is not quite proportional to GDP (as it was in the case of oil) but rather to GDP plus firms' energy costs as a share of GDP. In practice, energy costs are less than 10% of GDP so a rule of thumb that sets the unit tax on coal equal to $\gamma\phi$ times GDP is still approximately correct.

4.2.2 Costs of Carbon When Taxes are not Optimally Set

What is the social cost of carbon at the laissez-faire allocation? It is $\gamma\phi(y + \zeta E)$, where y is laissez-faire GDP and E is laissez-faire carbon use, where we know that $y < y^*$ and $E > E^*$. Unlike in the case of oil, it is not clear whether this amount is smaller than the OSCC. The subtlety here is that the production of coal itself—an intermediate input—is hampered by a damage from climate change and thus the total externality from coal production is not just $\gamma\phi y$.

Consumption in the laissez-faire allocation is lower by a fraction λ that satisfies

$$1-\lambda=\frac{e^{-\gamma\phi E}k^{\alpha}n^{1-\alpha-\nu}E^{\nu}-\zeta E}{e^{-\gamma\phi E^*}k^{\alpha}n^{1-\alpha-\nu}\left(\bar{E}^*\right)^{\nu}-\zeta E^*}=\frac{e^{-\gamma\phi E}k^{\alpha}n^{1-\alpha-\nu}E^{\nu}}{e^{-\gamma\phi E^*}k^{\alpha}n^{1-\alpha-\nu}\left(\bar{E}^*\right)^{\nu}}\frac{1-\nu}{1-\nu+\gamma\phi E^*},$$

where for the second equality we have used the equilibrium and planner's conditions, respectively. This expression is, unlike in the oil example, not explicit in terms of primitives. In general, it depends nontrivially on the size of the economy (of course, one can derive first-order conditions determining both E and E^* as a function of primitives but, for the latter, not in closed form).

4.2.3 Coal Production Only Requires Labor: Our Benchmark Model

The case where coal is produced at a constant marginal cost in terms of output units is somewhat less tractable than the following alternative: coal production does not require capital and does not experience TFP losses from climate change. Ie, $E=\chi n_E$, where n_E is labor used in coal production and χ is a productivity parameter. This case is less realistic but given that energy production is a rather small part of firms' costs, it is convenient to use this specification for some purposes. In this case, we have output given as

$$y=e^{-\gamma\phi\chi n_E}k^{\alpha}\left(1-n_E\right)^{1-\alpha-\nu}\left(\chi n_E\right)^{\nu},$$

where total labor is now normalized: $n=1$. In a laissez-faire allocation, we obtain that $n_E=\frac{\nu}{1-\alpha}$. The planner's allocation delivers optimal n_E^* from

$$-\gamma\phi\chi+\frac{\nu}{n_E^*}=\frac{1-\alpha-\nu}{1-n_E^*}.$$

It is straightforward to check that higher productivity in producing coal will increase emissions both in the laissez-faire allocation and in the optimal one.

Here, moreover, the social cost of carbon will be exactly proportional to GDP, as in the oil case: $\gamma\phi y^*$. The reason is that no indirect externality (through the production of fossil fuel) is involved in this case. Similarly, we can solve for laissez-faire measures of the cost of carbon and the welfare gap relative to the full optimum.

In what follows, when we focus on coal production or oil production that occurs at positive marginal cost, we will use this formulation since it allows for simpler algebra without forsaking quantitatively important realism.

4.3 Calibration

We will now calibrate the static model. This is of course heroic, given that so many aspects of the climate-economy nexus feature dynamics, but the point here is merely to show that the static model can be thought of in quantitative terms. It is also possible to compare the results here to those in the calibration of the fully dynamic model in Section 5.2.

So let the heroics begin by calling our model period 100 years. The benchmark model will have coal as the only source energy; as we will argue later, the stock of oil is rather small relative to the stock of coal, and we leave out renewables for now (in the dynamic model in the later section, we calibrate the production of energy services as using three sources: oil, coal, and green). We assume that coal is produced from labor alone as in the previous section, and the model thus has five parameters: γ, ϕ, α, ν, and χ. We thus need five observations to pin these down.

Output being a flow, we can straightforwardly set α and ν based on average historic data; we select 0.3 and 0.04, respectively (see Hassler et al., 2015). For the rest of the model parameters, let us relate the model's laissez-faire equilibrium to some other observables. We thus need to relate the equilibrium outcomes for the key variables—E, S, n_E, and y—to relevant data targets. A business-as-usual scenario with continuously increasing emissions can lead to increases of the temperature of around 4°C at the end of the century.[bh] We interpret business as usual as our laissez-faire allocation. Let us use this information to find out the associated atmospheric concentration and emissions implied to generate this result, given our model. Arrhenius's formula gives

$$4 = \Delta T = \lambda \frac{\log \frac{S+\bar{S}}{\bar{S}}}{\log 2} = 3 \frac{\log \frac{S+600}{600}}{\log 2},$$

which allows us to solve for S as roughly 900 (GtC, in excess of the preindustrial level 600). What are the corresponding emissions required? The model says $S = \phi E$. To select ϕ, use the estimated linear carbon depreciation formula in Section 3.2.5 above for computing the average depreciation from emitting a constant amount per decade. This amounts to a straight average of the consecutive depreciation rates and a value for ϕ of 0.48: the atmospheric carbon concentration rises by about one half of each emitted unit.

To calibrate γ, let us take IPCC's upper estimate from Fig. 9: at a warming of 4 ∘C, they report a total loss of 5% of GDP. This is a flow measure and thus easy to map into our present structure. We thus need $e^{-\gamma S}$ to equal 0.95. This delivers $\gamma = 5.7 \cdot 10^{-5}$.

It remains to calibrate the parameter χ of the coal sector: its labor productivity. We can find it as follows. To reach 900 GtC, one needs to emit 900/0.48 units given the calculation above. In the model solution, $n_E = \nu/(1-\alpha)$. This means that $900/0.48 = \chi n_E = \chi \cdot 0.04/0.7$, which delivers a χ of approximately 32,813.

4.4 A Few Quantitative Experiments with the Calibrated Model

We now illustrate the workings of the simple baseline model with coal with a few quantitative experiments. The chief purpose is to check robustness of the main results.

[bh] Scenario RCP8.5 from IPCC's 5th Assessment Report.

Similar exercises could be carried out in all of the applications that follow (dealing with uncertainty, tipping points, tax-vs-quota policy comparisons, and so on). We have left such quantitative analysis out for brevity but for each application it would be valuable to use the baseline calibration as discussed here, calibrate the new parameters relevant to the application, and then produce output in the form of tables and graphs. Indeed, such exercises appear ideal for teaching the present material.

Starting out from the calibrated benchmark, let us vary two of the parameters within reasonable ranges. We first look at the effect of the damage elasticity of output, varying it from a half of its estimated value to much higher ones. We see that a doubling of the damage elasticity a little more than doubles the GDP gap between laissez-faire and the optimum. For damages 10 × higher than the baseline estimate, the loss of GDP is almost a quarter of GDP.

Externality cost	$1-\frac{y}{y^*}$
$\gamma/2$	0.0037
γ	0.0177
2γ	0.0454
4γ	0.0983
6γ	0.1482
8γ	0.1954
10γ	0.2400

Turning to carbon depreciation, the robustness looks at a tighter range around the baseline calibration as compared to that for damages (the uncertainty about damages, after all, is much higher). Modest changes in carbon depreciation, as depicted in the table later, do nevertheless have some impact: a change of ϕ by 25 percentage point changes the output gap by about seven tenths of a percent and temperature by a little over half a degree.

1–carbon depreciation	ΔT	$1-\frac{y}{y^*}$
0.75ϕ	3.2624	0.0107
0.95ϕ	3.8340	0.0164
ϕ	3.9658	0.0177
1.05ϕ	4.0938	0.0192
1.15ϕ	4.3388	0.0219
1.25ϕ	4.5707	0.0247

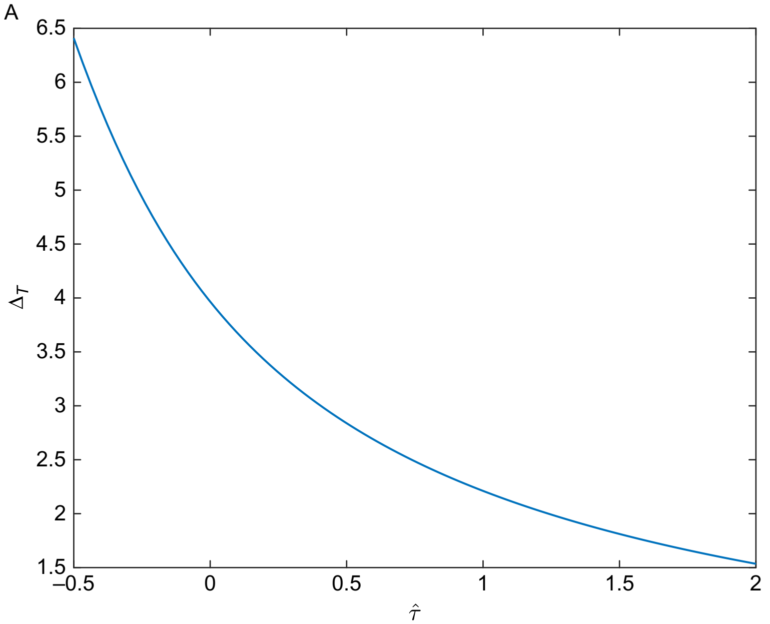

Fig. 11 Outcomes as a function of the tax-GDP rate, $\hat{\tau}$h. (A) Temperature change.

Finally, let us look at a more complete range of suboptimal taxes for the baseline calibration. The table and figures below illustrate by varying the tax, measured as a percent of GDP. Fig. 11 illustrates rather clearly that the model is more nonlinear for negative than for positive taxes: if the tax is turned into a sizeable subsidy the warming and output losses are substantial.

$(\tau/y)/(\tau^*/y^*)$	ΔT	$1-\frac{y}{y^*}$	n_E
−0.5	6.4084	0.0975	0.1294
0	3.9658	0.0177	0.0571
0.5	2.8365	0.0024	0.0353
1	2.2110	0	0.0254
2	1.5346	0.0035	0.0162

4.5 Summary: Core Model

We have built a simple static model which can be used to think about the key long-run aspects of carbon emissions and climate change. Though only a full dynamic, and much more complex, model can do the analysis of climate change full justice, our simple model does have some features that makes it quantitatively reasonable. The mapping from

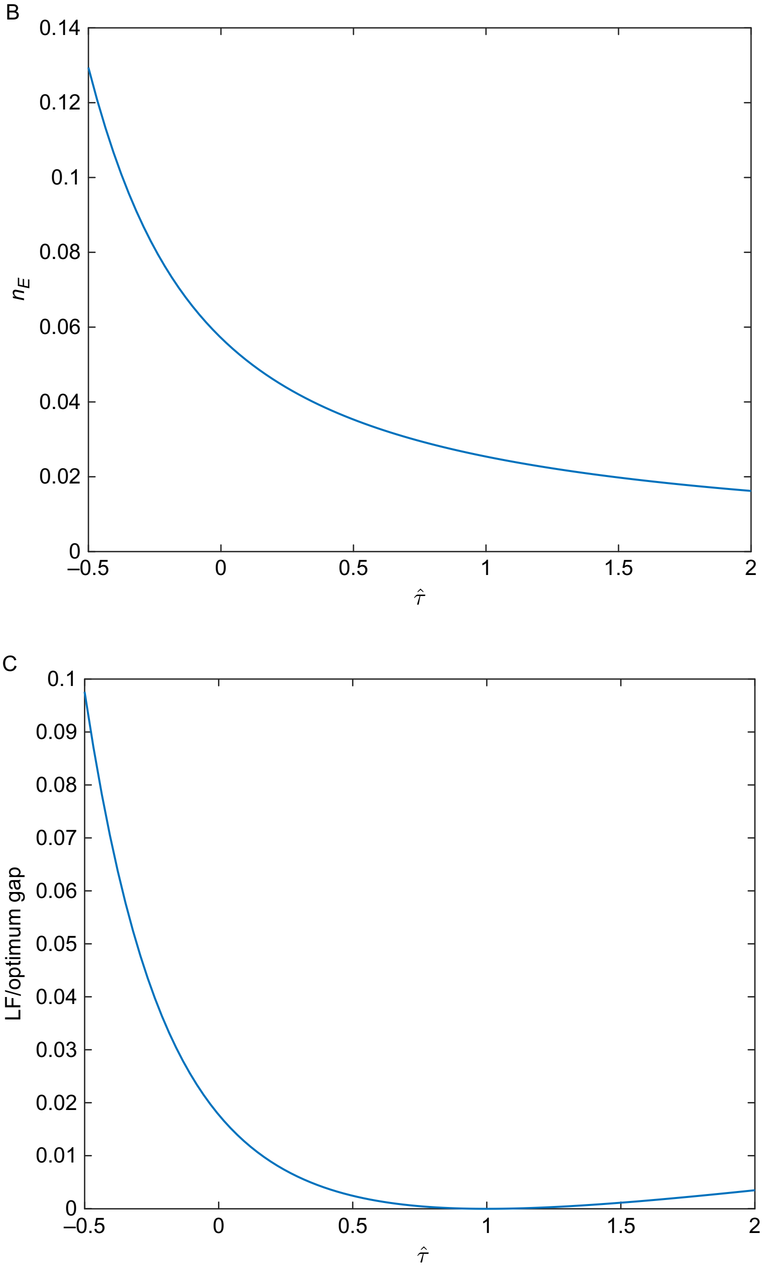

Fig. 11—cont'd (B) Labor in coal sector. (C) Output gap.

emissions to damages is described with a simple closed form but it captures the key features of this mapping in much more elaborate dynamic models, such as Nordhaus's DICE and RICE models. The role of fossil fuels in the economy is also described in a very rudimentary way but it too is the most natural starting point in dynamic quantitative models.

The simple model implies that the optimal social cost of carbon—the marginal externality damage at the optimal allocation—is proportional to GDP; this result is exactly true in some special cases of the model and approximately true otherwise. Also more generally, evaluated as a fraction of output, the (marginal) social cost of carbon (ignoring indirect effects on behavior of raising emissions) is independent of the allocation at which it is measured. This also means that the social cost of carbon is lower in the laissez-faire allocation than in the optimal allocation, because in the static model where damages appear to TFP optimal output by definition is higher than laissez-faire output. This feature will disappear in a dynamic model—where laissez-faire output tends to be higher (in the short run) than in the optimal allocation because less energy is used—and in a model where damages do not affect output, eg, by affecting utility directly. We will of course look at these kinds of extensions below. Moreover, in the simple static model we formulated here, the utility loss from not using taxes to curb carbon use, expressed in percentages of consumption, is scale-independent.

Next, we use the simple model to address some issues that have featured prominently in the literature. These include the choice of policy instruments—in particular the comparison between price and quantity regulations (taxes vs quotas)—along with extensions to consider utility damages, uncertainty, tipping points, technological change, and more.

4.6 Utility Damages

We can, instead of or in addition to the damages to TFP, imagine that higher global temperatures affect welfare directly. This could occur in a variety of ways, through effects on health, the value of leisure, or more generally perceived life quality. Ignoring TFP damages for simplicity, consider first a utility function of a specific functional form:

$$u(c, E) = \log c - \gamma S,$$

where, again, $S = \phi E$ is carbon concentration in excess of the preindustrial level. Here, thus, atmospheric carbon concentration, and hence emissions, influence utility linearly, whereas consumption has decreasing marginal utility. This means that the value of one less unit of emissions in terms of consumption increases as the economy gets richer: $u_E/u_c = \gamma\phi c$. This implies, immediately, that the social cost of carbon in this economy is identical to that above: it is proportional to output. Thus, if the utility cost has the structure just assumed, the implications for how to tax carbon remain the same as in the more common case of TFP damages. In fact, we can now interpret the formulation with TFP damages as possibly coming from two sources: direct damages to TFP and utility damages.

With the remaining parts of the economy unchanged (except that we now view TFP as unaffected by emissions), we can solve for the laissez-faire equilibrium exactly as before. For sake of illustration, let us focus on coal and on the case where energy is produced linearly from labor. The social planner's problem is to solve

$$\max_{n_E} \log\left(k^{\alpha}(n-n_E)^{1-\alpha-\nu}(\chi n_E)^{\nu}\right)-\gamma\phi\chi n_E.$$

The problem simplifies to solving

$$\max_{n_E}(1-\alpha-\nu)\log(n-n_E)+\nu\log n_E-\gamma\phi\chi n_E.$$

The first-order condition gives $\frac{\nu}{n_E}=\frac{1-\alpha-\nu}{n-n_E}+\gamma\phi\chi$, which is the exact same equation as in the corresponding model with TFP damages.

What is the optimal tax/the OSCC in this model? The consumption-good firm's first-order condition for energy (assuming a unit tax τ) is $p+\tau=\nu k^{\alpha}(n-E/\chi)^{1-\alpha-\nu}E^{\nu-1}$, whereas the energy firm's first-order condition reads $p\chi=w$, with $w=(1-\alpha-\nu)k^{\alpha}(n-E/\chi)^{-\alpha-\nu}E^{\nu}$. This delivers $\frac{1-\alpha-\nu}{\chi}k^{\alpha}(n-E/\chi)^{-\alpha-\nu}E^{\nu}+\tau=\nu k^{\alpha}(n-E/\chi)^{1-\alpha-\nu}E^{\nu-1}$, from which we see that $\tau^{*}=\gamma\phi y^{*}$ is the optimal tax here as well.

More generally, the SCC at any consumption/energy allocation here can be obtained as $-u_E(c,E)/u_c(c,E)=\gamma\phi c$, and since consumption is GDP in the static model we again have that the SCC equals $\gamma\phi y$. We can, finally, define the utility loss in the laissez-faire allocation, measured in terms of a percentage consumption loss (ie, from $u(c^{*}(1-\lambda), E^{*})=u(c,E)$). We obtain $\log(1-\lambda)=\log\frac{c}{c^{*}}-\gamma\phi(E-E^{*})$ and thus that $1-\lambda=e^{-\gamma\phi(E-E^{*})}\frac{c}{c^{*}}$ which has the same form as before and, thus, is scale-independent.

4.7 Other Damage Functions

Our assessment in the section earlier on damages from climate change is that this is the subarea in the climate-economy literature with the most striking knowledge gaps. Integrated assessment models differ to some extent in how they formulate damages as a function of climate (temperature) and how they parameterize their functions but the functional form used in Nordhaus's work (the DICE and RICE models) is the most common one. One possibility is that the overall damage *levels* are very different from the most common estimates in the literature, and another is that the functional-form assumptions are wrong. For this discussion, let us use the utility-damage formulation just outlined, and where we argued that $\log c-\gamma S$ is a formulation that is quantitatively close to that used by Nordhaus, given that this function should be viewed as a composition of the mapping from emissions to atmospheric carbon concentration and the mapping from the latter to damages. Let us therefore think about the choice of damage functions in terms of the more general formulation $\log c - \Gamma(S)$, with Γ being a more nontrivial function.[bi] The function Γ, if truly described globally, should probably be increasing for positive values of S (since $S=0$ corresponds to the preindustrial concentration) and convex. For sufficiently low values of S (below 0), the function ought to be decreasing, since there is a reasonable notion of an "appropriate" climate: human beings could not survive if it is too cold either.

A concrete argument for a convex $\Gamma(S)$, rather than the linear one we use in our benchmark, is based on the arguments in Section 3.2.6: there appears to be an approximate reduced-form relationship between the global temperature and the unweighted cumulative amount of past anthropogenic emissions (since the industrial era began), which is *linear*. This was labeled the *CCR* (Carbon-Climate Response) formulation. Then take, say, Nordhaus's global damage function mapping temperature to output losses as given, and combine it with this approximate linear relationship. The resulting $\Gamma(S)$ must then be convex.[bj]

With the more general damage function $\Gamma(S)$, all the earlier analysis goes through with the only difference being that $\Gamma'(S)$ now replaces γ earlier. Obviously, Γ could be calibrated so that $\Gamma'(S)=\gamma$ (with a standard calibration for γ) for current total emission levels, so the added insights here are about how the OSCC (and optimal tax) and the SCCs evolve as GDP evolves.

The SCC in this case becomes $\Gamma'(S)y$, where y again is GDP. Thus, to the extent Γ is convex, the optimal tax (as well as the SCC more generally) would not just be proportional to output but it would also increase with emissions; how much it would increase simply depends on the degree of convexity of Γ. Moreover, imagine an exogenous improvement in TFP. Such a shock would now increase the OSCC (the optimal tax) through two channels. The first channel was present before: a direct positive effect on y (leading to a higher tax by the same percentage amount). The second channel is an indirect effect via a higher demand for E. In terms of the decentralized economy, a higher TFP would, for a given tax, make firms demand a higher E, and since $\Gamma'(S)$ is increasing, this would then call for a further increase in the optimal tax rate.[bk]

[bi] We maintain logarithmic curvature without loss of generality.

[bj] Note, however, that the approximate linearity appears to be in somewhat of a conflict with Arrhenius's insight that the temperature change is proportional to the logarithm of the atmospheric carbon concentration (thus, a concave function). The conflict is not as strong as it seems, however. Our approximation that $\Gamma(S)$ is linear relies on a description of a carbon cycle that is rather realistic (eg, has more complex dynamics) and that uses Arrhenius's formula, which still has widespread acceptance. The upshot of this really is that the just-mentioned convexity after all cannot be very strong.

[bk] This discussion is a reminder that the optimal-tax formula $\tau^* = \Gamma'(S^*)y^*$ is not a closed form, since S^* and y^* are endogenous.

Similarly, the percentage consumption equivalent loss in welfare λ from remaining at laissez-faire can be computed from

$$\log(1-\lambda) = \log\frac{c}{c^*} - (\Gamma(S) - \Gamma(S^*)).$$

To the extent Γ is convex, this expression potentially increases faster in $S - S^*$ (and, more generally, depends on both these emission levels separately).

Now consider a highly nonlinear damage function, and let us investigate whether such a case poses a difficulty for the Pigou approach to the climate problem. Consider the possibility that at a low level of emissions, so for a low S, the social cost of carbon is actually zero: $\Gamma'(S) = 0$. However, $\Gamma(S)$ is at the same time increasing rapidly for higher values of S, after which it again levels off and becomes flat: $\Gamma'(S) = 0$ also for high enough values of S. The latter amounts to a "disaster" outcome where more atmospheric carbon concentration actually does not hurt because all the horrible events that could happen have already happened given that S is so high. Here, though low emissions have a zero SCC, such low emissions are not what Pigou's formula would prescribe: they would prescribe that the SCC equal the net private benefits from emissions, and they are high for low emission levels. The net private benefits of emissions are, in particular, globally declining here (and, since damages appear in preferences and not to production in the particular case under study, always positive). So instead, it is optimal to raise emissions to a point with a S^* such that $\Gamma'(S^*)$ is positive, perhaps one where Γ is increasing rapidly. The example shows that although a rapidly rising damage function in some sense poses a threat, the Pigou approach still works rather well. A key here is that for any given tax rate, the market equilibrium is unique; in the argument earlier, this manifested itself in the statement that the net private benefits from emissions are globally declining. They may not be, ie, there may be multiple market equilibria, but such cases are unusual. We consider such examples in Section 4.14.1 in the context of coordination problems in technology choice.

In conclusion, the model is well-designed also for incorporating "more convex" damage functions, and the qualitative differences in conclusions are not major nor difficult to understand. The key conclusion remains: more research on the determination and nature of damages—including the mechanisms whereby a warmer climate imposes costs on people—is of utmost importance in this literature, and integrated assessment modeling stands ready to incorporate the latest news from any such endeavors.

4.8 Tipping Points

A tipping point typically refers to a phenomenon either in the carbon cycle or in the climate system where there is a very strong nonlinearity. Ie, if the emissions exceed a certain level, a more drastic effect on climate, and hence on damages, is realized. As discussed earlier in the natural-science part of the chapter, one can for example imagine a departure from the Arrhenius approximation of the climate model. Recall that the Arrhenius approximation was that the temperature increase relative to that in the preindustrial era is proportional to the logarithm of the atmospheric carbon concentration (as a fraction of the preindustrial concentration), where the constant of proportionality—often labeled λ—is referred to as climate sensitivity. One way to express a tipping point is that λ shoots up beyond some critical level of carbon concentration. Another is that the carbon cycle has a nonlinearity making ϕ a(n increasing) function of S, due to carbon sinks becoming less able to absorb carbon. Finally, we can imagine that damages feature a stronger convexity beyond a certain temperature point; for example, sufficiently high temperature and humidity make it impossible for humans and animals to survive outdoors.

Notice that all these examples simply amount to a different functional form for damages than that assumed earlier (whether damages appear to TFP or to utility). Thus, one can proceed as in the previous section and simply replace the total damage γS by a damage function $\Gamma(S)$, where this function has a strong nonlinearity. One could imagine many versions of nonlinearity. One involves a kink, whereby we would have a linear function $\gamma_{lo}S$ for $S \leq \underline{S}$ and $\gamma_{hi}S$ for $S > \underline{S}$, with $\gamma_{lo} << \gamma_{hi}$. A second possibility is simply a globally more convex (and smooth) function Γ. One example is Acemoglu et al. (2012), who assume that there is something labeled "environmental quality" that, at zero, leads to minus infinity utility and has infinitely positive marginal utility (without quantitative scientific references). One can also imagine that there is randomness in the carbon cycle or the climate, and this kind of randomness may allow for outcomes that are more extreme than those given by a simple (and deterministic) linear function γS. Finally, the $\Gamma(S)$ function could feature an irreversibility so that it attains a higher value if S ever has been above some threshold, thus even if S later falls below this threshold.

As discussed in the previous subsection, the formulation with a tipping point does not change the analysis of the laissez-faire equilibrium. It does, however, alter the social planner's problem. In particular, in place of γ as representing the negative externality of emissions in the planner's first-order condition we now have $\Gamma'(S)$ and this derivative may be very high. It is still possible to implement the optimum with a carbon tax, though it will no longer just be proportional to the optimal level of GDP and may respond nonlinearly to any parametric change, as discussed earlier. Suppose, for example, that γ becomes "infinite" beyond some $\underline{S}$. Then, from the perspective of a government choosing the optimal tax rate on carbon emissions, the objective function would have highly asymmetric payoffs from the tax choice: if the tax rate is chosen to be too low, the damage would be infinite, and more generally changes in the environment (such as increases in the capital stock or labor input, which would increase the demand for energy) would necessitate appropriate increases in the tax so as to avoid disaster.

Overall, in order to handle tipping points in a quantitative study based on an integrated assessment model one would need to calibrate the nonlinear damage function.

In terms of our first example, how would one estimate $\underline{S}$? As we argued in the natural-science sections 3.1.2 and 3.3.4 earlier, our interpretation of the consensus is that whereas a number of tipping points have been identified, some of which are also quantified, these are tipping points for rather local systems, or systems of limited global impact in the shorter run. To the extent there is a global (and quantitatively important) tipping point, there does not appear to be a consensus on where it would lie in S space. Therefore, at this point and in waiting for further evidence either on aggregate nonlinearities in the carbon cycle or climate system or in how climate maps into economic costs, we maintain a linear formulation (or, in the case damages appear in TFP, in the equivalent exponential form). Performing comparative statics on γ is of course very important and we return to it later.

4.9 Uncertainty

It is possible to analyze uncertainty in a small extension of the simple benchmark model. Suppose we consider a prestage of the economy when the decisions on emissions need to be made—by markets as well as by a fictitious planner. We then think of utility as of the expected-utility kind, and we begin by using a utility formulation common in dynamic macroeconomic models: $u(c) = \log c$. Thus, the objective is $E(\log(c))$. Uncertainty could appear in various forms, but let us simply consider a reduced-form representation of it by letting γ, the damage elasticity of output, be random. That is, in some states of nature emissions are very costly and in some they are not. Recall that the uncertainty can be about the economic damages given any temperature level or about how given emissions influence temperature.

For the sake of illustration, we first consider the simplest of cases: γ is either high, γ_{hi}, or low, γ_{lo}, with probabilities π and $1-\pi$, respectively. The emissions decision has to be made—either by a planner or by actors in decentralized markets—ex-ante, but there is no "prior period" in which there is consumption or any other decisions than just how high to make E. We consider the case of coal here, and with coal production requiring labor only, without associated TFP damages.

Looking at the planning problem first, we have

$$\max_E \pi \log\left(e^{-\gamma_{hi}\phi E}k^\alpha\left(1-\frac{E}{\chi}\right)^{1-\alpha-\nu}E^\nu\right) + (1-\pi)\log\left(e^{-\gamma_{lo}\phi E}k^\alpha\left(1-\frac{E}{\chi}\right)^{1-\alpha-\nu}E^\nu\right).$$

Save for a constant, this problem simplifies to

$$\max_E -(\pi\gamma_{hi} + (1-\pi)\gamma_{lo})\phi E + (1-\alpha-\nu)\log\left(1-\frac{E}{\chi}\right) + \nu \log E.$$

A key feature of this maximization problem is that the damage elasticity appears only in expected value! This means that the solution of the problem will depend on the expected value of γ but not on any higher-order properties of its distribution. This feature, which of course holds regardless of the distributional assumptions of γ, will not hold exactly if coal/oil is produced with constant marginal cost in terms of final output (as in our very first setting above), but approximately the same solution will obtain in any calibrated version of the model since the fossil-fuel costs are small as a fraction of output.

Notice that the "certainty equivalence" result obtains here even though the consumer is risk-averse. However, it obtains for logarithmic utility only. If the utility function curvature is higher than logarithmic, the planner will take into account the variance in outcomes: higher variance will reduce the choice for E.[bl] Formally, and as an example, consider the utility function $c^{1-\sigma}/(1-\sigma)$ so that the planner's objective is

$$\mathbf{E}_{\gamma}\frac{\left(e^{-\gamma E}k^{\alpha}\left(1-\frac{E}{\chi}\right)^{1-\alpha-\nu}E^{\nu}\right)^{1-\sigma}}{1-\sigma}.$$

Since E is predetermined, we can write this as

$$\frac{\left(k^{\alpha}\left(1-\frac{E}{\chi}\right)^{1-\alpha-\nu}E^{\nu}\right)^{1-\sigma}}{1-\sigma}\mathbf{E}_{\gamma}e^{-\gamma E(1-\sigma)}.$$

Assume now that γ is normally distributed with mean $\overline{\mu}$ and variance σ_{μ}^{2}. Then we obtain the objective

$$\frac{\left(e^{-\Gamma(E)}k^{\alpha}\left(1-\frac{E}{\chi}\right)^{1-\alpha-\nu}E^{\nu}\right)^{1-\sigma}}{1-\sigma},$$

with

$$\Gamma(E)=-\overline{\gamma}E+\frac{\sigma_{\mu}^{2}E^{2}(1-\sigma)}{2}.$$

Thus, the objective function is a monotone transformation of consumption, with consumption determined as usual in this model except for the fact that the damage expression γE is now replaced by $\Gamma(E)$, a convex function for $\sigma>1$ (higher curvature than logarithmic). To the extent that the variance σ_{μ}^{2} is large and σ is significantly above 1, we thus have uncertainty play the role of a "more convex damage function," as discussed earlier. We see that the logarithmic function that is our benchmark does apply as a special case.

[bl] The asset pricing literature offers many utility functions that, jointly with random processes for consumption, can deliver large welfare costs; several of these approaches have also been pursued in the climate-economy literature, such as in Barro (2013), Gollier (2013), Crost and Traeger (2014), and Lemoine (2015).

4.9.1 The Dismal Theorem

In this context let us briefly discuss the so-called *Dismal Theorem* derived and discussed by Weitzman in a series of papers (eg, Weitzman, 2009; see also the discussion in Nordhaus, 2009). Weitzman provides conditions under which, in a rather abstract context where governmental action could eliminate climate uncertainty, expected utility is minus infinity in the absence of appropriate government action. Thus, one can (as does Weitzman) see this as an argument for (radical) government action. His result follows, very loosely speaking, if the uncertainty has fat enough tails, the risk aversion is high enough, and the government is able to entirely eliminate the tail uncertainty, but the details of the derivation depend highly on specifics. In our present context, a normal distribution for γ is clearly not fat-tailed enough and the only way for the government to shut down tail risk is to set E to zero. However, imagine that the economy has an amount of free green energy, denoted $\widetilde{E}$, ie, the production function is $e^{-\gamma E}k^{\alpha}\left(1-\dfrac{E}{\chi}\right)^{1-\alpha-\nu}(\widetilde{E}+E)^{\nu}$; then setting $E=0$ still allows positive output. Now imagine that γ has a distribution with fat enough tails, ie, one allowing infinitely high values for γ and slowly decreasing density there. Then expected utility will become infinite if σ is large enough.[bm]

The Dismal Theorem is not connected to data, nor applied in a quantitatively specified integrated assessment model. It relies fundamentally on a shock structure that allows infinitely negative shocks (in percentage terms), and our historical data is too limited to allow us to distinguish the shape of the left tail of this uncertainty in conjunction with the shape of marginal utility near zero; at this point, it seems hard enough to be sure of the mean of the shocks.

4.10 Taxes vs Quotas

In the discussion earlier, we have been focusing on a tax as the obvious candidate policy instrument. Indeed the damage externality is a pure externality for which the Pigou theorem applies straightforwardly. What are alternative policies? The Coase theorem applies too as well but it does not seem possible in practice to define property rights for the atmosphere (into which emissions can then be made, in exchange for a payment to the owner). What about regulating quantities? Indeed the "cap-and-trade" system, which is a quota-based mechanism, has been the main system proposed in the international negotiations to

[bm] A simpler, reduced form setting is that where consumption is given by a t distribution (which has fatter tails than the normal distribution), representing some risk which in this case would be labeled climate risk. Then with power utility, $u(c)=c^{1-\sigma}/(1-\sigma)$, and if σ is high enough, the marginal utility at zero goes to infinity fast enough that expected utility is minus infinity. This point was original made by Geweke (2001). If the government can shut down the variance, or otherwise provide a lower bound for consumption, it would then be highly desirable.

come to a global agreement on climate change. A cap-and-trade system is indeed in place in Europe since 2005.[bn] There is a debate on whether a tax or a quota system is better, and here we will only allude to the main arguments. Our main purpose here, instead, is to make a few basic theoretical points in the comparison between the two systems. These points are also relevant in practice.

Before proceeding to the analysis, let us briefly describe the "-and-trade" part, which we will not subject to theoretical analysis. If a region is subject to a quantity cap—emissions cannot exceed a certain amount—the determination of who gets to emit how much, among the users of fossil energy in the region, must still be decided on. The idea is then to allocate *emission rights* and to allow trade in these rights. The trading, in theory at least, will then ensure that emissions are made efficiently. The initial allocation of emission rights can be made in many ways, eg, through grandfathering (giving rights in proportion to historic use) or auctions. To analyze the trading system formally we would need to introduce heterogeneity among users, which would be straightforward but not yield insights beyond that just mentioned.

The first, and most basic, point in comparing quotas and taxes is that, if there is no uncertainty or if policies can be made contingent on the state of nature, both instruments can be used to attain any given allocation.[bo] If a tax is used, the tax applies to all users; if a quota is used, regardless of how the initial emission rights are used, the market price of an emission right will play the role of the tax: it will impose an extra cost per unit emission and this cost will be the same for all users, provided the market for emission rights works well.

Second, suppose there is uncertainty and the policy cannot be made state-contingent. This is a rather restrictive assumption—there is no clear theoretical reason why policies could not change as the state of nature changes—but still an interesting one since it appears that political/institutional restrictions of this sort are sometimes present. To analyze this case, let us again consider uncertainty and an ex-ante period of decisions. To capture the essence of the restriction we assume that the only decision made ex-ante is the policy decision. A policy could be either a unit tax or a quantity cap. We assume that the quantity cap is set so that it is always binding ex-post, in which case one can view the government as simply choosing the level of emissions ex-ante.

The choice between a tax and a quota when there is uncertainty (or private information on the part of "the industry") has been studied extensively in the environmental literature since Weitzman (1974) and similar analyses are available in other parts of economics (eg, Poole, 1970). One can clearly provide conditions under which one

[bn] The European Union Emission Trading System (EU ETS) was launched in 2005 covering about half the CO_2 emissions in the union (Ellerman and Buchner, 2007).

[bo] This statement requires a qualification for taxes in the (rather unusual) cases for which a Pigou rule is not sufficient, as discussed already.

policy or the other is better, along the lines of Weitzman's original paper. Weitzman considered a cost and a benefit of a pollutant, each of which depended on some random variable, and the two random variables were assumed to be independent. He then showed that what instrument would be best depended on the relative slopes of the marginal benefits and cost curves. Follow-up papers relaxed and changed assumptions in a variety of directions, but there appear to be no general theorems that apply in the climate-change application to conclude decisively in one way or the other. In fact, we know of no quantitatively parameterized dynamic model that looks at the issue so what we will do here is simply provide a straightforward example using our simple static model and then discuss a couple of separate, and we believe important, special cases.

For our example, we use one type of uncertainty only: that of the cost of producing fossil fuel, χ. With the calibrated model and a uniform distribution around the calibrated value for χ we obtained the ex-ante utility levels for a range of taxes and for a range of emissions, both committed to before the randomness is realized. Fig. 12 shows the results: a range of tax values around the optimal tax outperform the optimal quota. In this case, the precommitted tax rate is a fixed value. If it could be set as a proportion of output, which is ruled out now by assumption since the tax cannot be state-contingent

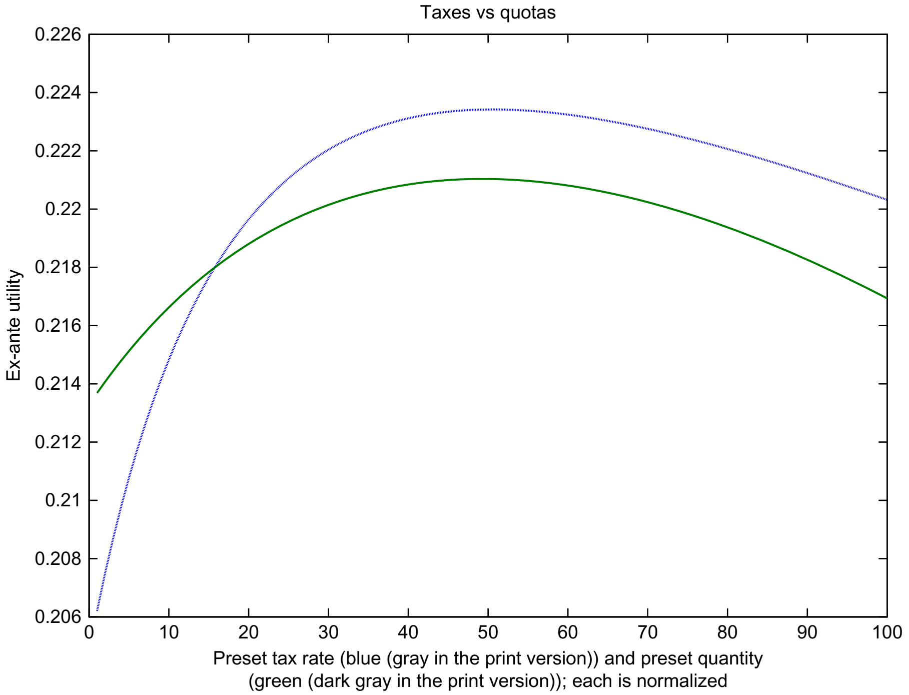

Fig. 12 Utility from precommitting to a unit tax (blue (gray in the print version), with the tax on the *x*-axis) or a quantity cap (green (dark gray in the print version), with the quantity cap on the *x*-axis).

but output will be, it would be fully optimal also ex-post, since the best tax ex-post is always a fraction $\gamma\phi$ of output. Apparently, the ex-post randomness of output is not significant enough to overturn this result. It is straightforward to look at other types of shocks. Shocks to γ deliver more similar welfare outcomes for (optimal and precommitted) taxes and quotas.

Now suppose that we consider a case of a tipping point and that the uncertainty is coming from energy demand (through, say, a separate, exogenous and random TFP factor) or from the cost of coal production (through χ). If the tipping point is known to be $\underline{E}$, and $\Gamma(E)$ is equal to zero for $E < \underline{E}$ but positive and very high otherwise, what is then the best policy from an ex-ante perspective? Clearly, a policy with an emissions cap would simply be set at $\underline{E}$, a cap that may or may not bind ex-post: if the demand for energy is low, or the cost of producing it is high, the ex-post market solution will (efficiently) be to stay below $\underline{E}$, and otherwise the cap will (efficiently) bind. A tax will not work equally well. One can set the tax so that the economy stays below the tipping point, but in case the energy demand is low, or its production costs are high, ex-post, output will be inefficiently depressed. Thus, when we are dealing with *asymmetric* payoffs of this sort (relative to the amount of emissions), a quantity cap is better.

The previous example would have emissions rights trading at a positive price sometimes and at a zero price otherwise. Thus, the system with a quantity cap leads to a random cost for firms of emitting carbon dioxide (beyond the price the firms pay the energy producers). Variations in the supply of emissions rights, decided on by regulatory action, influence the price of the trading rights as well. The experience in Europe since the cap-and-trade system illustrates these points well: carbon prices have fluctuated between over 30 euro and virtually zero since the system started. Such fluctuations are observed also in other regions with cap-and-trade systems (eg, New Zealand). Clearly, since optimal carbon pricing should reflect the social cost of carbon, such fluctuations are only efficient if the social cost of carbon experiences fluctuations. Damages from carbon emissions are likely not experiencing large fluctuations, but our assessments of how large they are of course change over time as scientific knowledge accumulates. The recent large drops in the price of emission rights can therefore be viewed as problematic from a policy perspective.

A cap-and-trade system could be augmented with a "central emission bank" that would have as its role to stabilize the price of emission rights by trading actively in this market, hence avoiding the large and inefficient swings observed in the EU system. Notice, however, that we would then be very close in spirit to a tax system: a tax system would just be a completely stable (provided the chosen tax is stable) way of implementing a stable price of emissions for firms.[bp]

[bp] This and other issues in this policy discussion are covered in Hassler et al. (2016).

4.11 Carbon Taxation in the Presence of Other Distortionary Taxes

Suppose the government needs to raise revenue and needs to do this in a distortionary manner; the most common example would involve labor taxation and it is also a form of taxation that can be studied in the baseline model here by the addition of valued leisure. How, then, will the optimal carbon tax change? For example, suppose preferences are $\log c+\psi\log l$, where l is leisure, so that the labor input in the final-goods sector would be $1-n_E-l$ (and, as before, n_E in the coal sector). Suppose also that the government has a distortionary tax on labor income, τ_l. Taxes are used to pay for an exogenous amount G of consumption good (that does not enter agents' utility). Lump-sum taxation is ruled out (but lump-sum transfers are not), and thus the setup mimics a typical second-best situation in public finance.[bq]

Consider first a planning solution where the government is unrestricted and can just mandate quantities. Thus, it maximizes

$$\log\left(e^{-\gamma\phi\chi n_E}(1-n_E-l)^{1-\alpha-\nu}(\chi n_E)^{\nu}-G\right)+\psi\log l$$

by choice of n_E and l. This delivers two first-order conditions. One is familiar from our baseline model:

$$-\gamma\phi\chi_E-\frac{1-\alpha-\nu}{1-n_E-l}+\frac{\nu}{n_E}=0.$$

The other is the standard macro-labor condition

$$-\frac{1}{c}\cdot\frac{(1-\alpha-\nu)y}{1-n_e-l}+\frac{\psi}{l}=0,$$

which says that the marginal utility of consumption times the marginal product of labor has to equal the marginal utility of leisure (in the expression, of course, y denotes $e^{-\gamma\phi\chi n_E}(1-n_E-l)^{1-\alpha-\nu}(\chi n_E)^{\nu}$ and $c=y-G$). These two first-order conditions can be solved for first-best levels of n_E and l given any G.

Now consider in contrast a competitive equilibrium which is laissez-faire with regard to the taxation of carbon and which only uses labor taxes to raise revenue. Then, the two conditions above would be replaced, first, by the laissez-faire condition for coal

$$-\frac{1-\alpha-\nu}{1-n_E-l}+\frac{\nu}{n_E}=0$$

[bq] One can also consider an alternative assumption: there is no need to raise revenue ($G=0$), there is an exogenous tax rate on labor income, $\tau>0$, and any tax revenues are rebated back lump-sum.

and, second, a distorted macro-labor condition

$$-\frac{1}{c}\cdot\frac{(1-\alpha-\nu)y(1-\tau_l)}{1-n_E-l}+\frac{\psi}{l}=0,$$

with the additional constraint that the government budget balances: $\tau_l(1-\alpha-\nu)y/(1-n_E-l)=G$. These three conditions now determine n_E, l, and τ_l and do not deliver the first best. In particular, one can think of two "wedges" defining different departures from the first best: the externality wedge due to climate damages and the tax wedge on labor supply (these are defined as the differences between the left-hand sides of the above equations with taxes and the corresponding ones from the first-best first-order conditions).

Now suppose we increase the carbon tax marginally from 0. Then (i) the climate wedge would become smaller and (ii) because τ_l falls—the government budget now reads $\tau_l(1-\alpha-\nu)y/(1-n_E-l)+\tau\chi n_E=G$ so that $\tau>0$ allows a lower τ_l—the labor wedge would fall as well. Hence relative to a laissez-faire situation from the perspective of coal, introducing coal taxation involves a *double dividend*: it diminishes the climate externality and it reduces the labor distortion. This is an often-discussed point in the climate literature; for example Jorgenson et al. (2013b,a) argue that the double dividends are quantitatively important for the United States and China, respectively.[br] Of course, the extent to which labor taxes can be reduced depends on the size of the coal tax base.

What, then, will the best level of carbon taxation be? Will carbon taxes be higher than in the absence of distortionary labor taxation? It would be straightforward to derive an answer in the present model by maximizing consumer welfare—with the same objective as that used by the planner—subject to the macro-labor first-order condition above, $\tau\chi/y-\frac{1-\alpha-\nu}{1-n_E-l}+\frac{\nu}{n_E}=0$ for the market's marginal condition for coal, and the government's budget constraint. One can derive a marginal condition for the planner's choice of τ which involves the setting of a weighted combination of wedges to zero; this condition can be solved numerically, together with the other equations, for the endogenous variables. The final level of taxes in this second-best solution is hard to characterize in terms of primitives but some intuition can perhaps be gleaned. If the use of coal is complementary with labor (which it is in the Cobb–Douglas formulation of production), on the margin the reduction of coal will hurt labor supply because it lowers the marginal product of labor. This speaks for a second best with a coal tax that is lower than in the absence of distortionary labor taxation. If coal were instead complementary with leisure (say because people burn coal to heat their homes when not working), this effect would go in the opposite direction on the margin. However, exactly how all these effects play

[br] One can also identify a third dividend from introducing coal taxation: the reduce in local pollution from the burning of coal, a factor which appears of first-order relevance particularly in China.

out depends on the details of preferences and technology. For recent work on these issues that in addition also addresses distortions due to capital taxation, see Schmitt (2014), who pursues this approach in a dynamic model closely related to the setup here, and Barrage (2015), who looks at a closely related setting and uses a primal approach to taxation.[bs]

4.12 A More Detailed Energy Sector

We set out with a stylized description of energy production using either oil, coal, or some green alternative. In practice it is not either or; rather, these sources can all be used and are partially, but not fully, substitutable. Some integrated assessment models include very complex energy systems (eg, WITCH or MERGE; the latter is described in Manne et al., 1995). One way to incorporate multiple energy sources explicitly is to keep one kind of energy as an input into production but let this energy itself be produced from an array of sources, including fossil fuel. Thus, consider the CES technology

$$E = \left(\kappa_o E_o^{\rho} + \kappa_c E_c^{\rho} + (1 - \kappa_o - \kappa_c) E_g^{\rho} \right)^{\frac{1}{\rho}},$$

where E_i is the energy produced from source i, with $i = o$ representing oil (and natural gas), $i = c$ representing coal, and $i = g$ representing energy generated without fossil fuel.[bt] This description is still stylized but it allows us to look into some interesting issues. The parameter $\rho \in (-\infty, 1]$ regulates the (constant) elasticity of substitution between the different energy sources.[bu] The κ_is are share parameters regarded as exogenous in all of our analysis. We continue to think about the production of oil, coal, and green energy as in the previous discussion.

It is straightforward to check that the social cost of carbon is still γy with this formulation. Thus, this extension is not interesting from the perspective of optimal policy. Its value, instead, is to deliver a much richer view of what the cost is of remaining at laissez-faire, or in any case far from the optimum, because this cost turns out to crucially depend on the elasticity of substitution between the different kinds of energy.

First, and just for illustration, let us look at the case where there is just oil and coal, ie, where there is no green energy. Clearly, then, if the degree of substitutability between oil and coal is very low, the difference between laissez-faire and the optimum is small. Consider the extreme case: a Leontief function, ie, $\rho = -\infty$. Then if the total stock of oil is small enough that the optimum involves using it all, the laissez-faire and optimal

[bs] As is typically the case, in dynamic analyses it makes a difference whether the government has commitment or not; Schmitt considers cases without commitment.

[bt] It would be natural to consider a slight extension of this formulation with a nested CES between a composite of oil and coal, on the one hand, and green energy on the other. Thus, oil and coal would form a separate CES aggregate and one could consider the quantitatively reasonable case with a high degree of substitutability between oil and coal and a lower one between the oil–coal composite and green energy.

[bu] The elasticity is $1/(1-\rho)$.

allocations are identical. With some more substitutability, the laissez-faire allocation is not optimal, because coal use should be reduced given the externality and its unlimited supply (recall its constant marginal cost in terms of labor). However, the difference is still limited. In practice, however, oil and coal are rather good substitutes, so let us instead (again, for illustration only) consider the opposite extreme case: perfect substitutability ($\rho = 1$). Then the level of coal is determined very differently: laissez faire is far from the optimum (provided γ is large). Thus, in this case there will be significant total losses from government inaction.

According to available estimates, the remaining amount of (low-cost) oil left is quite limited, in particular in comparison with the amount of remaining coal, so oil is not of key importance for climate change.[bv] What is of importance, however, is the substitutability with green energy. So, second, let us consider fossil fuel (interpreted as coal) vs green energy. In a metastudy, Stern (2012) reports a long-run elasticity of substitution of 0.95, as an average of oil–coal, oil–electricity, and coal–electricity elasticity measures. Thus, this unweighted average is close to a Cobb–Douglas specification. In this case, there can be a rather significant difference between the optimum and laissez-faire; relatedly, price incentives, or the effects of imposing a tax, are large if there is a nontaxed good that is a close substitute.[bw] However, it is conceivable that green technology in the future will be a very good substitute with fossil fuel. Considering a higher elasticity than the unitary Cobb–Douglas elasticity is therefore a relevant robustness check. In this case, the difference between the optimum and laissez-faire is rather large. For example, Golosov et al. report, using a calibrated dynamic counterpart of the model here, that an elasticity of 2 leads laissez-faire coal use 100 years from now to rise to levels that imply exhaustion of all the coal deposits and would likely have catastrophic consequences for the climate. In contrast, in the optimum, coal use in 100 years is *lower* than it is today, and the climate as a result is rather manageable.

By definition, in the case of green energy vs fossil fuel, the observation that a high elasticity of substitution leads to large welfare losses from not imposing a carbon tax (or a quota) at the same time means that there is a large potential social benefit from climate change action. A closely related implication is that there are, in such a case, strong incentives—high social payoffs—from doing research to come up with green alternatives. We turn to this issue in Section 4.14.

4.13 The Substitutability Between Energy and Other Inputs

What aspects of the earlier analysis are influenced by the nature of the production function? We have assumed a Cobb–Douglas structure in part for simplicity and part because the energy share, though having gone through large swings over shorter periods of time,

[bv] See McGlade and Ekins (2015) for supply curves of different types of fossil fuel.

[bw] The Cobb–Douglas case is very similar to the case with only coal considered above.

has remained fairly stable over the longer horizon (recall Fig. 1 in Section 2). It is nevertheless necessary to also discuss departures from unitary elasticity. In this discussion, we will maintain the assumption of a unitary elasticity between the capital and labor inputs, thus confining attention to a different elasticity between the capital-labor composite, on the one hand, and energy on the other.

Consider the aggregate production function $e^{-\gamma S}F(Ak^{\alpha}n^{1-\alpha}, A_E E)$, where F is CES and A and A_E are technology parameters, thus maintaining the assumption that damages appear as decreases in TFP. The social cost of carbon with this formulation will then obey the same structure as before, ie, the marginal externality damage of fossil fuel (through increased emissions E) is $\gamma\phi y$. What is different, however, is the difference between the laissez-faire allocation and the optimum or, expressed differently, the consumption equivalent cost of a suboptimal allocation. Consider oil, ie, a fossil fuel with zero extraction costs in a finite supply $\bar{E}$. Assume that it is not optimal to use all of the oil, and let us simply examine the two extreme cases: Leontief and perfect substitutability.

We begin with the Leontief case. Here, output is given by $e^{-\gamma\phi E}\min\left\{Ak^{\alpha}n^{1-\alpha}, A_E E\right\}$. Ie, there is no substitutability between the capital-labor composite and oil. In laissez-faire, oil use is $\bar{E}$. It is easy to show from the planner's first-order condition that $E^{*}=1/(\gamma\phi)$ in this case.[bx] Recall from Section 4.1.3 that, under Cobb–Douglas, the optimal allocation is $E^{*}=\nu/(\gamma\phi)$ and that the ratio of optimal to laissez-faire output is $e^{\gamma\phi(\bar{E}-\nu/(\gamma\phi))}\left(\frac{\nu}{\gamma\phi\bar{E}}\right)^{\nu}>1$. Now we obtain $e^{\gamma\phi(\bar{E}-1/(\gamma\phi))}\frac{1}{\gamma\phi\bar{E}}$. Because $-\nu+\nu\log\nu$ is decreasing we therefore conclude that in the Leontief case, the difference between the optimal and the laissez-faire allocation is smaller than under unitary elasticity. The fall in energy use is smaller, and this effect dominates the stronger impact on output of any given fall in energy.

Under perfect substitutability, we have output given by $e^{-\gamma S}\left(Ak^{\alpha}n^{1-\alpha}+A_E E\right)$ and we assume that capital and labor are in use. Now the planner's first-order condition leads to $E^{*}=1/(\gamma\phi)-Ak^{\alpha}n^{1-\alpha}/A_E$, which (as for the unitary-elasticity case) is a smaller amount than in the Leontief case. It is also possible to show that the wedge between optimal and laissez-faire output in this case is smaller than in the Leontief case.

In sum, we see that the energy use can be different than in the case with unitary elasticity between energy and other inputs. With production functions with very low substitution elasticity between energy and other inputs, energy use will dictate that energy use in the optimum fall more, but there is also a corresponding gain in a higher TFP. There does not, perhaps surprisingly, therefore appear to be a very strong effect on

[bx] This holds so long as there is an interior solution, ie, if $1/(\gamma\phi)<Ak^{\alpha}n^{1-\alpha}/A^{E}$. Note that there is abundance of capital and labor now: on the one hand, the market uses oil to the point where $E=Ak^{\alpha}n^{1-\alpha}$, so that there is excessive oil. On the other hand, the planner may want to decrease the oil use if the just stated inequality holds, so that from the planner's perspective, there is an abundance of capital and labor instead.

the net gap between optimal output and laissez-faire output as the elasticity of substitution between inputs is varied. This is comforting given that the Cobb–Douglas formulation is much easier to handle analytically.

4.14 Green Technology and Directed Technical Change

The existence of the green technology was taken as given earlier; green technologies of various sorts—versions of water and wind power—have of course existed since before the industrial revolution. These technologies have been improved and there are also new sources of electricity production that do not involve fossil fuels, such as nuclear power and solar power.[by] A central issue of concern in the area of climate change is the further development of these technologies and research toward new ones. In the macroeconomically oriented literature on climate change, various models have been developed, with early papers by Bovenberg and Smulders and others (see, eg, Bovenberg and Smulders, 1995). More recently, Acemoglu et al. (2012) provided a setting of directed technical change and made the point that there may be *path dependence* in R&D efforts toward the development of different energy technologies. We will now use the simple model to illustrate these facts and some other points that have been made in the literature.

A static model cannot fully do justice to the much more elaborate dynamic settings where many of the arguments in this part of the literature have been developed. It does, however, allow us to make a number of basic points. One simplification in our analysis here is that we will not explicitly describe a decentralized R&D sector.[bz] We will distinguish between two different kinds of technological developments: new techniques for the efficient use of energy ("energy saving") and new techniques for the production of energy. We begin with the latter.

4.14.1 Energy Production

We will mostly abstract from the determination of the overall efforts toward technological developments, which one could model as well (say as a tradeoff between these activities and using labor directly in production), and simply assume that there is an R&D input available in fixed supply; we set the total amount to 1 without loss of generality. The use of this input can be *directed* toward either improving the productivity in producing energy from fossil sources, m_c, or from green sources, m_g, with the constraint that $m_c + m_g = 1$. Eg, we can think of this choice as one between improving the drilling/extraction technologies for North Sea oil and technological improvements in the

[by] Nuclear power is problematic from an environmental perspective too but we do not discuss this issue here.

[bz] We could have developed such a version even in our static model but it would have complicated notation without adding much of significance.

cost-efficiency of solar-based units. The most straightforward setting would maintain the production function in a two-energy-input form:

$$e^{-\gamma E_c} k^{\alpha} n^{1-\alpha-\nu} \left(\lambda_c E_c^{\rho} + (1-\lambda_c) E_g^{\rho} \right)^{\frac{\nu}{\rho}},$$

with the production of energy given by

$$E_c = \chi_c n_c \quad \text{and} \quad E_g = \chi_g n_g$$

with $n + n_c + n_g = 1$. Along the lines indicated earlier, for given values of χ_c and χ_g, this model is straightforwardly solved either for the optimum or for a laissez-faire allocation.

A very simple way of modeling research into making energy production more efficient can now be expressed as follows:

$$\chi_c = \overline{\chi} m_c \quad \text{and} \quad \chi_g = \overline{\chi} m_g,$$

with $m_c + m_g = 1$. (If $\lambda_c = 1/2$, this setting is now entirely symmetric.)

A decentralized version of this model would have no agent—either the producer or the user of fossil fuel—take into account the negative externality. However, notice that there are increasing returns to scale in producing energy: double n_c, n_g, m_c, and m_g, and E_c and E_g more than double. A decentralized equilibrium here would then have a much more elaborate structure of varieties within each energy type, either with variety expansion à la Romer or fixed variety but creative destruction Aghion and Howitt (1992), monopolistic competition with profits, and then perfectly competitive research firms producing new varieties (in the Romer case) or product improvements (in the Aghion–Howitt case). We will not spell the variety structure out, but we will make the assumption that the aggregation across varieties is identical for fossil fuel and green energy, eg, implying identical markups across these two energy sectors. Finally, there would normally (in dynamic models) also be spillovers, mostly for tractability, but they are not needed here.[ca] We will, however, discuss spillovers later because there are substantive issues surrounding them.

A decentralized model such as that just described delivers equilibrium existence despite the technological nonconvexity but we omit the description of it for brevity; see Romer (1990) for the basic variety-expansion structure and Acemoglu (2009) for a more recent description of a range of endogenous-growth models and many of their uses. Monopolistic competition would distort the allocation, in the direction of underprovision of energy, which itself would be beneficial for counterbalancing the climate externality and thus to some extent relieve the government of the pressure to tax fossil fuel. In the laissez-faire equilibrium, in the case of symmetry between fossil fuel and

[ca] The reason they improve tractability is that if the researchers' output does not give the researcher herself dynamic gains, the R&D decision becomes static.

energy, the markets will produce whatever the total energy composite is in an efficient manner.[cb] Denoting this level E, the laissez-faire allocation will minimize $n_c + n_g$ subject to

$$E_c^\rho + E_g^\rho \geq E^\rho, \quad E_c = n_c \overline{\chi} m_c, \quad E_g = n_g \overline{\chi} m_g, \quad \text{and} \quad m_c + m_g = 1.$$

The solution to this problem depends critically on ρ. So long as $\rho < 1/2$, ie, so long as the two sources of energy are poor enough substitutes, the solution is to set $n_g = n_e$ and $m_c = m_g = 1/2$; it is straightforward to compute the implied total labor use. If, on the other hand, $\rho > 1/2$, then the outcome is to set either $n_c = m_c = 0$ or $n_g = m_g = 0$, ie, a corner solution obtains, with another easily computed labor use. So if the energy inputs are substitutable enough, there are multiple equilibria. The multiplicity is knife-edge in this case since we assumed full symmetry. However, the essential insight here is not multiplicity but rather sensitivity to parameters, as we will now elaborate on.

Suppose now, instead, that we change the setting slightly and assume

$$\chi_c = \overline{\chi}_c m_c \quad \text{and} \quad \chi_g = \overline{\chi}_g m_g,$$

ie, we assume that there are two separate constants in the two research production functions. Then, in the case where ρ is high enough, there will be full specialization but the direction of the specialization will be given by the relative sizes of $\overline{\chi}_c$ and $\overline{\chi}_g$. If the former is higher, the energy will be produced by fossil fuel only; if the latter is higher, the energy will be produced by green energy only. If the economy experienced a small change in these parameters switching their order, we would have a complete switch in the nature of the energy supplies. Crucially, now, note that we can think of $\overline{\chi}_c$ and $\overline{\chi}_g$ as given by historical R&D activities. Then we can identify the kind of *path dependence* emphasized in Acemoglu et al. (2012). These authors argued that temporary efforts, via subsidies/taxes, to promote the research on "clean goods"—those produced using green energy—would have permanent effects on our energy supplies by managing to shift our dependence on fossil fuel over to a dependence on green energy.[cc] This can be thought of, in terms of this model, as having managed to make $\overline{\chi}_g > \overline{\chi}_c$ by past subsidies to green R&D. Acemoglu et al. used a dynamic model with details that differ from those here—among other things, they assumed much stronger convexities in damages so that a switch to green energy was necessary or else utility would be minus infinity—but this is the gist of their argument.

One can question whether the substitutability is strong enough for the path-dependence argument to apply. For example, Hart (2013) argues that there are strong

[cb] The assumption of symmetry across the two energy sectors, and hence identical markups, is an important assumption behind this result.

[cc] In their analysis, the authors use a notion of two kinds of goods, one clean and one dirty, with labels deriving from the energy source used to produce them. The setting we use here, with an energy composite relevant for the whole economy, is of course also an abstraction but we prefer it because it lends itself more easily to calibration and comparison with data.

complementarities in research across dirty and clean technologies. These complementarities could, in practice, take the form of external effects/spillovers. For example, research into improving electric cars can be helpful for improving the efficiency of cars running on gasoline or diesel, and whether these complementarities are fully paid for or not in the marketplace is not obvious. A way of expressing this formally within our simple framework is a further generalization of our framework as follows:

$$\chi_c = \overline{\chi}_c m_c^{\zeta} m_g^{1-\zeta} \quad \text{and} \quad \chi_g = \overline{\chi}_g m_g^{\zeta} m_c^{1-\zeta}.$$

To the extent ζ is not too much higher than 1/2 here, there are strong complementarities in technology development and path dependence would not apply. Hart (2013) argues this is the relevant case, but it would be hard to argue that the case is settled. Aghion et al. (2014), furthermore, show that there is empirical support for persistence, though whether these effects are strong enough to generate the kind of path dependence emphasized in Acemoglu et al. (2012) is still not clear.

Turning, finally, to the planning problem in these economies, it is clear that the planner faces a tradeoff between the forces discussed here and the climate externality generated by fossil fuel. The setting is rather tractable and it is straightforward to determine the optimal mix of energy supplies. We leave out the detailed analysis for brevity.

4.14.2 Energy Saving

Research into alternative (green) energy supplies is definitely one way of decreasing our fossil-fuel use. Another is energy saving. To formalize this idea, let the energy composite be written in a somewhat more general way, again emphasizing two energy sources (c and g) only:

$$E = \left(\lambda_c (A_c E_c)^{\rho} + (1-\lambda_c)\left(A_g E_g\right)^{\rho}\right)^{\frac{1}{\rho}}.$$

The technology factors A_i here indicate the "efficiency" with which different energy sources are used. Note, parenthetically, that there is a direct parallel with how we treated energy vs a capital-labor composite in Section 2. Now the A_is introduce asymmetry between the different energy sources through another channel, and moreover we can think of them as being chosen deliberately. One interpretation of these choices is temporary decisions to save on energy, eg, by directing effort toward closing windows or making sure machines don't run unnecessarily. Another interpretation emphasizes research toward energy efficiency that are of a permanent nature. One example is the development of more fuel-efficient cars; another is to develop methods for using less jet fuels when airplanes land. In parallel with our treatment of energy production, we then add the equations

$$A_c = \bar{A}_c m_c^{\zeta} m_g^{1-\zeta} \quad \text{and} \quad A_g = \bar{A}_g m_g^{\zeta} m_c^{1-\zeta},$$

again with the constraint $m_c + m_g = 1$.[cd] With this structure as well, market allocations may end up with specialization for a range of parameter configurations, as will the solution to the planning problem, and path dependence is again possible.

An important concern in the modeling of energy saving or the efficiency of producing energy is that there is a natural upper limit to efficiency. For example, light produced with LED has almost reached the efficiency limit and the same is true for electrical engines. However, this does not mean that we are close to maximal energy efficiency in the production of transportation services. For the transportation example it is less appropriate to capture efficiency through A_g; rather, improvements come about through increasing general energy efficiency (say, a coefficient in front of E in the overall production function). The limits to efficiency are normally not made explicit in economic models but arguably should be in quantitative applications.

4.14.3 Are Subsidies for Green Technology Needed?

To attain the optimal allocation, the planner will of course need to tax the use of fossil fuel. What other taxes and subsidies might be necessary? To the extent there is monopoly power, and the energy sources undersupplied, subsidies are needed. Should the green R&D sector be subsidized? Following Pigou's principle, it should be to the extent there are positive spillovers. So in the absence of technology spillovers in the green R&D sector, there would actually be no reason to subsidize. Moreover, if there are spillovers but they are identical for the two sorts of energy, it is not clear that green technology should receive stronger subsidies than should fossil-fuel technology, so long as fossil fuel is taxed at the optimal rate.

In a second-best allocation, of course, matters are quite different. Suppose no coal tax is used. Then subsidies to the production of green energy, or to the development of new green technologies, would be called for. In political debates, subsidies to the development of green technology appear to be quite popular, and our analysis is in agreement with this view insofar as an optimal (global) carbon tax is not feasible. In practical policy implementation, though less so in debates, it also appears that coal subsidies are popular, perhaps not as per-unit instruments but as support in the construction of plants. A study (Hassler and Krusell, 2014) in fact claims that the average global tax on carbon is set at about the right magnitude but with the wrong sign—owing to large subsidies for coal production across the world.

The view expressed in Acemoglu et al. (2012) appears to contrast somewhat with ours. They argue, based on their model of path dependence, that subsidies to green technology are necessary for attaining an optimum and that carbon taxes would not suffice.

[cd] One can also state these constraints using other functional forms, such as $(\bar{A}_c A_c)^{\zeta} + (\bar{A}_g A_g)^{\zeta} \leq A^{\zeta}$. It is an empirical matter what formulation works best, and it is probably fair to say that the literature is so far silent on this issue.

They obtain this result not only because their model features strong intertemporal spillovers to R&D but also because they make assumptions such that if the "clean good" does not take over from the "dirty good," the climate damages will be infinitely costly (thus, they have strong nonconvexities in their damage function, a tipping point of sorts). Moreover, their model has a second-best structure with spillovers and very limited patent lives. How can we understand this result from the perspective of Pigou taxation? Recall that we pointed out that Pigou taxation may not work if there are multiple market equilibria, and the kind of setting Acemoglu et al. describe has a feature of this kind. The simplest parallel in our static model is the coal-green setup we described in Section 4.14.1. There, we looked at a planning problem with a choice between two energy sources. So suppose that $\overline{\chi}_c = \overline{\chi}_g = \chi$ there, and let us imagine a market allocation where the labor productivity of coal and green energy production, χm_c and χm_g, respectively, derive from variety expansion in patent efforts (m_c and m_g) driven by monopoly profits for intermediate, specialized goods. Suppose, moreover, that there are no research spillovers in this setting: this assumption is perhaps natural in a static model (but less so in a dynamic one). In this framework, then, there would be two equilibria if ρ, the parameter guiding the key energy elasticity, is high enough. Suppose, moreover, that damages are to preferences, as in Section 4.6, and with highly nonlinear features, as discussed in Section 4.7: the marginal damages are first zero for a range of low emission levels, then high and positive, and then again zero in a "disaster zone." Suppose, moreover, that if the economy ends up using coal, emissions will end up in the disaster zone. Then the Pigou procedure would amount to finding the optimal solution—that with green technology only—and an associated tax on carbon that is zero, since the marginal damage at zero emissions is zero. So here Pigou's procedure is highly problematic, since there are now two market outcomes given a zero tax on carbon, and one of them is a disaster outcome! Thus another instrument would be needed to select among the two market outcomes, and one option would be a large enough subsidy to green technology creation to rule out an equilibrium where markets engage in the research on coal technologies.[ce]

4.14.4 Green Technology as a Commitment Mechanism

Some argue that future decision makers cannot be trusted to make good decisions and that, therefore, to the extent we can affect their decisions with irreversible decisions made today, we should. Why would future decision makers not make good decisions? One reason is based on time-inconsistent discounting, as discussed earlier: the current decision maker may have lower discount rates between any two future cohorts than that between the current and next cohort, and if this profile of decreasing discount rates is shared by future cohorts—updated by the appropriate number of cohorts—then profiles are

[ce] With monopolistic competition, one would in general also need to encourage production to prevent undersupply for those technologies that end up being patented.

time-inconsistent. In particular, from the perspective of the current cohort, future cohorts look too impatient. Since future carbon taxes cannot literally be committed to today, then, the current cohort is restricted and appears to not be able to attain its preferred outcome.[cf] Another conceptually distinct reason for disagreements is that politicians (and possibly the voters who support them) may be "myopic"; Amador (2003) shows that rationality-based dynamic voting games in fact can lead to reduced forms characterized by time-inconsistent preferences of politicians.[cg] Finally, Weitzman (1998) provides further arguments for falling discount rates based on the idea that the true future discount rate may be uncertain.

If current decision makers cannot decide directly on the future use of fossil fuels, they may be able to at least influence outcomes, for example by investing in green technology that, ex-post, will tilt the decision makers in the future in the right direction. To illustrate, consider a model where production is given by

$$e^{-\gamma\phi\chi_E n_E}(1-n_E-n_g)^{1-\alpha-\nu}(\chi_E n_E+\chi_g n_g)^{\nu}.$$

$E=\chi_E n_E$ is coal-produced energy and $E_g=\chi_g n_g$ is green energy; we make the assumption, only for obtaining simpler expressions, that these two energy sources are perfect substitutes. Now assume that there is an ex-ante period where an irreversible decision can be made: that on n_g. The cost is incurred ex-post, so only the decision is made ex-ante. Moreover, it is possible to increase n_g ex-post but not decrease it: it is not possible to literally reverse the first decision.[ch] Finally, assume that the ex-ante decision maker perceives a different damage elasticity than the ex-post decision maker (they have different γs, with the ex-ante value higher than the ex-post value): this captures, in a simple way, the intertemporal disagreement.

We make two further simplifying assumptions, for tractability. First, we take the ex-post decision maker to perceive a damage elasticity of exactly 0 and the ex-ante decision maker to use the value $\gamma>0$. Second, we assume that $\chi_E>\chi_g$, ie, that—climate effects aside—the coal technology is a more efficient one for producing energy, regardless of the level at which the two technologies are used (due to the assumption of perfect substitutability). How can we now think about outcomes without commitment?

It is clear that the ex-post decision maker sees no reason to use the green technology at all. Facing a given amount of n_g that he cannot decrease (and will not want to increase), the level of n_E will be determined by the first-order condition

[cf] Karp (2005), Gerlagh and Liski (2012), and Iverson (2014) analyze optimal taxes in the presence of time-inconsistent preferences.

[cg] See also Azzimonti (2011) for a similar derivation.

[ch] We may think of this setup as a reduced-form representation for a case when an ex-ante investment in capital or a new technology makes it profitable to use at least n_g units of labor in green energy production, even if it the emission reduction is not valued per se. In a dynamic model, the cost of this investment would at least partly arise ex-ante, but this is not of qualitative importance for the argument.

$$\frac{1-\alpha-\nu}{1-n_E-n_g}=\frac{\nu\chi_E}{\chi_E n_E+\chi_g n_g}. \tag{17}$$

This expression delivers a linear (affine) and decreasing expression for n_E as a function of n_g: $n_E = h(n_g)$, with $h' < 0$ and independent of n_g.

What is the implied behavior of the ex-ante decision maker without commitment? She will want to maximize

$$e^{-\gamma\phi\chi_E h(n_g)}\left(1-h(n_g)-n_g\right)^{1-\alpha-\nu}\left(\chi_E h(n_g)+\chi_g n_g\right)^{\nu}$$

by choice of n_g, a decision that delivers a second-order polynomial equation as first-order condition, just like in the baseline case (though now with somewhat more involved coefficients in the polynomial). Does this first-order condition admit the first best outcome of the ex-ante decision maker? Such a first best would amount to the solution of the two first-order conditions

$$\gamma\phi\chi_E+\frac{1-\alpha-\nu}{1-n_E-n_g}=\frac{\nu\chi_E}{\chi_E n_E+\chi_g n_g} \tag{18}$$

and

$$\frac{1-\alpha-\nu}{1-n_E-n_g}=\frac{\nu\chi_g}{\chi_E n_E+\chi_g n_g} \tag{19}$$

which result from taking derivatives with respect to n_E and n_g, respectively. It is easy to see that these cannot deliver the same solution as the problem without commitment. For one, Eqs. (19) and (17) cannot deliver the same values for both n_E and n_g, since they differ in one place only and $\chi_E > \chi_g$. Thus, we are in a second-best world where the ex-ante decision maker uses her instrument but cannot, without an additional instrument, obtain her first-best outcome. Moreover, total energy use and/or total labor used to produce energy will be lower with the ex-ante decision on green energy than in the absence of it, comparing Eqs. (17) and (18). This model is stylized and it would appear that the specific predictions could change when moving to a more general setting. However, the second-best nature of the setting would remain.

4.14.5 The Green Paradox

The Green Paradox, a term coined by Sinn (2008), refers to the following logical chain. Decisions to subsidize green technology so as to speed up the research efforts in this direction will, if these efforts are successful, lead to better and better alternatives to fossil fuel over time. This, in turn, implies that fossil-fuel producers have an incentive to produce more in advance of these developments, given that their product is more competitive now than it will be in the future. As an extreme example, imagine that cold fusion is invented but takes one year to implement, so that one year from now we have essentially free, green energy in the entire economy. Then owners of oil wells will produce at maximum capacity today and, hence, there will be much higher carbon dioxide emissions than if cold fusion had not been invented. Hence the "paradox": green technology (appearing in the future) is good but therefore bad (in the short run).

Our static model fully cannot express the Green Paradox, of course, since the essence of the paradox has to do with how events play out over time. Consider therefore a very simple two-period version of the model that allows us to think about how the intertemporal decision for oil producers depends on the availability of green technology. We assume that consumers' preferences are linear so that the gross interest rate is given by $1/\beta$. We assume that fossil fuel is (free-to-produce) oil and that $\rho=1$, so that oil and green energy are perfect substitutes. We also assume that there is no green technology in the first period. A simplified production function thus reads $e^{-\gamma\phi_1 E_1} k^\alpha E_1^\nu$ for period 1 and $e^{-\gamma\phi_1(E_2+\phi_2 E_1)} k^\alpha (E_2+E_g)^\nu$ for period 2; for simplicity, we also abstract from the costs for producing green energy and set E_g to be exogenous, with $n=1$ in both periods). Here, ϕ_1 and ϕ_2 allow us to capture a carbon depreciation process that does not occur at a geometric rate, a feature we argued is realistic. Our notation reveals that capital cannot be accumulated in this example, but we will comment on accumulable capital later.

Given this setting, the price of oil in period 1 is given by $p_1=\nu e^{-\gamma\phi_1 E_1} k^\alpha E_1^{\nu-1}$ and in period 2 it is given by $p_2=\nu e^{-\gamma\phi_1(E_2+\phi_2 E_1)} k^\alpha (E_2+E_g)^{\nu-1}$. All of the available oil, $\bar{E}$, will be used up in the laissez-faire allocation and so oil use in the two periods will be given by the Hotelling condition, a condition we derived and analyzed in Section 2: $p_1=\beta p_2$. Recall that this equation expresses the indifference between producing a marginal unit of oil in period 1 and in period 2. This condition implies that E_1 can be solved for from $e^{-\gamma\phi_1 E_1} E_1^{\nu-1}=\beta e^{-\gamma\phi_1(\bar{E}-E_1(1-\phi_2))}(\bar{E}-E_1+E_g)^{\nu-1}$. Clearly, this equation has a unique solution and comparative statics with respect to E_g shows that more green energy in period 2 makes E_1 rise and E_2 fall. Hence the Green Paradox.

Is the move of emissions from period 2 to period 1 bad for welfare? The negative externality (SCC) of emissions in period 1 is $\gamma\phi_1(y_1+\beta\phi_2 y_2)$ and the present value of the corresponding externality in period 2 is $\gamma\phi_1\beta y_2$. In the absence of a green technology in period 2 ($E_g=0$) it is easy to show that $y_2<y_1$ in the laissez-faire allocation and, hence, at least for a range of positive values of E_g, the externality damage is higher for early emissions. Intuitively, emissions in period 2 have two advantages. One is that they hurt the economy only once: emissions in period 1 will, except for the depreciated fraction $1-\phi_2$, remain in the atmosphere—a significant factor given calibrated carbon-cycle dynamics—and hence also lower second-period TFP. The second advantage of emissions in the future is that their negative effect is discounted (to the extent we assume $\beta<1$). Note, finally, that the possibility of accumulating physical capital would not change any of these conclusions: with more green energy in the second period, capital accumulation with rise somewhat to counteract the initial effect, and it would work toward an increase in p_2, but this mechanism would not overturn our main observation.

Can the future appearance of green technology also make overall welfare go down in the laissez-faire allocation? This is much less clear, as an additional unit of E_g (for free) has a direct positive welfare effect.[ci] However, now consider competitive production of green energy under laissez-faire, at a unit labor cost χ_g. Here, a second-best argument would suggest that there is a negative "induced externality" of green energy production: since the economy is far from the optimum, and emissions in period 1 would be detrimental, any additional unit of E_g would have a negative side-effect on welfare. Hence, a(t least a small) *tax* on green energy production would be desirable! The reason for this perhaps counterintuitive effect—aside from the Green-Paradox logic—is that the total amount of fossil fuel used will still be $\bar{E}$: green technology, in this setting, will not curb the use of fossil fuel, only change the timing of emissions (in the wrong direction).

The previous example points to counterintuitive policy implications: green technology should be discouraged. However, aside from the assumptions that make the Green Paradox relevant, this result also relies on second-best analysis. In the social optimum, green technology should not be taxed (nor subsidized): there is, simply, no externality from producing green technology in this model. If green technology is developed in an R&D activity, then support of this activity (relative to other activities) may be called for, but only if there is an R&D externality to green technology development that is, in the appropriate sense, larger than the corresponding one for fossil-fuel technology developments. Hence, the optimum (in this economy, where oil is free to produce) involves fossil-fuel taxes but no net support to green technology.

Is the Green Paradox empirically relevant? The key assumption that leads to the paradox is that the accumulated use of fossil fuel is the same under laissez-faire as in the optimal allocation. In this case, suboptimality only comes from the speed at which the fossil reserves are used. That all reserves are used also in the optimal allocation is arguably reasonable when it comes to conventional oil with low extraction costs (eg, Saudi oil). However, it is not reasonable for nonconventional reserves and coal. Here, policy, including subsidies to the development of future green energy production, can and should affect how much fossil resources are left in ground. So suppose, instead, that we focus on fossil fuel in the form of coal and that we maintain our assumption that the marginal cost of coal is constant (in terms of labor or some other unit). Then an increase in E_g would lead to a lower demand for coal and hence have an impact on coal use: it would clearly induce lower coal production in the second period. Lower coal use, in turn, has a positive externality on the economy. Moreover, coal use in period 1 is not affected. Hence, the conclusion here is the opposite one: green energy has a positive effect on the economy (beyond its direct positive effect, to the extent it comes for free).

[ci] If there are strong nonlinearities, like a threshold CO_2 concentration level above which climate damages are catastrophic, then the introduction of a green technology in the second period could make laissez-faire welfare fall.

In addition, relative to a laissez-faire allocation it would be beneficial to subsidize, not tax, green energy production. Which case appears most relevant? We take the view that the latter is more relevant. The argument has two parts. First, the intertemporal reallocation of emissions emphasized in the Green-Paradox argument, though logically coherent, is not, by our measure, quantitatively important. The main reason is that the total amount of oil is rather small and its effect on climate is limited, and a reallocation of emissions due to oil over time is of second-order importance compared to being able to control the cumulated (over time) emissions. Second, if the fossil fuel is costly to extract then there would be lower emissions, as argued earlier, and in terms of the total amount of fossil fuel available, most of it is costly to extract (most of it is coal). Coal is produced at a price much closer to marginal cost and the Hotelling part of the coal price appears small. This argument, moreover, is quantitatively important given the large amounts of coal available.

4.15 Regional Heterogeneity

Nordhaus's basic DICE model is a one-region integrated assessment model, but there are by now several calibrated models in the literature with more than one region. His own RICE (R for Regional) model was perhaps the first multiregion model and it had 7 regions, defined by geographic and economic indicators; Krusell and Smith (2015) have developed a model at the extreme end of heterogeneity, treating one region as a 1-by-1-degree square with land mass on the global map. Regional models can serve a variety of purposes and we first briefly discuss the chief purposes. We then use a multiregion version of our basic model as an illustration; in particular, we use a simple version of Hassler and Krusell (2012) and look at some extensions.

A major purpose for looking at regional heterogeneity comes from recognizing that damages are very different in different parts of the world; some regions, such as Canada and most of Russia, are even expected to gain from a warmer climate. Thus, using a multiregion IAM as a simulation device, one can trace out the heterogeneous effects of climate change under different policy scenarios. Even if there is no agreement on a social welfare function for the world, surely policymakers are very interested in this heterogeneity.

Another purpose of a multiregion IAM is to look at the effects of regionally heterogeneous policies. Suppose the Western world adopts a strict carbon tax and the rest of the world does not. How effective will then the western policies be in combatting climate change, and what will its distributional consequences be?

Relatedly, one of the key concepts in policymakers' studies of climate change is *carbon leakage*. The idea here is simply that when carbon is taxed at higher rates in some regions than in others, the decreases in carbon use in the high-tax regions will presumably be (partially, or fully) offset by increases in carbon use in other regions. *Direct carbon leakage* would for example occur if the oil shipments are simply redirected away from low-tax to high-tax regions. But there can also be *indirect carbon leakage* in that the other factors of production (capital and/or labor) can move to where carbon taxes are lower—and hence carbon will be used more there as a result. Differential policies can also affect outcomes through trade (see, eg, Gars, 2012 and Hémous, 2013). Finally, when there is R&D in the development of fossil-fuel and green technologies, differential policies in this regard come into play as well (Hémous, 2013, looks at this case as well).

Still another important aspect of a multiregion IAM is its potential for discussing *adaptation* to climate change through the migration of people (along with other production factors).[cj] Adaptation is not just important in practice but it is important to think about from a theoretical and quantitative perspective since the damages from climate change really are endogenous and depend on how costly it is to migrate. If migration were costless, significant warming would potentially be less detrimental to human welfare since there are vast areas on our continents that are too cold today but, with significant warming, inhabitable. There is very little research on this issue so far (Brock et al., 2014 and Desmet and Rossi-Hansberg, 2015 are promising exceptions) but we believe it is an important area for future research and one with much potential. Empirical research on the costs of migration is also scant, but some work does exist (Feng et al., 2010 and, for a study of conflict in this context, see Harari and La Ferrara (2014); see also the review Burke et al., 2015).

4.15.1 A Two-Region IAM with Homogeneous Policy: Oil

Our simple model is easily extendable to include another region (or more). Let us look at a series of simple cases in order to illustrate some of the main points made in the literature.[ck] Let us first look at heterogeneous damages, so assume that production in region 1 is $e^{-\gamma_1 E}k_1^{\alpha}n_1^{1-\alpha-\nu}E_1^{\nu}$ whereas production in region 2 is $e^{-\gamma_2 E}k_2^{\alpha}n_2^{1-\alpha-\nu}E_2^{\nu}$. Energy is coming from fossil fuel only, and let us first assume that it is (costless-to-produce) oil available at a total amount $\bar{E}$ in a third region of the world, which supplies the oil under perfect competition (the third region thus plays no role here other than as a mechanical supplier of oil). Let us also for simplicity start out by assuming that the two regions are homogeneous in the absence of climate damages, so that $k_1 = k_2 = k$ and $n_1 = n_2 = n$. It is easy to work out a laissez-faire equilibrium for this world and we can look at different cases, the first of which is that when neither capital nor labor can move. Thus, the only trade that occurs takes the form that the oil-producing region sends oil to the two other regions and is paid in consumption goods; regions 1 and 2 do not interact, other than by trading in the

[cj] For a recent example, see Krusell and Smith (2015), who allow for the migration of capital.

[ck] It should be noted, however, that there are very few examples of multiregion IAM that are studied in full general equilibrium. Thus the number of formal results from the literature is therefore very limited relative to the number of informal conjectures.

competitive world oil market. All of the oil will be used and the equilibrium oil distribution will now be determined by the following condition:

$$e^{-\gamma_1 \bar{E}} E_1^{\nu-1} = e^{-\gamma_2 E} E_2^{\nu-1},$$

ie, by ($E_1 + E_2 = \bar{E}$ and)

$$\frac{E_1}{E_2} = e^{\frac{\gamma_2 - \gamma_1}{1-\nu} \bar{E}}.$$

Thus, the relative use of oil is higher in the country with lower climate damages.[cl] Suppose that region 1 experiences stronger damages. Clearly, then, region 1 is worse off and the damage has a small "multiplier effect" to the extent that its energy used is curbed: more energy is used in region 2. In other words, we would see lower TFP in region 1 but lower activity there also because of reduced energy use. Consumption is a fraction $1-\nu$ of output, with the remainder sent to the third, oil-producing region.

If we also allow capital to move—but maintain that the populations cannot move—the output effect will be somewhat strengthened as capital will also move to region 2 to some extent. If half of capital is owned by each region, this makes region 1 gain, however, because its GNP will rise even though its GDP will fall. In the real world, there are moving costs and cultural and other attachments to regions, so full and costless migration is probably not an appropriate assumption even in the long run (as the static model is supposed to capture a longer-run perspective).

Suppose now that regions 1 and 2 consider a common tax τ on carbon and suppose that this tax is collected in each country and redistributed back lump-sum to the local citizens. Would such a tax be beneficial? To regions 1 and 2, yes. The analysis depends on the size of the tax but suppose the tax is low enough that firms are not sufficiently discouraged from using oil that the total amount of oil use is lowered. Then the relative energy uses in the two regions will still satisfy the equations above and the levels will not change either. The price of oil, p, will satisfy

$$p = \nu y_1 / E_1 - \tau,$$

the first term of which is independent of the tax size (for a small enough tax). Hence, country i's consumption will now be $y_i - (p+\tau)E_i + \tau E_i = (1-\nu)y_i + \tau E_i$ so that consumption is strictly increasing in τ for both regions. Thus, the two regions can use the tax to shift oil revenues from the oil-producing region to its own citizens, without affecting output at all.[cm] When the tax is high enough that p reaches zero, the level of production responds to taxation: as producers now receive nothing for their oil, they

[cl] Of course this result depends on damages occurring to TFP; if they affect utility, oil use is identical in the two regions.

[cm] This argument is of course unrelated to any climate externality; the climate is unaffected by the taxation.

are indifferent as to how much to supply. At that tax level, the total energy supply will still be given by $\bar{E}$ and the equations above, but now consider a slightly higher tax, still with a zero price of oil. Then the total amount of energy E is then lower and is determined from

$$\tau = \nu e^{-\gamma_1 E} k^{\alpha} n^{1-\alpha-\nu} E_1^{\nu-1} \quad \text{and} \quad \frac{E_1}{E-E_1} = e^{\frac{\gamma_2-\gamma_1}{1-\nu}E}.$$

It is straightforward to show, if the γs are not too far apart, that these two equations imply a lower E and E_1 as τ is raised and that E_1/E_2 will rise. Now, for each region there would be an optimal τ and there would be a conflict between these two values. Generally, the region with a higher climate externality would favor a higher tax.

4.15.2 A Two-Region IAM with Homogeneous Policy: Coal

These discussions all refer to the case of oil, ie, a free-to-extract fossil fuel. Suppose we instead look at coal, and assume that coal is domestically produced: it costs $1/\chi_i$ units of labor per unit, as in most of our analysis earlier. We also assume that the transport costs for coal are inhibitive so that there is no trade at all. The only connection between the regions is thus the climate externality. In the absence of taxes the world equilibrium is then determined independently of the externality and according to

$$\frac{1-\alpha-\nu}{\chi_i - E_i} = \frac{\nu}{E_i}$$

for $i=1,2$.

Now the reason to tax in order to transfer resources away from a third region and to the home country is no longer applicable; the only reason to tax is the climate externality. As in the oil case, let us assume that any tax on coal is lump-sum transferred back to domestic consumers. What is then the best outcome for each of the two regions? The two countries can, in principle, act in a coordinated fashion so as to maximize overall welfare—by maximizing world output—and then choose a point on the Pareto frontier by the use of transfers. World output is maximized by setting the tax equal to the marginal damage externality in the world, ie, $\gamma_1 y_1 + \gamma_2 y_2$. Thus, the social planner chooses E_1 and E_2 to solve

$$\gamma_1 e^{-\gamma_1(E_1+E_2)} k_1^{\alpha} \left(1 - \frac{E_1}{\chi_1}\right)^{1-\alpha-\nu} E_1^{\nu} + \gamma_2 e^{-\gamma_2(E_1+E_2)} k_2^{\alpha} \left(1 - \frac{E_2}{\chi_2}\right)^{1-\alpha-\nu} E_2^{\nu} =$$

$$e^{-\gamma_1(E_1+E_2)} k_1^{\alpha} \left(1 - \frac{E_1}{\chi_1}\right)^{1-\alpha-\nu} E_1^{\nu} \left(\frac{1-\nu-\alpha}{\chi_1 - E_1} - \frac{\nu}{E_1}\right) =$$

$$e^{-\gamma_2(E_1+E_2)} k_2^{\alpha} \left(1 - \frac{E_2}{\chi_2}\right)^{1-\alpha-\nu} E_2^{\nu} \left(\frac{1-\nu-\alpha}{\chi_2 - E_2} - \frac{\nu}{E_2}\right).$$

The first line represents the global damage externality (which is also the optimal tax on coal); it has to be set equal to the net benefit of emissions in each of the two regions (the following two lines). The allocation will have lower E_1 and E_2 amounts (provided, at least, both γs are positive) than in the laissez-faire allocation.

Suppose, however, that the regions cannot use transfers to arrive at a Pareto-optimal allocation. Then an optimal allocation would be obtained by maximizing a weighted value of the utilities of consumers in the two regions. Often, macroeconomic models adopt the utilitarian approach. Assuming, as in a benchmark case above, logarithmic utility of consumption, and a utilitarian social welfare function, we would then need to solve

$$\max_{E_1,E_2} \log\left(e^{-\gamma_1(E_1+E_2)}k_1^{\alpha}\left(1-\frac{E_1}{\chi_1}\right)^{1-\alpha-\nu}E_1^{\nu}\right)+\log\left(e^{-\gamma_2(E_1+E_2)}k_2^{\alpha}\left(1-\frac{E_2}{\chi_2}\right)^{1-\alpha-\nu}E_2^{\nu}\right).$$

This problem delivers two simple first-order conditions:

$$\gamma_1+\gamma_2=\frac{1-\nu-\alpha}{\chi_1-E_1}-\frac{\nu}{E_1}=\frac{1-\nu-\alpha}{\chi_2-E_2}-\frac{\nu}{E_2}.$$

It is easy to see from these two equations the only parameters that influence emissions in country i are parameters specific to that country plus the damage elasticity parameter of the other country. Suppose now that we try to back out what tax on coal in country i would be necessary to attain this allocation. From the firm's first-order condition we obtain

$$\tau_i=e^{-\gamma_1(E_1+E_2)}k_i^{\alpha}\left(1-\frac{E_i}{\chi_i}\right)^{1-\alpha-\nu}E_i^{\nu}\left(\frac{1-\nu-\alpha}{\chi_i-E_i}-\frac{\nu}{E_i}\right).$$

Let us now evaluate the right-hand side at the utilitarian optimum as given by the previous equations. This delivers

$$\tau_i=(\gamma_1+\gamma_2)e^{-\gamma_1(E_1+E_2)}k_i^{\alpha}\left(1-\frac{E_i}{\chi_i}\right)^{1-\alpha-\nu}E_i^{\nu}.$$

Does this imply a uniform tax across countries? The answer is no. We obtain, in particular, that

$$\frac{\tau_1}{\tau_2}=\left(\frac{k_1}{k_2}\right)^{\alpha}\left(\frac{1-\dfrac{E_1}{\chi_1}}{1-\frac{E_2}{\chi_2}}\right)^{1-\alpha-\nu}\left(\frac{E_1}{E_2}\right)^{\nu}=\frac{\gamma_1}{\gamma_2}.$$

Clearly, this expression is not 1 in general. It depends on the ratio of capital stocks (note that E_1 and E_2 do not) and the expression involving the Es and χs is also not equal to 1 in general: it is above (below) 1 if χ_1 is above χ_2. In the latter case, the richer country imposes a larger tax on carbon. Note, however, that we obtain a common tax rate, ie, a *common tax on coal per output unit.*

We have learned from the earlier analysis (i) that the Pareto optimum involves a globally uniform tax on coal (along with some chosen lump-sum transfers across regions) but (ii) the utilitarian optimum assuming no transfers across regions does not, and instead prescribes—in the benchmark case we look at—a tax that is proportional to the country's output. It is straightforward to go through a similar exercise with population sizes differing across regions; in this case, the optimal tax rate in region i is equal to the region's per-capita income times the world's population-weighted γs.

4.15.3 Policy Heterogeneity and Carbon Leakage

International agreements appear hard to reach and it is therefore of interest to analyze policy heterogeneity from a more general perspective. So suppose region 1 considers a tax on its fossil fuel but knows that region 2 will not use taxes. What are the implications for the output levels of the two regions and for the climate implied by such a scenario? We again begin the analysis by looking at the case of oil, and we start off by assuming that neither capital nor labor can move across regions.

In a decentralized equilibrium, oil use in region 1 is given by

$$p+\tau=\nu e^{-\gamma_1(E_1+E_2)}k_1^\alpha n_1^{1-\alpha-\nu}E_1^{\nu-1}$$

and in region 2 it is given by

$$p=\nu e^{-\gamma_2(E_1+E_2)}k_2^\alpha n_2^{1-\alpha-\nu}E_2^{\nu-1}.$$

Thus, we can solve for E_1 and E_2 given $E_1+E_2\leq\bar{E}$. Clearly, we must have $p>0$—otherwise, region 2 would demand an infinite amount of oil—and so we first conclude that $E_1+E_2=\bar{E}$: there is no way for one country, however large, to influence total emissions. What the tax will do is change energy use across regions: region 1 will use less and region 2 more. Moreover, in utility terms region 1 is worse off and region 2 better off from this unilateral tax policy. This example illustrates direct (and full) carbon leakage: if one region taxes oil, oil use will fall in this region but there will be an exact offset elsewhere in the world.

In the coal example, the situation is rather different. The laissez-faire allocation is now given by

$$\tau_1=e^{-\gamma_1(E_1+E_2)}k_1^\alpha\left(1-\frac{E_1}{\chi_1}\right)^{1-\alpha-\nu}E_1^\nu\left(\frac{1-\nu-\alpha}{\chi_1-E_1}-\frac{\nu}{E_1}\right)$$

and

$$0 = \frac{1-\nu-\alpha}{\chi_2 - E_2} - \frac{\nu}{E_2}.$$

We see that coal use in region 2 now is independent of the tax policy in region 1.[cn] It is easy to show that region 1's coal use will fall and that, at least if both γs are positive and locally around $\tau_1 = 0$, welfare will go up in both regions. There will be an optimal tax, from the point of view of region 1's utility, and it is given by the SCC (computed ignoring the negative externality on region 2), ie, $\gamma_1 y_1$.

If one allows capital mobility, as in Krusell and Smith (2015), there will be indirect carbon leakage. In the case of oil, a tax in region 1 would act as a multiplier and tilt the relative oil use more across regions, ie, increase the leakage. In the case of coal, whereas there is no leakage when capital cannot flow, there is now some leakage: the lower use of coal will decrease the return to capital in region 1 and some capital will then move to region 2, in turn increasing emissions there. We thus see that the extent of leakage depends on (i) how costly fossil fuel is to extract and (ii) to what extent other input factor flow across regions.[co]

It would be straightforward to apply this model, and even dynamic versions of it as they can allow closed-form analysis, for a range of qualitative and quantitative studies. A recent example is Hillebrand and Hillebrand (2016), who study tax-and-transfer schemes in a dynamic multiregion version of the model.

4.15.4 More Elaborate Regional Models

Multiregion models of the sort discussed here can be applied rather straightforwardly, and without much relying on numerical solution techniques, in a number of directions. However, some extensions require significant computational work. One example is the case where the intertemporal cross-regional trade is restricted; a specific case is that where there are shocks and these shocks cannot be perfectly insured. Krusell and Smith (2014, 2015) study such models and also compare outcomes across different assumptions regarding such trade; in their models with regional temperature shocks, the model is similar to that in Aiyagari (1994), with the Aiyagari consumers replaced by regions, and where the numerical methods borrow in part from Krusell and Smith (1998). The Krusell and Smith (2015) model has regions represent squares that are 1 by 1 degree on the map; Nordhaus's G-Econ database with population and production on that level of aggregation can then

[cn] Our particular assumptions on how coal is produced explains why there is no effect at all on coal use in region 2: the costs and the benefits of coal are both lowered by the same proportion as a result of the tax in region 1. With coal produced with a constant marginal cost in terms of output (as opposed to in terms of labor), there would be a small effect on region 2's coal use.

[co] We did not consider the case where coal is costless to trade and potentially produced in a third region but it is straightforwardly analyzed.

be used to calibrate the model. Thus, the calibration makes the initial model output distribution match that in the data, and the marginal products of capital are assumed to be equal initially—these two restrictions are made possible by choosing TFP and capital-stock levels for each region. There is also heterogeneity in two aspects of how regions respond to climate change. One is that for any given increase in global temperature, the regional responses differ quite markedly according to certain patterns, as discussed in Section 3.1.4; Krusell and Smith use the estimates implied by a number of simulations of advanced climate models to obtain region-specific parameters. These estimated "climate sensitivities" are plotted by region on the global map in left panel of Fig. 13.

A second element is differences in damages from climate change across regions. In the latest version of their work and as mentioned in Section 3.3.3, Krusell and Smith use the assumption that there is a common, U-shaped damage function for all regions defined in terms of the local temperature, ie, there ideal temperature is the same at all locations. This common damage function has three parameters which are estimated to match, when the model is solved, the aggregate (global) damages implied by Nordhaus's DICE damage function for three different warming scenarios (1, 2.5, and 5 degrees of global warming). The estimates imply that an average daily temperature of 11.1°C (taken as a 24-h average) is optimal.

The right panel of Fig. 13 displays the model's predicted laissez-faire outcomes in year 2200. We see large gains in percent of GDP in most of the northern parts of the northern hemisphere and large losses in the south. Overall, the damage heterogeneity is what is striking here: the differences across regions swamp those obtained for any comparisons over time of global average damages. The results in this figure of course rely on the assumption that the damage function is the same everywhere so that warming implies gains for those regions that are too cold initially and losses for those that are too warm. This, however, seems like a reasonable assumption to start with and, moreover, is in line with recent damage-function estimates using cross-sectional data: see Burke et al. (2015). These results at the very least suggest that the returns from further research on heterogeneity should be rather high.

We already mentioned Hémous's (2013) work on the R&D allocation across regions, emphasizing the importance of understanding the determinants and consequences of the regional distribution of R&D and of trade in goods with different carbon content.[cp] Another very promising and recent line of research that we also made reference to above is that on endogenous migration pursued in Brock et al. (2014) and Desmet and Rossi-Hansberg (2015). The latter study, which is an early adopter of the kind of damage-function assumption (for both agriculture and manufacturing) used in the later study by Krusell and Smith (2015), assumes free mobility and that there is technology heterogeneity across regions, with operative region-to-region spillovers. The model

[cp] See also Acemoglu et al. (2014).

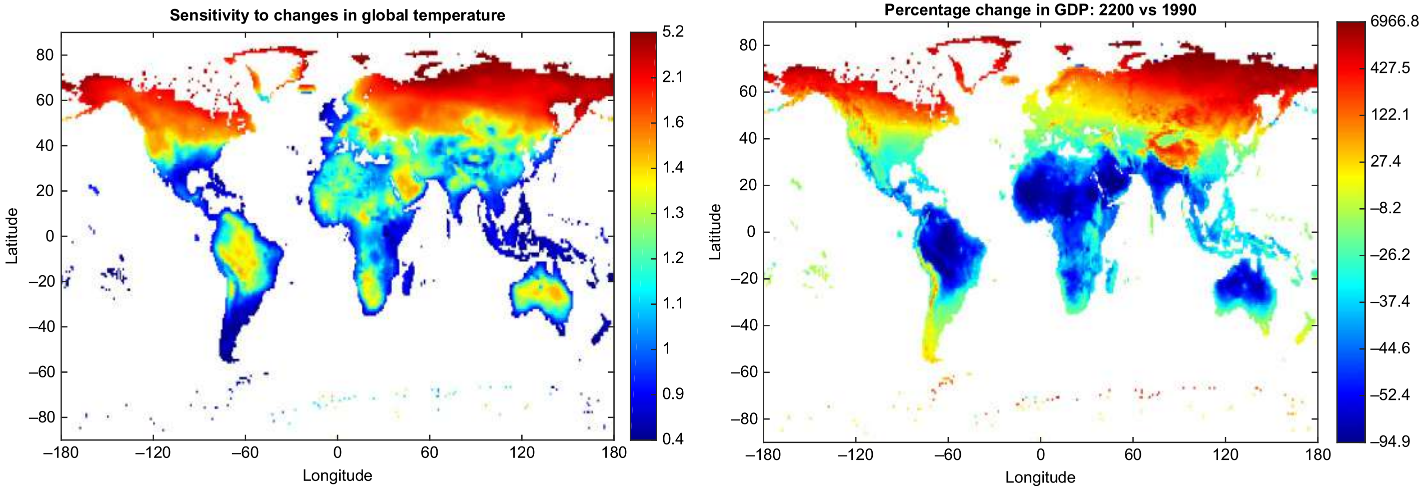

Fig. 13 *Left*: temperature increases for global warming of 1 degree. *Right*: simulation of Krusell and Smith (2015) model, future % GDP losses under laissez-faire.

structure used by Desmet and Rossi-Hansberg is particularly tractable for the analysis of migration, as it uses indifference conditions to distribute agents across space. In contrast, models where location is a state variable (in a dynamic sense) and moving is costly are much more difficult to characterize, as moving then is a highly multidimensional and nonlinear problem both with regard to state and control variables. Stylized two-region models like those studied herein and in Hémous's work can perhaps be solved for endogenous migration outcomes but full dynamics are probably very challenging to solve for.

5. DYNAMIC IAMS

Even though the static IAM setting analyzed in the previous section is useful in many ways, its value in quantitative evaluations is limited: climate change plays out very slowly over time—the dynamics of the carbon cycle especially—and the intertemporal economics aspects involving the comparison between consumption today and consumption far out in the future are therefore of essence. Thus, a quantitatively oriented integrated assessment model of economics and climate change needs to incorporate dynamics. In addition, there are some conceptual issues that cannot be properly discussed without a dynamic setting, such as time preferences.

To our knowledge, the first steps toward modern integrated assessment model appear in Nordhaus (1977). A little over a decade later, Nordhaus developed a sequence of dynamic models, all in the spirit of the simple model above, but formulated in sufficient complexity that numerical model solution is required. The core, one-region version of Nordhaus's model is DIce: a Dynamic Integrated Climate-Economy model, described in detail in Nordhaus and Boyer (2000). In one respect, almost all the dynamic IAMs, including Nordhaus's, are more restrictive than the setting in our previous section: they focus on a planning problem, ie, on characterizing optimal allocations. That is, decentralized equilibria without carbon policy, or with suboptimal carbon policy, are rarely analyzed, let alone explicitly discussed in dynamic models.[cq] In our present treatment, we insist on analyzing both optima and suboptimal equilibria, in large part because the quantitative assessments of the "cost of inaction" cannot be computed otherwise.

In what follows we will discuss a general structure for which we define the social cost of carbon and, under some additional assumptions, can derive a simple and directly interpretable formula for the tax. It is a straightforward extension of the results from the static model above. This material is contained in Section 5.1. In Section 5.2 we then make further assumptions, relying also on the finite-resource modeling from Section 2, and simplify the general structure so as to arrive at an easily solved, and yet quantitatively reasonable, model that can be used for positive as well as normative analysis. Throughout, the discussion follows Golosov et al. (2014) rather closely.

[cq] For an exception, see, eg, Leach (2007).

5.1 The Social Cost of Carbon in a General Dynamic Model

We now focus on how the SCC is determined in a dynamic setting that is reasonably general. For this, we use a typical macroeconomic model with a representative (for the global economy, at this point) agent, as in Nordhaus's DICE model, a production structure, and a specification of the climate system as well as the carbon cycle.

The representative agent has utility function

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t U(C_t),$$

where U is a standard, strictly concave utility function of (the one and only) consumption good C and where $\beta \in [0,1)$ is the discount factor. The resource constraint for the consumption good is more broadly a constraint for the final good, because like in most of the macroeconomic literature we treat consumption and investment as perfect substitutes. The constraint thus reads

$$C_t + K_{t+1} = Y_t + (1-\delta)K_t,$$

which involves a typical capital accumulation specification with geometric depreciation at rate δ and where Y denotes global output. Global output, in turn, is generated from

$$Y_t = F_{0,t}(K_{0,t}, N_{0,t}, \mathbf{E}_{0,t}, S_t).$$

Here, "0" represents the sector producing the final good. The function F_0 is assumed to display constant returns to scale in the first three inputs. $N_{0,\ t}$ is labor used in this sector and $\mathbf{E}_{0,t} = (E_{0,1,t}, \ldots, E_{0,I,t})$ denotes a vector of different energy inputs. We use a subindex t on the production function to indicate that there can be technical change over time (of various sorts and deterministic as well as stochastic). S, finally, is atmospheric carbon concentration, and it appears in the production function because it causes damages—through the effect of S on the climate (in particular through the temperature).

In our formulation here, as discussed earlier, we adopt the common assumption that damages only appear in the production function. Moreover, they only appear in the time-t production function through atmospheric carbon concentration at t, thus subsuming the mapping from S to temperature and that from temperature to output loss in one mapping. As we already argued, these assumptions are convenient in that they map neatly into Nordhaus's DICE model. We should remind the reader that the inclusion of only S_t in the damages at t captures a lack of dynamics; as we pointed out, this should still be a reasonable approximation to a more complex setting where, conceptually, one would include past values of S in the production function at t as a way of capturing the full dynamics. An extension to include such lagged variables is straightforward but would not greatly change the results as the temperature dynamics are rather quick.

Turning to energy production, we assume that there are $I_g - 1$ "dirty" energy sources (involving fossil fuel), $i = 1, \ldots, I_g - 1$, and a set of green sources, $i = I_g, \ldots, I$. Each component of $\mathbf{E}_{0,\,t}$, $E_{0,\,i,\,t}$ for $i = 1, \ldots, I$, is then produced using a technology $F_{i,\,t}$, which uses the three inputs capital, labor, and the energy input vector. Some energy sources, such as oil, may be in finite supply. For those i in finite supply, $R_{i,\,t}$ denotes the beginning-of-period stock at t and $E_{i,\,t}$ the total amount extracted (produced) at t. Thus, the exhaustible stock i evolves as

$$R_{i,t+1} = R_{i,t} - E_{i,t} \geq 0. \tag{20}$$

Production for energy source i, whether it is exhaustible or not, is then assumed to obey

$$E_{i,t} = F_{i,t}(K_{i,t}, N_{i,t}, \mathbf{E}_{i,t}, R_{i,t}) \geq 0. \tag{21}$$

The resource stock appears in the production function because the production costs may depend on the remaining resource stock. Notice, also, that S_t does not appear in these production functions: we assume that climate change does not cause damages to energy production. This, again, is a simplification we make mainly to adhere to the TFP damage specification that is common in the literature, but it also simplified formulas and improves tractability somewhat. Given that the energy sector is not so large, this simplification should not be a major problem for our quantitative analysis.

To close the macroeconomic part of the model, we assume that inputs are allocated across sectors without costs, again a simplifying assumption but one that appears reasonable if the period of analysis is as long as, say, 10 years. Thus we have

$$\sum_{i=0}^{I} K_{i,t} = K_t, \quad \sum_{i=0}^{I} N_{i,t} = N_t, \quad \text{and} \quad E_{j,t} = \sum_{i=0}^{I} E_{i,j,t}. \tag{22}$$

We assume that the sequence/process for N_t is exogenous.

Finally, we let the carbon cycle generally be represented by a function $\widetilde{S}_t$ as follows:

$$S_t = \widetilde{S}_t\left(E^f_{i,-T}, E^f_{-T+1}, \ldots, E^f_t,\right). \tag{23}$$

Here, T periods back represents the end of the preindustrial era and $E^f_s \equiv \sum_{i=1}^{I_g - 1} E_{i,s}$ is fossil emission at s and we recall that $E_{i,\,s}$ is measured in carbon emission units for all i. When we specialize the model, we will adopt a very simple structure for $\widetilde{S}_t$ that is in line with the discussion in the section earlier on the carbon cycle.

We are now ready to state an expression for the SCC. Using somewhat abstract (but obvious) notation, and denoting the social cost of carbon at time t, in consumption units at this point in time, by SCC_t, we have

$$\text{SCC}_t = \mathbb{E}_t \sum_{j=0}^{\infty} \beta^j \frac{U'(C_{t+j})}{U'(C_t)} \frac{\partial F_{0,t+j}}{\partial S_{t+j}} \frac{\partial S_{t+j}}{\partial E^f_t}. \tag{24}$$

Before we discuss this equation, let us emphasize—as we pointed out in the context of the static model—that this expression amounts to keeping decisions fixed as emissions are increased incrementally. Ie, this concept of the social cost of carbon does not correspond to a policy experiment (where presumably induced changes in decisions would add indirect damage effects, positive or negative). Golosov et al. (2014) derive this equation as part of an optimal allocation but then the interpretation really is that the right-hand side equals the OSCC$_t$.

Eq. (24) is easily interpreted. First, $\frac{\partial S_{t+j}}{\partial E_t^f}$ captures the carbon cycle dynamics: it tells us how much the atmospheric carbon content j periods ahead is increased by a unit emission at t. That amount of increase in S_{t+j} then changes final output in period $t+1$ by $\frac{\partial F_{0,t+j}}{\partial S_{t+j}}$ per unit. The total effect (the multiplication of these two factors), which is presumably negative, is the marginal damage in that period in terms of the final output good arising from a unit of emission at t. To translate this amount into utils at $t+j$ one multiplies by $U'(C_{t+j})$, and to bring the utils at $t+j$ back to time-t utils one multiplies by β^j: utility discounting. The division by $U'(C_t)$ then translates the amount back into consumption units at t. Finally, since one needs to take into account the effect of emissions at all points in time $t, t+1, \ldots$, one needs the infinite sum.

Conceptually, thus, Eq. (24) really is straightforward. However, in its general form it is perhaps not so enlightening. A key result in Golosov et al. (2014) is that with some assumptions that the authors argue are weak, one can simplify the formula considerably and even arrive at a closed-form expression in terms of primitive parameters. We present the assumptions one by one.

Assumption 1. $U(C) = \log C$.

Logarithmic utility, both used and relaxed in our static model, is very often used in macroeconomic models and seems appropriate as a benchmark. It embodies an assumption about the intertemporal elasticity of consumption but obviously also about risk aversion.

Assumption 2.

$$F_{0,t}(K_{0,t}, N_{0,t}, \mathbf{E}_{0,t}, S_t) = \exp(-\gamma_t S_t)\widetilde{F}_{0,t}(K_{0,t}, N_{0,t}, \mathbf{E}_{0,t}),$$

where we have normalized so that S is the atmospheric CO_2 concentration in excess of that prevailing in preindustrial times, as in the earlier section, and where γ can be time- and state-dependent.

This assumption was discussed in detail in Section 3.3: we argue that it allows a good reduced-form approximation to the most commonly used assumptions on the S-to-temperature and the temperature-to-damage formulations in this literature.

Assumption 3.

$$S_t = \sum_{s=0}^{t+T} (1 - d_s) E^f_{t-s} \tag{25}$$

where $d_s \in [0, 1]$ for all s.

A linear carbon cycle was also discussed Section 3.2.4 on carbon circulation above and argued to be a good approximation. The linear structure was also simplified further there, and we will use that simplification below.

Assumption 4.
C_t/Y_t does not depend on time.

This assumption, which is tantamount to that used in the textbook Solow model, is not an assumption on primitives as we usually define them. However, it is an assumption that can be shown to hold exactly for some assumptions on primitives—as those that will be entertained below—or that holds approximately in a range of extensions; see Barrage (2014). Major changes in saving behavior away from this assumption are needed to drastically alter the quantitative conclusions coming out of our SCC formula.

Now given these four assumptions only a minor amount of algebra suffices to arrive at a formula for the SCC, as well as for the optimal tax on carbon. It is

$$\text{SCC}_t = Y_t \left[\mathbb{E}_t \sum_{j=0}^{\infty} \beta^j \gamma_{t+j} (1 - d_j) \right]. \tag{26}$$

As can be seen, this formula is a straightforward extension of that arrived at for the static economy. As in the static economy, the formula for the tax as a fraction of output is a primitive: there, simply γ; here, a present value of sorts of future γs. Note, of course, here as well as for the static model, that if one needs to assign a specific value to the optimal tax, one would strictly speaking need to evaluate output at its optimal level, and the optimal level of output is not expressed in closed form here (and may be cumbersome to compute). However, given our quantitative analysis later, we note that the optimal tax rate does not alter current output so much. Hence, a good approximation to the optimal tax rate is that given by the expression in brackets in Eq. (26) times current output.[cr]

In the static economy, we assumed a Cobb–Douglas form for output, as we will in the next section as well for our positive analysis. However, Cobb–Douglas production

[cr] In the dynamic model, this approximation would overstate the exact value of the tax since optimal output in the short run will be lower than laissez-faire output. In the static model with TFP damages, the reverse inequality will hold.

is apparently not necessary for the result earlier. What is true is that Cobb–Douglas production, along with logarithmic utility and 100% depreciation for capital, are very helpful assumptions for arriving at a constant C/Y ratio (Assumption 4), but we also know that an approximately constant C/Y ratio emerges out of a much broader set of economies.

We note that, aside from the damage parameter γ, utility discounting and carbon depreciation now matter very explicitly as well. This is quite intuitive: it matters how long a unit of emitted carbon stays in the atmosphere and it also matters how much we care about the future. As for how γ appears, note that the formula is an expectation over future values—as in the static model, a certainty equivalence of sorts applies—but that one could also imagine γ as evolving over time, or incorporating different amounts of uncertainty at different points in time.[cs] Of course, suppose more information is revealed about γ as time evolves, the optimal tax will evolve accordingly (as, eg, in a specification where γ is assumed to follow a unit-root process).

A final expression of our SCC is obtained by (i) assuming that $\mathbb{E}_t\left[\gamma_{t+j}\right]=\overline{\gamma}_t$ for all j (as for example for a unit root process) and (ii) letting the $1-d_j$s be defined by Eq. (13) (which we argued gives a good account of the depreciation patterns). Then we obtain

$$\mathrm{SCC}_t/Y_t=\overline{\gamma}_t\left(\frac{\varphi_L}{1-\beta}+\frac{(1-\varphi_L)\varphi_0}{1-(1-\varphi)\beta}\right). \tag{27}$$

Here, the expression inside the parenthesis on the right-hand side can be thought of as the *discount-weighted duration of emissions*, an object that is stationary by assumption here.

A remarkable feature of the formula for the SCC as a fraction of output as derived here is that it depends on very few parameters. In particular, no production parameters appear, nor do assumptions about technology or the sources of energy. In contrast, we will see in the positive analysis below that such assumptions matter greatly for the paths of output, the climate, energy use, and the total costs of suboptimal climate policy. These are obviously important as well, so we need to proceed to this analysis. However, for computing what optimal policy is, straightforward application of the formula above works very well, and in some sense is all that is needed to optimally deal with climate change. To compute the optimal quantity restrictions is much more demanding, because then precisely all these additional assumptions are made, and to predict the future of technology (especially that regarding energy supply) is extremely difficult, to say the least. Section 5.2.3 calibrates the key parameters behind the formula above and Section 5.2.4 then displays the numerical results for the social cost of carbon.

[cs] Learning (about γ or the natural-science parameters) could also be introduced formally, as in the planning problem studied by Kelly and Kolstad (1999).

5.2 A Positive Dynamic Model

The positive dynamic model will be a straightforward extension of the static model in Section 4 in combination with the basic model from Section 2.3.2 (without endogenous technical change).

Thus we assume a production function that is Cobb–Douglas in capital, labor, and an energy input, along with TFP damages from climate:

$$Y_t = e^{-\gamma_t S_t} A_t K_t^{\alpha} N_{0t}^{1-\alpha-\nu} E_t^{\nu}. \tag{28}$$

Here, we maintain the possibility that γ changes over time/is random.

There are three energy-producing sectors, as in one of the extensions of the static model. Sector 1 thus produces "oil," which is in finite supply and is extracted at zero cost. The accounting equation $E_{ot} = R_t - R_{t+1}$ thus holds for oil stocks at all times. The second and third sectors are the "coal" and the "green" sectors, respectively. They deliver energy using

$$E_{i,t} = \chi_{it} N_{it} \text{ for } i = c, g. \tag{29}$$

Here, $N_t = N_{0t} + N_{ct} + N_{gt}$. We will focus on parameters such that coal, though in finite supply, will not be used up; hence, its Hotelling premium will be zero and there will be no need to keep track of the evolution of the coal stock.[ct] This specification captures the key stylized features of the different energy sectors while maintaining tractability. In practice, oil (as well as natural gas) can be transformed into useable energy quite easily but these resources are in very limited supply compared to coal. Coal is also more expensive to produce, as is green energy.

Here, energy used in production of the final good, E_t, then obeys

$$E_t = \left(\kappa_o E_{ot}^{\rho} + \kappa_c E_{ct}^{\rho} + \kappa_g E_{gt}^{\rho}\right)^{1/\rho} \tag{30}$$

with $\sum_{i=o,c,g} \kappa_i = 1$. As before, $\rho < 1$ regulates the elasticity of substitution between different energy sources; the κs are share parameters and also influence the efficiency with with the different energy sources are used in production. In addition, coal is "dirtier" than oil in that it gives rise to higher carbon emissions per energy unit produced. With E_{ot} and E_{ct} in the same units (of carbon emitted), the calibration therefore demands $\kappa_o > \kappa_c$.

The variables A_t, χ_{it}, and N_t are assumed to be exogenous and deterministic. Population growth is possible within our analytically tractable framework but we abstract from considering it explicitly in our quantitative exercises below, since A and N play the same

[ct] This will, under some specifications, require that a *back-stop technology* emerge at a point in the future, ie, a technology that simply replaces coal perfectly at lower cost.

role.[cu] Our final assumption, which is key for tractability, is that capital depreciates fully between periods ($\delta = 1$). This is an inappropriate assumption in business-cycle analysis but much less so when a model focusing on long-run issues; a model period will be calibrated to be 10 years.

5.2.1 Solving the Planner's Problem

For brevity, we do not state the planner's problem; it is implicit from the description earlier. The first-order conditions for C_t and K_t yield

$$\frac{1}{C_t} = \beta \mathbb{E}_t \frac{\alpha}{C_{t+1}} \frac{Y_{t+1}}{K_{t+1}}.$$

Together with the resource constraint

$$C_t + K_{t+1} = Y_t$$

we then obtain an analytical solution for saving as $K_{t+1} = \alpha\beta Y_t$ for all t. It follows that C_t/Y_t is equal to $1-\alpha\beta$ at all times, and we have therefore demonstrated that Assumption 4 is verified for this economy. A byproduct of our assumptions here, then, are that the formula for the optimal carbon tax, Eq. (26), holds exactly.

What is the planner's choice for the energy inputs, and what is the resulting effect on atmospheric carbon concentration and, hence, the climate? First, we assume that $\rho < 1$, and from this Inada property we then conclude that the energy choices will be interior at all times. Looking at the first-order conditions for E_t and E_{ot}, we obtain

$$\frac{\nu\kappa_o}{E_{ot}^{1-\rho} E_t^{\rho}} - \frac{\mathrm{SSC}_t}{Y_t} = \beta \mathbb{E}_t \left(\frac{\nu\kappa_o}{E_{o,t+1}^{1-\rho} E_{t+1}^{\rho}} - \frac{\mathrm{SSC}_{t+1}}{Y_{t+1}} \right), \tag{31}$$

where SSC_t/Y_t is, again, defined Eq. (26). This equation expresses Hotelling's formula in the case where there is a cost of using carbon: the damage externality (thus, playing a similar role to an extraction cost).

Looking at the other two energy source, by choosing $N_{i,\ t}$ optimally we obtain

$$\chi_{ct} \left(\frac{\nu\kappa_c}{E_{ct}^{1-\rho} E_t^{\rho}} - \frac{\mathrm{SCC}_t}{Y_t} \right) = \frac{1-\alpha-\nu}{N_t - \dfrac{E_{ct}}{\chi_{ct}} - \dfrac{E_{gt}}{\chi_{gt}}} \tag{32}$$

and

[cu] We formulate the utility function in terms of total consumption, and we do not adjust discounting for population growth. One might want to consider an alternative here, but we suspect that nothing substantial will change with this alternative.

$$\chi_{gt}\frac{\nu\kappa_g}{E_{gt}^{1-\rho}E_t^{\rho}}=\frac{1-\alpha-\nu}{N_t-\dfrac{E_{ct}}{\chi_{ct}}-\dfrac{E_{gt}}{\chi_{gt}}}. \tag{33}$$

From the perspective of solving the model conveniently, it is important to note now that SSC_t/Y_t is available in closed form as a function of primitives: the remaining system of equations to be solved is a vector difference equation but only in the energy choices. Ie, the model can be solved for energy inputs first, by solving this difference equation, and then the rest of the variables (output, consumption, etc.) are available in the simple closed forms given above.

To solve the vector difference equation—to the extent there is no uncertainty—is also simple, though in general a small amount of numerical work is needed.[cv] A robust numerical method goes as follows. With any given value for E_{ot}, the Eqs. (32) and (33) can be used to solve for E_{ct} and E_{gt}, and thus E_t. The solution is nonlinear but well defined. For any given initial stock of oil R_0, one can now use a simple shooting algorithm. The "shooting" part is accomplished by (i) guessing on a number for E_{o0}; (ii) deriving the all the other energy inputs at time 0; (iii) using the Hotelling Eq. (31), which is stated in terms of E_{o1} and E_1, to obtain E_{o1} as a function of E_1; (iv) combining this relation between E_{o1} and E_1 with Eqs. (32) and (33) evaluated for period 1 to obtain all the energy choices in period 1; and (v) going back to step (iii) to repeat for the next period. The so-obtained path for all energy inputs in particular delivers a path for oil extraction. To check whether the fired shot hits the target involves simply checking that the cumulated oil use exactly exhausts the initial stock asymptotically. If too much or too little is used up, adjust E_{o0} appropriately and run through the algorithm again.

If there is uncertainty about γ that is nontrivial and does not go away over time, one needs to use recursive methods, given the nonlinearity of the vector difference equation. It is still straightforward to solve, however, with standard versions of such methods.

5.2.2 Competitive Equilibrium

It is straightforward to define a dynamic (stochastic) general equilibrium for this economy as for the static model. All markets feature perfect competition. Firms in the final-goods sector make zero profits, as do firms in the coal and green-energy sectors. In the oil sector, there is a Hotelling rent, and hence profits. These profits are delivered to the representative consumer, who otherwise receive labor and capital income and, to the extent there is a tax on fossil fuel, lump-sum transfers so that the government budget balances. When taxes are used, we assume that they are levied on the energy-producing firms (oil and coal). The consumer's Euler equation and the return to capital satisfying the first-order condition for capital from the firm's problem deliver the constant saving rate $\alpha\beta$. The energy supplies (or, equivalently, the labor allocation) is then given by a set of

[cv] Solving the model with only coal or only green energy is possible in closed form.

conditions similar to those from the planning problem. Assuming that the carbon tax in period t is set as an exogenous fraction of output in period t, we then obtain from the energy producers' problems

$$\frac{\nu\kappa_o}{E_{ot}^{1-\rho}E_t^{\rho}}-\tau_t=\beta\mathbb{E}_t\left(\frac{\nu\kappa_o}{E_{o,t+1}^{1-\rho}E_{t+1}^{\rho}}-\tau_{t+1}\right), \tag{34}$$

$$\chi_{ct}\left(\frac{\nu\kappa_c}{E_{ct}^{1-\rho}E_t^{\rho}}-\tau\right)=\frac{1-\alpha-\nu}{N_t-\dfrac{E_{ct}}{\chi_{ct}}-\dfrac{E_{gt}}{\chi_{gt}}}, \tag{35}$$

and

$$\chi_{gt}\frac{\nu\kappa_g}{E_{gt}^{1-\rho}E_t^{\rho}}=\frac{1-\alpha-\nu}{N_t-\dfrac{E_{ct}}{\chi_{ct}}-\dfrac{E_{gt}}{\chi_{gt}}}. \tag{36}$$

Since this vector difference equation is very similar to the planner's vector difference equation, it can be solved straightforwardly with the same kind of algorithm. The laissez-faire allocation is particularly simple to solve.

5.2.3 Calibration and Results

In the spirit of quantitative macroeconomic modeling, the calibration of our model parameters is critical. Also in this part, we follow Golosov et al. (2014) in selecting parameter values. The calibration is important to review in some detail here, as calibration of this class of models is not standard in the macroeconomic literature. Given our assumptions, two parameters are easy to select: we assume that α and ν are 0.3 and 0.04, respectively; the value for the capital share is standard in the macroeconomic literature and the energy share is taken from the calibration in Hassler et al. (2015).

5.2.3.1 Discounting

As will be clear from our results, the discount factor matters greatly for what optimal tax to recommend. We do not take stand here but rather report our results for a range of values for β. Nordhaus's calibrations start from interest-rate data; interest rates should mirror the interest rate, if markets work, so to set $1/\beta-1=0.015$ is then reasonable. Stern, in his review on climate change, takes a very different view and uses what is essentially a zero rate: $1/\beta-1=0.001$. A view that sharply differs from the market view can be motivated on purely normative grounds, though then there may be auxiliary implications of this normative view: perhaps capital accumulation should then be encouraged more broadly, eg, using broad investment/saving subsidies. Sterner and Persson (2008), however, argue informally that it is possible to discount consumption and climate services—to the extent the latter enter separately in utility—at different rates.

A third and, we think, interesting argument for using a lower discount rate is that it is reasonable to assume that discounting is time-inconsistent: people care about themselves and the next generation or so with rates in line with observed market rates but thereafter, they use virtually no discounting. The idea would be that I treat the consumption of my grand-grand-grand children and that of my grand-grand-grand-grand children identically in my own utility weighting. If this is a correct description of people's preferences, and if people have commitment tools for dealing with time inconsistency, we would see it in market rates, but there are not enough market observations for such long-horizon assets to guide a choice of discount rates. Hence, it is not easy to reject a rate such as 0.1% (but, by the same token, there is no market evidence in favor of it either). If people have no commitment tools for dealing with time inconsistency, observed market rates today would be a mix of the short- and long-run rates (and very heavily weighted toward present-bias), thus making it hard to use market observations to back out the longer-run rates. These arguments can be formalized: it turns out that the present model—if solved with a simplified energy sector (say, coal only)—can be solved analytically also with time-inconsistent preferences (see Karp, 2005, Gerlagh and Liski, 2012, and Iverson, 2014).

5.2.3.2 The carbon cycle

We calibrate the carbon cycle, as indicated, with a linear system implying that the carbon depreciation rates are given by Eq. (13). Thus with the depreciation rate at horizon j given by $1-d_j=\varphi_L+(1-\varphi_L)\varphi_0(1-\varphi)^j$, we have to select three parameter: φ_L, φ_0, and φ. Recall the interpretation that φ_L is the share of of carbon emitted into the atmosphere that stays there forever, $1-\varphi_0$ the share that disappears into the biosphere and the surface oceans within a decade, and the remaining part, $(1-\varphi_L)\varphi_0$, decays (slowly) at a geometric rate φ. We set φ_L to 0.2, given the estimate in the 2007 IPCC report that about 20% any emission pulse remains in the atmosphere for several thousand years.[cw] Archer (2005), furthermore, argues that the excess carbon that does depreciate has a mean lifetime of about 300 years. Thus, we set $(1-\varphi)^{30}=0.5$, implying $\varphi=0.0228$. Third, the 2007 IPCC report asserts that about 50% of any CO_2 emission pulse into the atmosphere has left the atmosphere after about 30 years. This means that $d_2=0.5$ so that $1-\frac{1}{2}=0.2+0.8\varphi_0(1-0.0228)^2$, and hence $\varphi_0=0.393$. Finally, to set the initial condition for carbon concentration we showed above that the assumed depreciation structure is consistent with the existence of two "virtual carbon stocks" S_1 (the part that remains in the atmosphere forever) and S_2 (the part that depreciates at rate φ), with $S_{1,t}=S_{1,t-1}+\varphi_L E_t^f$ and $S_{2,t}=\varphi S_{2,t-1}+\varphi_0(1-\varphi_L)E_t^f$, and $S_t=S_{1,\ t}+S_{2,\ t}$. We choose starting values so that time-0 (ie, year-2000) carbon equals 802, with the division

[cw] Archer (2005) argues for a slightly higher number: 0.25.

$S_1 = 684$ and $S_2 = 118$; the value of S_1 comes from taking the preindustrial stock of 581 and adding 20% of accumulation emissions.[cx]

5.2.3.3 Damages

Turning to the calibration of damages, recall that we argued that for a reasonable range of carbon concentration levels the exponential TFP expression $e^{-\gamma S}$ is a good approximation to the composed S-to-temperature and temperature-to-TFP mappings in the literature. It remains choose γ, deterministic or stochastic. Here, in our illustrations, we will focus on a deterministic γ and only comment on uncertainty later. Following the discussion in the damage section earlier and Golosov et al. (2014), with S measured in GtC (billions of tons of carbon), an exponential function with parameter $\gamma_t = 5.3 \times 10^{-5}$ fits the data well.

5.2.3.4 Energy

Turning, finally, to the energy sector, we first need to select a value for ρ, which guides the elasticity of substitution between the energy sources. Stern (2012) is a metastudy of 47 studies of interfuel substitution and reports the unweighted mean of the oil–coal, oil–electricity, and coal–electricity elasticities to be 0.95. Stern's account of estimates of "long-run dynamic elasticities" is 0.72. In terms of our ρ, the implied numbers are -0.058 and -0.390, respectively, and the former will constitute our benchmark.

As for the different energy sources, for oil we need to pin down the size of the oil reserve. According to BP (2010), the proven global reserves of oil are 181.7 gigaton. However, these figures only refer to reserves that are economically profitable to extract at current conditions. Rogner (1997), on the other hand, estimates the global reserves of potentially extractable oil, natural gas, and coal taken together to be over 5000 Gt, measured as oil equivalents.[cy] Of this amount, Rogner reports around 16% to be oil, ie, 800 Gt. We use a benchmark that is in between these two numbers: 300 Gt. To express fossil fuel in units of carbon content, we set the carbon content in crude oil to be 846 KgC/t oil. For coal, we set it to the carbon content of anthracite, which is 716 KgC/t coal.[cz] As for coal, as implied by Rogner's (1997) estimates, the coal supply is enough for several hundreds of years of consumption at current levels, and hence we have assumed the scarcity rent to be zero.

[cx] These number include the preindustrial stock and, hence, do not strictly follow the notation above, where S_t denotes the concentration in excess of preindustrial levels.

[cy] The difference in energy content between natural gas, oil, and various grades of coal is accounted for by expressing quantities in oil equivalents.

[cz] IPCC (2006, table 1.2–1.3).

To calibrate κ_o and κ_c we use relative prices of oil to coal and oil to renewable energy, given by

$$\frac{\kappa_o}{\kappa_c}\left(\frac{E_{ot}}{E_{ct}}\right)^{\rho-1} \quad \text{and} \quad \frac{\kappa_o}{1-\kappa_o-\kappa_c}\left(\frac{E_{ot}}{E_{gt}}\right)^{\rho-1},$$

respectively. The average price of Brent oil was \$70 per barrel over the period 2005–09 (BP, 2010); with a barrel measuring 7.33 metric tons and a carbon content of 84.6%, the oil price per ton of carbon is then \$606.5. As for coal, its average price over the same period is \$74 per ton. With coal's carbon content of 71.6%, this implies a price of \$103.35 per ton of carbon.[da] The implied relative price of oil and coal in units of carbon content is 5.87.

As for renewables/green energy, there is substantial heterogeneity between different such sources. With unity as a reasonable value of the current relative price between green energy and oil, we employ data on global energy consumption to finally pin down the κs. Primary global energy use in 2008 was 3.315 Gtoe (gigaton of oil equivalents) of coal, 4.059 of oil, 2.596 of gas, and $0.712+0.276+1.314=2.302$ of nuclear, hydro, and biomass/waste/other renewables. Based on the IPCC tables quoted earlier, the ratio of energy per ton between oil and anthracite is then $\frac{42.3}{26.7}=1.58$, implying that 1 t of oil equivalents is 1.58 t of coal.[db] With these numbers and the value for ρ of -0.058, we can finally use the equations above to back out $\kappa_o=0.5008$ and $\kappa_c=0.08916$.

The parameters χ_{ct}, which determines the cost of extracting coal over time, are set based on an average extraction cost of \$43 per ton of coal (see IEA, 2010, page 212). Thus, a ton of carbon in the form of coal costs \$43/0.716. The model specifies the cost of extracting a ton of carbon as $\frac{w_t}{\chi_{ct}}$, where w_t is the wage. The current shares of world labor used in coal extraction and green energy production is very close to zero, so with total labor supply normalized to unity we can approximate the wage to be $w_t=(1-\alpha-\nu)Y_t$. With world GDP at \$700 trillion per decade and a gigaton of carbon (our model unit) costing $w_t/\chi_{ct}=(1-\alpha-\nu)Y_t/\chi_{ct}$ to produce delivers $43\cdot 10^9/0.716=0.66\cdot 700\cdot 10^{12}/\chi_{c0}$ and hence $\chi_{c0}=7693$. This means, in other words, that a share $\frac{1}{7693}$ of the world's labor supply during a decade is needed to extract one gigaton of carbon in the form of coal. The calibration of χ_{g0} comes from using the fact that χ_{g0}/χ_{c0} equals the relative price between coal and green energy, thus delivering $\chi_{g0}=7693/5.87=1311$ since the prices

[da] BP (2010) gives these estimates for US Central Appalachian coal.

[db] The amounts of oil and coal in carbon units is obtained by multiplying by the carbon contents 84.6 and 71.6%, respectively.

of oil and green are assumed to be equal and the relative price of oil in terms of coal is 5.87. Lastly, we posit growth in both χ_{ct} and χ_{gt} at 2% per year.[dc]

5.2.4 Results

We begin by reporting what our model implies for the optimal tax on carbon. Given our calibration, and expressed as a function of the discount rate, we plot the tax per ton of emitted carbon in Fig. 14, given annual global output of 70 trillion dollars.[dd]

Fig. 14 displays our benchmark as a solid line along with two additional lines representing two alternative values for γ, the higher one of which represents a "catastrophe scenario" with losses amounting to about 30% of GDP and the lower one representing an opposite extreme case with very low losses. The numbers in the figure can be compared to the well-known proposals in Nordhaus and Boyer (2000) and in the Stern review (Stern, 2007), who suggest a tax of \$30 and \$250 dollar per ton of carbon, respectively. As already pointed out, these proposals are based on very different discount rates, with Nordhaus using 1.5% per year and Stern 0.1%. For these two discount-rate values, the optimal taxes using our analysis are \$56.9 per ton and \$496 per ton, respectively, thus showing larger damages than in these studies. There are a number of differences in assumptions between the model here and those maintained in, say, Nordhaus's work; perhaps the most important one quantitatively is that we calibrate the duration of carbon in the atmosphere to be significantly higher.

The figure reveals that, to the extent the catastrophe scenario—which comes from a hypothesis Nordhaus entertained in a survey study—might actually materialize, there will

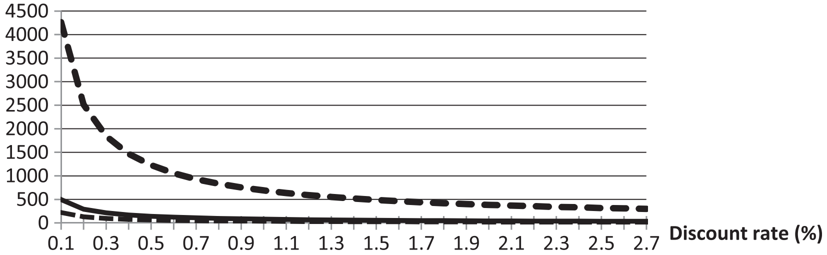

Fig. 14 Optimal tax rates in current dollars per ton of emitted fossil carbon vs yearly subjective discount rate.

[dc] Under our calibration, coal use does not go to zero, which contradicts it being a finite resource. Strictly speaking, one should instead, then, solve the model under this assumption and the implication that coal would have scarcity value. But we consider it quite likely that a competitive close and renewable substitute for coal is invented over the next couple of hundred years, in which case our solution would work well as an approximation.

[dd] The graphs are taken from Golosov et al. (2014).

be dramatic consequences on the level of the optimal tax: we see that the tax is roughly multiplied by a factor 20.

5.2.5 Positive Implications

Fossil fuel use in the optimal allocation and in the *laissez-faire* allocation are shown in Fig. 15. We base our results in this section on the discount rate 1.5%.

Looking at the comparison between the optimum and laissez faire, we see a markedly lower use of fossil fuel in the optimum.[de] In the laissez-faire scenario, there would be a continuous increase in fossil fuel use, but in the optimum the consumption of fossil fuel is virtually flat.

It is important to realize that the difference between the fossil-fuel use in the optimum and in laissez faire is almost entirely coming from a lower coal use in the former. In Figs. 16 and 17, we look separately at coal use and oil use in the optimal vs the laissez-faire allocations. Although the tax on carbon is identical for oil and coal in the optimal allocation, its effects are very different: coal use is simply curbed significantly—the whole path is shifted down radically—but oil use is simply moved forward slightly in time. With optimal taxes,

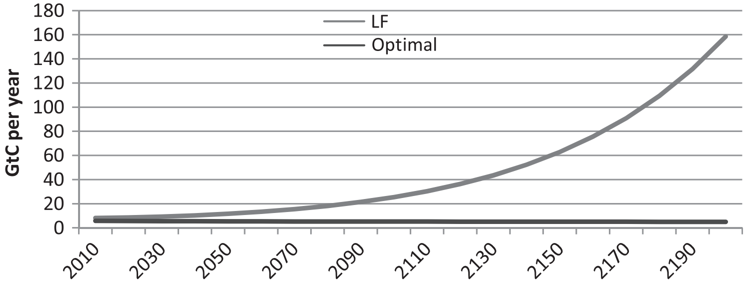

Fig. 15 Fossil fuel use: optimum vs laissez faire.

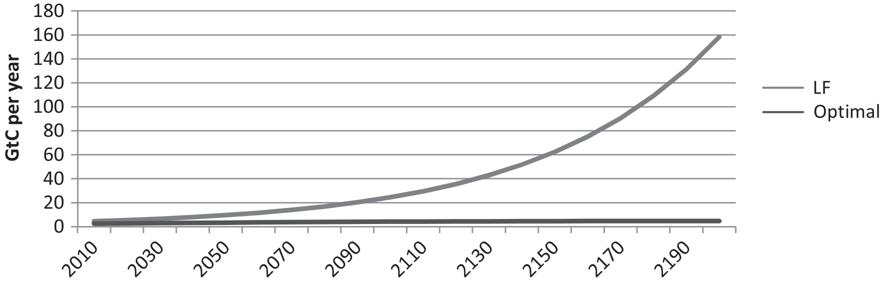

Fig. 16 Coal use: optimum vs laissez faire.

[de] The model predicts coal use in laissez faire of 4.5 GtC during the coming decade; it is currently roughly 3.8 GtC. It predicts oil use of 3.6 GtC, which is also close to the actual value for 2008 or 3.4 GtC.

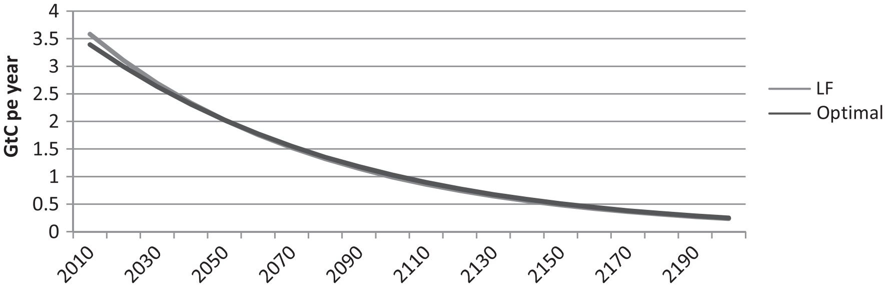

Fig. 17 Oil use: optimum vs laissez faire.

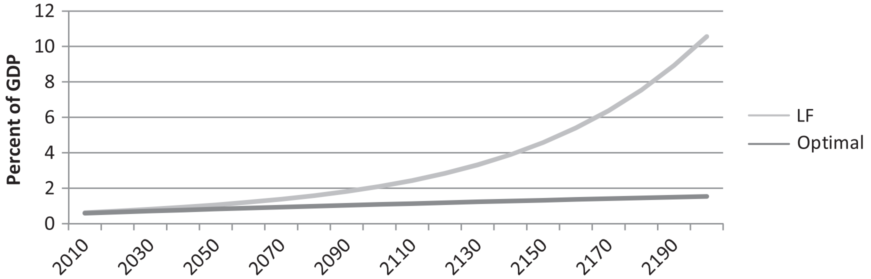

Fig. 18 Total damages as a percent of global GDP: optimum vs laissez faire.

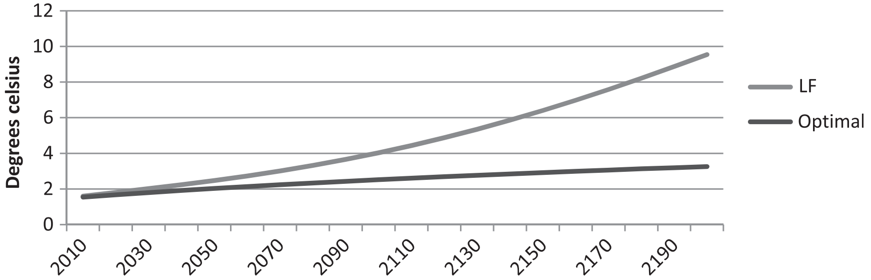

Fig. 19 Increases in global temperature: optimum vs laissez faire.

coal use would fall right now to almost half; a hundred years from now, laissez-faire coal use would be 7 × higher than optimally. Green energy use is very similar across the optimum and laissez-faire allocations.

Total damages are shown in Fig. 18. We note large, though not gigantic, gains from moving from laissez faire to the optimum allocation. The gains grow over time, with damages at a couple of percent of GDP in the laissez-faire allocation, thus about double its optimal value at that time. In 2200, the difference is a factor of six.

We can also back out the path for global temperature in the two scenarios, using the known mapping from S to temperature. Fig. 19 illustrates that laissez faire is associated

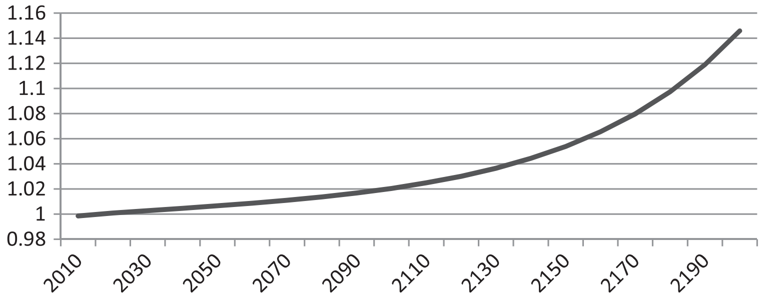

Fig. 20 Net output: optimum vs laissez faire.

with a temperature rise of 4.4°C a hundred years from now; in the optimum, heating is only 2.6 degrees. Toward the end of the simulation period, however, due to massive coal use, laissez faire predicts increased heating by almost 10°C; the optimum dictates about 3 degrees.

Finally, Fig. 20 displays the evolution of the (net-of-damage) production of final-good output (GDP). The intertemporal trade-off is clear here, but not as striking as one might have guessed: the optimal allocation involves rather limited short-run losses in GDP, with optimal output exceeding that of laissez faire as early as 2020. 100 years later, GDP net of damages is 2.5% higher in the optimum and in year 2200, it is higher by almost 15%.

5.2.6 Discussion

How robust are the quantitative results in Section 5.2.4? First, the tax formula appears remarkably robust. The point that only three kinds of parameters show up in the formula is a robustness measure in itself; eg, no details of the fossil-fuel stocks, production technologies, or population matter. Strictly speaking, these features begin mattering once one or more of the main assumptions behind the formula are not met, but they will only matter indirectly, eg, insofar as they influence the consumption-output path, and if their impact here is minor, the formula will be robust. In a technical appendix to the Golosov et al. (2014) paper, Barrage (2014) considers a version of the model where not all of the assumptions are met. In particular, this version of the model has more standard transitional dynamics (with a calibration in line with the macroeconomic literature). For example, the assumption that the consumption-output ratio is constant will not hold exactly along a transition path, but the departures almost do not change the results at all. Also, at least US data show very minor fluctuations in this ratio so to the extent a model delivers more drastic movements in the consumption-output ratio it will have trouble matching the data. Higher curvature in utility also delivers very minor changes in the tax rate, with the correction that discounting now involves not just β but also the consumption growth rate raised to $1-\sigma$, where $\sigma=1$ gives logarithmic curvature and $\sigma>1$ higher curvature.

Second, when it comes to the positive analysis—eg, the implications for temperature and damages under different policy scenarios—the message is quite different: many of the assumptions can matter greatly for the quantitative results. Perhaps the best example of nonrobustness is the example considered in Golosov et al. (2014): the elasticity of substitution between energy sources was raised by setting $\rho=0.5$, ie, assuming an elasticity of 2 instead of one slightly below one. If the different energy sources are highly substitutable, coal can easily be used instead of oil, making the laissez-faire allocation deliver very high coal use. On the other hand, taxes are now more powerful in affecting the use of different energy sources. This means, in particular, that the difference in outcomes between an optimal tax and laissez-faire is very large compared to the benchmark, where the different energy sources are less substitutable. Hence, the substitutability across energy sources is an example of an area where more work is needed. Relatedly, we expect that the modeling of technical change in this area—energy saving, as in Section 2.3.3 or making new energy resources available—will prove very important.

A number of straightforward extensions to the setting are also possible and, in part, they have been pursued by other researchers.[df] One is the inclusion of damages that involve growth effects; Dell et al. argue that such effects may be present.[dg] It is easy to introduce such damages to the present setting by letting the TFP term read $e^{-\gamma_l S+\gamma_g St}$, where γ_l regulates level effect of carbon concentration S, and γ_g the damages to the growth rate of output; the baseline model admits closed-form solution. As already pointed out, the baseline model can also accommodate time-inconsistent preferences rather easily.[dh]

Finally, the discussion of dynamic integrated assessment models here is based entirely on the simple baseline model in Golosov et al. (2014) not because it is the only model of this sort, or even the most satisfactory one in some overall sense; rather, this model has been chosen, first, because it is the model with the closest links to standard macroeconomic settings (with forward-looking consumers, dynamic competitive equilibrium with taxes, and so on). Second, the baseline model in Golosov et al. admits highly tractable analysis (with closed-form solutions) and hence is very well suited for illustrations; moreover, for the optimal carbon tax it gives a very robust formula that is also quantitatively adequate. The model is also useful for positive analysis but here it is important to point out that many other approaches can offer more realistic settings and, at least from some

[df] For example, Rezai and van der Ploeg (2014).

[dg] See Moyer et al. (2013).

[dh] Such cases have been discussed by Karp (2005) and, in settings closely related to the model here, Gerlagh and Liski (2012) and Iverson (2014) show that it is possible to analyze the case without commitment relatively straightforwardly; lack of commitment and Markov-perfect equilibria are otherwise quite difficult to characterize.

perspectives, do a better job at prediction. It would require a long survey to review the literature and such an endeavor is best left for another paper; perhaps the closest relative among ambitious, quantitative settings is the WITCH model, which also builds on forward-looking and, among other things, has a much more ambitiously specified energy sector.[di]

CHAPTER 25

The Staying Power of Staggered Wage and Price Setting Models in Macroeconomics

J.B. Taylor
Stanford University, Stanford, CA, United States

Contents

Abstract

After many years, many critiques, and many variations, the staggered wage and price setting model is still the most common method of incorporating nominal rigidities into empirical macroeconomic models used for policy analysis. The aim of this chapter is to examine and reassess the staggered

Handbook of Macroeconomics, Volume 2B
ISSN 1574-0048, http://dx.doi.org/10.1016/bs.hesmac.2016.04.008

wage and price setting model. The chapter updates and expands on my chapter in the 1999 *Handbook of Macroeconomics* which reviewed key papers that had already spawned a vast literature. It is meant to be both a survey and user-friendly exposition organized around a simple "canonical" model. It provides a guide to the recent explosion of microeconomic empirical research on wage and price setting, examines central controversies, and reassesses from a longer perspective the advantages and disadvantages of the model as it has been applied in practice. An important question for future research is whether staggered price and wage setting will continue to be the model of choice or whether it needs to be replaced by a new paradigm.

1. INTRODUCTION

The staggered wage and price setting model has had remarkable staying power. Originating in the 1970s before the advent of real business cycle models, it has been the theory of choice in generation after generation of monetary business cycle models. In their review of over 60 macroeconomic models in their chapter for this Handbook, Wieland et al. (2016) define three such generations each with representative models that are based on staggered price or wage setting theories.[a]

This chapter examines the role of staggered wage and price setting as a method of incorporating nominal rigidities in empirical macroeconomic models used for policy analysis. It is both an exposition and a survey. It builds on my earlier *Handbook of Macroeconomics* chapter (Taylor, 1999) which reviewed original research papers that had already spawned a vast literature. It focuses on new research since that *Handbook* chapter, and, though it is largely self-contained, a more complete history of thought in this area requires looking at that chapter too. This chapter considers the explosion of microeconomic empirical research on wage and price setting behavior, the main critiques of the model, such as by Chari et al. (2000), and the complementary work on state-dependent pricing by Dotsey et al. (1999) and Golosov and Lucas (2007). Finally, the chapter reassesses from a longer vantage point the advantages and disadvantages of the model as it has been applied in practice, and it considers possible directions for future research.

2. AN UPDATED EMPIRICAL GUIDE TO WAGE AND PRICE SETTING IN MARKET ECONOMIES

I started off my 1999 *Handbook of Macroeconomics* chapter with "an empirical guide to wage and price setting in market economies" noting that "one of the great accomplishments of research on wage and price rigidities in the 1980s and 1990s is the bolstering of case studies and casual impression with the evidence from thousands of observations of price and wage setting collected at the firm, worker, or union level." The same could be said of the new research on microeconomic data during the past two decades except that there is much more of it—a virtual explosion of "Big Data" microeconomic studies, especially in the United States and European countries. These studies have confirmed much of the earlier work, but they have also uncovered new important facts about the timing, frequency, and determinants of price and wage change which are relevant for future research and model building. Accordingly, in this section I give an "*updated* empirical guide to wage and price setting in market economies."

As a starting point, recall that informal observation informed the original theoretical research on staggered wage and price setting models in the 1970s since there was virtually no microeconomic empirical research to guide it.[b] For many firms and organizations, whether in a formal employment contract or not, wages—including fringe benefits—appeared to be adjusted about once per year after a performance review and after consideration of prevailing wages in the market. A large fraction of the wage payment appeared to be a fixed amount, though overtime pay, bonuses, profit sharing, and piece rates were not uncommon, with as many similarities as differences between union and nonunion workers. Indexing of wages was seen to be rare in wage setting arrangements of 1 year or less. And wage adjustments looked to be unsynchronized—occurring at different times for different firms throughout the year—though there were exceptions such as the Shunto (spring wage offensive) in Japan.

Regarding prices, research work by Stigler and Kindahl (1970) had begun to document the extent of price rigidity for a wide variety of products and led people to distinguish informally between "auction markets" where prices changed continuously and "customer markets" where they changed infrequently, a terminology coined by Okun (1981). Though online purchasing has begun to blur this distinction, price changes, like wage changes, appeared to be unsynchronized and firms appeared to take the prevailing price of competing sellers into account.

Fortunately, a huge number of microeconomic studies of wage and price setting over the past few decades have given modelers much more to go on than informal observation. I first consider microeconomic empirical research on wage setting and then on price setting.

[b] I will describe the 1970s modeling research in the next section. Informal observation, of course, guided earlier models of price and wage adjustment, going way back to the time of Hume's (1742) classic essay "On Money" in which he wrote "by degrees the price rises, first of one commodity, then of another."

2.1 Microeconomic Evidence on Wage Setting

To my knowledge, the first empirical study to use actual microeconomic wage data to validate or calibrate the staggered wage setting models of the 1970s was my (1983) study using union wage contracting data in the United States. At the time, the Bureau of Labor Statistics had been calculating detailed data on major collective bargaining agreements for about 10 million workers in the United States and publishing the results in *Current Wage Developments*. The "major" contracts included agreements affecting 1000 or more workers. Although that sector represented only 10% of US employment, it was where the data were, and it was a place to begin.

The data indicated that wage setting was highly nonsynchronized, with agreements spread throughout the year though with relatively more settlements in the second and third quarters. Of these 10 million workers only about 15% had contract adjustments each quarter and only 40% each year. I used these micro data to calibrate a staggered wage setting model with heterogeneous contract lengths and simulated various monetary policies, and in a companion study (Taylor, 1982), I assumed that the remaining workers had shorter contracts. Looking at the union data over a period of time, Cecchetti (1984) found that the average period between wage changes declined with higher inflation, but was still more than 1 year during the high inflation period of the 1970s. There were few international comparisons at that time, though Fregert and Jonung (1986) found that wage setting in Sweden was unsynchronized and that contract length decreased with higher inflation, but it never dropped below 1 year on average.

There was then a lull in research on microeconomic wage setting practices, perhaps due to the increased interest in real business cycles and a corresponding "dark age" of research on wage and price rigidities, as I described in Taylor (2007). In any case, a gap was left between macroeconomic models of wage setting and the microeconomic evidence.

An explosion of research since the early 2000s (just after the completion of the *Handbook of Macroeconomics*, *Volume 1*!) has gone a long way to filling that gap. An important example, which has contributed greatly to our knowledge of micro wage setting, is the research enabled by the data collected from firms in a survey by the Wage Dynamics Network (WDN). The WDN was created after the founding of the European Central Bank; it consists of researchers at the central banks in the Eurosystem. The WDN surveyed wage and price setting practices at 17,000 European firms. The sample was designed to reflect firm employment size and sector distribution in each country. The survey covered both firms with employees in and out of unions. The percentage of employees in unions varies greatly across countries, ranging from over 70% in Scandinavian countries to less than 10% in Central and Eastern European countries, France, Spain, a percentage similar to the United States.

The report by Lamo and Smets (2009) summarizes the research on this survey referring to 81 different WDN papers and publications. They report that about 60% of the 17,000 firms surveyed change wages once a year, while 26% change wages less frequently.

The average duration of wages is about 15 months and is longer than the average duration of prices, which is about 9.5 months according to a parallel price setting survey in European countries.

Lamo and Smets (2009) also report "strong evidence of time dependence in wage-setting" with 55% of firms reporting that their wage changes occur in a particular month.[c] The timing of wage changes is characterized by a mix of staggering and synchronization. Indeed, there is a lot of heterogeneity across countries; the percentage of firms that change wages "more frequently than once a year ranges from 2.6% in Hungary and 4.2% in Italy to 33.9% in Greece, and 42.1% in Lithuania" according to Lamo and Smets.

There is also related time series work for specific European countries. Lünnemann and Wintr (2009), for example, examined monthly micro data from the Luxembourg social security authority. The data are reported by employers about their employees and pertain to the period from January 2001 to December 2006. They report that measurement error biases upwards the frequency of wage change, but adjusting for this measurement error they find a frequency of wage change of 9–14% per month, which is lower than for consumer prices at 17%. They also find a great deal of heterogeneity across forms. There is clear time dependence with many wages set around the month of January.

Le Bihan et al. (2012) examine a time series of French wage data. They use a quarterly panel of 38,000 French establishments with 6.8 million employees. They examine the base wage for 12 employee categories over 1998–2005. They argue that the base wage is a relevant indicator of wages in France because the base wage represents 77.9% of gross earnings. Furthermore, most bonuses (like "13th month" payments or holidays bonuses) constitute a fixed part of the earnings (5.2%) and are linked to the base wage. The frequency of quarterly wage change is around 38%, and in the case of France, there is not much cross-sectoral heterogeneity in wage stickiness.

They estimate a hazard function—the probability of a change in the wage conditional on an unchanged wage spell of a given duration. Their estimates of the hazard function are shown in Fig. 1. The authors state that the hazard function has a "noticeable spike at four quarters but is rather flat otherwise" and note that "such a pattern is consistent with the prevalence of Taylor-like, 1-year contracts."

Le Bihan et al. (2012) also estimate and report the frequency of wage change each quarter and the variation of that frequency over time. Their estimates are shown in Fig. 2 for all wages as well as for wages near the minimum wage. As they argue "there is evidence of a large degree of staggering since the frequency of wage changes is in no quarter lower than 20%." Note that there is some synchronization in the first quarter for all wages and in the third quarter for minimum wages, the later corresponding

[c] Some of the terminology used in this section—such as time dependence, state dependence, Taylor fixed-length contracts, Calvo model—is defined later in the chapter.

to the national minimum wage update in France each summer. They also report that their "micro-econometric evidence … suggests wage adjustment is mainly time dependent in France." And while wage changes are largely staggered across establishments, the authors report that there is a large degree of synchronization of wage changes within establishments.

Avouyi-Dovi et al. (2013) also examine the wage setting process in France. In contrast to Le Bihan et al. (2012), they collect and examine data on wage bargaining agreements, as Taylor (1983) did for the United States, but with much more detail. Their data pertain to both firms and industries. They find a sharp peak in the distribution of wage contract durations at 12 months. They also find that the "hazard rate shows a peak above 40% at twelve months and remains flat below 10% elsewhere." Indeed, their plots of the hazard function look like much like those in Figure 1 in this chapter with even more pronounced peaks. Finally, they find that the "wage change decisions are staggered over the year" with some evidence of seasonality that also shows up in the aggregate data. In many respects the findings Avouyi-Dovi et al. (2013) and those of Le Bihan et al. (2012) are very similar even though they use completely different data sets.

Another time series study is the paper by Sigurdsson and Sigurdardottir (2011) which examines wage setting behavior in Iceland. They use a micro wage dataset with a monthly frequency for the years 1998–2010. They find that average frequency of wage change is 10.8% per month. They find that "wage setting displays strong features of time dependence: half of all wage changes are synchronized in January, but other adjustments are staggered through the year" though later work by Sigurdsson and Sigurdardottir (2016), which focuses more on the global financial crisis, finds more evidence of state-dependent wage setting. The authors also estimate a hazard function and find that it has a large spike at 12 months. These facts indicate that, as the authors put it, "wage setting is consistent with the Taylor (1980) fixed duration contract model, but there exist contracts with both shorter and longer duration than precisely 1 year."

Recent work by Barattieri et al. (2014) has added important time series information about wage setting in the United States. They use high frequency panel data from the Survey of Income and Program Participation which follows people for a period of from 24 to 48 months with interviews every 4 months. The authors focus on hourly wage data (rather than salaries) which leaves them with a panel of 17,148 people from March 1996 to February 2000. The panel consisted of 49.4% women; ages ranged from 16 to 64 years and the average wage is $10.03 per hour. As with individual data reported by Lünnemann and Wintr (2009), the authors found a great deal of measurement error which adds noise to the wage series and effectively reduces the reported time that a wage is fixed. They corrected for this measurement error using structural break tests commonly used in time series analysis to look for big and persistent changes by filtering out smaller and more temporary changes.

They find that the quarterly frequency of wage adjustment, after correcting for measurement error, ranges from 12% to 27%, which is much lower than the 56% without correction for measurement error. They note that this corrected range is comparable to that found in the European studies reviewed earlier when reported on a common quarterly frequency:

Lünnemann and Wintr (2009)	19–36%
Le Bihan et al. (2012)	35%
Sigurdsson and Sigurdardottir (2011)	13–28%

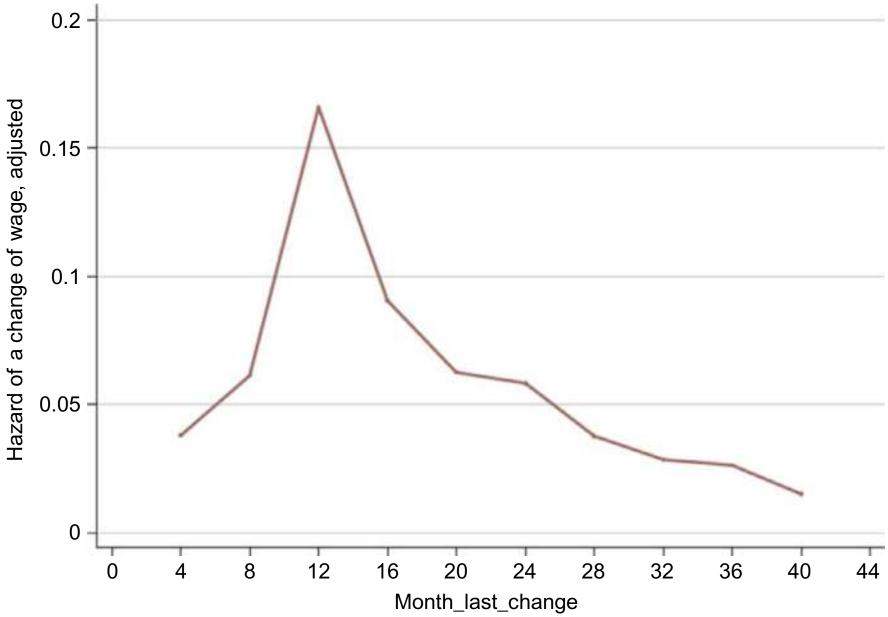

Fig. 3 Estimated hazard function for a within job wage change in the United States. Source: *Barattieri, A., Basu, S., Gottschalk, P., 2014. Some evidence on the importance of sticky wages. Am. Econ. J. Macroecon. 6 (1), 70–101.*

Finally, Barattieri et al. (2014) estimate a hazard function for the United States with their data corrected for measurement error. Their estimates are shown in Fig. 3. There is a sharp peak at 12 months leading the authors to conclude that "Taylor-type fixed-length contracts have stronger empirical support than Calvo-type constant-hazard models." This corresponds with the time series studies on wage setting in France and Iceland reported earlier.

If some structural assumptions about the general form of wage setting are made, it is also possible to extract information about individual wage setting mechanisms indirectly from the autocorrelation functions of aggregate time series data, as I explained in my chapter in the first *Handbook of Macroeconomics* with examples of these indirect methods including Backus (1984), Benabou and Bismut (1987), Levin (1991), and Taylor (1993). In a more recent example, Olivei and Tenreyro (2010) show that the impact of monetary policy shocks depends on the timing of wage changes, suggesting that time-dependent wage setting has important macroeconomic implications. They compare the effect of Japan's Shunto with different wage change timing in the United States and Germany, and they show that the impact of an aggregate monetary shock is larger when it occurs at a time when only a few wages are being adjusted. Estimates of time-varying distributions are also reported in Taylor (1993a) to accommodate the Shunto mechanism in Japan.

2.2 Microeconomic Evidence on Price Setting

Until the recent explosion of microeconomic research on price setting, the evidence on the prices of particular products showed remarkably long periods of set prices. Carlton (1989) found that the time between adjustment of prices ranged from 14 years for steel, cement, and chemicals to 4 years for plywood and nonferrous metals. Cecchetti (1986) found that the average length of time between price changes for magazines was 7 years in the 1950s and about 3 years in the 1970s. Kashyap (1995) found that mail order catalog prices were fixed for as long as 2 years. Blinder et al. (1998) found that about 40% of firms change their prices once per year, 10% change prices more frequently than once per year; and 50% leave their prices unchanged for more than a year. Dutta et al. (2002) found evidence of more frequent price changes for several types of frozen and refrigerated orange juice.

In contrast more recent detailed research by Bils and Klenow (2004), Klenow and Kryvtsov (2008), Nakamura and Steinsson (2008), and the ECB surveys in Europe shows more frequent changes in prices. A very useful review of this research is provided in a chapter in the *Handbook of Monetary Economics* by Klenow and Malin (2011), so there is no need to summarize it again here. They report that the average time between price changes is every 4 months for items in the consumer price index (CPI) and every 6–8 months for items in the producer price index. However, there is a great deal of heterogeneity across items with service prices changing less rapidly than good prices. They also report that price setting is unsynchronized, a finding that also goes back to Lach and Tsiddon (1996) who also noted within-store synchronization. Finally, Klenow and Malin (2011) emphasize that reference prices tend to be changed less frequently than regular prices.

As with wage setting, useful information about price setting in Europe comes from surveys of firms conducted by central banks. Fabiani et al. (2006) investigated the pricing behavior of more than 11,000 firms based on a survey conducted by the Eurosystem of national central banks. They found that "price reviews happen with a low frequency, of about one to three times per year in most countries, but prices are actually changed even less." They also found that "one-third of firms follow mainly time-dependent pricing rules, while two-thirds allow for elements of state dependence." The majority of the firms take into account both past and expected economic developments in their pricing decisions.

2.3 Pertinent Facts About Microeconomic Data on Wage and Price Setting

Though it is difficult to glean key facts from so many empirical studies, I would emphasize the following general features of price and wage setting as relevant to theoretical research on models of staggered wages and prices which I will review in the following sections:

(1) Both wage setting and price setting are staggered or unsynchronized over time. Even in unusual situations when there is a specific time of year for changing wages—such as in the spring in Japan and in January in some European counties, there are many other months where wages are changed. An example of evidence for staggered wage setting is that there was not one quarter where the frequency of wage change fell below 20% in France during the years from 1998 to 2006. Similarly, price changes are also typically not synchronized, as Klenow and Malin (2011) emphasize in their review.

(2) There is considerable evidence that most wages are set for a fixed length of time rather than changed at random intervals. The most common interval for wage changes is four quarters or 12 months. In Europe, the WDN survey shows that 60% of firms adjust wages once per year. Moreover, when it has been estimated, such as in France and the United States, the hazard function has a sharp peak at four quarters or 12 months.

(3) Wages and prices are set at a constant level during the length of time that they are set, rather than predetermined in advance to increase by certain amounts. Although originally clear from informal observation, this fact was confirmed for prices in empirical work by Klenow and Kryvtsov (2008) and Nakamura and Steinsson (2008). An exception in the case of wages occurs in the case of multiyear union contracts where deferred increases in later years are often agreed to in advance.

(4) There is strong evidence of time dependence in wage-setting and slightly less in price setting. Regarding wage setting, 55% of European firms report that wage changes occur in a particular month. In contrast, one-third of European firms follow mainly time-dependent pricing practices and two-thirds allow for elements of state dependence.

(5) Wage adjustment is less frequent than price adjustment, according to the most recent microeconomic empirical research, a finding which reverses the order reported in my 1999 *Handbook of Macroeconomics* chapter. In the European survey, the average duration of wages is greater than the average duration of prices. According to Barattieri et al. (2014), the quarterly frequency of wage adjustment in the United States, when correcting for measurement error, is much less than the CPI data as summarized by Klenow and Malin (2011). Price and wage rigidities are temporary, but prices and wages do not all change instantaneously and simultaneously, as if determined on a spot market with full information. There is no empirical reason—aside from the need for a simplifying assumption or the desire to illustrate a key point—to build an empirical model in which wages are perfectly flexible (determined on a spot market with full information) while prices are temporarily rigid, or vice versa.

(6) The frequency of wage and price changes depends on the average rate of inflation. While this is a robust finding, it should be emphasized that for the range of inflation rates observed in recent years in the developed economies, the average duration of wages and prices remains high. For a given target inflation rate, constant frequency of price adjustment is a good assumption to make in an empirical or policy model.

(7) There is a great deal of heterogeneity in wage and price setting practices across countries, across firms, across products, and across types of workers. Though the data reveal certain tendencies, as describe in the six points above, there is no practice that applies 100%. Wages in some industries change once per year on average, while in others wages change once per quarter or once every 2 years. There is a mixture of state dependence and time dependence in most countries. The price of services changes less frequently than goods. Wages of unskilled workers change more frequently than for skilled workers. One might hope that a model with homogeneous "representative" price or wage setting would be a good approximation to this more complex world, but models with some degree of heterogeneity are needed to describe reality accurately.

3. ORIGINS OF THE STAGGERED WAGE AND PRICE SETTING MODEL

When you look through graduate level textbooks in monetary theory and policy you find that the chapters on modern macro models with nominal rigidities begin with the idea of staggered contracts or staggered wage and price setting that had its origin in the 1970s at about the same time that the idea of rational expectations was being introduced to macroeconomics. Carl Walsh's treatment in his third edition (Walsh, 2010) of "early models of intertemporal nominal adjustment" starts with Taylor's (1979b, 1980) model of staggered nominal adjustment and then goes on to examine the version due to Calvo (1983). David Romer's chapter in his fourth edition (Romer, 2012) starts off with three modeling frameworks from this period: Phelps and Taylor (1977), Taylor (1979b), and Calvo (1983). Likewise, Woodford's (2003) chapter on nominal rigidities is mainly about staggered price or wage setting models that emanate from those days.

It is no coincidence that staggered contract models arose at about the same time as rational expectations were introduced to macroeconomics. Rational expectations meant that one could not rely on slow adjustment of expectations—so-called adaptive expectations—or on ad hoc partial adjustment models as the reason why prices and wages moved sluggishly over time. One had to think more about the economics in modeling the adjustment of prices and wages and the impact of monetary policy.

The earliest work by Fischer (1977), Gray (1976), and Phelps and Taylor (1977) assumed that the price or wage was set in advance of the period it would apply and at a value such that markets would be expected to clear.[d] In other words, prices would be set to bring expected demand into equality with expected supply. In the case of Phelps and Taylor (1977), the price was set one period in advance, and the price could change every period—no matter how short the period—much like in perfectly flexible

[d] These researchers were working largely independently of each other even though the papers were eventually published at the same time (and two in the same issue of the *Journal of Political Economy*). One possible exception was a conversation I had at the time with Stan Fischer who asked me what I was working on. I replied by describing a paper I was working with Phelps on sticky prices and rational expectations. Stan replied that he thought that it was a good topic, but I do not recall that he mentioned that he was working on the topic.

price models. In the case of Fischer (1977) and Gray (1976), the wage could be set more than one period in advance but at a different level each period, so that expected supply could equal expected demand in every period, again not much different empirically from flexible price models.

In all these models the price or the wage would change continuously, period by period. If the model was quarterly, then the price or wage could change every quarter; if the model was monthly, the price or wage could change every month. However, in the real world prices are set at the same level for more than one period; they usually remain at the same level for several weeks, months, or even quarters; and the same is true for wages with the representative period of constancy being about 12 months.

In addition to being inconsistent with the microeconomic data (as later confirmed in formal microeconomic empirical research referred to in the previous section), this type of model was completely inconsistent with the aggregate dynamics of wages, prices, or output. I realized this as soon as I tried to bring models along the lines of Phelps and Taylor (1977) to the data. Such models could not come close to generating the time series persistence or autocorrelation that was in real world data. In effect, the price or wage setting assumption in these models was only slightly different from the assumption that prices and wages were market clearing. I proposed the staggered contract model and its key property—the contract multiplier—as a way to generate needed persistence and solve this problem. The model was explicitly designed to capture the key characteristics of the micro data and at the same time to match the aggregate dynamics.

4. A CANONICAL STAGGERED PRICE AND WAGE SETTING MODEL

The simplest way to see this is to consider the canonical staggered price setting model illustrated in Fig. 4 using a degree of abstraction and simplification similar to expositions of the overlapping generations model. Later in this chapter, I will discuss a range of

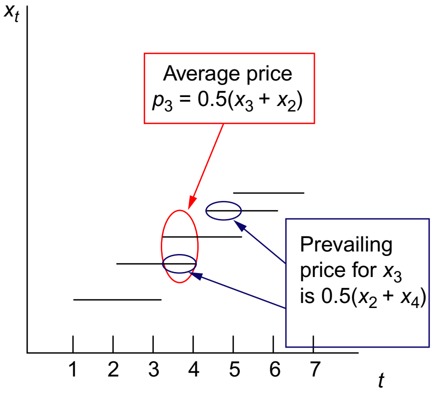

Fig. 4 Illustration of a canonical staggered contract model.

variations and extensions of this simple form. The basic idea of staggered price setting is that firms do not change their prices instantaneously from period to period. Instead there is a period of time during which the firm's price is fixed, and the pricing decisions of other firms are made the same way but at different times. Price setting is thus staggered and unsynchronized.

This "contract" or "set" price x_t is shown in Fig. 4. Note that it is fixed at the same level for two periods. Half the firms set their price each period in the canonical model. In the case where x is a wage rather than a price, it would also be set for two periods. There is no reason for either the price or the wage to be a formal contract or even an implicit contract; rather the price or wage set by the firm could apply to any particular good purchased or any worker of a certain type hired.

4.1 Canonical Assumptions

Two essential assumptions of staggered price setting are clear in Fig. 4. First, the set price lasts for more than an instant, or in this discrete time setup for more than one period. Second, the price setting is unsynchronized or overlapping. When you think about how a market might work in these circumstances, you realize two more important things not in the classic supply and demand framework. First, you realize that some firms' prices will be outstanding when another firm is deciding on a price to set. So firms need to look back at the price decisions of other firms. Second, you realize that the firm's price will be around for a while, so the firm will have to think ahead and forecast the price decisions of other firms.

Fig. 4 also illustrates two important concepts: the average price $p_t = (x_t + x_{t-1})$ and the prevailing price. For period t, the prevailing price is the average of the price in effect in period $t-1$ and the price expected to be in effect in period $t+1$, that is $0.5(x_{t-1} + E_{t-1}x_{t+1})$. This is what is relevant for the price decision of the firm in period t.

Given this setup, a decision rule for the firm setting the price x_t at time t can be written down directly, as I originally did in Taylor (1979a,b,c), as a function of the prevailing price (set by other firms in the market) and a measure of demand pressure in the market during the period the price will be in effect. The intuitive idea is simply that firms increase their price above the prevailing price if they see that demand conditions in the market are strong, and vice versa if demand conditions are weak. There can also be a random shock reflecting mistakes or other factors affecting the pricing decision. The result is shown in Eq. (1). As we will see later in this chapter, this equation can be derived explicitly from a specific profit maximization problem of a firm in monopolistic competition.[e]

[e] Note that (ignoring the expectations operator) the first term on the right-hand side of Eq. (1) can be written as $\frac{1}{2}(p_t + p_{t+1})$ because this equals $\frac{1}{2}\left[\frac{1}{2}(x_t + x_{t-1}) + \frac{1}{2}(x_{t+1} + x_t)\right]$ and thus $x_t = \frac{1}{2}(x_{t-1} + x_{t+1}) + \cdots$.

The term E_{t-1} represents the conditional expectations operator, the term y_t is a measure of demand (which for simplicity I will take to be the percentage deviation of real output from potential output), and ε_t is a serially uncorrelated, zero mean random shock.

$$x_t = \frac{1}{2}(x_{t-1} + E_{t-1}x_{t+1}) + \frac{\gamma}{2}(E_{t-1}y_t + E_{t-1}y_{t+1}) + \varepsilon_t \tag{1}$$

As I explain later, the "demand" variable on the right-hand side of Eq. (1) can also be interpreted as marginal cost in the case of a price decision (Woodford, 2003) or marginal revenue product in the case of a wage decision (Erceg et al., 2000) rather than the output gap.

4.2 Two More Equations and a Dynamic Stochastic General Equilibrium Model

To derive the implications of the staggered contracts assumption for aggregate dynamics and the persistence of shocks, we need to embed the staggered price setting equation into a model of the economy. For this purpose, consider two additional simple equations: An aggregate demand equation based on a money demand function (which could be derived from a money-in-the-utility or cash-in-advance framework) and an equation describing a monetary policy rule in which the money supply is adjusted by the central bank in response to movements in the price level. The two equations are thus:

$$y_t = \alpha(m_t - p_t) + v_t \tag{2}$$

$$m_t = gp_t \quad (g < 1) \tag{3}$$

which can be combined to get

$$y_t = -\beta p_t + v_t \tag{4}$$

where $\beta = \alpha(1-g)$ is the key policy parameter.

Here we define y to be the log of real output (detrended) as in Eq. (1) and m to be the log of the money supply. In the case where $\alpha = 1$, ν is simply the log of velocity, which can be a random variable with zero mean. The policy rule is effectively a price rule with a price level target of 0 for the log of the price level. Now if we insert the staggered contract Eq. (1) into the model we get the following difference equation with lags and leads

$$\begin{aligned} x_t &= \frac{1}{2}(x_{t-1} + E_{t-1}x_{t+1}) + \frac{\gamma}{2}\left[-\beta\left(\frac{E_{t-1}x_t + x_{t-1}}{2}\right) - \beta\left(\frac{E_{t-1}x_{t+1} + E_{t-1}x_t}{2}\right)\right] + \varepsilon_t \\ &= \frac{1}{2}(x_{t-1} + E_{t-1}x_{t+1}) - \frac{\gamma\beta}{4}[E_{t-1}x_{t+1} + 2E_{t-1}x_t + x_{t-1}] + \varepsilon_t \end{aligned}$$

The solution is

$$x_t = ax_{t-1} + \varepsilon_t \tag{5}$$

where $a = c \pm \sqrt{c^2 - 1}$ and where $c = (1 + \beta\gamma/2)/(1 - \beta\gamma/2)$. Clearly $c > 1$, and we can chose stable root for uniqueness. In terms of the aggregate price level, this implies that

$$p_t = ap_{t-1} + 0.5(\varepsilon_t + \varepsilon_{t-1}) \tag{6}$$

an ARMA(1,1) from which steady-state variances can easily be found

$$\sigma_p^2 = 0.5\sigma_\varepsilon^2/(1 - a)$$
$$\sigma_y^2 = \beta^2\sigma_p^2$$

Note that the three equation macro model consists of a staggered price setting Eq. (1), a policy transmission Eq. (2), and a policy rule (3). The model is a combination of sticky prices and rational expectations which is the hallmark of *New Keynesian* models, a term which distinguishes them from *Old Keynesian* models in which expectations are not rational and prices are either fixed or determined in a purely backward-looking manner, unlike Eq. (1). To be sure, the term New Keynesian is used in different ways by different researchers and can be misleading. For example, in some usages the term refers only to models in which the monetary transmission equation is an IS curve—perhaps derived from a Euler equation—relating the policy interest rate to aggregate demand and the policy rule is an interest rate rule like the Taylor rule.

Observe that the persistence of the aggregate price level, which is determined by the parameter a in Eq. (6), and aggregate output depends on the structure of the staggered pricing γ but also on the policy rule g. In other words, persistence is a general equilibrium phenomenon depending on both the price setting mechanism and on policy. This idea that one needs a whole model rather than a single price setting equation to assess the degree of aggregate persistence will come up again in this chapter.

Also note that in this simple model the money supply is stationary so the persistence is in the price level rather than the inflation rate. In a more realistic model, the growth rate of the money rather than the money supply would be stationary.

4.3 The Policy Problem and the Output and Price Stability Tradeoff Curve

An objective function or loss function for monetary policy in this model can be written in terms the variances of y_t and p_t. For example, if the loss function is $\lambda\text{var}(p_t) + (1 - \lambda)\text{var}(y_t)$, then the monetary policy problem is to choose a value of g (which determines β and thus a) to minimize this loss function. As the policy parameter is changed, the variances of p and y move in opposite directions tracing out a variance tradeoff curve. The lower panel of Fig. 5 illustrates this variance tradeoff curve. Inefficient monetary policies would be outside the curve. Points inside the curve are not feasible. Performance could be improved by moving toward the curve.

The upper panel of Fig. 5 is an aggregate demand–aggregate supply diagram which illustrates how the choice of g, and thus β, affects the variance of p and y. Suppose that there is a shock ε to the price setting equation. Then a steep aggregate demand

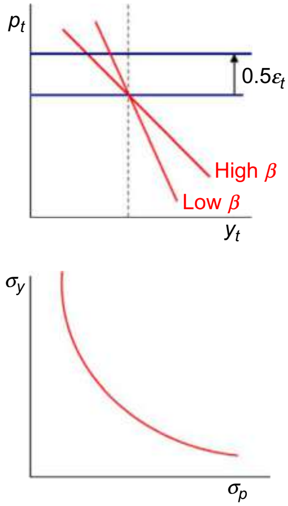

Fig. 5 Output and price stability tradeoff curve with graphical explanation.

curve (a monetary policy choice) makes for smaller fluctuations in y, but also means that a given shock to the price level takes a long time to diminish and thus a larger average fluctuation in p.

4.4 Key Implications

A number of important implications of staggered contracts can be illustrated with the canonical model, and they also hold in more complex models. I summarize these implications here.

(1) The theory centers around a simple equation that can be used and tested. I list this result first because if the theory had not yielded an equation, such as Eq. (1), it would have been difficult to achieve the progress I report in this chapter—including the empirical validation exercises reported in the previous section and the theoretical derivation of the equation using a profit maximization with monopolistic competition framework reported later. A key variable in this equation is the prevailing price (or wage) set by other firms. The prevailing price itself is an average of prices set in the past and prices to be set in the future. In this case the coefficients on past and the future are equal.

(2) Expectations of future prices matter for pricing decisions today. This is shown clearly in Eq. (1). The reason is that with the current price decision expected to last into the future, some prices set in the future will be relevant for today's decision. This is an important result because expectations of *future* inflation now come into play in the theory of inflation. It gives a rationale for central bank credibility and for having an inflation target.

(3) There is inertia or persistence in the price setting process; past prices matter because they are relevant for present price decisions. The coefficients on past prices can be calculated from the staggered price setting assumptions. This implication can be most readily seen in Eq. (5). The contract price is serially correlated. It is persistent and it can be described by an autoregressive process.

(4) The inertia or persistence is longer than the length of the period during which prices are fixed. Price shocks take a long time to run through the market because last period's price decisions depend on price decisions in the period before that and so on into the distant past. I originally called this phenomenon the "*contract multiplier*" because it was analogous to the Keynesian multiplier where a shock to consumption builds up and persists over time as it works its way through the economy from income to consumption to income back again and so on. This is most easily seen in Eq. (5) or the ARMA model in Eq. (6). The first-order autoregression implies an infinite autocorrelation function or an infinite impulse response function. The larger the autoregressive coefficient (that is, a) is, the larger will be the contract multiplier.

This is one of the most important properties of the staggered contract model because it means that very small rigidities at the micro level can generate large persistent effects for the aggregates. Klenow and Malin (2011) explain it well: "Real effects of nominal shocks … last three to five times longer than individual prices. Nominal stickiness appears insufficient to explain why aggregate prices respond so sluggishly to monetary policy shocks. For this reason, nominal price stickiness is usually combined with a 'contract multiplier' (in Taylor's, 1980 phrase)."

(5) The degree of inertia or persistence depends on monetary policy. That is, the autoregressive coefficient a depends on the policy parameter g. The more accommodative the central bank is to price level movements (higher g), the more inertia there will be (higher a).

(6) The theory implies a tradeoff curve between price stability and output stability. This tradeoff curve has provided a framework for discussion and debate about the role of policy in economic performance for many years. Originally put forth in Taylor (1979a) it is referred to as the Taylor curve in various contexts (King, 1999; Bernanke, 2004; Friedman, 2010). Bernanke (2004) used such a tradeoff curve to explain the role of monetary policy during the Great Moderation. His explanation was that monetary policy improved and this brought performance from the upper right-hand part of the diagram down and to the left closer to or even on the curve.

King (1999) made similar arguments. However, when the Great Recession and the slow recovery moved the performance in the direction of higher output instability—the end of the Great Moderation—King (2012) argued that the tradeoff curve itself shifted. As he put it, "A failure to take financial instability into account creates an unduly optimistic view of where the Taylor frontier lies …Relative to a Taylor frontier that reflects only aggregate demand and cost shocks, the addition of financial instability shocks generates what I call the Minsky-Taylor frontier."

Note that the tradeoff implies that there is no "*divine coincidence*" as put forth by Blanchard and Gali (2007). Divine coincidence means that there is no such tradeoff between output stability and price stability, completely contrary to the existence of the tradeoff in Fig. 5. Divine coincidence could occur if there were no shocks to the contract price or wage equation, but that is not the basic assumption of the staggered contract model. Broadbent (2014) suggested that the Great Moderation was due to the sudden appearance of divine coincidence, rather than to an improved monetary policy performance that brought the economy closer to the tradeoff curve as Bernanke (2004) and others argued.

(7) The costs of reducing inflation are less than in a backward-looking expectations augmented Phillips curve. In the staggered contract model, disinflation could be less costly if expectations of inflation were lower because of the forward-looking component of the model, as explained in Taylor (1982) though with reservations from others such as Gordon (1982). The disinflation costs would not normally be zero as in the case of rational expectations models with perfectly flexible prices, but they would be surprisingly small. This prediction proved accurate when people later examined the disinflation of the early 1980s.

5. GENERALIZATIONS AND EXTENSIONS

These results remain robust to variations in the model. An important variant is to allow for a greater variety of time intervals during which prices are fixed. Of course one could have longer contracts as in Taylor (1980) where contracts were of a general length *N*. However, a model with all price and wage setting being the same length is a simplifying assumption, not something that could be used in empirical work. The high degree of heterogeneity described in the microeconomic research reviewed earlier makes this very clear. Not all contracts are *N* periods in length; some are shorter and some are longer. Indeed, there is a whole distribution of contracts and this is what I assumed in early empirical work with these models. For example, a generalized distribution of price–wage setting intervals was used by Taylor (1979c) in an estimated model of the United States.

Eq. (1) was thus modified as follows:

$$x_t = \sum_{i=0}^{N-1} \theta_{it} E_t(p_{t+i} + \gamma y_{t+i} + \varepsilon_{t+i}) \tag{7}$$

$$p_t = \sum_{i=0}^{N-1} \delta_{it} x_{t-i} \tag{8}$$

The weights θ_{it} and δ_{it} were estimated using aggregate wage data in the United States. The estimation of the lag and lead coefficients was only mildly restricted, allowing for a peak somewhere between one and eight quarters. The estimated distribution from Taylor (1979c, table 4) is plotted in Fig. 6. It has a peak at three quarters with 24% of workers; only 7% had one quarter contracts and only 2% had eight quarter contracts.

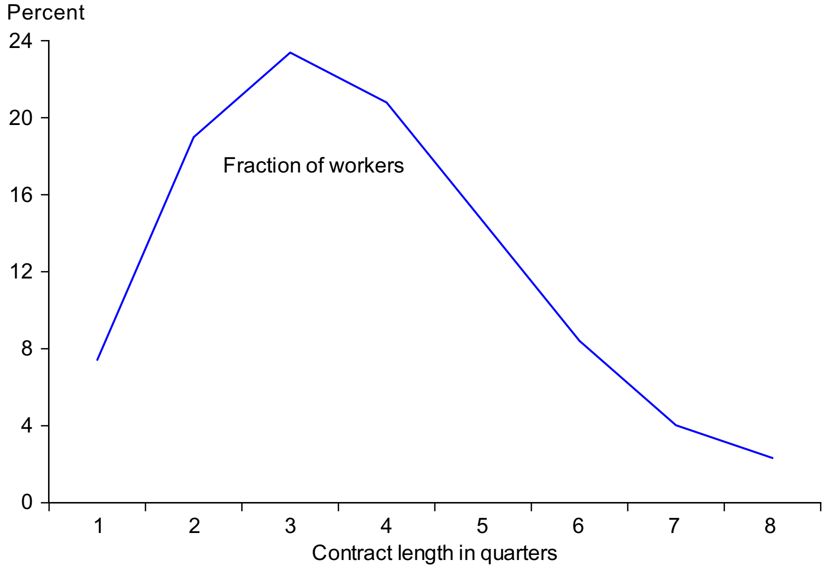

Fig. 6 The estimated distribution of workers by contract length.

The interpretation was that the economy consisted of a whole variety of price and wage setting practices.

Observing this empirical distribution of wage setting intervals in Taylor (1979c) gave my then colleague at Columbia University, Guillermo Calvo, the idea of an important simplification. Why not assume a geometric distribution, which would be considerably simpler? Moreover, such a distribution could be interpreted as being generated probabilistically rather than deterministically if each wage contract expired randomly rather than deterministically. The resulting model came to be called the Calvo model and the random selection process came to be called the Calvo fairy. The equation for the price change is a specific version of Eqs. (7) and (8) and can be written as follows:

$$x_t = (1-\beta\omega)\sum_{i=0}^{\infty}(\beta\omega)^i E_t(p_{t+i} + \gamma y_{t+i} + \varepsilon_t) \tag{9}$$

$$p_t = (1-\omega)\sum_{i=0}^{\infty}\omega^i x_{t-i} \tag{10}$$

After some manipulation, these two equations can be rewritten as

$$x_t = \beta\omega E_t x_{t+1} + (1-\beta\omega)(p_t + \gamma y_t + \varepsilon_t)$$
$$p_t = \omega p_{t-i} + (1-\omega)x_t$$

Once a model for y and the impact of monetary policy is added, you have a well-defined rational expectations model as before.

The two equations can also be rewritten in an interesting form:

$$\pi_t = \beta E_t \pi_{t+1} + \delta \gamma y_t + \delta \varepsilon_t \tag{11}$$

where

$$\delta = \left[\frac{(1-\omega)(1-\beta\omega)}{\omega} \right]$$

Which is very simple and reminiscent of an old expectations augmented Philips curve except that the expected inflation rate next period rather than this period is on the right-hand side. Calvo's modifications helped the staggered contract model grow in use and popularity.

Indeed, the form of the staggered price setting model in Eq. (1) came to be popularly known as the New Keynesian Phillips curve.

6. DERIVATION OF STAGGERED PRICE SETTING WHEN FIRMS HAVE MARKET POWER

Another important development regarding the staggered contract model was its derivation from an optimization problem in which firms face a downward sloping demand curve and decide on an optimal price subject to the staggered contract restriction that they cannot change prices every period. The idea of using market power to derive a price setting equation goes back to Svensson (1986), Blanchard and Kiyotaki (1987), and Akerlof and Yellen (1991) as I reviewed in Taylor (1999). As described below, Chari et al. (2000) used the approach as part of a critique of staggered price setting. For expository purposes here, I focus on a simple derivation used in Taylor (2000) in which firms maximize profits taking the downward sloping demand curve for their products as given.

Consider a firm selling a product that is differentiated from the other goods. The demand curve facing each firm is linear in the difference between the firm's own price for its product and the average price for the other differentiated products. Such a linear demand curve can be derived from models of consumer utility maximization. Suppose that this linear demand curve is written as

$$y_t = \varepsilon_t - \beta(x_t - p_t) \tag{12}$$

where y_t is production, x_t is the price of the good, and p_t is the average price of other (differentiated) goods. The term ε_t is a random shift to demand.

Suppose that the firm sets its price to last for two periods, and that it sets its price every second period. Other firms set their price for two periods, but at different points in time. These timing assumptions correspond to the canonical model in Fig. 1, and the average price is just as in the canonical model $p_t = 0.5(x_t + x_{t-1})$.

Let c_t be the marginal cost of producing the good. Under these assumptions, the firm's expected profit for the two periods to which the price set in period t applies is given by

$$\sum_{i=0}^{1} E_t(x_t y_{t+i} - c_{t+i} y_{t+i}) \tag{13}$$

where x_t applies in period t and period $t+1$. (I have assumed for simplicity that the discount factor is 1.) Firms maximize profits taking marginal cost and average price at other firms as given.

Differentiating with respect to x_t results in the solution for the optimal price

$$x_t = 0.25 \sum_{i=0}^{1} (E_t c_{t+i} + E_t p_{t+i} + E_t \varepsilon_{t+i}/\beta) \tag{14}$$

which is analogous to the canonical staggered contracting equation in Eq. (1) (see also Footnote a). Note however that it is marginal cost that enters the equation rather than the output gap, an issue I will come back to later in this chapter. Note that the coefficient of 0.25 implies that an increase in the price and marginal cost at other firms results in the same increase in the firm's price.

6.1 Pass-Through Implications

Though the derivation generates the same basic staggered price setting equation as assumed in the canonical model, it reveals another important implication of the theory—an "eighth" implication: a more price stability focused monetary policy—say due to inflation targeting—implies a smaller pass-through of price shocks (commodities or exchange rates) to inflation. That this implication might be borne out by reality was noted in Taylor (2000), but has now been documented in empirical studies in many countries. The reason originally given for the empirically observed decline in pass-through was that there was a reduction in the "pricing power" of firms. But another view is that the decline in pass-through is due to the low inflation rate achieved by a change in monetary policy.

To see this note that, according to Eq. (14), the amount by which a firm matches an increase in marginal cost with an increase in its own price depends on how permanent that marginal cost increase is. Similarly, the extent to which an increase in the price at other firms will lead to an increase in the firm's own price will depend on how permanent that increase in other firms' prices is expected to be. However, in neither case does the extent of this pass-through depend on the slope of the demand curve.

To see how the pass-through of an increase in marginal costs depends on the persistence of the increase, suppose that marginal cost follows a simple first-order autoregression:

$$c_t = \rho c_{t-1} + u_t$$

In this case, the pass-through coefficient will be proportional to $(1+\rho)$. Thus, less persistent marginal costs (lower ρ) reduce the pass-through coefficient, even though it might seem like a reduction in pricing power. The general point is that if an increase in costs is expected to last, then the increase will be passed-through to a greater extent. A more stable price level will reduce the persistence.

For firms that import inputs to production, marginal cost will depend on the exchange rate. Currency depreciation will raise the cost of the imports in domestic currency units. According to this model, if the depreciation is viewed as temporary, the firm will pass-through less of the depreciation in the form of a higher price. Hence, less persistent exchange rate fluctuations will lead to smaller exchange rate pass-through coefficients.

6.2 Marginal Cost vs the Output Gap

Note that Eq. (14) has marginal cost driving price movements rather than output as assumed in Eq. (1). To make the connection between Eqs. (14) and (1) (again keeping Footnote a in mind) we need to think of marginal cost as moving proportionately to the movements in the output gap. Gali and Gertler (1999) or Gali et al. (2005) argue that there are plenty of reasons why marginal cost and the output gap might diverge from time to time. So they look at a version of Eq. (11) in which marginal costs appear rather than the gap (they use the geometric distribution assumption of Calvo rather than the canonical form used here). Though the empirical accuracy of this equation was questioned by Mankiw (2001), the paper by Gali et al. (2005) finds that marginal cost is significant and quantitatively important. However, they introduce a modification in that model. They assume that a fraction of firms changes price with a backward looking "rule of thumb" which simply depends on past inflation. They thereby create a hybrid model with the lagged inflation rate on the right-hand side. The modification is ad hoc—especially compared with the theory that goes into deriving the staggered price setting equation.

Another issue noted by Nekarda and Ramey (2013) is that the markup of price over marginal cost needs to move in a countercyclical way if the equation is to explain empirically the effects of a change in demand on prices. They report, however, that markups are either "procyclical or acyclical conditional on demand shocks" and thereby conclude that the "New Keynesian explanation for the effects of government spending or monetary policy is not supported by the behavior of the markup."

Fuhrer (2006) raised further questions about the New Keynesian Phillips curve. He shows that in the New Keynesian Phillips curve inflation it is persistence of the shock rather than the equation itself that is the dominant source of persistence.

6.3 Debate Over the Contract Multiplier

Yet another issue is whether the contract multiplier is capable of explaining the persistence of prices or output. In the canonical model, including its derivation from profit maximization, the contract multiplier can be represented by the size of the autoregressive coefficient in the aggregate price equation. Chari et al. (2000) argued that for the parameters derived from the maximization problem, this coefficient is not large enough to be capable of explaining persistence, at least for contract lengths of one quarter in length and their particular measure of aggregate persistence. Woodford (2003, pp. 193–194) argues that their conclusion "depends on an exaggeration of the size of the contract multiplier that would be needed and an underestimate of the empirically plausible degree of strategic complementarities." He also argues that Chari et al. (2000) setup too high a persistence hurdle for the contract multiplier, in effect asking it to explain persistence that is more reasonably due to other serially correlated variables in the model.

Christiano et al. (2005) argue that assuming that the representative length of contracts is only one quarter is too small. If one uses somewhat longer contracts, say close to the survey summarized by Klenow and Malin (2011), the contract multiplier seems to work fine. Christiano et al. (2005) also question the persistence measure used by Chari et al. (2000).

7. PRICE AND WAGE SETTING TOGETHER

Much of this review has focused thus far on staggered *price* setting, but the original work on staggered contracts was about wages, where the time between wage changes is quite a bit longer according to the recent microeconomic empirical research summarized in this chapter. In Taylor (1980), the staggering of wages was the key part of the model, and this created a persistence of prices through a simple fixed markup of prices over wages. The micro finding summarized by Klenow and Malin (2011) that "price changes are linked to wage changes" supports this idea. Of course the markup need not be literally fixed. In the empirical multicountry model in Taylor (1993), the staggered wage contracting equations were estimated for seven countries and markups of prices over wages were influenced by the price of imports.

Erceg, Henderson, and Levin (2000) brought the focus back on wages, but with an important innovation. Rather than simply marking up prices over wages, they built a model which combined staggered price and wage setting, and, moreover, they derived both equations from profit or utility maximization considerations as in Section 5. Their work in turn helped enable the development of more empirically accurate estimated policy models, such as those due to Christiano et al. (2005), Smets and Wouters (2003), and many others that have become part of Volker Wieland's model database described in Wieland et al. (2012).

The model of Christiano et al. (2005) assumes staggered contracts for prices and wages with Calvo contracts. It was the first medium-sized, estimated example of a New Keynesian model explicitly derived from optimizing behavior of representative households and firms. It stimulated the development of similar optimization-based models for many other countries and has been dubbed the second-generation New Keynesian model along with Smets and Wouters (2003) by Wieland et al (2016).

Smets and Wouters (2003, 2007) also showed how to use Bayesian techniques (Geweke, 1999; Schorfheide, 2000) in estimating such models.

An important question for research is how the overall properties of the models changed as a result of the innovations. The eight implications mentioned earlier still hold in my view but the quantitative sizes of the impacts are important to pin down. Taylor and Wieland (2012) investigated this question using Wieland's database of models designed for this purpose. They considered a first-generation model—the Taylor (1993) multi-country model mentioned in the previous section with staggered contracts. And they compared this with two second-generation models—the Christiano et al. (2005) model and the Smets and Wouters (2007) model. Although the models differ in structure and sample period for estimation, the impacts of unanticipated changes in the federal funds rate are surprisingly similar. In the chapter prepared for this handbook, Wieland et al. (2016) show that these surprising results continue to hold if one adds a third-generation of models in which credit market frictions play a role in the monetary transmission mechanism.

There is a difference between the models in the evaluation of monetary policy rules, however. Model-specific policy rules that include the lagged interest rate, inflation, and current and lagged output gaps are not robust. Policy rules without interest-rate smoothing or with GDP-growth replacing the GDP gap are more robust, but performance in each model is worse with the more robust rule.

8. PERSISTENCE OF INFLATION AND INDEXING

Prior to the work of Chari et al. (2000), Fuhrer and Moore (1995) raised questions about the ability of the staggered contract model to explain the persistence of inflation rather than the persistence of the price level. They proposed a modification of the model to deal with this problem. As I reviewed in Taylor (1999), they transformed the model from price levels into the inflation rate, noting that it was *relative* wages rather than absolute wages that would go into the staggering equations. But the rationale for focusing on relative wages was weak and questions about this issue continued into the 2000s.

In recent years many have argued that the degree of persistence implied by the basic staggered contract model is just fine and consistent with the data. Guerrieri (2006), for example, argued that when the staggered contract model is viewed within the context of a fully specified macro model, inflation persistence and its changes over time could be explained with the regular staggered contract setup. I illustrated this idea with the canonical model I presented earlier in this chapter in which persistence is a general equilibrium phenomenon.

Guerrieri (2006) used a vector autoregression with inflation, the interest rate, and output to represent the facts that a staggered contract model should explain. He found that the basic staggered contract model did as well as the Fuhrer and Moore (1995) relative contract model in generating the actual inflation persistence in the United States through the 1990s. The impulse response functions reported in his paper show the degree to which both specifications can explain the inflation process. The staggered contract models are well within the 95% confidence bands with the exception of the cross-impulse response functions for output and inflation.

Nevertheless, both Christiano et al. (2005) and Smets and Wouters (2003) felt the need to modify the staggered price and wage setting equations in order to get the proper persistence and better match the other cross correlations. They assumed backward-looking indexation in those periods when prices and wages were not allowed to adjust. The Christiano et al. (2005) model assumes wages and prices are indexed to last period's inflation rate during periods between changes. The Smets–Wouters model assumes firms index to a weighted average of lagged and steady-state inflation.

None of these modifications are part of the optimization process; they are akin to simply assuming that wage and price inflation is autoregressive in an ad hoc way rather than deriving the equations: Why bother with a microfounded staggered wage and price setting model if you are just going to add ad hoc lag structure anyway?

According to recent research it appears that the persistence problem is not due the staggered contract model but rather to the special Calvo form it takes in these models.

9. TAYLOR CONTRACTS AND CALVO CONTRACTS

Much has been written comparing "Calvo contracts" described in Section 5 and "Taylor contracts" which appear in the canonical model in the case of two period contracts in Section 4. Walsh (2010, p. 243) notes some of the similarities between equations (his eqs. 6.17 and 6.36) derived from the two staggered price setting models, but others, including Kiley (2002), have emphasized the differences. For example, the persistence of inflation and output appears to be greater in the Calvo contracts for the same average frequency of price change.

There is no question that there is a much longer tail in the Calvo model than for any fixed-length contract, but Dixon and Kara (2006) argue that Kiley's comparison is flawed because it compares "the average age of Calvo contracts with the completed length of Taylor contracts." When Dixon and Kara (2006) compare average age Taylor contracts with the same average age Calvo contracts, the differences become much smaller. They also show that output can be more autocorrelated with Taylor contracts with "age-equivalent" Calvo contracts.

Carvalho and Schwartzman (2015) examine the differences in monetary neutrality in the two types of models by distinguishing between Taylor contracts and Calvo contracts in terms of their "selection effect." At any point in time after a monetary shock, some firms have a lot of old prices and some do not. "Positive" selection is defined as a situation where old prices are overrepresented among adjusting prices. In Taylor contracts, selection favors old prices; in Calvo contracts there is no selection, since prices change completely at random. This selection effect characterizes pricing frictions. Taylor contracts imply smaller nonneutralities of money on output than Calvo contracts because of differences in selection.

Of course there is no reason to focus—as these studies do—on the special case of "Taylor contracts" in which all contracts are the same length as in the simple exposition in the canonical model. The microeconomic evidence and casual observation suggest rather that there is a great deal of heterogeneity of lengths of both wage contracts and price contracts. In a series of papers, Dixon and Kara (2005, 2006, 2011) and Kara (2010) develop models which are built on this heterogeneity. They call these models a generalized Taylor economy (GTE) in which many sectors have staggered contracts with different lengths. When two such economies have the same average length contracts, monetary shocks are more persistent with longer contracts. They also show that when two GTE's have the same distribution of completed contract lengths, the economies behave in a similar manner. See also Huw Dixon's comprehensive web page http://huwdixon.org/GTE.html on the GTE and his paper with Dixon and Le Bihan (2012).

In a more recent paper, Kara (2015) shows that adding the heterogeneity in price stickiness to the Smets and Wouters model deals with criticisms of the staggered contract model including the Chari et al. (2009) criticism that the Smets and Wouters model relies on unrealistically large price mark-up shocks to explain the data on inflation and the Bils et al. (2012) criticism that reset price inflation in the model is more volatile than the data show. Kara (2015) shows that adding heterogeneity in the length of contracts to correspond with the data implies smaller price mark-up shocks and less volatile reset price inflation.

In yet another study comparing the two approaches, Knell (2010) examined survey data on wage setting in 15 European countries from the WDN discussed in Section 2. It is informative to quote from his paper: "There are at least four dimensions along which the data contradict the basic model with Calvo contracts. First, the majority of wage agreements seems to follow a predetermined pattern with given contract lengths. Second, while for most contracts this predetermined length is 1 year (on average 60% in the WDN survey) there exists also some heterogeneity in this context and a nonnegligible share of contracts has longer (26%) or shorter (12%) durations. Third, 54% of the firms asked in the WDN survey have indicated that they carry out wage changes in a particular month (most of them—30%—in January). Fourth, 15% of all firms report to use automatic indexation of wages to the rate of inflation. In order to be able to take these real-world characteristics of wage setting into account one has to move beyond the convenient but restrictive framework of Calvo wage contracts." Knell then presents a model along the lines of Taylor (1980) that allows one to incorporate all of these institutional details.

Musy (2006) and Ben Aissa and Musy (2010) have investigated the differences between the Calvo contracts model and the Taylor contracts model and others. Their analysis shows that criticism of a lack of persistence or an under estimate of the costs of disinflation are due to very special features of the Calvo assumptions. Recall that the "Calvo fairy" is a mechanism for randomly choosing a price to change each period. That probability is a constant, so in effect Calvo contracts are neither time dependent nor state dependent. The work of Musy and Ben Aissa shows that a change in money growth will not be accomplished in a costless manner in the Taylor model even though it is in the Calvo model, and that persistence is greater.

10. STATE-DEPENDENT MODELS AND TIME-DEPENDENT MODELS

Another development has been to relax the simplifying assumption that prices are set for an exogenous interval and allow the firm's price decision to depend on the state of the market, which gave rise to name "state dependent" pricing models and created the need to give the original canonical model a new name, "time dependent" (see Dotsey et al., 1999; Golosov and Lucas, 2007; Gertler and Leahy, 2008). There are some benefits from these improvements as Klenow and Kryvtsov (2008) have shown using new microeconomic data. Many of the key policy implication mentioned earlier hold, but the impact of monetary shocks can be smaller.

Alvarez and Lippi (2014) consider a state-dependent model with multiproduct firms, which is otherwise similar to the state-dependent model of Golosov and Lucas (2007). They find that as they alter the model from one product firm to a multiproduct firm, the impact of monetary shocks becomes larger and more persistent. For a large number of products they show that the economy works as in the staggered contract model: it has the same aggregation and impulse response to a monetary shock. In this sense, the menu cost models with multiproduct firms gives another basis to the staggered contract model.

Woodford (2003, p. 142) questions whether the state-dependent models are really any better than the staggered contract models. Not only are they more complex, he argues, but they may be less realistic and have inferior microfoundations. The idea that firms are constantly evaluating the price misses the point that firms set their prices for a while to reduce "the costs associated with information collection and decision making." Kehoe and Midrigan (2010) have developed a model in which formal considerations of such management costs do indeed increase the impact and persistence of shocks.

Bonomo and Carvalho (2004) develop a model of the microfoundations of the time-dependent model in which the length of time that prices are fixed is endogenous. In their model firms face a joint lump-sum adjustment and information cost rather than a pure adjustment cost, and for this reason optimal pricing is not state dependent. Their model is thus a way to deal with the observation that contract length depends on the rate of inflation and the variability of inflation and other shocks. They not only show that time-dependent models are optimal, they derive the optimal contract length.

They examine the effect of different policies such as a disinflation and examine the difference with invariant time-dependent arrangements. In a subsequent paper, Bonomo and Carvalho (2010) estimate the macroeconomic costs of a lack of credibility of monetary policy. They find that the costs are greater for the endogenous time-dependence model than for an exogenous time-dependent model.

11. WAGE-EMPLOYMENT BARGAINING AND STAGGERED CONTRACTS

In recent years, there has been an increased interest in explaining fluctuations in unemployment as well as output. As explained by Hall (2005), the standard wage-employment bargaining model needs to assume some form of sticky wages if it is to be consistent with the data, and for this reason the idea of nominal rigidities is common to this research. It is not surprising therefore that many of the models built to examine this question have combined staggered contracts with a formal treatment of the wage-employment bargaining. Ravenna and Walsh (2008), Gertler et al. (2008), and Christiano et al. (2013) are examples.

There are some by-products of this research too. The Christiano et al. (2013) model is able to drop the arbitrary indexing assumption in Christiano, Eichenbaum, and Evans and still get the requisite persistence. This works because when a monetary shock increases the demand for output which sticky price firms produce, the firms also purchase more wholesale goods. With this model, the authors argue that "alternating offer bargaining mutes the increase in real wages, thus allowing for a large rise in employment, a substantial decline in unemployment, and a small rise in inflation."

12. STAGGERED CONTRACTS VS INATTENTION MODELS

Mankiw and Reis (2001) have argued that the staggered wage and price setting should be replaced by a model with inattention. They argue in favor of sticky information rather than sticky prices, mainly because such a model would solve the persistence problem alluded to earlier. Recall that the concern is that there may be too little persistence of inflation following monetary shocks in staggered price setting models. Though some would argue that the persistence is fine, the lack of persistence may be more related to the specific form of the Calvo model rather than to the staggered contracts per se.

Why do Mankiw and Reis (2001) find that there is more persistence with inattention than with staggered contracts? Upon examination of their model, it appears that in the sticky information model, the price could be set to increase during the period where it is fixed in the regular model. For example in a staggered contract model of four periods the price would be 1.015, 1.015, 1.015, and 1.015 while in the sticky information it could be set as 1.0, 1.01, 1.02, and 1.03 and not change from that path. In effect, some inflation persistence is built in. Fig. 7 illustrates this and can be compared with Fig. 4.

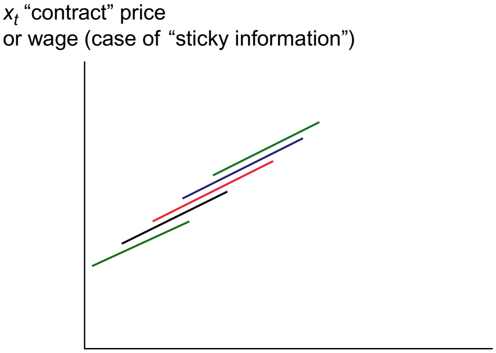

Fig. 7 Price setting with sticky information (for comparison with Fig. 4).

If prices or wages are set in this way, it is clear that there will be more persistence of inflation. It is very rare, however, for prices or wages to be set in this manner except in multiyear union contracts as explained in Taylor (1983) and Avouyi-Dovi (2013).

13. CRITICAL ASSESSMENT AND OUTLOOK

From its origins nearly four decades ago to its applications today, the staggered wage and price setting model continues to be a focus of attention in empirical and theoretical research in macroeconomics, especially in monetary business cycle models and monetary models used for policy analysis. In recent years, "Big Data" style research projects have radically expanded our knowledge of the microeconomics of wage and price setting behavior from a few salient facts about magazine prices or personal salary experiences into complex datasets with thousands or millions of observations. These datasets require new methods of analysis, but they also permit researchers to test and discriminate much more thoroughly between one type of model and another. Criticisms—whether about inadequate microfoundations, inability to explain certain facts, or questionable policy implications—have led to constructive improvements, clarifications, variations, new research lines, and, in some cases, less than fully satisfactory fixes.

In assessing the outlook for future research and applications of these models, one cannot help but be struck by a certain tension in current research. The large-scale surveys and empirical research show a great deal of heterogeneity in wage and price setting behavior, yet most models still employ simplified models clearly at odds with this heterogeneity. Yes, there is evidence that prices are set at a fixed level for 6 months or more, especially if sales and reference prices are accounted for properly. Yes, there is evidence that wages are set a fixed level for longer periods and that there is a peak in the estimated hazard function at 1 year that precludes certain simplifications such as the Calvo model. Yes, there is evidence that both wage and price decisions are staggered or unsynchronized over time, and that this staggering creates a contract multiplier which converts short spells of rigidity at the micro level into longer persistence at the macro level. Yes, there is more evidence of time dependence than state dependence. But in each of these dimensions—length, degree of staggering, shape of the hazard function, degree of state dependence—there is a great deal of heterogeneity across countries, types of product, types of employment, and types of industry structure.

This heterogeneity is not simply a nuisance; it has major implications for aggregate dynamics, and it has been offered as a response to criticism of staggered wage and price setting models. Often that criticism applies to a particular simple staggered contract model that does not capture either the regularities mentioned earlier or the heterogeneity, and that criticism disappears when heterogeneity is taken into account as Kara (2010) and Knell (2010) have emphasized. Rather than "jury-rig" simple staggered contract models with ad hoc add-ons, such as indexing in the models by Christiano et al. (2005) or Smets and Wouters (2003), this research suggests that building the heterogeneity into the model would both better fit the micro data and provide a straight forward explanation of macro persistence.

In other words, future research would likely yield large benefits if it moved on from "representative" staggered wage and price setting models to "heterogeneous" staggered wage and price setting models. The suggestion is similar to the idea of moving from "representative agent models" to "heterogeneous agent models," though the gains from such a move could be much greater.

The challenge is that building in this heterogeneity would complicate existing macro models which are already quite complicated, as I found when I began to build in such heterogeneity in my early research (Taylor, 1979c) including in a multicountry model (Taylor, 1993) with different degrees of staggered wage setting in different countries. Indeed, their complexity is the main object of criticism of the existing models as expressed by Chari et al. (2009) and others.

At the least future research could go beyond continued comparisons of simplest textbook style models—such as the random-length-contract Calvo model and the N-period-length-contract Taylor model—and look at heterogeneous or generalized models with a mix of contract types. But more fundamentally the challenge for future work is to take account of the rich variety of wage and price setting procedures in a way that is tractable and understandable for policy analysis. Indeed, that has been the challenge for all areas of macroeconomic research from the very beginning.

ACKNOWLEDGMENT

I wish to thank Susanto Basu, John Cochrane, Huw Dixon, Robert Hall, Jim Hamilton, Engin Kara, Pete Klenow, Olivier Musy, Carlos Viana de Carvalho, Harald Uhlig, and Carl Walsh for helpful comments.

Abstract

This chapter develops a toolkit of neoclassical macroeconomic models, and applies these models to the US economy from 1929 to 2014. We first filter macroeconomic time series into business cycle and long-run components, and show that the long-run component is typically much larger than the business cycle component. We argue that this empirical feature is naturally addressed within neoclassical models with long-run changes in technologies and government policies. We construct two classes of models that we compare to raw data, and also to the filtered data: *simple neoclassical models*, which feature standard preferences and technologies, rational expectations, and a unique, Pareto optimal equilibrium, and *extended neoclassical models*, which build in government policies and market imperfections. We focus on models with multiple sources of technological change, and models with distortions arising from regulatory, labor, and fiscal policies. The models account for much of the relatively stable postwar US economy, and also for the Great Depression and World War II. The models presented in this chapter can be extended and applied more broadly to other settings. We close by identifying several avenues for future research in neoclassical macroeconomics.

1. INTRODUCTION

This chapter analyzes the role of *neoclassical models* in the study of economic growth and fluctuations. Our goal is to provide macroeconomists with a toolkit of models that are of interest in their own right, and that easily can be modified to study a broad variety of macroeconomic phenomena, including the impact of economic policies on aggregate economic activity.

Since there is no generally recognized definition of neoclassical macroeconomics within the profession, we organize the development of these models around two principles. One is based on the exogenous factors driving changes in aggregate time series, and the other is based on the classes of model economies that we consider.

The primary sources of changes in macroeconomic variables that we study are long-run changes in technologies and government policies. We focus on these factors because of the observed large changes in productivity and in policies that affect the incentives and opportunities to produce and trade. Policy factors that we consider include changes affecting competition and business regulatory policies, labor policies, and fiscal policies.

We study two classes of intertemporal models that we call *neoclassical macroeconomic models*. The first has standard preferences and technologies, competitive markets, rational expectations, and there is a unique equilibrium that is Pareto optimal. We call these *Simple Neoclassical Models*. This class of models is the foundation of neoclassical macroeconomics, and provides the most transparent description of how competitive market forces operate within a dynamic, general equilibrium environment.

In contrast to common perceptions about neoclassical macroeconomics, we acknowledge that economies are affected by policy distortions and other market imperfections that go beyond the scope of simple models. The second class of models modifies simple models as needed to incorporate changes that require departing from the model assumptions described above. We call the second class of models *Extended Neoclassical Models*, which are constructed by building explicit specifications of government policies or market imperfections and distortions into simple models.

This method nests simple models as special cases of the extended models. Developing complex models in this fashion provides a clear description of how market imperfections and economic policies affect what otherwise would be a *laissez-faire* market economy. We modify the models in very specific ways that are tailored to study episodes in US economic history, and which provide researchers with frameworks that can be applied more broadly. All of the models presented in this chapter explicitly treat fluctuations and growth within the same framework.

Neoclassical frameworks are a powerful tool for analyzing market economies. An important reason is because the US economy has displayed persistent and reasonably stable growth over much its history while undergoing enormous resource reallocation through the competitive market process in response to changes in technologies and government policies. These large reallocations include the shift out of agriculture into manufacturing and services, the shift of economic activity out of the Northern and Mideastern sections of the United States to the Southern and Western states, and large changes in government's share of output, including changes in tax, social insurance, and regulatory labor policies. This also includes the reallocation of women's time from home production to market production, and the increased intensity of employment of highly-skilled labor. Most recently, this has included the reallocation of resources out of the development of mature, mechanical technologies to the development of information processing and communication technologies, including the integrated circuit, fiber optics, microwave technology, laptop computers and tablets, software applications, cellular technology, and the internet.

Our focus on technologies and policies connects with considerable previous research. This ranges from Schumpeter (1927) and Stock and Watson (1988), who argued that changes in entrepreneurship and the development of new ideas are the primary drivers of a market economy, to Kydland and Prescott (1982) and Long Jr and Plosser (1983), who focused on technology shocks and fluctuations. This also includes Lilien (1982), who argued that sectoral shifts significantly affect fluctuations and resource reallocation, Davis and Haltiwanger (1992), who established that resource reallocation across US manufacturing establishments is very large and is continuously evolving, and Greenwood and Yorokoglu (1997) and Manuelli and Seshadri (2014), who analyze the diffusion of new technologies and their long-run economic effects. The analysis also connects with studies of the long-run consequences of government policies, including research by Ljungqvist and Sargent (1998), Prescott (2004), and Rogerson (2008), who analyze how public policies such as tax rate changes, and changes in social insurance programs, have affected long-run labor market outcomes.

Our principle of focusing on long-run movements in data requires a quantitative approach that differs from standard practice in macroeconomics that involves both the selection of the data frequencies that are analyzed, and how the model is compared to data. The standard approach removes a trend from the data that is constructed using the Hodrick–Prescott (HP) filter (1997), hereafter referred to as HP filter, with a smoothing parameter of 1600, and then typically compares either model moments to moments from the HP-filtered data, or compares model impulse response functions to those from an empirical vector autoregression (VAR).This analysis uses a band pass filter to quantify movements not only at the HP-business cycle frequency, but also at the lower frequencies. Our quantitative-theoretic analysis evaluates model economies by conducting equilibrium path analyses, in which model-generated variables that are driven by identified shocks are compared to actual raw data and to filtered data at different frequencies.

We report two sets of findings. We first document the empirical importance of very long-run movements in aggregate variables relative to traditional business cycle fluctuations using post-Korean War quarterly US data, long-run annual US data, and postwar European data. We find that low frequency movements in aggregate time series are quantitatively large, and that in some periods, they are much larger than the traditional business cycle component. Specifically, we analyze movements in periodicities ranging from 2 to 50 years, and we find that as much as 80% of the fluctuations in economic activity at these frequencies is due to the lower frequency component from 8 to 50 years.

The dominant low frequency nature of these data indicates that the business cycle literature has missed quantitatively important movements in aggregate activity. Moreover, the fact that much of the movement in aggregate data is occurring at low frequencies suggests that models that generate fluctuations from transient impediments to trade, such as temporarily inflexible prices and/or wages, may be of limited interest in understanding US time series.

The importance of low frequency movements also has significant implications for the two dominant episodes of the last 35 years, the *Great Moderation* and the *Great Recession*.

The Great Moderation, the period of stable economic activity that occurred between 1984 and 2008, features a sharp decline in volatility at the traditional business cycle frequency, but little volatility change at low frequencies. Similarly, the Great Recession and its aftermath feature a large, low frequency component. These data suggest that the Great Recession was not just a recession per se. Instead, much of this event appears to be a persistent decline in aggregate economic activity.

Following the decomposition of data into low and high frequency components, we report the results of quantitative-theoretic analyses that evaluate how well neoclassical models account for the US historical macroeconomic record from 1929 to 2014.

Our main finding is that neoclassical models can account for much of the movement in aggregate economic activity in the US economic historical record. Neoclassical models plausibly account for major economic episodes that previously were considered to be far beyond their reach, including the Great Depression and World War II. We also find that neoclassical models account for much of the post-Korean War history of the United States.

The chapter is organized as follows. Section 2 presents the United States and European data that we use in this study, and provides a decomposition of the data into low frequency and business cycle frequency components. Section 3 introduces the basic neoclassical macroeconomic model that serves as the foundation for all other models developed in the chapter. Section 4 presents one-, two-, and three-sector *simple neoclassical model* analyses of the post-Korean War US economy. Section 5 presents *extended neoclassical models* to study Depressions. Section 6 presents *extended neoclassical models* with fiscal policies with a focus on the US economy during World War II. Given the importance of productivity shocks in neoclassical models, Section 7 discusses different frameworks for understanding and interpreting TFP changes. Given the recent interest in economic inequality, Section 8 discusses neoclassical models of wage inequality. Section 9 presents a critical assessment of neoclassical models, and suggests future research avenues for neoclassical macroeconomic analysis. Section 10 presents our conclusions.

2. THE IMPORTANCE OF LOW FREQUENCY COMPONENTS IN MACROECONOMIC DATA

It is common practice in applied macroeconomics to decompose time series data into specific components that economists often refer to as *cyclical components, trend components*, and *seasonal components*, with the latter component being relevant in the event that data are not seasonally adjusted. These decompositions are performed to highlight particular features of data for analysis. The most common decomposition is to extract the cyclical component from data for the purpose of business cycle analysis, and the HP filter is the most common filtering method that is used.

Band-pass filters, which feature a number of desirable properties, and which resolve some challenges involved with applying the HP filter, are increasingly being used to filter data.[a] Band-pass filtering allows researchers to choose components that correspond to periodicities over a specific data frequency. An exact band pass filter requires an infinite length of data, so Baxter and King (1999) and Christiano and Fitzgerald (2003) have constructed approximate band pass filters. These two approaches are fairly similar. The main difference is that the Baxter–King filter is symmetric, and the Christiano–Fitzgerald filter is asymmetric.

This section presents decompositions of aggregate data into different frequency components for (i) US post-Korean War quarterly data, (ii) US annual data that extends back to 1890, and (iii) post-World War II annual European data. We use the Baxter–King filter, given its wide use in the literature. The band pass filter isolates cyclical components in data by smoothing the data using long moving averages of the data. Baxter and King develop an approximate band pass filter that produces stationary data when applied to typical economic time series.[b] Since the exact band pass filter is an infinite order process, Baxter and King construct a symmetric approximate band pass filter. They show that the optimal approximating filter for a given maximum lag length truncates the filter weight at lag K as follows:

$$y_t^* = \sum_{k=-K}^{K} a_k y_{t-k} \tag{1}$$

In (1), y^* is the filtered data, y is the unfiltered data, and the a_k denote coefficients that produce the smoothed time series. The values of the a_k coefficients depend on the filtering frequency (see Baxter and King, 1999).

Following early work on business cycles by Burns and Mitchell (1946), Baxter and King study business cycles, which they define as corresponding to periodicities associated with 6–32 quarters. In contrast, we use the band-pass filter to consider a much broader range of frequencies up to 200 quarters. Our choice to extend the frequency of analysis to 200 quarters is motivated by Comin and Gertler (2006), who studied these lower frequencies in a model with research and development spending.

We consider much lower frequencies than in the business cycle literature since changes in technologies and government policies may have a quantitatively important effect on low frequency movements in aggregate data. Relatively little is known about the nature and size of these low frequency fluctuations, however, or how these low frequency fluctuations compare to business cycle fluctuations. We therefore band-pass filter data between 2 and 200 quarters, and we split these filtered data into two components:

[a] In terms of the challenges with the HP filter, it is not clear how to adjust the HP smoothing parameter to assess data outside of the cyclical window originally studied by Hodrick and Prescott (1997). Moreover, HP-filtered data may be difficult to interpret at data endpoints.

[b] The Baxter–King filter yields stationary time series for a variable that is integrated of up to order two. We are unaware of any macroeconomic time series that is integrated of order three or higher.

a 2–32 quarters component, which approximates the business cycle results from the standard parameterization of the HP filter ($\lambda = 1600$), and a 32–200 quarters component. This allows us to assess the relative size and characteristics of these fluctuations. To our knowledge, these comparative decompositions have not been constructed in the literature.

2.1 Band-Pass Filtered Quarterly US Data

This section analyzes US quarterly post-Korean war data from 1954 to 2014, which facilitates comparison with much of the business cycle literature. We then analyze annual US data extending back to 1890, followed by an analysis of postwar European data.[c]

Figs. 1–6 show filtered real GDP, consumption of nondurables and services, gross private domestic investment, hours worked, total factor productivity (TFP), and the relative price of capital equipment. Real GDP, consumption, and investment are from the NIPA.

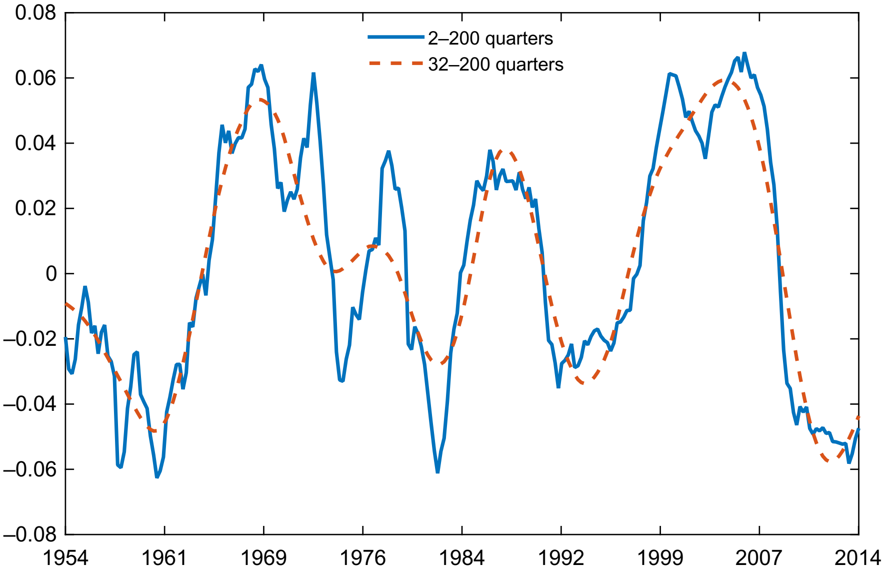

Fig. 1 Log of real GDP.

[c] The Baxter–King filter loses data at the beginning and the end of a dataset. We therefore padded all the data series at both the starting and ending dates by simulating data from ARMA models fit to each series. These simulated data extend the series before the starting date and after the end date, which allows us to construct filtered data for the entire period length. We conducted a Monte Carlo analysis of this padding procedure by generating extremely long artificial time series, and comparing band-pass filtered series using the padded data, to filtered data that doesn't use padding. The length of the data padding is equal to the number of moving average coefficients, k. We use $k = 50$ for the quarterly data, and $k = 12$ for the annual data. The results were insensitive to choosing higher values of k.

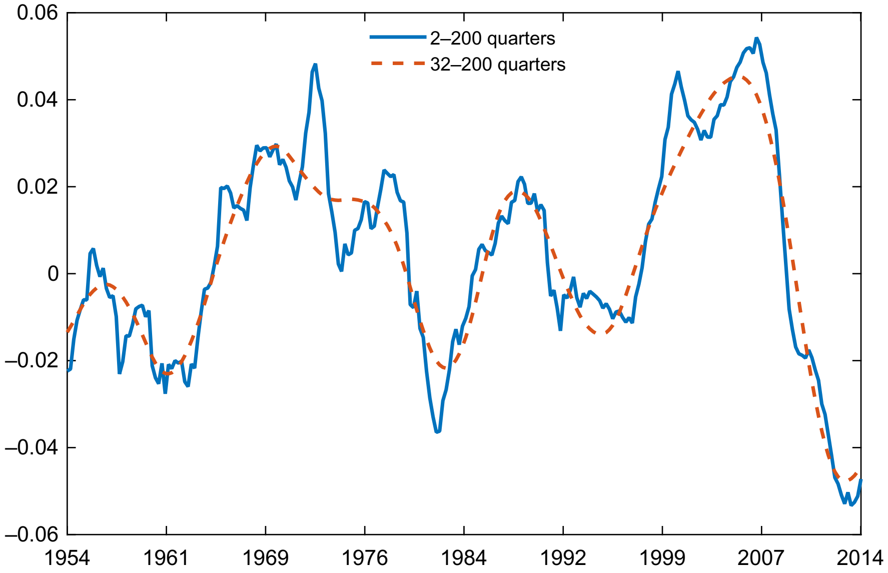

Fig. 2 Log of consumption of nondurables and services.

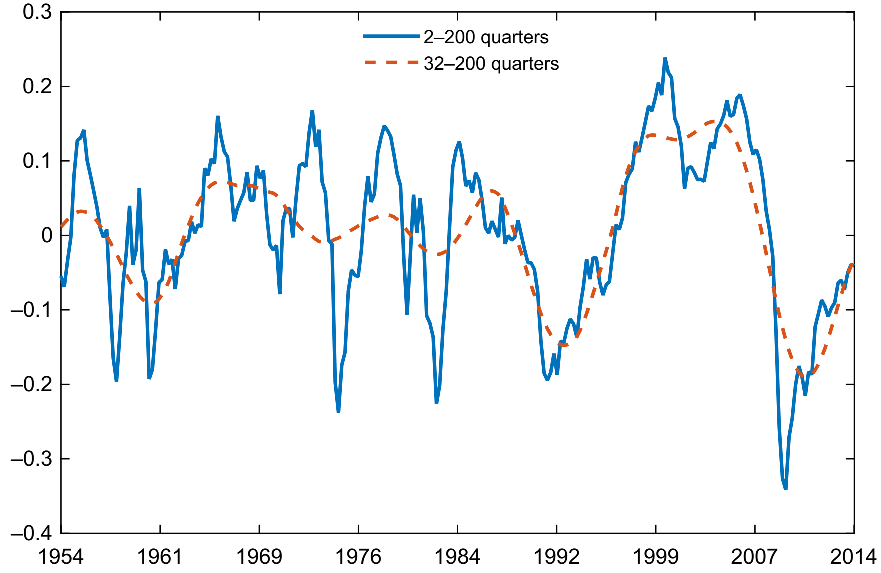

Fig. 3 Log of fixed investment.

Hours worked is constructed by updating the hours worked data of Cociuba et al. (2012), who use hours from the Current Population Survey. TFP is constructed by dividing real GDP by a Cobb–Douglas aggregate of capital, which is the sum of private and public capital stocks, and which has a share of 0.4, and hours worked, which has a share of 0.6.

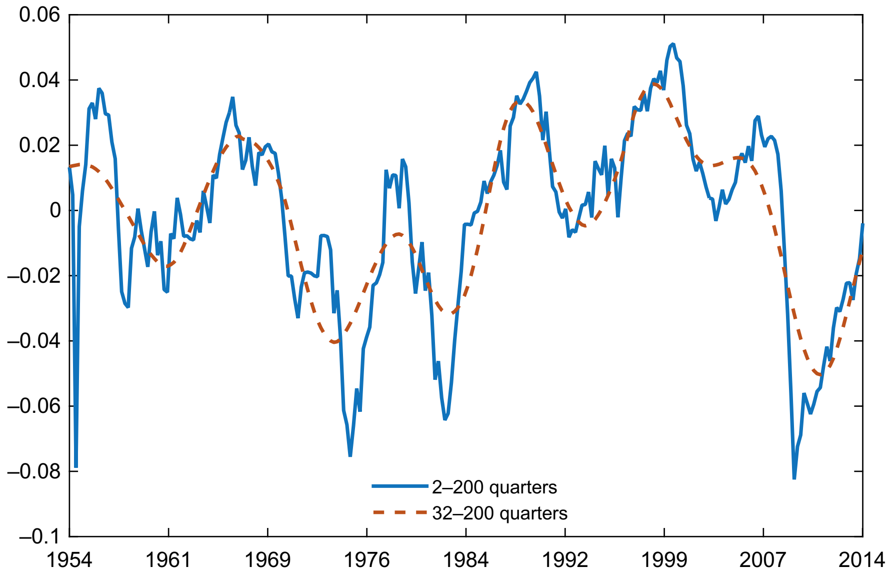

Fig. 4 Log of total hours worked.

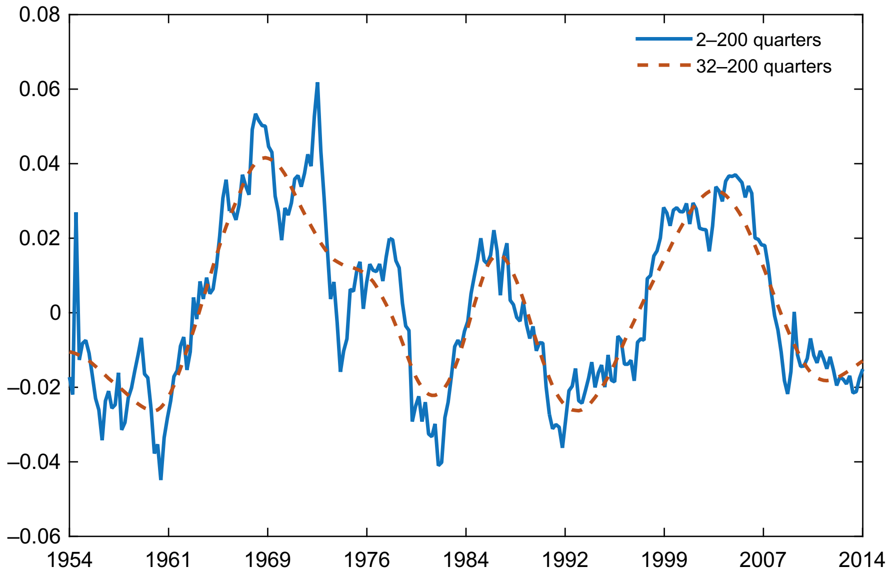

Fig. 5 Log of total factor productivity.

We include the relative price of capital equipment in this analysis because there is a large change in this relative price over time, and because the inverse of this relative price is a measure of equipment-specific technological change in some classes of models, including Greenwood et al. (1997) and Krusell et al. (2000). We construct the relative price of

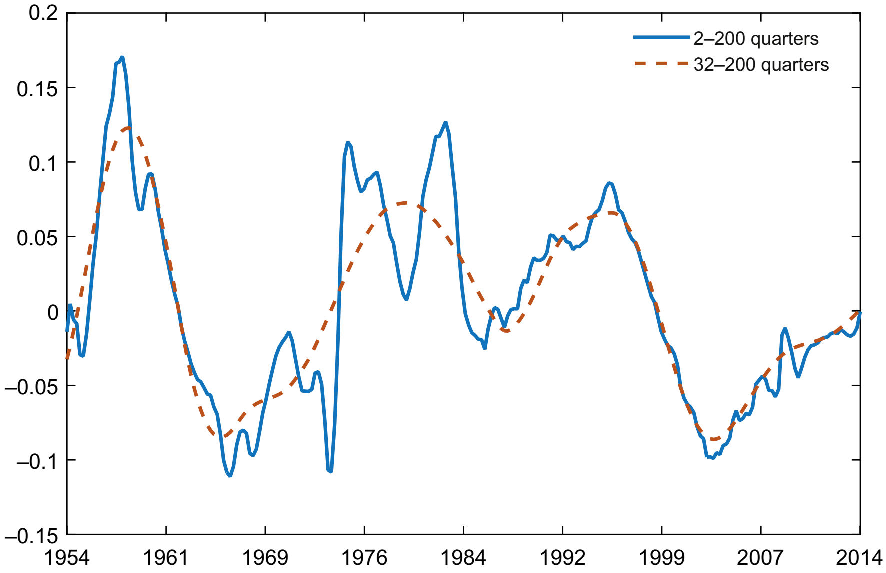

Fig. 6 Log of relative price of equipment.

equipment as the ratio of the quality-adjusted deflator for producer durable equipment, to the NIPA nondurable consumption deflator. Gordon (1990) initially constructed the quality-adjusted equipment deflator, and this time series has been continued in Cummins and Violante (2002) and in DiCecio (2009).[d]

The figures show the 2–200 component and the 32–200 component. Since the band pass filter is a linear filter, the difference between these two lines is the 2–32 component. The most striking feature of all of these filtered data is that much of the movement in the 2–200 component is due to the 32–200 component. These filtered data indicate that business cycle variability, as typically measured, accounts for a relatively small fraction of the overall post-Korean war history of US economic variability. The graphs do show that there are some periods in which the traditional business cycle component is sizeable. This occurs during part of the 1950s, which could be interpreted as the economy readjusting to peacetime policies following World War II and the Korean War. There is also a significant 2–32 component from the 1970s until the early 1980s.

[d] We do not use the NIPA equipment deflator because of Gordon's (1990) argument that the NIPA equipment price deflator does not adequately capture quality improvements in capital equipment. We use DiCecio's (2009) updating of the Gordon–Cummins–Violante data. This data is updated by DiCecio on a real time basis in the Federal Reserve Bank of St. Louis's FRED database (https://research.stlouisfed.org/fred2/series/PERIC). The mnemonic for this series is PERIC.

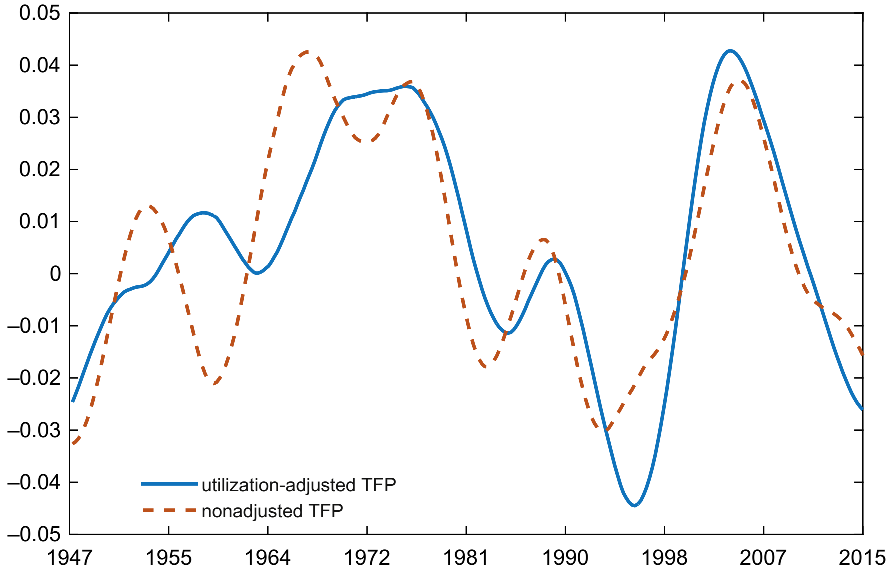

Fig. 7 Fernald TFP (filtered 32–200 quarters).

The 32–200 component of TFP has important implications for the common critique that TFP fluctuations at the standard HP frequency are affected by unmeasured cyclical factor utilization. Fernald's (2014) TFP series is a widely used measure of TFP that is adjusted for unmeasured factor utilization. Fig. 7 shows the 32–200 component of Fernald's adjusted and unadjusted measures of business sector TFP. The long-run components of the adjusted and unadjusted series are very similar, particularly over the last 40 years. This indicates that unmeasured factor utilization is not an issue for measuring TFP at these lower frequencies.

To quantify the relative contribution of the 32–200 component for these variables, we construct the following ratio, which we denote as z_i, in which x_i is the 32–200 filtered component of variable i, and y_i is the 2–200 filtered component of variable i :

$$z_i = \sum_t \frac{(x_{it})^2}{(y_{it})^2} \tag{2}$$

On average, the 32–200 component accounts for about 80% of the fluctuations in output, consumption, TFP, and the relative price of equipment and about 64% of hours. It accounts for about 56% of fluctuations in gross private domestic investment, which includes the highly volatile category of inventory change.

The 32–200 component is also large during the Great Moderation. Specifically, the well-known volatility decline of the Great Moderation, which is typically dated from

1984 to 2007, is primarily due to lower volatility of the 2–32 component. The figures show that the volatility of the 32–200 component remains quantitatively large during the Great Moderation. This latter finding may reflect the large and persistent technological advances in information processing and communications that occurred throughout this period.

This finding regarding the nature of these frequency components in the Great Moderation is consistent with the conclusions of Arias et al. (2007) and Stock and Watson (2003), who report that the traditional business cycles frequency shocks that affected the economy during this period were smaller than before the Great Moderation. This finding about the Great Moderation may also reflect more stable government policies that reduced short-run variability. Taylor (2010) has argued that more stable monetary policy is important for understanding the Great Moderation.

The 32–200 component is also important for the Great Recession and its aftermath. This largely reflects the fact that there has been limited economic recovery relative to long-run trend since the Great Recession.

2.2 Band-Pass Filtered Annual US and European Data

This section presents band-pass filtered annual long-run US data and annual European data. The output data were constructed by splicing the annual Kuznets–Kendrick data (Kendrick, 1961) beginning in 1890, with the annual NIPA data that begins in 1929. The annual Kendrick hours data, which also begins in 1890, is spliced with our update of the hours worked data from Cociuba et al. (2012). These constructions provide long annual time series that are particularly useful in measuring the low frequency components.

Figs. 8 and 9 show the filtered annual US data. The low frequency component, which is measured using the band pass filter from 8 to 50 years for these annual data, is also very large. Extending the data back to 1890 allows us to assess the importance of these different components around several major events, including the Panic of 1907 and World War I. The data show that both the Depression and World War II were dominated by lower frequency components, while the traditional business cycle component was significant during World War I and the Panic of 1907.

The large low frequency component of World War II stands in contrast to World War I, and also stands in contrast to standard theoretical models of wartime economies. These models typically specify wars as a highly transient shock to government purchases. The low frequency component is also large for the Great Depression. Sections 5 and 6 develop neoclassical models of Depressions and of wartime economies, in which both of these events are driven by persistent changes in government policies.

The decomposition ratio presented in (2), and that was used to construct the share of variation in the 2–200 quarter component due to the 32–200 quarter component, is used in a similar way to construct the share of variation in the 2–50 year component due to the

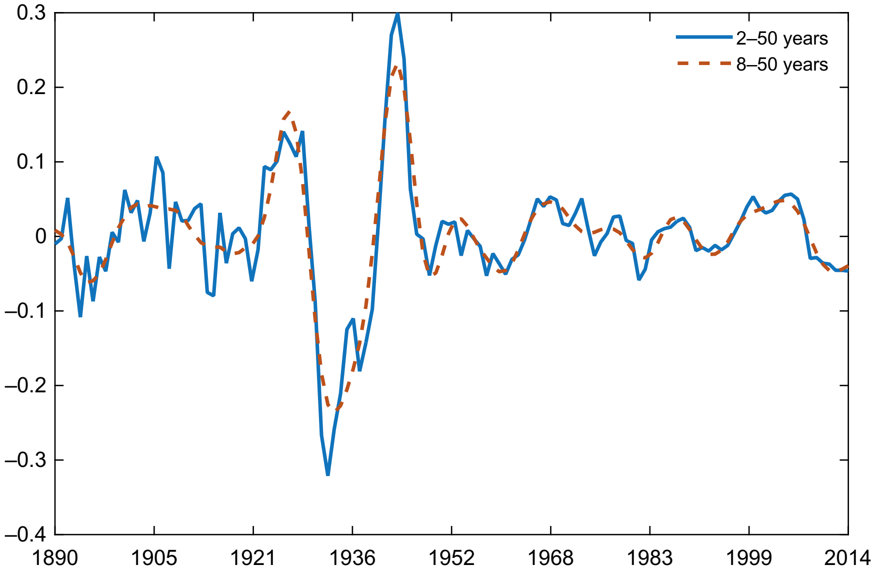

Fig. 8 Annual log of real GDP.

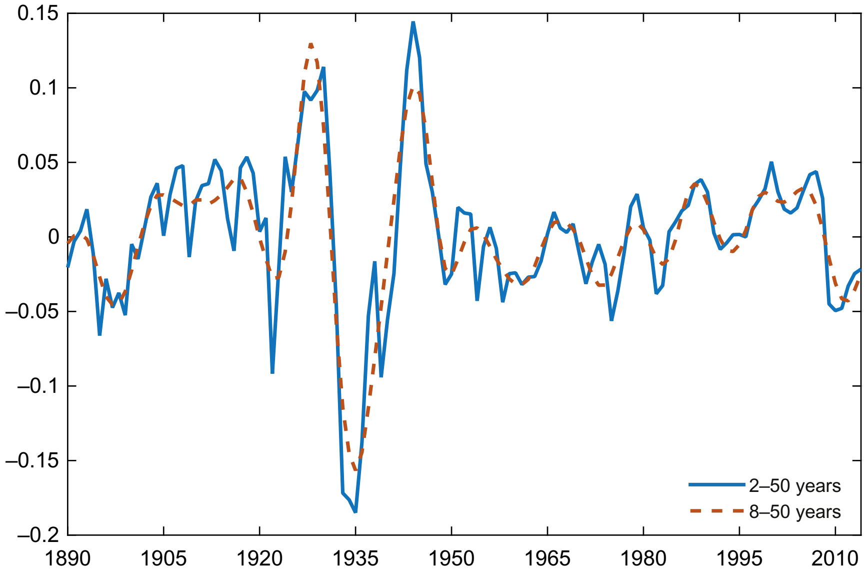

Fig. 9 Annual log of hours worked.

8–50 year component. This low frequency component share is also large in the annual data, ranging between 80% and 85% for real GNP and hours worked.

We also construct the decomposition using annual postwar logged real output data from several European economies: Germany, France, Italy, Spain, and Sweden.

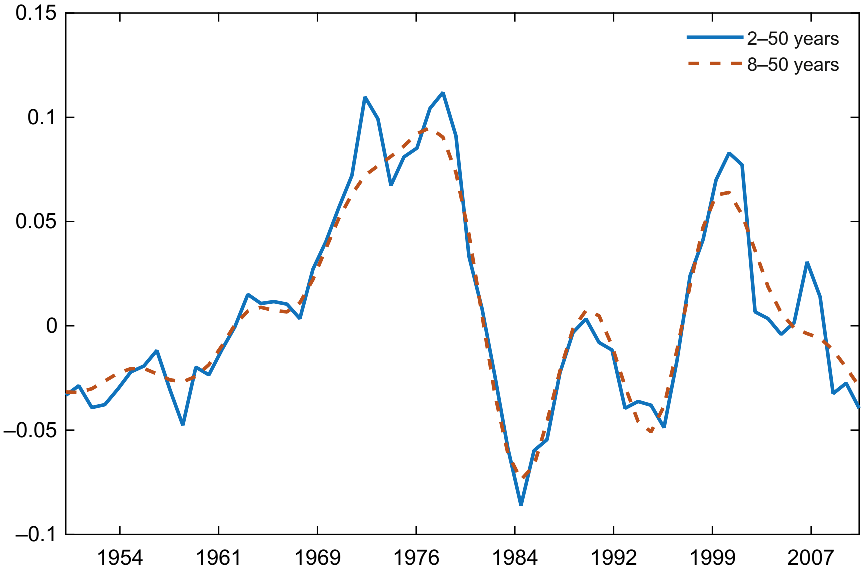

Fig. 10 Log of real GDP—France.

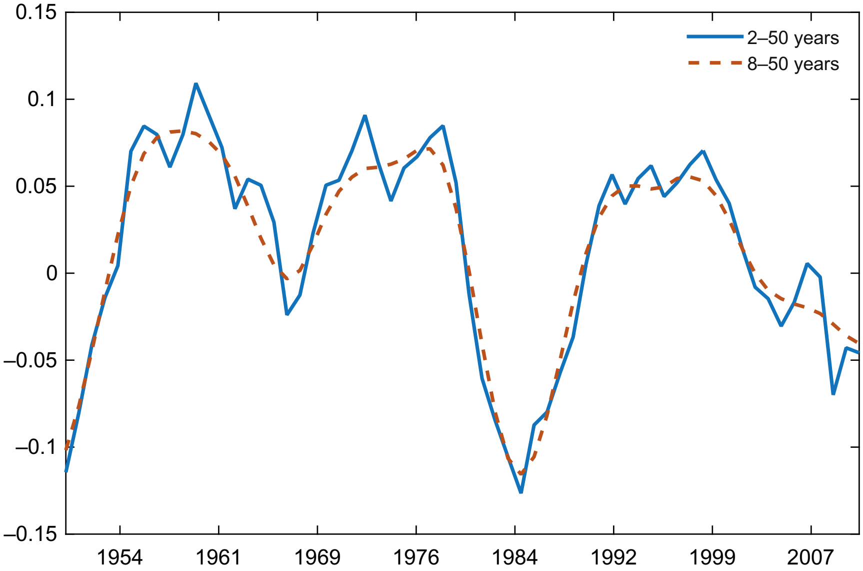

Fig. 11 Log of real GDP—Germany.

These data are from the Penn World Tables (Feenstra et al., 2015). Figs. 10–14 present the filtered data. Most of the variation in the European output data in the 2–50 year component also is accounted for by the low frequency (8–50) component. The long-run European components reflect clear patterns in these data. All of the European economies

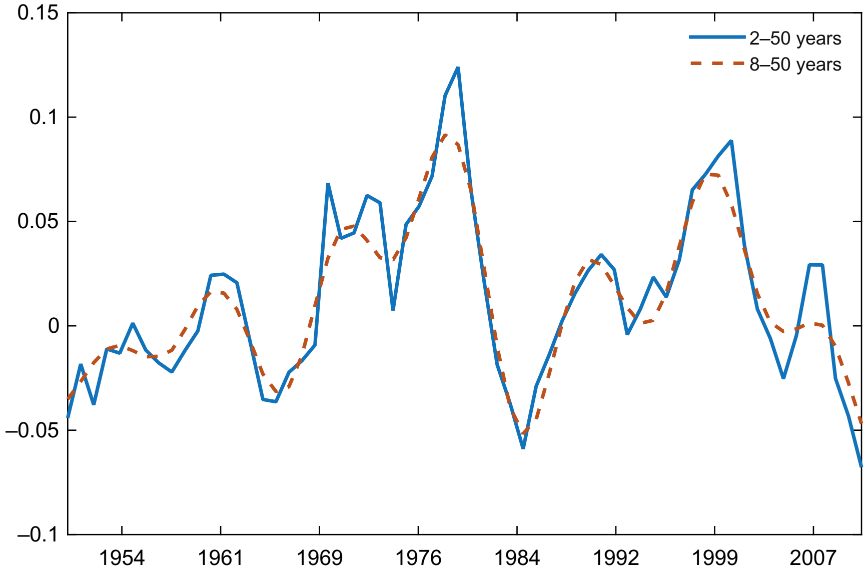

Fig. 12 Log of real GDP—Italy.

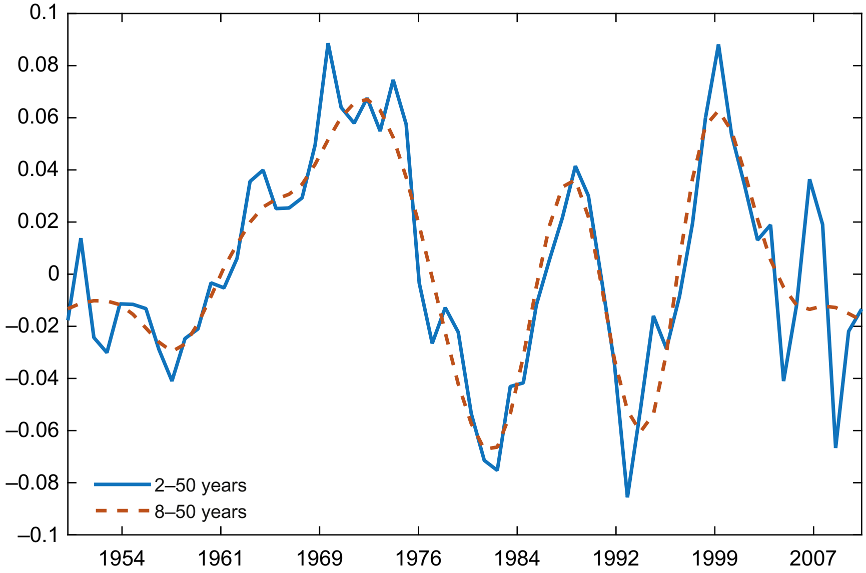

Fig. 13 Log of real GDP—Spain.

grow more rapidly than the US during the 1950s and 1960s. All of these economies then experience large declines relative to trend that begin in the early 1970s and continue to the mid-1980s. The share of the 2–50 component that is accounted for by the 8–50 component is about 80% for Germany, France, Spain, and Sweden, and is about 71% for Italy.

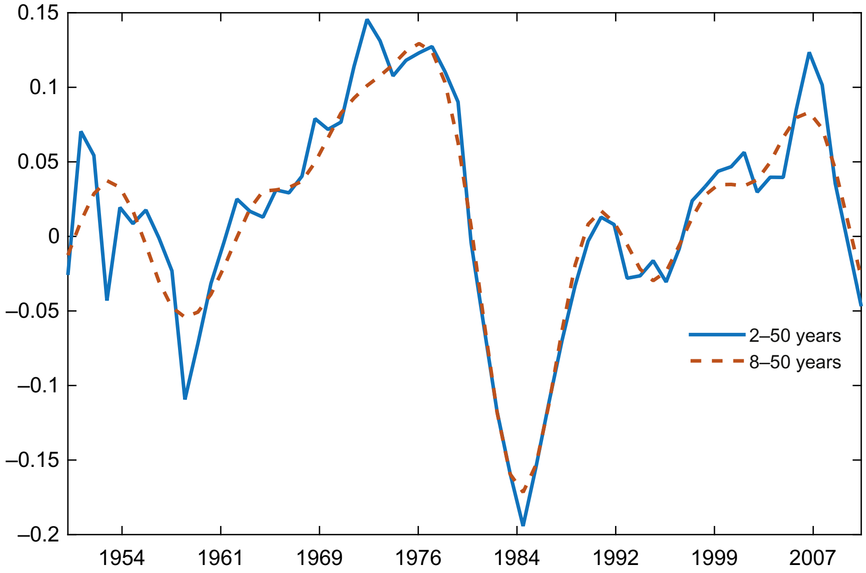

Fig. 14 Log of real GDP—Sweden.

2.3 Alternative to Band-Pass Filtering: Stochastic Trend Decomposition

This section presents an alternative decomposition method, known as stochastic trend decomposition, for assessing the relative importance of low frequency components. One approach to stochastic trend decompositions was developed by Beveridge and Nelson (1981), and is known as the Beveridge–Nelson decomposition. Watson (1986) describes an alternative approach, which is known as unobserved components model decomposition. In both frameworks, a time series is decomposed into two latent objects, a stochastic trend component, and a stationary component, which is often called the cyclical component.

Decomposing the time series into these latent components requires an identifying restriction. The Beveridge–Nelson identifying restriction is that the two components are perfectly correlated. This identifying assumption is thematically consistent with our view that permanent changes in technologies and policies generate both stationary and permanent responses in macroeconomic variables.[e]

[e] The unobserved components models have traditionally achieved identification of the two latent components by imposing that the trend and stationary components are orthogonal. More recently, Morley et al. (2003) show how to achieve identification in unobserved components models with a nonzero correlation between the two components. Morley et al. find that the decomposition for real GDP for their unobserved components model is very similar to the Beveridge–Nelson decomposition. They also present evidence that the zero correlation identifying restriction that traditionally has been used in unobserved components models is empirically rejected.

The Beveridge–Nelson decomposition, which is simple and widely used, is applied in this chapter. The Beveridge–Nelson statistical model begins with a variable that is assumed to have a stochastic trend component. The variable may also have a drift term, which drives secular growth in the variable. The Beveridge–Nelson decomposition removes the drift term, and then decomposes the variable, which we denote as y_t, into a stochastic trend component, x_t and a stationary stochastic component, s_t. The stochastic trend is a random walk, and the innovation term, which is denoted as ε_t, is a white noise process:

$$y_t = x_t + s_t \tag{3}$$

$$x_t = x_{t-1} + \varepsilon_t, E(\varepsilon) = 0, E(\varepsilon^2) = \sigma_\varepsilon^2 \tag{4}$$

This decomposition is applied to the log of US real GDP. The decomposition first requires specifying an ARIMA model for the data. We selected an ARIMA (0,1,1) model for the log of real GDP, given that the first three autocorrelations of the first difference of the logged data are 0.34, 0.19, and 0.06. Stock and Watson (1988) also use this ARIMA specification for the log of real output. The estimated statistical model for the log of real GDP using quarterly data between 1954:1 and 2013:4 is given by:

$$\Delta \ln(GDP_t) = 0.0077 + \varepsilon_t + 0.40\varepsilon_{t-1}. \tag{5}$$

These estimated coefficients are similar to the Stock and Watson estimates that were based on a shorter dataset. Stock and Watson estimated a slightly higher drift term of about 0.008, and a somewhat smaller moving average coefficient of 0.30 rather than 0.40.

Using the Wold decomposition, Beveridge and Nelson show that the permanent component for this estimated statistical model is given by:

$$1.4 * \sum_{j=1}^{t} \varepsilon_j \tag{6}$$

Fig. 15 plots the detrended log of real GDP, which is constructed as the log of real GDP less its accumulated drift component, and the Beveridge–Nelson permanent component of these detrended data. The figure shows that almost all of the movement in detrended real GDP is due to the permanent component, rather than the transitory component. This finding is consistent with the band-pass filtered results regarding the large size of the long-run component.

The results presented in this section show that the bulk of observed fluctuations in aggregate time series are from longer-run changes than those associated with traditional business cycle frequencies. This finding motivates our focus on neoclassical models that are driven by long-run changes in technologies and policies, as opposed to models that are driven by very transient shocks, such as monetary shocks that operate in models with temporarily inflexible prices and/or wages.

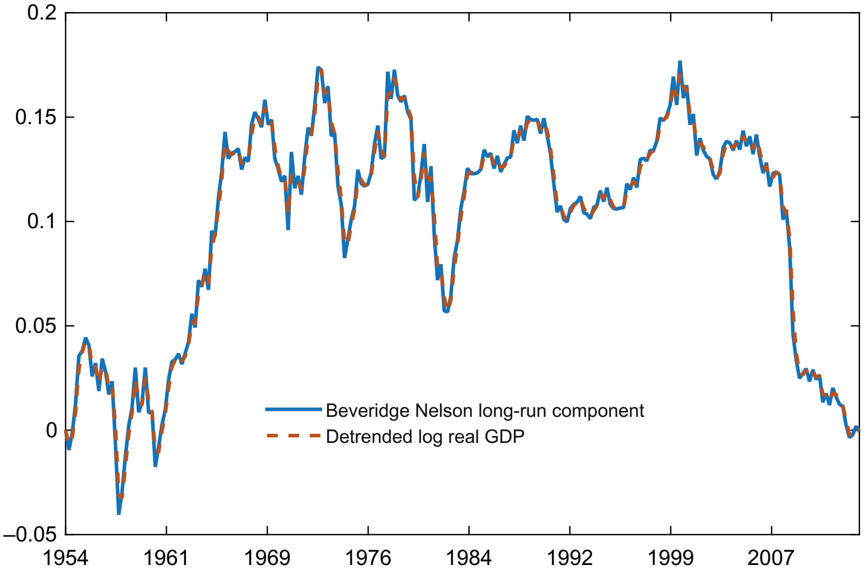

Fig. 15 Beveridge–Nelson decomposition of real GDP.

3. CASS-KOOPMANS: THE FOUNDATION OF SIMPLE MODELS

This section summarizes the one-sector Cass-Koopmans optimal growth model with elastically supplied leisure, as it serves as the foundation for the other models that are developed in this chapter. This model features (1) standard utility maximization problems for households, and standard profit maximization problems for firms, both of whom behave competitively and who have rational expectations, (2) complete markets, (3) a unique and Pareto optimal equilibrium, and (4) constant returns to scale technology.

Since the welfare theorems hold in this economy, we express this model as a social planning problem. For heuristic purposes, we assume perfect foresight. The planner's maximization problem is given by:

$$\max \beta^t \sum_{t=0}^{\infty} u(c_t, l_t). \tag{7}$$

Maximization is subject to the economy's resource constraint, a household time constraint, a transition equation for the capital stock, and nonnegativity constraints on consumption, hours, and capital:

$$f(k_t, h_t) \geq c_t + i_t \tag{8}$$

$$1 \geq h_t + l_t \tag{9}$$

$$k_{t+1} = (1-\delta)k_t + i_t \tag{10}$$

$$c_t \geq 0, h_t \geq 0, k_t \geq 0, k_0 \text{ given.} \tag{11}$$

It is also necessary to impose the transversality condition to rule out explosive paths for the capital stock:

$$\lim_{t \to \infty} \beta^t u_1(c_t, l_t) f_1(k_t, h_t) k_t = 0 \tag{12}$$

The utility function satisfies the usual restrictions: it is concave in its arguments and twice continuously differentiable. The technology, *f*, is constant returns to scale in the two inputs capital, *k*, and labor, *h*, and is also twice continuously differentiable.

We will tailor the construction of different neoclassical models to focus on policies and technological change that we highlight for specific historical episodes. This should not be confused with the idea that fundamentally different models are needed to address different time periods in the history of the US economy. Rather this means that the relative importance of different policies and different types of technological change has varied over time. Specifically, this includes the importance of biased technological change for understanding the post-Korean War US history, cartelization and unionization government policies for understanding the 1930s, and changes in government fiscal policies for understanding the 1940s.

4. NEOCLASSICAL MODELS OF THE US POST-KOREAN WAR ECONOMY

In this section we present a series of neoclassical models, driven by permanent changes in technologies to study the post-Korean War US economy. Our approach, which we describe in detail below, compares the equilibrium paths of the model economies in response to identified shocks, to the actual time series data. We will compare model results to unfiltered data, and also to the three different filtering frequencies described in Section 2. In addition to evaluating the fit of the model for the raw data, this will allow us to assess how well the model matches data at the traditional business cycle frequencies (2–32 quarters), and also at low frequencies (32–200) quarters.

4.1 Quantitative Methodology

Neutral technological change that affects all sectors identically is the standard specification of technology in neoclassical macroeconomic models. However, there is a growing body of evidence that technological change is advancing much more quickly in the information processing sectors of the economy, particularly in capital equipment. This includes the areas of computer hardware, computer peripherals, photocopying equipment and telecommunications equipment, among others.

As described earlier in this chapter, Gordon (1990), Cummins and Violante (2002), and DiCecio (2009) construct capital equipment price data that they argue captures much more of the quality change that has occurred in these goods than is present in the NIPA equipment price data. Fig. 16 shows the relationship between real GDP

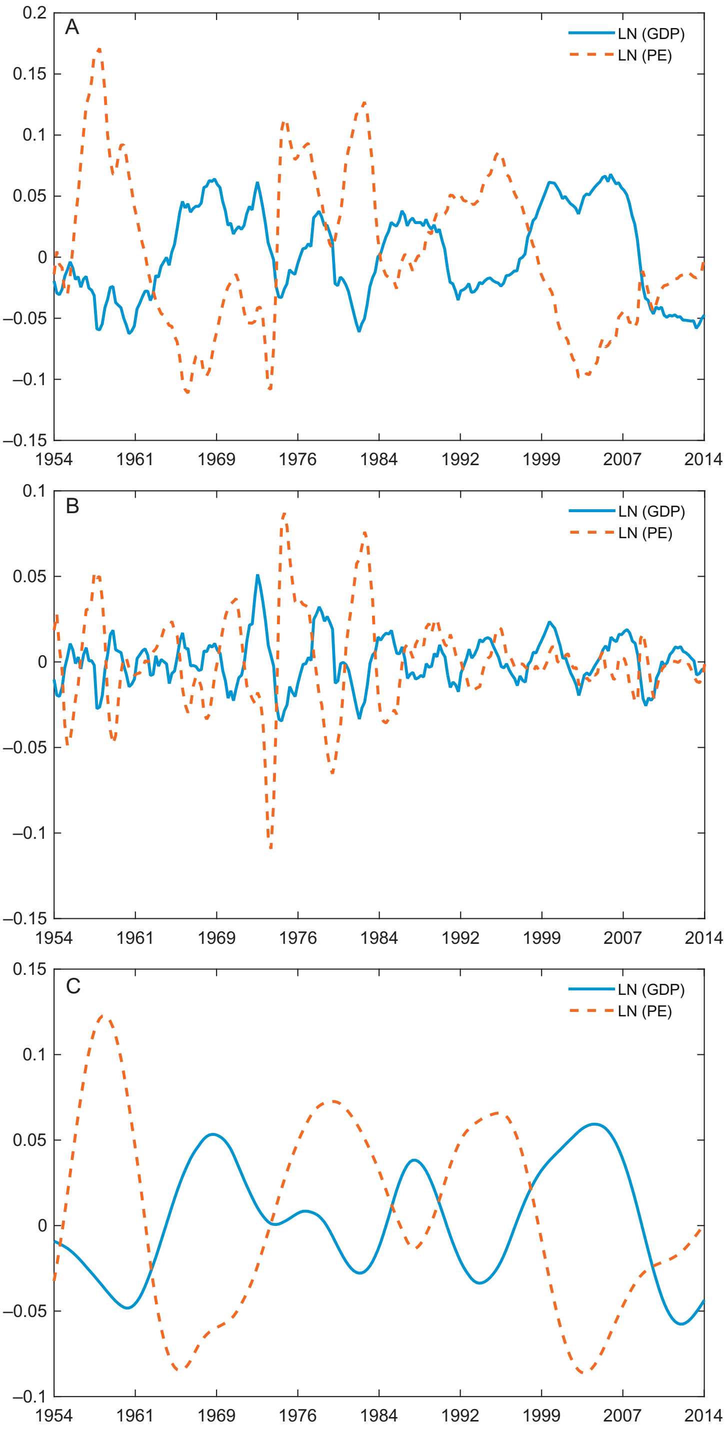

Fig. 16 Filtered GDP and the relative price of equipment. (A) 2–200 quarters. (B) 2–32 quarters. (C) 32–200 quarters.

and the relative price of equipment at the three sets of frequencies that we consider. These figures show that the relative price of equipment is strongly countercyclical at all frequencies.

These strong countercyclical patterns are interesting as a growing number of neoclassical studies are using these data to identify capital-equipment specific technological change. The following sections develop multisector growth models that include both neutral and equipment-specific technological change to study the evolution of the post-Korean War US economy. This is a particularly interesting period for applying multisector models with biased technological change since this period features a number of major advances in information processing and telecommunications technologies, including the integrated circuit, personal computers and tablet technologies, fiber optics, software applications, cellular technologies, and the internet.

Focusing on this period also allows us to connect this analysis with the large business cycle literature, including Kydland and Prescott (1982), Hansen (1985), and the studies in Cooley (1995), which have analyzed the post-Korean War US economy. Note that the post-Korean War period also includes a number of interesting subperiods: the Vietnam War (1957–71), the oil shock years (1974–81), the Great Moderation (1984–2007), and the Great Recession and its aftermath (2008–present).

Our quantitative approach differs from the standard approach used in the real business cycle literature. The real business cycle approach specifies a dynamic stochastic general equilibrium model, which includes a specification of the stochastic process for the exogenous shocks that generate fluctuations in the model economy. The equilibrium decision rules and laws of motion are computed using numerical methods, and these equations plus a random number generator are used to simulate time series for the artificial economy. Summary statistics are then computed and compared with the same summary statistics computed from actual US time series.

The approach we follow is similar to that employed in Hansen and Prescott (1993). We begin with a two-sector growth model in which movements in aggregate time series are the result of two factors we identify from US data that we take to be the exogenous forcing processes in the model. These include technology shocks that are identified with total factor productivity and equipment specific technological change, which we identify from the relative price of equipment. We then calibrate and solve the model in a manner consistent with the real business cycle literature. But, rather than drawing random realizations of the exogenous shock processes, we identify time paths for our two technology shocks from US time series data. We then compute the equilibrium time paths for the endogenous variables (output, consumption, investment and hours worked) using the actual time path of the exogenous shocks. As noted above, we compare model variables to quarterly real variables for the unfiltered data over 1954–2014, as well as for frequency bands corresponding to 2–200, 2–32, and 32–200 quarters.

After comparing the time paths from the two-sector model with the corresponding time paths from US data, we then compare these time paths with those of a standard one-sector neoclassical model in which neutral technology shocks are the only exogenous process hitting the economy. We then consider a three-sector model that adds a nonmarket home production sector to our baseline two-sector model. This extension allows us to study how equipment biased technological change may have induced movements in labor from the home production sector to the market sector.

We omit the details of numerically solving these models. Instead, we focus on the specifics of the model economies, the construction of US data counterparts to the model variables, and the calibration that we use in our computational analyses.

In terms of assessing model fit, our approach differs considerably from the recent approach that is used in the New Keynesian literature. In New Keynesian models, such as Smets and Wouters (2007), as many shocks are added to the model as needed so that the model fits all of the data very closely. While this approach delivers a very good model fit, some of the shocks in the model are often difficult to interpret. Our approach to model fit follows from our theme that permanent changes in technologies are key drivers of the economy. The models analyzed in the following sections have very few shocks, which allows us to transparently evaluate the models' successes and deviations.

4.2 A Two-Sector Model with Aggregate and Investment-Biased Technological Change

This section develops a model with investment-specific technological change, as well as aggregate technological change that impacts all sectors equally. This approach was first developed in Greenwood et al. (1997), who document and discuss investment-specific technological change and its impact on long-run growth. Biased technological change has also been used to study wage inequality (Krusell et al., 2000) and business cycles (Fisher, 2006; Justiniano et al., 2010).

The two-sector stochastic growth model we study consists of a primary sector, $i=1$, producing C_{Mt}, which is the sum of consumer services, nondurable consumption and government consumption, and I_{st}, which is investment in structures.[f] The second sector, $i=2$, produces equipment I_{et} and consumer durables I_{dt}. The technologies associated with each sector are as follows:

$$C_{Mt}+I_{st}=Y_{1t}=z_tAK_{e1t}^{\theta_1}K_{s1t}^{\theta_2}H_{1t}^{1-\theta_1-\theta_2} \tag{13}$$

$$I_{dt}+I_{et}=Y_{2t}=q_tz_tAK_{e2t}^{\theta_1}K_{s2t}^{\theta_2}H_{2t}^{1-\theta_1-\theta_2} \tag{14}$$

All variables are measured in per capita terms with a population growth factor η. Here, K_{eit},K_{sit} and H_{it} are equipment, structures and hours worked, each in sector i.

[f] We will also lump investment in intellectual property with investment in structures.

The variables z_t and q_t are technology shocks that impact these sectors. The laws of motion for the stocks of equipment, structures, and durables is given by the following, where $K_{e,t} = K_{e1t} + K_{e2t}$ and $K_{s,t} = K_{s1t} + K_{s2t}$:

$$\eta K_{e,t+1} = (1-\delta_e)K_{et} + I_{et} \tag{15}$$

$$\eta D_{t+1} = (1-\delta_d)D_t + I_{dt} \tag{16}$$

$$\eta K_{s,t+1} = (1-\delta_s)K_{st} + I_{st} \tag{17}$$

The logarithms of the two shocks, z and q, follow random walks with drift.

$$\log z_{t+1} = \log z_t + \varepsilon_{1,t+1}\ ,\ \varepsilon_1 \sim N(\mu_1, \sigma_1^2) \tag{18}$$

$$\log q_{t+1} = \log q_t + \varepsilon_{2,t+1}\ ,\ \ \varepsilon_2 \sim N(\mu_2, \sigma_2^2) \tag{19}$$

The random variables ε_1 and ε_2 are i.i.d. across time and are contemporaneously uncorrelated.

There is a stand-in household who maximizes the expected discounted sum of utility defined over consumption of nondurables and services, the stock of durables, and leisure:

$$\max E_0\left\{\sum_{t=0}^{\infty}(\beta\eta)^t[\alpha\log C_{Mt} + (1-\alpha)\log D_t + \phi\log(1 - H_{1t} - H_{2t})]\right\} \tag{20}$$

Optimality implies that the value marginal product of each input will be equalized across sectors. Given that identical Cobb–Douglas production functions are assumed, this implies the fraction of the total quantity of each input assigned to each sector is the same across inputs. Letting $H_{Mt} = H_{1t} + H_{2t}$, this implies that $\frac{K_{eit}}{K_{et}} = \frac{K_{sit}}{K_{st}} = \frac{H_{it}}{H_{Mt}}$ for $i = 1{,}2$. Given this result, and the fact that the technology is constant returns to scale, it is possible to aggregate over sectors to obtain the aggregate resource constraint:

$$C_{Mt} + I_{st} + \frac{1}{q_t}(I_{dt} + I_{et}) = z_t A K_{et}^{\theta_1} K_{st}^{\theta_2} H_{Mt}^{1-\theta_1-\theta_2} \equiv Y_t \tag{21}$$

Note that in this aggregate resource constraint, the outputs I_d and I_e are divided by q. In the decentralized version of this economy, $\frac{1}{q}$ is the price of equipment goods relative to output from sector 1. This result shows that data on the relative price of equipment can be used to measure equipment-specific technological change.

Given values for K_{e0}, K_{s0} and D_0, the equilibrium stochastic process for this economy can be found by solving the planner's problem maximizing (20) subject to (15)–(19) and (21).

4.2.1 Balanced Growth Path

Due to the positive drift in the random walks (18) and (19), this model exhibits stochastic growth. In a certainty version of the model in which $\sigma_1 = \sigma_2 = 0$, there is a balanced growth path where the asymptotic growth factors are given by $g_c = \frac{Y_{t+1}}{Y_t} = \frac{C_{M,t+1}}{C_{Mt}} = \frac{I_{s,t+1}}{I_{st}} = \frac{K_{s,t+1}}{Kst} = e^{\frac{\mu_1 + \theta_1 \mu_2}{1-\theta_1-\theta_2}}$ and $g_e = \frac{I_{e,t+1}}{I_{et}} = \frac{I_{d,t+1}}{I_{dt}} = \frac{K_{e,t+1}}{Ket} = \frac{D_{t+1}}{D_t} = g_c e^{\mu_2}$. Given these growth factors, the asymptotic growth path can be written $Y_t = g_c^t \bar{Y}$, $H_{Mt} = \bar{H}_M$, $C_{Mt} = g_c^t \bar{C}_M$, $I_{st} = g_c^t \bar{I}_s$, $K_{st} = g_c^t \bar{K}_s$, $I_{et} = g_e^t \bar{I}_e$. $I_{dt} = g_e^t \bar{I}_d$, $K_{et} = g_e^t \bar{K}_e$ and $D_t = g_e^t \bar{D}$, where the steady state values are the solutions to the following equations (given $\bar{q}$ and $\bar{z}$):

$$\frac{g_c}{\beta} = \theta_2 \frac{\bar{Y}}{\bar{K}_s} + 1 - \delta_s \tag{22}$$

$$\frac{g_e}{\beta} = \theta_1 \frac{\bar{Y} \ \bar{q}}{\bar{K}_e} + 1 - \delta_e \tag{23}$$

$$\frac{g_e}{\beta} = \frac{(1-\alpha)\bar{C}_M \ \bar{q}}{\alpha \bar{D}} + 1 - \delta_d \tag{24}$$

$$\frac{\phi}{1 - \bar{H}_M} = \alpha(1 - \theta_1 - \theta_2) \frac{\bar{Y}}{\bar{H}_M \bar{C}_M} \tag{25}$$

$$\bar{Y} = A \bar{K}_e^{\theta_1} \bar{K}_s^{\theta_2} \bar{H}_M^{1-\theta_1-\theta_2} \tag{26}$$

$$\bar{C}_M = \bar{Y} - \bar{I}_s - \frac{1}{\bar{q}}[\bar{I}_e + \bar{I}_d] \tag{27}$$

$$\bar{I}_s = (\delta_s + \eta g_c - 1)\bar{K}_s \tag{28}$$

$$\bar{I}_e = (\delta_e + \eta g_e - 1)\bar{K}_e \tag{29}$$

$$\bar{I}_d = (\delta_d + \eta g_e - 1)\bar{D} \tag{30}$$

We use this nonstochastic asymptotic growth path to help us calibrate the model and to construct capital stock series that are consistent with the model's balanced growth properties.

4.2.2 Calibrating the Model with US Data

We proceed by connecting each endogenous variable of this model with a counterpart taken from the US National Income and Product Accounts. The data we use runs from

1954Q1 to 2014Q4. On the product side, the model has one nondurable consumption good (C_{Mt}) which we take to be the sum of nondurable consumption, services and government consumption. There are three forms of investment: I_e is the sum of private and government investment in equipment; I_s is the sum of private investment in structures, intellectual property, residential structures, and government investment in structures and intellectual property; and I_d is purchases of consumer durables. Given that we have not allocated every component of Gross Domestic Product to one of these expenditure categories, we take total output to be $Y_t = C_M + I_s + \frac{1}{q}(I_d + I_e)$. The relative price of equipment in our model is equal to $\frac{1}{q_t}$, so we identify q_t from the relative price of equipment calculated by Riccardo DiCecio (see DiCecio, 2009).[g]

The capital stocks, which are the sum of both private and government fixed assets, are computed from annual quantity indexes of fixed assets obtained from the Bureau of Economic Analysis and is the stock associated with each investment series. In particular, K_s is nonresidential and residential structures along with intellectual property, K_e is the stock of equipment, and D is the stock of consumer durables. To obtain quarterly real stocks of capital, the annual quantity indexes are multiplied by the corresponding 2009 nominal value and quarterly series are obtained by iterating on the laws of motion (15)–(17) using the corresponding quarterly investment series.[h] Per capita capital stocks and output are obtained by dividing by the civilian population (16–64) plus military personnel. Finally, the hours series we use is average weekly hours per person (including military hours) based on data from the Current Population Survey. In particular, we have updated the series created by Cociuba et al. (2012).

Given these empirical counterparts, the growth factor for population is $\eta = 1.003$ and the growth factor for per capita output is $g_c = 1.0036$. The parameter $\mu_2 = 0.0104$, which is the average of $\log q_{t+1} - \log q_t$. This implies that $g_e = g_c e^{\mu_2} = 1.014$.

[g] This data series is available on the FRED database maintained by the Federal Reserve Bank of St. Louis.

[h] Given that the model assumes constant depreciation rates, which does not hold in our data sample, we allow the depreciation rate to vary across 10 year periods when constructing the quarterly capital stock series. That is, an initial value for the annual series in year t and a terminal value in year t + 10, we find the depreciation rate such that iterations on the law of motion of the capital stock hits the terminal value in 40 quarters using the corresponding quarterly investment series.

In particular, we find the depreciation rate δ_i for decade i such that $K_{i+10} = (1-\delta_i)^{40} K_i + \sum_{j=1}^{40} (1-\delta_i)^{40-j} I_j$, where K_i is the capital stock at the beginning of year i, K_{i+10} is capital at the beginning of year i + 10, and $\{I_j\}_{j=1}^{40}$ is investment for each quarter between those dates. Once we know δ_i for each subperiod in our sample, it is straightforward to construct quarterly capital stocks for each quarter of year i.

The capital stock obtained, however, is inconsistent with the trend introduced by our empirical measure of q, which is based on different price deflators than those used in producing the NIPA capital stocks. As a result, we also adjust the trend growth of the capital stocks so that these stocks are consistent with long-run growth properties of the model. That is, a trend is added to our quarterly series for K_s so that it has an average growth rate equal to g_c and D and K_e are similarly adjusted to have an average growth factor g_e.

We calibrate the model by setting $\beta = 0.99$, labor's share, $1 - \theta_1 - \theta_2$, equal to 0.6 and the depreciation rates equal to the average of the depreciation rates obtained when forming the quarterly capital stock series. This gives us $\delta_e = 0.021$, $\delta_s = 0.008$, and $\delta_d = 0.05$. The individual capital shares are based on estimates in Valentinyi and Herrendorf (2008) renormalized so they sum to 0.4. In particular, we set $\theta_1 = 0.21$ and $\theta_2 = 0.19$. The parameter α is computed from a version of equation (24) where the term $\frac{\bar{C}_M \ \bar{q}}{\bar{D}}$ is replaced with the average value of $\frac{C_{M,t} \ q_t}{D_t}$ from the empirical counterparts to these variables. This gives $\alpha = 0.817$.

Next, we set $\bar{Y}$, $\bar{H}_M$, and $\bar{q}$ equal to the initial observation in the time series for each of these variables. The seven remaining steady states ($\bar{K}_s$, $\bar{K}_e$, $\bar{D}$, $\bar{I}_s$, $\bar{I}_e$, $\bar{I}_d$, and $\bar{C}_M$) are obtained by solving seven equations (22)–(24) and (27)–(30). So that the steady state capital stocks are equal to the first observations for these variables, we multiply all observations of K_s by $\frac{\bar{K}_s}{K_{s,0}}$, all observations of K_e by $\frac{\bar{K}_e}{K_{e,0}}$ and all observations of D by $\frac{\bar{D}}{D_0}$. These are the capital stocks used to construct the empirical counterpart to z_t.

We construct a quarterly time series for the exogenous shock, z_t, from 1954Q1 to 2014Q4 by setting $z_t = \frac{Y_t}{A K_{et}^{\theta_1} K_{st}^{\theta_2} H_{Mt}^{1-\theta_1-\theta_2}}$ where the parameter A is chosen so that the first observation of z is equal to one. This implies $A = 6.21$. Somewhat surprisingly, the growth rate of z_t when computed in this way turns out to be zero ($\mu_1 = 0$). That is, when measured through the lens of this model, the average rate of growth in per capita income during the postwar period is accounted for entirely by equipment specific technological improvement.

We summarize the calibration of the model in Table 1 in the column labeled "Two sector." This table reports the calibrated parameter values for all models considered, so we will refer back to this table as we discuss these alternatives.

4.2.3 Comparison of Model with Data

Given our time series for z_t and q_t, times series for the endogenous variables of the model are computed for the sample period 1954Q1–2014Q4. This is done using log-linear approximations of the decision rules that solve the planner's problem obtained using standard numerical methods (see, for example, Uhlig, 1999). Fig. 17 shows our measures of output and hours from US data along with the time series for these variables implied by our model.

Output from the data and model are quite close to each other until the mid-1980s when model output becomes lower than in the data. By 2002, however, model output has recovered. Model hours tend to be higher than in the data during the 1960s and 1970s, and lower from the mid-1980s until the Great Recession. Following the Great Recession, the data shows some recovery in hours worked that the model does not.

Table 1 Calibrated parameter values

Parameter description		Two sector	One sector	Three sector (1)	Three sector (2)
Equipment share	θ_1	0.21		0.21	0.21
Structures share	θ_2	0.19		0.19	0.19
Capital share	θ		0.4		
Depreciation rate—Equipment	δ_E	0.021		0.021	0.021
Depreciation rate—Structures	δ_S	0.008		0.008	0.008
Depreciation rate—Durables	δ_D	0.05		0.05	0.05
Depreciation rate—Capital	δ		0.013		
Growth rate—z	μ_1	0		0	0
Growth rate—q	μ_2	0.0104		0.0104	0.0104
Growth rate—z	μ		0.0021		
Population growth factor	η	1.003	1.003	1.003	1.003
Discount factor	β	0.99	0.99	0.99	0.99
Utility share for mkt. consumption	α	0.82		0.33	0.53
Utility parameter for leisure	ϕ	2.37	2.37	1.19	1.19
Scale parameter—Market production	A	6.21	2.7	6.21	6.21
Elasticity parameter—Home production	σ			0	0.4
Elasticity parameter—Mkt./non-mkt. cons.	ω			0.6	0
Durable share—Home production	φ			0.25	0.13
Scale parameter—Home production	A_N			4.19	4.87

Three sector (1)—Standard home production
Three sector (2)—Calibration inspired by Greenwood et al. (2005)

Fig. 18 consists of four panels showing output, hours, consumption and investment—from both the model and the data—that has been filtered to show only fluctuations between 2 and 32 quarters. The real business cycle literature has demonstrated that neoclassical models of this sort generate fluctuations similar to those in postwar US data at this frequency. As the figure illustrates, this is particularly true for output and investment.

Less studied, however, are the low frequency fluctuations exhibited by models of this sort. Fig. 19 is a plot of model and US data for the same four variables that has been filtered to show fluctuations between 32 and 200 quarters. The model seems to do a pretty good job in tracking fluctuations in output, consumption and investment in this frequency band. For hours worked, the model captures some of the low frequency movements, but not others. In the late 1950s, the model shows hours falling sooner than it does in the data, while the model and data track pretty closely during the 1960s and early 1970s. In the late 1970s, the data shows an increase in hours worked that the model does not capture, but the model and data follow each other throughout the 1980s and 1990s. At the time of the Great Recession, the decline in hours—as well as other macro aggregates—is less in the model than in the data.

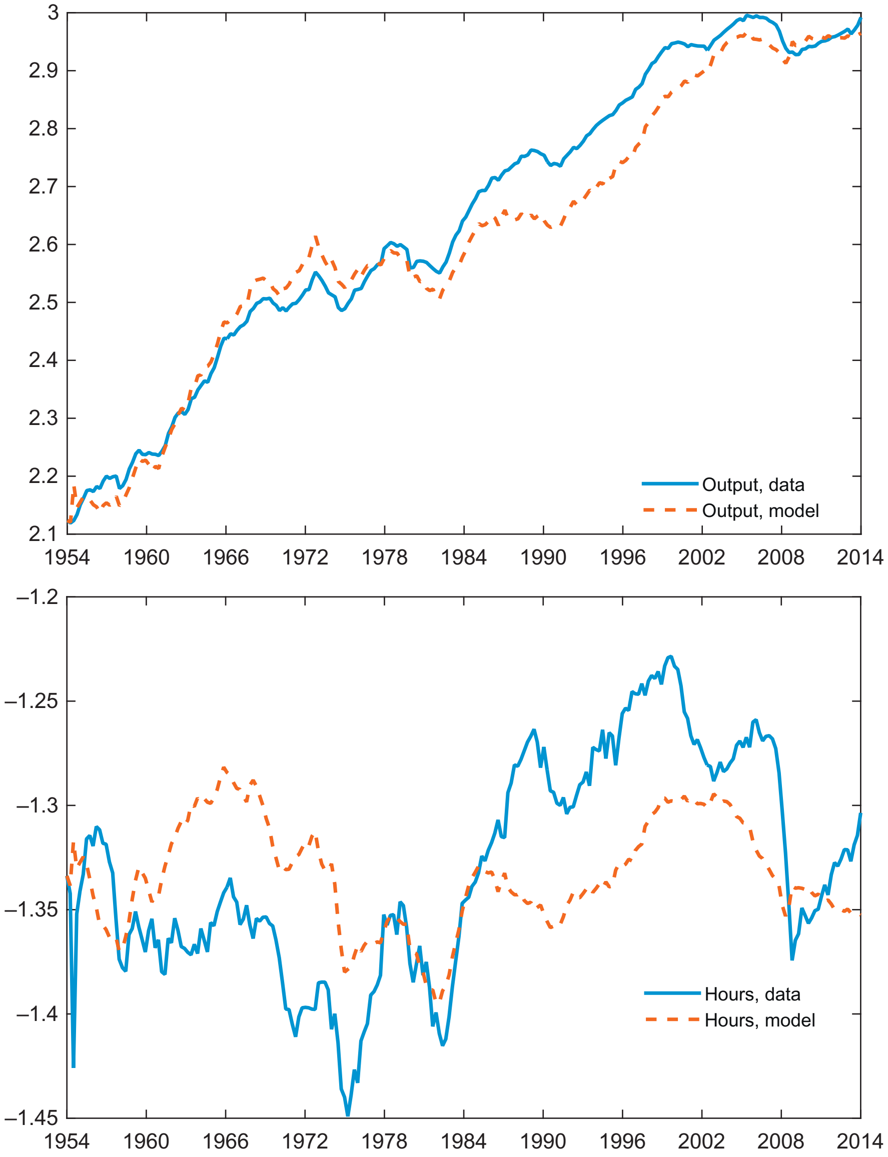

Fig. 17 Output and hours worked, data and two-sector model.

Fig. 20 plots the same data as the previous figure for filtered output and hours for both the 2–32 quarter frequency and the 32–200 quarter frequency. The difference is that we have included a third time series in each plot that shows simulated data under the assumption that there were no fluctuations in z_t and only fluctuations in q_t. That is, when

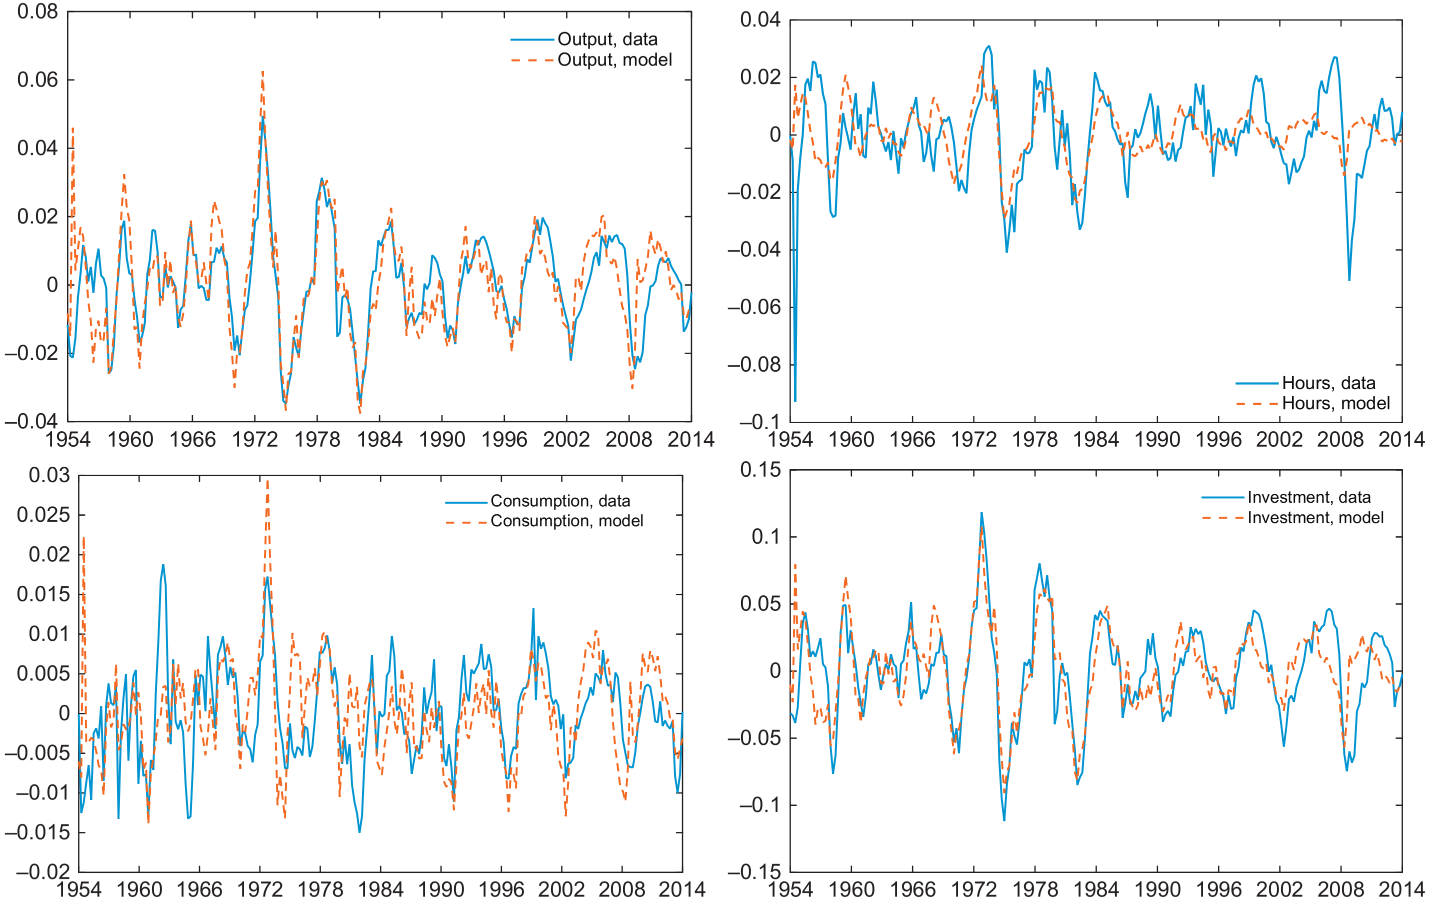

Fig. 18 Filtered actual and two-sector model data (2–32 quarters).

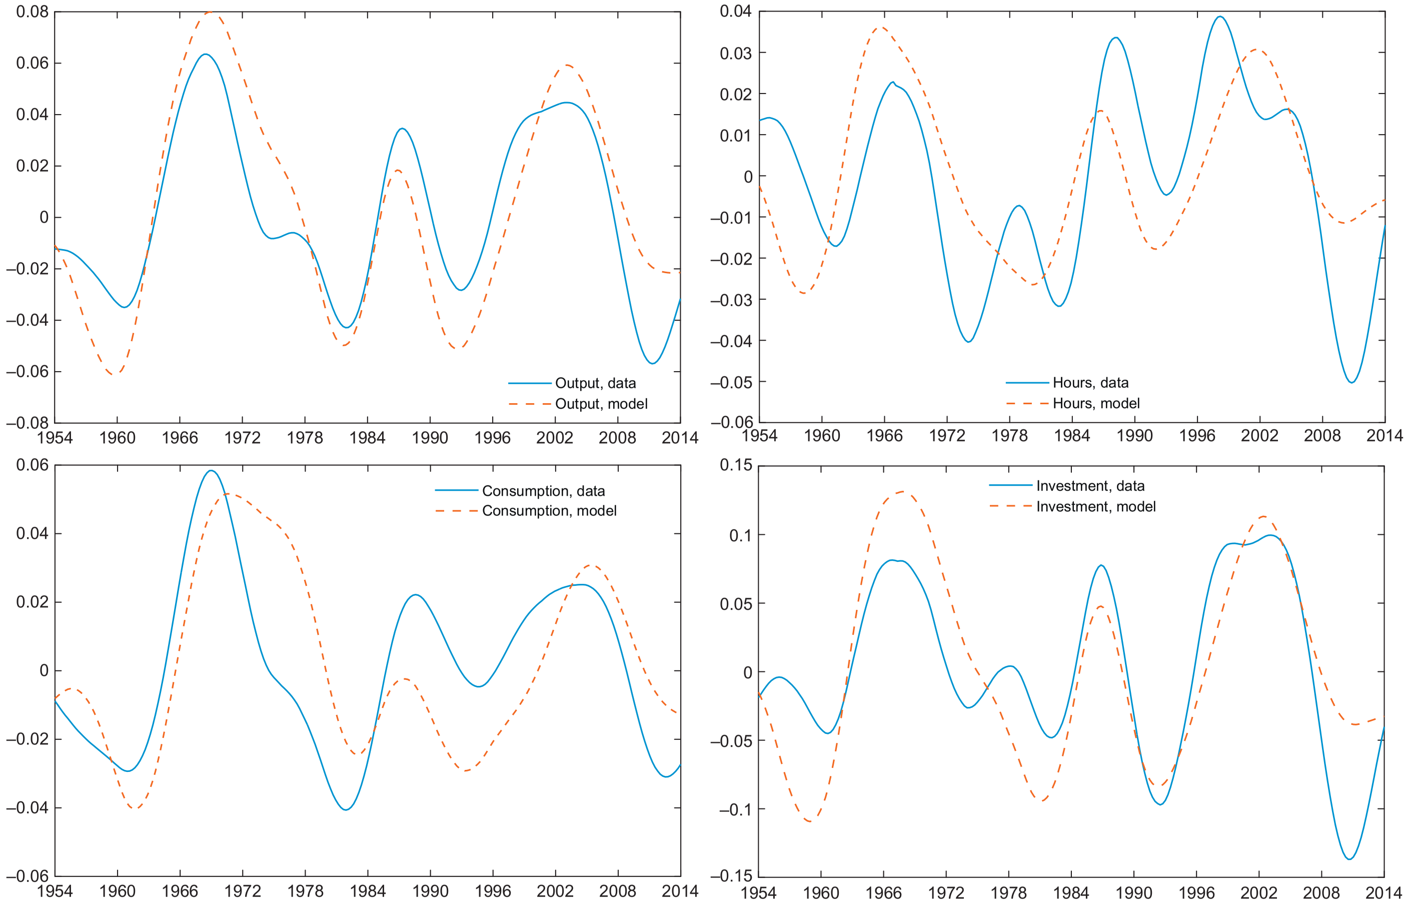

Fig. 19 Filtered actual and two-sector model data (32–200 quarters).

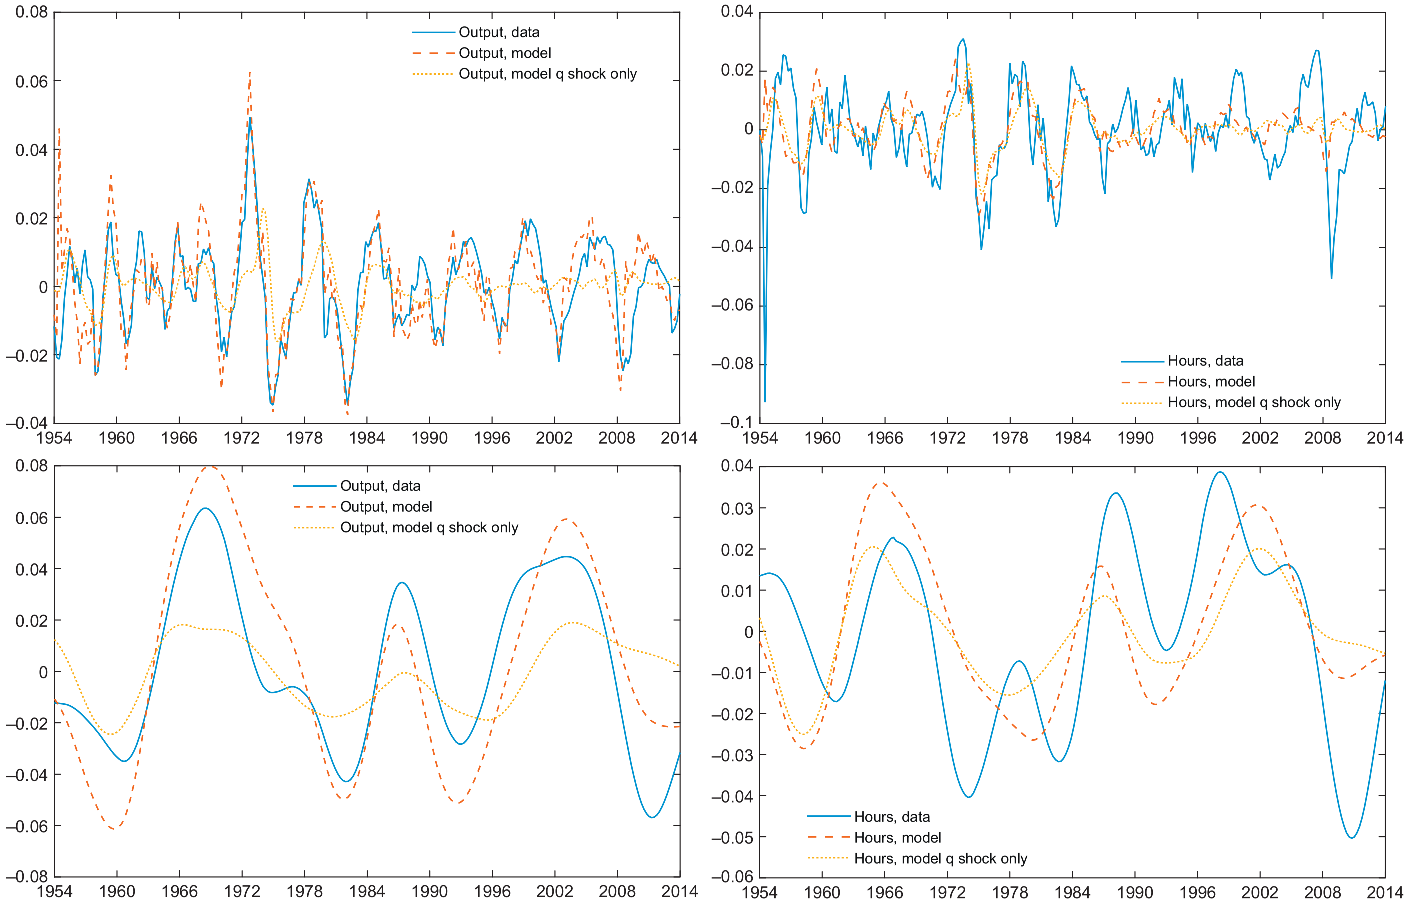

Fig. 20 Contribution of equipment specific technology fluctuations.

computing the simulation, the time series for z_t is replaced by the nonstochastic growth path for z. That is, $z_t = e^{t\mu_1}$ for all t.

This figure shows that much of the high and low frequency fluctuations in hours worked are due to movements in q_t, but this is not as true for fluctuations in output. It is also less true for business cycle fluctuations in hours worked in more recent decades.

4.3 One-Sector Model

We now proceed to compare the fluctuations exhibited by the two-sector model with a standard one-sector neoclassical stochastic growth model. This one-sector economy consists of a single production sector that produces output from capital and labor that can be consumed or invested. It differs from the two-sector model in that there is only one type of capital stock, no separate role for consumer durables, and one type of technology shock. In particular, the resource constraint, which replaces equation (21), is

$$C_t + I_t = Y_t = z_t A K_t^{\theta} H_t^{1-\theta}. \tag{31}$$

The law of motion for capital next period is given by

$$\eta K_{t+1} = (1-\delta)K_t + I_t \tag{32}$$

where the depreciation rate is $0 < \delta \leq 1$ and $1 \leq \eta \leq \frac{1}{\beta}$ is the population growth factor. The logarithm of the technology shock, z_t, is assumed to follow a random walk with drift ($\mu \geq 0$). We assume that the period t realization of z is observed at the beginning of the period.

$$\log z_{t+1} = \log z_t + \varepsilon_{t+1}\ ,\ \varepsilon \sim N(\mu, \sigma^2) \tag{33}$$

The preferences of the representative infinitely-lived household are given by

$$E\sum_{t=0}^{\infty} (\beta\eta)^t [\log C_t + \phi \log L_t] \tag{34}$$

where $0 < \beta < 1$ and $\phi > 0$. The variable L_t is leisure, where

$$L_t + H_t = 1. \tag{35}$$

Given K_0, we compute an equilibrium sequence for $\{C_t, I_t, Y_t, H_t, L_t, K_{t+1}\}$ by maximizing (34) subject to (31)–(33) and (35).

4.3.1 Calibrating the One-Sector Model with US Data

For comparison purposes, we begin by keeping the definition of output the same as in the two-sector model, $Y = C + I_s + \frac{1}{q}(I_d + I_e)$. Given that there is no separate role for consumer durables in this model, we define investment in the one-sector model to be

$I = I_s + \frac{I_e}{q}$ and consumption to be the sum of nondurable consumption plus services and $\frac{I_d}{q}$. That is, $C_t = C_{Mt} + \frac{I_d}{q}$, where C_M is consumption from the two-sector model. The capital stock is the sum $K = K_e + K_s$. The quarterly capital stock series for this sum is formed using the same method as for the two-sector model and the quarterly depreciation rate turns out to be $\delta = 0.013$. As in the two-sector model, $\beta = 0.99$ and labor's share is taken to be 0.6, so $\theta = 0.4$. Given this, a quarterly time series for the exogenous shock z_t, from 1954Q1 to 2014Q4, is constructed by setting $z_t = \frac{Y_t}{AK_t^{\theta} H_t^{1-\theta}}$, where the parameter A is set so that $z_0 = 1$. This implies that $A = 2.7$. In addition, the drift parameter, μ, turns out to be 0.0021.

As in the two-sector model, we set the steady state values for K, H and Y equal to the first observation in our data sample (for 1954Q1). Steady state consumption is then obtained from the steady state version of the resource constraint (31). We can then calibrate the parameter ϕ from the steady state condition for hours worked. That is, $\phi = \frac{(1-\theta)\bar{Y}(1-\bar{H})}{\bar{C} \;\; \bar{H}} = 2.37$.

To facilitate comparison across models, the parameter values are also reported in Table 1.

4.3.2 Comparing the One- and Two-Sector Models with US Data

Table 2 provides two metrics for comparing the closeness of the one- and two-sector model simulations with filtered data. These measures include the ratio of the standard deviations of the model series with the standard deviation of the data series. This provides a measure of how well the model is capturing the volatility in the data. The second measure is the correlation between the model simulations and the data. We report these measures for data filtered to extract fluctuations of 2–32 quarters, 32–200 quarters and 2–200 quarters. In all cases, a number closer to one implies a better fit.[i]

The table shows that the correlation between model and data for business cycle fluctuations is higher for the two-sector model, with the exception of consumption. For low frequency fluctuations, the one-sector model does slightly better, although the correlation between hours worked from the model and data is slightly higher for the two-sector model. The volatility of the various series is generally better accounted for by the two-sector model. Hence, the main conclusion we draw from this table is that the two-sector model fits the data better than the one-sector model, with the exception of consumption fluctuations. We find it interesting that the two-sector model is able to account for

[i] In this table and subsequent tables, we only use data starting from 1955Q1. The reason is that there is an unusual hours observation in 1954 that can be seen in Fig. 17, and we don't want that observation distorting the statistics reported in these tables.

Table 2 Comparing models with data (1955Q1–2014Q4)

	One-sector model		Two-sector model	
	Standard deviation model/data	Correlation model and data	Standard deviation model/data	Correlation model and data
2–32 Quarters				
Y	0.86	0.80	1.09	0.84
C	0.73	0.82	1.00	0.56
I	0.71	0.64	0.86	0.79
H	0.30	0.18	0.63	0.48
32–200 Quarters				
Y	0.85	0.88	1.21	0.86
C	0.70	0.78	1.07	0.64
I	0.81	0.82	1.08	0.81
H	0.35	0.51	0.81	0.53
2–200 Quarters				
Y	0.86	0.86	1.21	0.84
C	0.72	0.77	1.09	0.62
I	0.80	0.77	1.05	0.79
H	0.33	0.40	0.74	0.50

volatility in spite of the fact that we have assumed random walk technology shocks and divisible labor. These are both assumptions that tend to reduce the size of fluctuations.[j]

Fig. 21 provides the same information as Fig. 20 except that the comparison is now with the one-sector simulation for output and hours rather the "q-shock" only simulation. The figure illustrates that much of the low frequency movements in output can be accounted for by the one-sector model almost as well as the two sector. The low frequency volatility of hours, however, is better explained by the two-sector model than the one sector.

4.4 A Three-Sector Model

This section studies a model constructed by adding a nonmarket home production sector to the two-sector model. We develop the three-sector model with two alternative home production specifications. One is the standard home production specification of Benhabib et al. (1991) and much of the literature that follows from this. This formulation

[j] See Hansen (1985) concerning the impact of divisible labor on fluctuations and Hansen (1997) for the impact of random walk technology shocks.

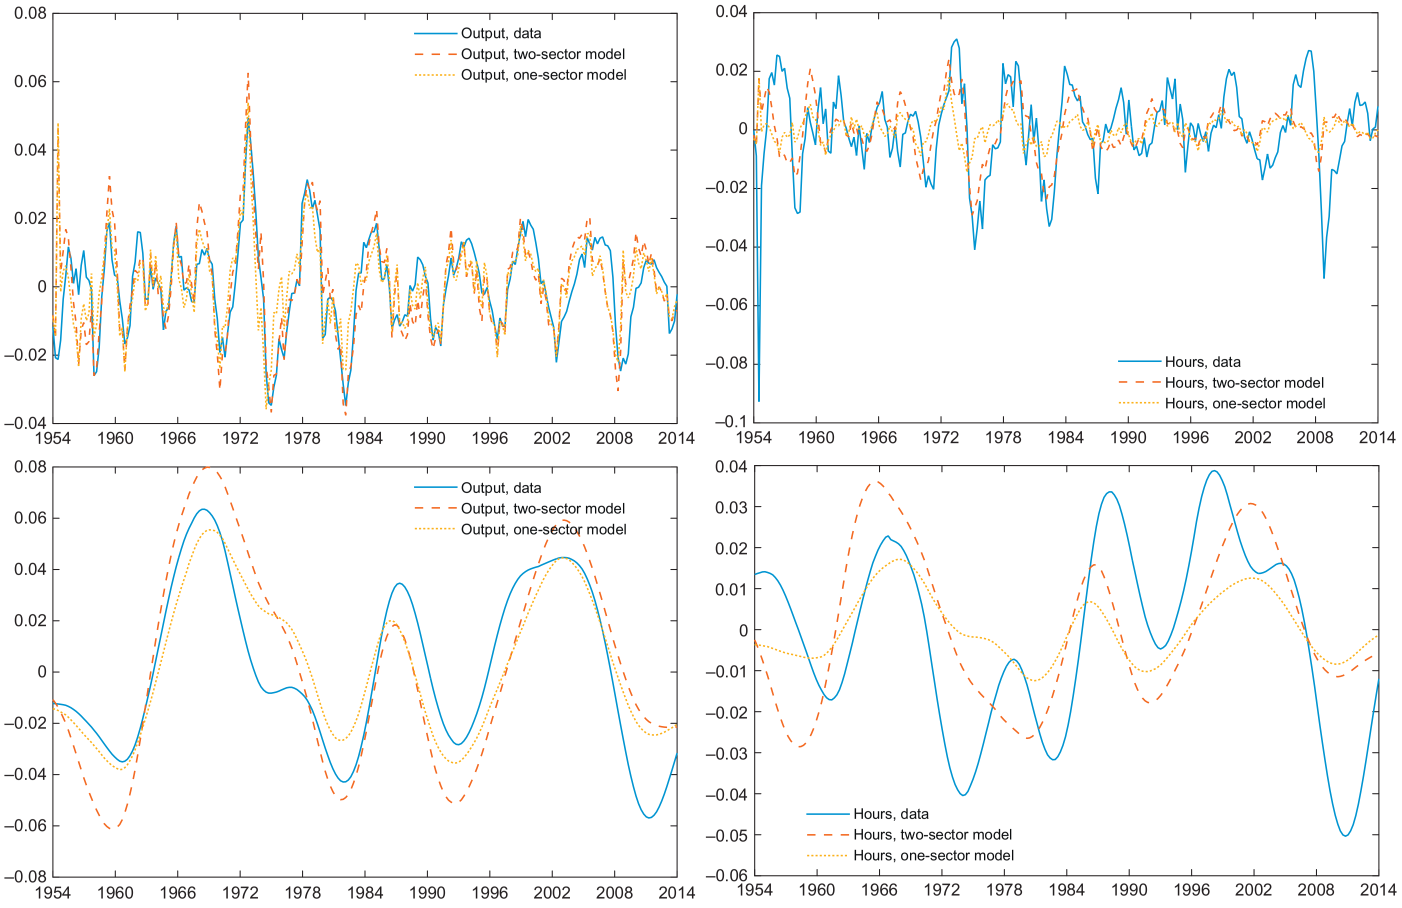

Fig. 21 Comparison of two-sector and one-sector models.

provides an additional margin of substitution for the household in which time can be allocated to market production, home production, or leisure. In the Benhabib, Rogerson and Wright model, there is a relatively high substitution elasticity between home-produced goods and market-produced goods, and this high elasticity generates significant movement of labor between the home sector and market sector in response to shocks. Home goods are produced using a Cobb–Douglas technology with labor and consumer durables.

The alternative home production formulation is motivated by Greenwood et al. (2005), which argues that rapid technological change in labor-saving consumer durables has secularly reallocated time from home production to market production, mainly by women moving into the labor force. In this specification, consumer durables are more substitutable with labor than in the Benhabib et al. (1991) specification that assumes a Cobb–Douglas technology for the home sector.

The model presented here nests both of these specifications. In particular, we assume that a nonmarket consumption good, C_{Nt}, is produced using labor (H_{Nt}) and the stock of consumer durables. As in Greenwood et al. (2005), we allow for the possibility that durables and labor are more substitutable than implied by the standard Cobb–Douglas production function. In particular, we assume the following functional form for the home production function with $\sigma > 0$:

$$C_{Nt} = A_N\left[\varphi\left(\frac{D_t}{e^{\mu_2 t}}\right)^{\sigma} + (1-\varphi)(g_c^t H_{Nt})^{\sigma}\right]^{\frac{1}{\sigma}} \tag{36}$$

The standard version of the model can be recovered by making σ close to zero. Note that the terms $e^{\mu_2 t}$ and g_c^t are included here to guarantee that C_{Nt} grows at the same rate as total output along the balanced growth path.

The second modification relative to the two-sector model is to replace the objective function (20) with the following:

$$\max E_0\left\{\sum_{t=0}^{\infty}(\beta\eta)^t[\log C_t + \phi\log(1 - H_{Mt} - H_{Nt})]\right\}, \tag{37}$$

where consumption, C_t, is a composite consumption good, standard in the home production literature, derived from market and nonmarket consumption goods

$$C_t = \left[\alpha C_{Mt}^{\omega} + (1-\alpha)C_{Nt}^{\omega}\right]^{\frac{1}{\omega}} \tag{38}$$

Given values for K_{e0}, K_{s0} and D_0, the equilibrium stochastic process for this economy can be found by solving the planner's problem maximizing (37) subject to (15)–(19), (21), (36), and (38).

4.4.1 Calibrating the Three-Sector Model to US Data

The calibration strategy is exactly the same as for the two-sector case, although the model introduces four new parameters (A_N, φ, ω, and σ) and two other parameters (α and ϕ) have different interpretations in this model. In addition, two new variables are introduced that are not directly observable in the US data. These are nonmarket consumption (C_N) and nonmarket hours worked (H_N). In the absence of measured counterparts to these variables, we assume that in steady state $\frac{\bar{C}_N}{\bar{C}_M} = 0.25$ and $\bar{H}_N = \frac{1}{6}$, which are values consistent with the home production literature. The mapping between all other model variables and US time series is the same as in the two-sector model.

The steady state values for $\bar{K}_s$, $\bar{K}_e$, $\bar{Y}$, $\bar{C}_M$, $\bar{I}_s$, $\bar{I}_e$, $\bar{I}_d$, $\bar{D}$, $\bar{H}_M$, $\bar{H}_N$, $\bar{C}_N$, and $\bar{C}$ are determined by Eqs. (22), (23), (26)–(30), and the following five equations:

$$\frac{g_E}{\beta} = \frac{(1-\alpha)A_N^{\sigma}\varphi\bar{q}\bar{C}_M^{1-\omega}}{\alpha\bar{C}_N^{\sigma-\omega}\bar{D}^{1-\sigma}} + 1 - \delta_D \tag{39}$$

$$\frac{\phi}{1-\bar{H}_M-\bar{H}_N} = \alpha(1-\theta_1-\theta_2)\frac{\bar{Y}}{\bar{H}_M\bar{C}^{\omega}\bar{C}_M^{1-\omega}} \tag{40}$$

$$\frac{\phi}{1-\bar{H}_M-\bar{H}_N} = \frac{(1-\alpha)A_N^{\sigma}(1-\varphi)}{\bar{H}_N^{1-\sigma}\bar{C}^{\omega}\bar{C}_N^{\sigma-\omega}} \tag{41}$$

$$\bar{C}_N = A_N\left[\varphi\bar{D}^{\sigma} + (1-\varphi)\bar{H}_N^{\sigma}\right]^{\frac{1}{\sigma}} \tag{42}$$

$$\bar{C} \;= \left[\alpha\bar{C}_M^{\omega} + (1-\alpha)\bar{C}_N^{\omega}\right]^{\frac{1}{\omega}}. \tag{43}$$

We experiment with two different sets of values for the parameters σ and ω to differentiate between our two home production specifications. Given values for these parameters, values for α, ϕ, φ and A_N can be obtained from equations (39) to (42) subject to $\frac{\bar{C}_N}{\bar{C}_M} = 0.25$, $\bar{H}_N = \frac{1}{6}$ and $\bar{C}$ is given by equation (43).[k]

The first calibration we consider is referred to as the "standard home production" model. In this case, $\omega = 0.6$ and $\sigma = 0$, which corresponds to values common in the home production literature (see Chang and Schorfheide, 2003). In this case, the utility function (38) allows for more substitutability between home consumption and market consumption than implied by a Cobb–Douglas specification while the home production

[k] We also use the fact that, as in the two-sector case, we choose parameters so that $\bar{q}$, $\bar{H}_M$ and $\bar{Y}$ are the first observation in our data sample.

function (36) is assumed to be Cobb–Douglas. The second calibration, which we refer to as the "alternative home production" model, is motivated by Greenwood et al. (2005) and sets $\omega = 0$ and $\sigma = 0.4$. Here, (38) is assumed to be Cobb–Douglas and we allow for an elasticity of substitution between durables and hours that is greater than 1 in the home production function (36). The parameter values associated with both calibrations are given in Table 1.

4.4.2 Fluctuations in the Three-Sector Model

We begin by comparing the simulations produced by the two versions of the three-sector model that we consider. Fig. 22 shows unfiltered output and hours from the two models as well as from the US time series. Both models account for output movements quite well, although the alternative calibration does a somewhat better job in the 1960s and 1970s while the standard home production calibration fits the data better in the 1980s and 1990s. Both models imply similar paths during the Great Recession period. The same is also true for hours worked—the alternative calibration does better during the early periods and less well during the 1980s and 1990s. Both calibrations give essentially identical results during the 2000s.

An interesting difference between hours worked from the two models can be seen from examining the period from about 1982 to 2000. The rise in hours worked predicted by the alternative calibration during this period is significantly larger than that predicted by the standard home production model. In the spirit of Greenwood et al. (2005), this calibration does a better job of capturing the secular increase in hours worked that occurs over this period, mainly due to women entering the labor force. As one can see from Fig. 23, this difference does not appear in the low frequency fluctuations that we report.

The two calibrations, however, give essentially the same results once the data is filtered. Fig. 23 illustrates this by plotting filtered data for output and hours from the two versions of the model. The data for both business cycle fluctuations as well as low frequency fluctuations essentially lay on top of each other. In particular, the alternative home production model does not exhibit the significantly larger increase in hours worked relative to the standard home production model during the 1980s and 1990s as was observed in Fig. 22.

The closeness of the filtered data from these models with filtered data from US time series is illustrated in Fig. 24 and Table 3. Fig. 24 shows filtered data from the standard home production calibration and the US economy for output and hours. When one compares the panels in Fig. 24 with the corresponding panels in Figs. 18 and 19, the results from the home production model appear very similar to the two-sector model with slightly more volatility in hours worked at both sets of frequencies.

The same sorts of conclusions that can be drawn from Fig. 24 are also apparent in Table 3. This table provides the same set of statistics as in Table 2 for comparing model data with actual data. Here, we compare both calibrations of our three-sector model with the US time series.

The final set of tables we present in this section report the statistics for comparing model simulation and actual data for three subperiods of the postwar period. Table 4 looks only at the early postwar period from 1955Q1 to 1983Q4 and Table 5 reports statistics for the Great Moderation period from 1984Q1 to 2007Q3. Finally, statistics for the Great Recession and after are reported in Table 6.

Which model best explains postwar fluctuations in output, consumption, investment and hours worked? These tables show that it depends on the sample period and the frequency band of interest.

In the early postwar period (Table 4), all three models do a similar job fitting the data, but different models are better at accounting for fluctuations in different frequency bands. Hours is explained the least well by all of the models, but the correlation between model and data hours is highest for the two-sector model at business cycle frequencies and the home production model for lower frequencies. Output fluctuations are best explained by the two-sector model in all frequency bands considered. Consumption fluctuations are best explained by the one-sector model and investment fluctuations are almost equally well explained by the two- and three-sector models.

A feature seen in all three of these tables is that the volatility of model data relative to actual data rises as the number of sectors is increased. This is due to the increased substitution opportunities offered by multisector economies.

During the Great Moderation (Table 5), the one-sector model provides the highest correlations between model and actual data for output, consumption and investment, which is different from what is observed in the earlier period. Hours, however, are slightly better explained by the three-sector model. At lower frequencies, the three-sector model shows the highest correlation for all variables except consumption.

In the most recent period (Table 6), which covers the Great Recession and aftermath, a striking finding emerges regarding hours fluctuations. All three models show negative correlations between model and data hours worked at business cycle frequencies. However, this correlation is quite high, especially for the two- and three-sector models, at lower frequencies. At business cycle frequencies, all three models do a similarly poor job in accounting for fluctuations in output and investment. Again, the one-sector model does best in explaining consumption. But, at lower frequencies, all three neoclassical models show high correlations between model and data for these three variables as well as hours worked.

It is interesting and important that the fit of the two- and three-sector models for the 32–200 component is no different during the Great Moderation than during the 1955–1983 period. This is important because some economists have argued that neoclassical models cannot fit data from this specific period because the business cycle correlation between labor productivity and hours worked becomes negative during the Great Moderation (see Gali and van Rens, 2014). We find that the change in this higher frequency statistic has no bearing on the ability of these models to fit the large, longer-run component in the data. We also note that these models also fit the 32–200 component of the data well during the Great Recession and its aftermath. However, it should be noted that this is a short data interval for measuring the long-run component.

5. NEOCLASSICAL MODELS OF DEPRESSIONS

This section describes neoclassical models of *depressions*, which are prolonged periods in which aggregate economic activity is far below trend. Kehoe and Prescott (2007) define a Great Depression as an event in which per capita real output is at least 20% below trend, in which trend is constructed using a 2% annual growth rate. They also require that real output is at least 15% below this trend within a decade, and that real output always grows at less than 2% per year during the episode.

Neoclassical modeling of depressions has become a very active research field in the last 15 years and is providing new insights into several episodes that have long been considered economic pathologies.[1] Some of the models presented here are tailored to capture features of specific episodes, but all of these models can be modified to study other episodes of depressed economic activity.

This section focuses on the US Great Depression, which is the most widely-studied depression in the literature, and is perhaps the most striking and anomalous period of macroeconomic activity in the economic history of the US. The Great Depression began in the Fall of 1929, and the economy did not recover to its predepression trend until the early 1940s.

Lucas and Rapping (1969) developed the first modern model of the US Great Depression. This model represented a breakthrough by analyzing the Depression within an equilibrium framework. Previous studies of the Depression noted the coincidence of deflation and depression in the early 1930s, and viewed deflation as causing the Depression. The Lucas–Rapping model provided a very different interpretation of this relationship. In the Lucas–Rapping model, deflation depresses output through imperfect information about nominal price changes. Specifically, workers misinterpret falling

[1] Recent models of the Great Depression analyze a number of policies and mechanisms in order to understand this episode. This includes the wage fixing and work-sharing policies of Herbert Hoover (Ohanian, 2009; Ebell and Ritschl, 2008; and Amaral and MacGee, 2015), the worker-industry cartels of the National Industrial Recovery Act and the National Labor Relations Act (Cole and Ohanian, 1999, 2004), changes in capital income tax rates (McGrattan, 2012), the cartel policies of Mussolini in Italy, and Hitler in Germany (Cole and Ohanian, 2016), the impact of tariffs on resource allocation and productivity (Bond et al., 2013), the impact of financial market imperfections and misallocation in the Depression (Ziebarth, 2014), and the impact of contractionary monetary policy on labor markets (Bordo et al., 2000).

nominal wages as reflecting a lower relative price for their labor services. This mistaken perception of the real wage leads to lower employment and lower output. This change in employment and production reflects intertemporal substitution, in which employment and output expand during periods in which workers perceive high real wages and contract during periods of perceived low real wages. The mechanism of imperfect information and nominal price changes was developed further in Lucas's 1972 seminal contribution that rationalized Phillips Curve type relationships within an optimizing model.

Lucas and Rapping's study spawned a large neoclassical literature on fluctuations that focused on intertemporal substitution as the principal channel for understanding business cycle fluctuations. This literature includes contributions by Barro (1981), Barro and King (1984), Lucas (1973a), Sargent (1973), Sargent and Wallace (1975), among others.

But many economists were skeptical of these early neoclassical interpretations of fluctuations, particularly for deep and prolonged crises such as the US Great Depression. Modigliani (1977) argued that neoclassical models of the Depression implausibly portrayed individuals as exhibiting a "a severe attack of contagious laziness" (p. 24). Modigliani, Rees (1970) and many other economists interpreted the substantial job loss of the Depression as involuntary unemployment, which stands in sharp contrast to the market-clearing equilibrium interpretation of Lucas and Rapping. The Modigliani quip has been repeated frequently over time, and is viewed widely as a fundamental critique of neoclassical macroeconomic modeling. This section presents neoclassical models of the Depression that directly confront Modigliani's criticism. The analysis shows how simple neoclassical models can be extended to assess economies with market distortions that create substantial and persistent involuntary job loss.

5.1 The Depth, Duration, and Sectoral Differences of the US Great Depression

The depth, duration, and sectoral differences in severity of the Depression represent a significant challenge for neoclassical models, or for any quantitative theoretic model. Tables 7–9 summarize these features by presenting data on output, consumption, investment, hours worked, and productivity. The data in these tables are divided by the population. In addition, all of the data except for hours worked are detrended at 2% per year. Thus, the value of 100 means that a variable is equal to its steady state growth path value.

Table 7 shows that real GDP declines by more than 35% between 1929 and the Depression's trough in 1933, and remains far below trend after that. Consumption also falls considerably, and remains near its trough level after 1933. Investment declines by about 75%, and remains at 50% below trend by the late 1930s. Hours worked decline about 27% between 1929 and 1933, and remain more than 20% below trend after that.

Total factor productivity (TFP) declines by about 14% below trend by 1933. Such a large drop in productivity raises questions about measurement, and whether this decline reflects factors other than changes in efficiency. Ohanian (2001) found that this TFP

Table 7 US Great Depression levels of real output and its components (index, 1929 = 100)

Year	Real output	Consumption: Nondurables and services	Consumption: Consumer durables	Business investment	Government purchases	Foreign trade: Exports	Foreign trade: Imports
1930	87.4	90.9	76.2	79.2	105.1	85.3	84.9
1931	78.1	85.4	63.4	49.4	105.4	70.6	72.4

1939	73.5	75.0	64.3	40.5	112.9	61.7	61.6

Data are measured in per capita terms and detrended.

Table 8 Five measures of labor input during US Great Depression (index, 1929 = 100)

Year	Aggregate measures: Total employment	Aggregate measures: Total hours	Aggregate measures: Private hours	Sectoral measures: Farm hours	Sectoral measures: Manufacturing hours
1930	93.8	92.0	91.5	99.0	83.5
1931	86.7	83.6	82.8	101.6	67.2
1932	78.9	73.5	72.4	98.6	53.0
1933	78.6	72.7	70.8	98.8	56.1
1934	83.7	71.8	68.7	89.1	58.4
1935	85.4	74.8	71.4	93.1	64.8
1936	89.8	80.7	75.8	90.9	74.2
1937	90.8	83.1	79.5	98.8	79.3
1938	86.1	76.4	71.7	92.4	62.3
1939	87.5	78.8	74.4	93.2	71.2

Data are measured in per capita terms.

decline was not easily reconciled with capacity utilization, labor hoarding, or compositional shifts in inputs, which suggests significant efficiency loss during this period. TFP recovers quickly and ultimately rises above trend by the late 1930s. This rapid productivity growth after 1932 led Field (2003) to describe the 1930s as "the most technologically progressive decade of the 20th century."

The severity of the Depression differed considerably across sectors. Table 8 shows that manufacturing hours declined enormously, but agricultural hours remained close to trend through the mid-1930s. These two sectors account for roughly 50% of employment at that time.

Table 9 Productivity and real wage rates during US Great Depression (index, 1929 = 100)

		Total factor productivity		Real wage rates		
Year	Labor productivity[a]	Private domestic	Private nonfarm	Total	Manufacturing	Nonmanufacturing
1930	95.3	94.8	94.8	99.3	101.9	98.2
1931	95.2	93.4	92.0	98.9	106.0	96.1
1932	89.4	87.6	85.8	95.8	105.3	92.3
1933	84.8	85.7	82.7	91.3	102.5	87.2
1934	90.3	93.1	92.7	95.7	108.8	91.1
1935	94.8	96.3	95.3	95.1	108.3	90.4
1936	93.7	99.5	99.5	97.6	107.2	94.1
1937	95.1	100.1	99.3	97.8	113.0	92.5
1938	94.6	99.9	98.1	99.1	117.4	92.8
1939	95.2	102.6	100.1	100.1	116.4	94.3

Data are detrended.
[a] Labor productivity is defined as output per hour.

The data summarized here challenge long-standing views of the Depression. Traditional studies omit productivity, and focus instead on monetary contraction and banking crises as the key determinants of the Depression (see Friedman and Schwartz, 1963 and Bernanke, 1983).

However, these factors cannot account for the early stages of the Depression, nor can they account for the post-1933 continuation of the Depression. In terms of the early stages of the Depression, industrial production declined by about 35% between the Fall of 1929 through November of 1930, but there were neither banking crises nor significant monetary contraction during this time.[m]

After 1933, the money stock expanded rapidly and banking crises were quickly eliminated by the introduction of bank deposit insurance. The Lucas–Rapping model and New Keynesian models, such as Eggertsson (2012), counterfactually predict a very rapid recovery to trend as a consequence of rapid monetary expansion and the end of banking crises. In the Lucas–Rapping model, monetary expansion stops deflation, and employment expands as workers perceive that the relative price of their labor services has recovered. In New Keynesian models, such as Eggertsson (2012), inflation moves the economy away from the zero lower interest rate bound, and hours worked increase substantially. These models cannot account for the failure of hours to remain significantly depressed after 1933. Rees (1970) and Lucas and Rapping (1972) discuss the failure of the Lucas and Rapping model to account for hours worked after 1933, and Ohanian (2011) discusses the failure of the Eggertsson model to account for hours worked after 1933.

[m] Ohanian (2010) discusses the immediate severity of the Great Depression that occurred before monetary contraction and before banking crises.

Moreover, the traditional view of the Depression counterfactually implies that the agricultural sector and the manufacturing sector were identically depressed. The large differences between these two sectors mean that any successful model of the Depression must account for the enormous manufacturing depression, but only a modest agricultural decline.

5.2 Diagnosing Depressions with Simple Neoclassical Models

Cole and Ohanian (1999) advocate using simple neoclassical models to *diagnose depressions*. Their idea is that both the successes and the deviations between model and data are informative for developing theories of specific episodes. Cole and Ohanian (1999) focused on the contribution of TFP for the Depression within a standard one-sector stochastic growth model for the 1930s.[n] They fed TFP shocks from 1930 to 1939 into the model and found that the TFP drop accounts for about 60% of the drop in output between 1929 and 1933, and about half of the drop in labor. However, the model generates a completely counterfactual path for the economy after 1933. The rapid recovery of TFP generates a rapid recovery in the model, with labor input recovering to trend by the mid-1930s. In contrast, the actual economy appears to have shifted onto a lower steady state growth path after 1933, with consumption and hours worked remaining near their 1932 trend-adjusted levels.

The post-1933 deviation between model and data provide valuable information about this episode. The results indicate that understanding the post-1933 data requires a large and persistent change in a state variable that substantially depressed and/or restricted the opportunities to produce and trade. The impact of the missing factor must be sufficiently large, such that it prevents recovery in hours worked, despite rapid productivity recovery and despite the low capital stock.

Business cycle accounting (BCA) is another neoclassical diagnostic tool, and its application provides insight regarding this state variable. Cole and Ohanian (1999, 2002), Mulligan (2005), Brinca et al. (2016), and Chari et al. (2007) use a standard one-sector neoclassical model to measure which of the decision margins in that model deviate from theory when actual data is substituted into the first order conditions of the model. For the Great Depression, the condition that equates the marginal rate of substitution between consumption and leisure to the marginal product of labor is significantly distorted. Specifically, the marginal product of labor is higher than the marginal rate of substitution throughout the decade. The deviation in this condition, which is typically called a labor wedge, grows further after 1933, and suggests a major factor that distorted the opportunities and/or the incentives to trade labor services.

[n] The idea of large productivity declines during depressions was initially met with skepticism by some economists. This skepticism is based on the narrow interpretation that lower TFP implies that society lost substantial knowledge over a short period of time. More recently, however, economists are interpreting aggregate productivity changes from alternative perspectives. Section 7 discusses this in detail.

Ohanian (2009) identified economic policies that significantly distorted the opportunities to trade labor services by depressing labor market competition and by preventing wages from adjusting. Simon (2001) analyzed "situation wanted" advertisements from the late 1920s and the early 1930s. These situation wanted advertisements are analogous to help wanted advertisements, but from the supply side of the labor market. In these ads, workers would describe their experience and qualifications, and the wage that they were seeking. Simon shows that the supply price of labor—the desired wage posted in the situation wanted ads—was much lower than the wages that were actually paid in the 1930s. This large gap between the supply price of labor and the wage was not present in the late 1920s, however, when the supply price and actual wages paid were very similar. This evidence suggests that wages were above their market–clearing level, which in turn created an excess supply of labor.

Table 9 provides further evidence of a significantly distorted labor market. The table presents wages from manufacturing and from the farm sector. These data are measured relative to trend, which is the average growth rate of productivity in these sectors (see Cole and Ohanian, 1999). These data show that wages in manufacturing are well above trend, which suggests that they are also above their market–clearing level. In contrast, real wages in the farm sector are well below trend.

Given this backdrop, a new neoclassical literature on the Depression has emerged that studies how government policy changes distorted labor markets. Ohanian (2009) studied the downturn phase of the US Great Depression, and Cole and Ohanian (2004) studied the delayed recovery from the Depression. Both papers use neoclassical frameworks that build on the facts described above. Given the large differences in hours worked and wages in the manufacturing and agricultural sectors, these models begin by modifying the standard one-sector growth model to incorporate multiple sectors, and then build in government policies.

5.3 A Neoclassical Model with Wage Fixing and Work-Sharing Policies

There were large shifts in government policies throughout the 1930s that distorted labor and product markets by significantly restricting competition in industrial labor and product markets, but not in agricultural markets. Ohanian (2009) describes how these policies began in November 1929, following the October stock market decline. President Herbert Hoover met with the leaders of the largest industrial firms, including General Motors, Ford, General Electric, US Steel, and Dupont. Hoover lobbied these firms to either raise wages, or at a minimum, to keep wages at their current levels. He also asked industry to share work among employees, rather than follow the typical practice of laying off workers and keeping retained workers on a full-time shift.

In return for maintaining nominal wages and sharing work, organized labor pledged to maintain industrial peace by not striking or engaging in any efforts that would disrupt production. The Hoover bargain was perceived by firms to be in their interest. Specifically, it is widely acknowledged that the major manufacturing firms had substantial market power at this time, with considerable industry rents. Kovacic and Shapiro (2000) note that this period represents the zenith of collusion and cartels among major industry, and capital's share of income was at an all-time high. Industry agreed to keep wages fixed, and Ford Motor in fact raised wages following the meeting with Hoover. However, as the price level declined, and as productivity declined, these fixed nominal industrial wages led to rising real wages and rising unit labor costs. Ohanian (2010) documents that industry asked Hoover several times for permission to reduce nominal wages, but Hoover declined these requests. Nominal wages among the biggest employers did not begin to fall until late 1931, after hours worked in industry had declined by almost 50%.

Ohanian (2009) develops a neoclassical model with a policy of nominal wage fixing and work-sharing that affected the industrial sector. This requires a model with multiple sectors, and also requires a distinction between hours per worker and employment in order to model work-sharing.

There is a representative family, and family members work in many industries. The population grows at rate n. Preferences over consumption and leisure, and the disutility of joining the workforce, are given by:

$$\max \sum_{t=0}^{\infty} \beta^t \{\ln(c_t) + e_{at}\mu \ln(1-h_{at}) + e_{mt}\mu \ln(1-h_{mt}) - \upsilon(e_{at}+e_{mt})\}(1+n)^t. \tag{44}$$

Preferences are scaled by the population, which grows at rate n. Consumption is denoted as c, e_a denotes the number of workers in the agricultural sector, e_m denotes the number of workers in the manufacturing sector, and h_a and h_m denote the length of the workweek in agriculture and manufacturing, respectively. The function $\upsilon(e_a + e_m)$ is increasing and weakly convex, and specifies the utility cost of sending different household members to work in the market. Rank-ordering family members by their position in the distribution of this utility cost, and assuming that these costs rise linearly across family members, yields:

$$-\upsilon(e_{at}+e_{mt}) = -\int_{i=0}^{e_t} (\xi_0 + 2\xi_1 x)dx = \xi_0 e_t + \xi_1 e_t^2. \tag{45}$$

Note that there will be an optimal number of family members working, as well as an optimal number of hours per worker.

There are two production sectors, agriculture and manufacturing, and there is a continuum of industries within each sector. Industry output is given by:

$$y_i = h_i e_s(i)^{\gamma} k_s(i)^{1-\gamma}, \tag{46}$$

in which the length of the workweek is given by h, employment is given by e, and capital is given by k. Kydland and Prescott (1988), Cole and Ohanian (2002), Hayashi and

Prescott (2002), Osuna and Rios-Rull (2003), and McGrattan and Ohanian (2010) use similar production technologies to study problems that require differentiating between employment and hours per worker.

The industry-level outputs are aggregated to produce sectoral output:

$$Y_s = \left(\int_0^1 y_s(i)^\theta di \right)^{\frac{1}{\theta}} \tag{47}$$

Final output, which is divided between consumption and investment, is a CES aggregate over the two sectoral outputs:

$$Y = [\alpha Y_m^\phi + (1-\alpha) Y_a^\phi]^{\frac{1}{\phi}} \tag{48}$$

The production of final goods is competitive, and the maximization problem is given by:

$$\max \{ Y - \int p_m y_m(i) di - \int p_a y_a(i) di \} \tag{49}$$

subject to:

$$Y = \left[\alpha \left(\int_0^1 y_m(i)^\theta di \right)^{\frac{\phi}{\theta}} + (1-\alpha) \left(\int_0^1 y_a(i)^\theta di)^{\frac{\phi}{\theta}} \right) \right]^{\frac{1}{\phi}} \tag{50}$$

The solution to the final good producer's profit maximization problem is standard, and is characterized by equating the marginal product of each intermediate input to the input price.

The parameter values for the household discount factor, the depreciation rate, and the capital and labor production share parameters are standard, with $\beta = 0.95$, $\delta = 0.06$, and $\gamma = 0.67$. The values for the three parameters that govern the disutility of hours per worker (the length of the workweek), and the utility cost of employment, are jointly set to target (i) an average employment to population ratio of 0.7, (ii) the average workweek length at that time, which was about 45 hours per week, and (iii) that employment change accounts for about 80% of cyclical fluctuations in hours worked.

Ohanian (2009) discusses the fraction of the economy affected by the Hoover program, and sets the production share parameter α so that about 40% of employment was produced in industries impacted by this program. The parameter ϕ governs the substitution elasticity between agriculture and manufacturing. This elasticity is set to 1/2, which is consistent with the fact that both the manufacturing share of value added and its relative price have declined over time.

To analyze the impact of the Hoover nominal wage-fixing and work-sharing policy, the observed real manufacturing wage sequence is exogenously fed into the model. This sequence of wages is interpreted as the result of Hoover's fixed nominal wage program in conjunction with exogenous deflation. Note that the analysis is simplified considerably by abstracting from an explicit role of money in the model, such as a cash-in-advance constraint. It is unlikely that the inclusion of explicit monetary exchange in the model would change the results in any significant way, provided that a more complicated model with monetary exchange generated the same real wage path for manufacturing.

We now discuss modeling the workweek for analyzing the Hoover program. First, recall that almost all of the cyclical change in labor input prior to the Depression was due to employment, rather than changes in hours per worker. However, about 40% of the decline in labor input between 1929 and 1931 was due to a shorter workweek. This suggests that the large decline in the workweek length was due to the Hoover work-sharing policy, rather than reflecting an optimizing choice.

The Hoover workweek is also exogenously fed into the model. The evidence that indicates that the workweek was not optimally chosen suggests that the Hoover work-sharing policy was inefficient. In this model, the inefficiency of forced work-sharing results in lower productivity, since reducing the length of the workweek operates just like a negative productivity shock. To see this, note that the Cobb–Douglas composite of employment and the capital stock in the production function is scaled by the length of the workweek.

The analysis is conducted between 1929:4 and 1931:4. The wage-fixing and work-sharing policies significantly depress economic activity by raising the cost of labor, which reflects both a rising real wage and declining labor productivity. The inflexible manufacturing wage means that the manufacturing labor market does not clear, and that the amount of labor hired is solely determined by labor demand. Table 10 shows the perfect foresight model predictions and data.[o] The model generates about a 16% output decline, which accounts for over 60% of the actual decline.[p] The model also is consistent with the fact that there is a much larger decline in manufacturing than in agriculture. Manufacturing hours fall by about 30% in the model and by about 44% in the data, and agricultural hours fall by about 12% in the model and by about 4% in the data.

The agricultural sector declines much less because it is not subject to the Hoover wage and work-sharing policies. However, the agricultural sector declines because of the general equilibrium effects of the Hoover policy. This reflects the fact that manufacturing

[o] The annual NIPA data are linearly interpolated to a quarterly frequency.

[p] The deterministic path solution is the reason for the immediate increase in economic activity. This reflects the fact that producers see higher future labor costs, and thus produce before these costs rise. Future research should assess the impact of these policies in a stochastic environment.

Table 10 US Great Depression—data and model with wage fixing and work sharing policies (index, 1929:3 = 100)

	Output		Manufacturing hours		Agricultural hours	
	Data	**Model**	**Data**	**Model**	**Data**	**Model**
1929:4	97	101	91	96	99	104
1930:1	93	98	84	92	98	102
1930:2	90	96	76	89	99	99
1930:3	87	94	69	85	99	97
1930:4	84	91	67	80	99	94
1931:1	82	87	65	76	98	92
1931:2	78	86	59	71	97	90
1931:3	75	84	56	69	96	88

output is a complement to agricultural output in final goods production. Thus, depressed manufacturing output depresses the agricultural wage, which in turn depresses agricultural hours.

Note that the model is consistent with Simon's (2001) finding of excess labor supply in manufacturing, and that job seekers in manufacturing were willing to work for much less than the manufacturing wage. The model also provides a theory for why deflation was particularly depressing in the 1930s compared to the early 1920s, when a very similar deflation coincided with a much milder downturn.

While this model was tailored to study the US Great Depression, it can be used more broadly to study nominal wage maintenance policies and/or work-sharing policies.

5.4 A Neoclassical Model with Cartels and Insider–Outsider Unions

The model economy with nominal wage-fixing, deflation, and work sharing accounts for a considerable fraction of the early years of the Depression. After 1933, however, deflation ended. Moreover, productivity grew rapidly, and real interest rates declined. These factors should have promoted a strong recovery, but the economy remained far below trend for the balance of the decade. The failure of the economy to return to trend is puzzling from a neoclassical perspective, given productivity growth, and it is puzzling from a Keynesian perspective, given the end of deflation and banking crises, and given much lower real interest rates.

The empirical key to understanding the post-1933 Depression is a growing labor wedge, as the marginal product of labor was far above the marginal rate of substitution between consumption and leisure. Cole and Ohanian (2004) develop a theory of the labor wedge that is based on changes in government competition and labor market policies. One policy was the 1933 National Industrial Recovery Act, which allowed a number of nonagricultural industries to explicitly cartelize by limiting production and raising prices. The government typically approved these cartels provided that industry raised the wages of their workers. Another policy was the 1935 National Labor Relations Act (NLRA), which provided for unionization and collective bargaining. The use of the "sit-down" strike under the NLRA, in which striking workers forcibly prevented production by taking over factories, gave workers considerable bargaining power. Cole and Ohanian describe how both of these policies created an insider–outsider friction, in which insiders received higher wages than workers in sectors that were not covered by these policies.

Cole and Ohanian present industrial wage and relative price data from individual industries covered by these policies. Industry relative prices and wages jumped around the time that the industry codes were passed, and continued to rise after that. Table 9 shows that real wages rise and ultimately are about 17% above trend by the late 1930s.

Cole and Ohanian (2004) develop a multisector growth model in which the industries in the manufacturing sectors are able to cartelize provided that they reach a wage agreement with their workers. They begin with a simple neoclassical environment, and then add in cartelization policies and a dynamic, insider–outsider model of a union, in which incumbent workers (insiders) choose the size of the insider group, and bargain over the wage. The objective of the insiders is to maximize the per-worker expected, present discounted value of the union wage premium.

While this model was developed to capture specific features of US policy, it easily can be modified to analyze a variety of dynamic bargaining games in which a firm and a union repeatedly negotiate over wages, and in which the insiders choose their size by maximizing the expected, discounted payoff to union membership. The choice of the size of the union is central in any insider–outsider environment, but is typically missing from earlier insider–outsider models.

We begin with a neoclassical, multisector growth model, and then build in these policies. Preferences are given by:

$$\max \sum_{t=0}^{\infty} \beta^t \{\ln(c_t) + \mu \ln(1 - n_t)\}. \tag{51}$$

Consumption is denoted as c, and the size of the household is normalized to 1. The model is simplified by assuming that work is full-time. The term $1 - n$ is the number of household members who are engaged in nonmarket activities (leisure). The household faces a present value budget constraint:

$$\sum_{t=0}^{\infty} Q_t \left[w_{ft} n_{ft} + w_{mt} n_{mt} + \Pi_0 - c_t - \sum_s r_{st} k_{st} - x_{st} \right] \geq 0, \tag{52}$$

in which Q_t is the date-t price of output, w_f is the competitive (noncartel) wage, n_f is the number of workers in the competitive sector, w_m is the cartel wage, n_m is the number of workers in the cartel sector, Π_0 are date zero profits, r_s is the rental price of sector s capital, which in turn is denoted as k_s, and x_s is investment in sector s capital. Time allocated to market activities is given by:

$$n_t = n_{ft} + n_{mt} + n_{ut}. \tag{53}$$

This indicates that total nonmarket time, n, is the sum of household time spent working in the agricultural (noncartel) sector, n_f, the time spent working in the manufacturing (cartel) sector, n_m, and the time spent searching for a job in the manufacturing sector, n_u.

There is also a law of motion for the number of workers in the cartel sector. This transition equation is given by:

$$n_{mt} \leq \pi n_{mt-1} + \upsilon_{t-1} n_{ut-1} \tag{54}$$

The transition equation for the number of workers in the manufacturing sector indicates that the number of these manufacturing workers at date t consists of two components. One is the number who worked last period, less exogenous worker attrition, in which $(1 - \pi)$ is the probability of a manufacturing worker exogenously losing their manufacturing job. The other component is $\upsilon_{t-1} n_{ut-1}$, and this is the number of new workers hired into manufacturing jobs. This is equal to the number of family members who searched for a manufacturing job in the previous period, n_{ut-1}, multiplied by the probability of finding a manufacturing job, which is denoted as υ_{t-1}.

Note that job search is required for an outsider to be newly hired into manufacturing. This search process captures competition by the outsiders in the model for the scarce insider jobs. The insider attrition probability, $1 - \pi$, captures features that generate job loss, but that are not explicitly modeled, such as retirement, disability, and relocation. Note that if $\pi = 1$, then there is no insider attrition, and there will be no hiring (or job loss) in the cartel sector in the steady state of the model.

The law of motion for industry capital stocks is standard, and is given by:

$$k_{st+1} = (1 - \delta) k_{st} + x_{st} \tag{55}$$

Industry output in sector i is given by:

$$y(i)_t = z_t k_t^{\gamma}(i) n_t^{1-\gamma}(i) \tag{56}$$

Sector output is given by:

$$Y_s = \left[\int_{\varphi_{s-1}}^{\varphi_s} y(i)^{\theta} di \right]^{\frac{1}{\theta}}, s = \{f, m\} \tag{57}$$

Final output is given as a CES aggregate of the two sectoral outputs:

$$Y = [\alpha Y_f^{\phi} + (1-\alpha) Y_m^{\phi}]^{\frac{1}{\phi}} \tag{58}$$

Producers in the cartel sector have a profit maximization problem that features their market power, and which depends on the elasticity parameters ϕ and θ. Using the fact that industry price is given by $p = Y^{1-\phi} Y_m^{\phi-\theta}$, the industry profit function is given by:

$$\Pi = \max_{n,k} \{ Y^{1-\phi} Y_m^{\phi-\theta} ((z_t n_t)^{1-\gamma} k_t^{\gamma})^{\theta} - wn - rk \} \tag{59}$$

In the insider–outsider union model, the objective for an incumbent worker (insider) is to maximize the expected present discounted value of industry wage premia. The value of being an insider, in which there are currently n insiders, is given by:

$$V_t(n) = \max_{\bar{w}_t, \bar{n}_t} \{ \min \left[1, \frac{\bar{n}}{n} \right] ([\bar{w}_t - w_{ft}) + \pi \left(\frac{Q_{t+1}}{Q_t} \right) V_{t+1}(\pi \bar{n})] \} \tag{60}$$

The insiders propose to the firm to hire $\bar{n}$ number of workers at the wage rate $\bar{w}_t$. If the offer is accepted, the current period payoff to each insider is the wage premium, which is the cartel wage less the competitive wage: $(\bar{w}_t - w_f)$. The insider's continuation value is the expected discounted value of being an insider next period, which is $\pi \left(\frac{Q_{t+1}}{Q_t} \right) V_{t+1}(\pi \bar{n})$. Note that the number of insiders at the start of period $t+1$ is given by $\pi \bar{n}$. Note that the attrition probability, π, affects the continuation value of union membership in two different ways. First, the probability that any individual insider at date t will remain in the cartel at date $t+1$ is π, which scales the date $t+1$ value function. Second, the total number of date t insiders who will remain in the cartel at date $t+1$ is $\pi \bar{n}$.

The insiders bargain with the firm at the start of each period. If a wage agreement is reached, then the firm hires $\bar{n}$ number of workers at wage $\bar{w}$. Note that the union's offer is efficient in the sense that given the wage offer, the number of workers hired, $\bar{n}$, is consistent with the firm's labor demand schedule. The bargaining protocol is that the union makes a take-it-or-leave-it offer to the firm.

In equilibrium, the union makes an offer that the firm weakly prefers to its outside option of declining the offer. The firm's outside option is given as follows. If the offer is declined, then the firm can hire labor at the competitive wage, w_f. With probability ω the firm will be able to continue to act as a monopolist. With probability $1 - \omega$, the government will discover that the firm did not bargain in good faith with the union, and the government will force the firm to behave competitively and thus the firm earns no monopoly profits.

This feature of the model empirically captures the fact that some firms did fail to reach wage agreements, or violated wage agreements, and that the government did enforce the wage bargaining provisions of the policy. The firm's outside option therefore is the expected level of monopoly profits earned by declining the insider's offer, and the firm will only accept the insider's offer of $(\bar{n}, \bar{w})$ if it delivers at least that level of profit. It is therefore optimal for the union to make an offer that does provide the firm with its outside option.

A key parameter in this model is the share of employment in the cartelized sector. While the cartel policy was intended to cover about 80% of the nonfarm economy, there is debate regarding how much of the economy was effectively cartelized. Therefore, the model conservatively specifies that only manufacturing and mining were cartelized, which is about 1/3 of the economy. Another key parameter is ω, which governs the probability that the government will identify a firm that breaks their wage agreement. This value was chosen so that the steady state cartel wage premium is about 20% above trend. This implies that ω is around 0.10. The attrition parameter, π, is set to 0.95, which yields an average job tenure in the cartel of 20 years.

Other parameters include the substitution elasticity across industries and across sectors. For these parameters, the industry substitution elasticity is picked so that the industry markup would be 10% in the absence of wage bargaining. The sectoral substitution elasticity, which refers to the substitution possibility between manufacturing and the farm sector, is picked to be 1/2. Other parameter values, including the household discount factor, the household leisure parameter, the income shares of capital and labor, and depreciation rates, are standard, and are described in Cole and Ohanian (2004).

The quantitative analysis begins in 1934. To generate model variables, the 1933 capital stocks from the manufacturing and farm sectors from this are specified, and the sequence of TFP from 1934 to 1939 is fed into the model. The model variables then transit to their steady state values. For comparative purposes, we show the results from the cartel model to those from the perfectly competitive version of this model. Table 11, which is taken from Cole and Ohanian (2004), shows the response of the competitive version of this model. Note that the rapid return of productivity to trend fosters a rapid recovery under competition, with hours worked rising above trend to rebuild the capital stock to its steady state level. Moreover, the wage is well below trend in 1933, and then recovers quickly after that, as both productivity and the capital stocks rise.

Table 11 Equilibrium path of recovery from depression in competitive model

	Output	Consumption	Investment	Employment	Wage
1934	0.87	0.90	0.73	0.98	0.89
1935	0.92	0.91	0.97	1.01	0.91
1936	0.97	0.93	1.18	1.03	0.94
1937	0.98	0.94	1.14	1.03	0.95
1938	0.98	0.95	1.12	1.02	0.96
1939	0.99	0.96	1.09	1.02	0.97

Table 12 shows the transition of the cartel model. This transition stands in sharp contrast to the transition in the competitive economy from Table 11. The cartel economy transits to a steady state that is well below the competitive economy. Despite rising productivity, the cartel economy remains depressed through the 1930s, as cartel policies create rents that raise wage rates far above trend, despite the fact that both consumption and time allocated to market activities are below trend. These results indicate that the cartel policy accounts for about 60% of the post-1933 Depression in output, consumption, and hours worked.

5.5 Neoclassical Models of Taxes and Depressions

This section describes how tax rate changes contributed to the US Great Depression and also for more recent episodes of depressed economic activity.

Tax rates rose in the United States during the Great Depression. McGrattan (2012) studies how changes in tax rates on dividends and corporate profits affected economic activity after 1933. Specifically, a new tax rate was applied to undistributed corporate profits in 1936. The goal of this new tax was to increase corporate payments to shareholders, which in turn was expected to stimulate spending.

McGrattan analyzes a representative household economy with log preferences over consumption and leisure, and with a standard constant returns to scale Cobb–Douglas production function with capital and labor inputs. She considers two formulations for taxes. In the traditional formulation, tax rates are applied to labor income (τ_h) and to capital income net of depreciation (τ_k). Tax revenue is the sum of labor income tax revenue and capital income tax revenue:

$$\tau_h wh + \tau_k(r-\delta)k \tag{61}$$

The alternative formulation includes a finer decomposition of taxes across revenue sources, and distinguishes between business and nonbusiness capital. Tax revenue in this alternative formulation is given by:

$$\begin{aligned}\tau_h wh &+\tau_p(r-\tau_k-\delta)k_b+\tau_c c+\tau_k k_b+\tau_u(k_b'-k_b)\\ &+\tau_d\{(rk_r-x_b)-\tau_p(r-\tau_k-\delta)k_b-\tau_k k_b-\tau_u(k_b'-k_b)\}\end{aligned} \tag{62}$$

In (64), τ_p is the tax rate on profits, τ_k is now the tax rate on business property, τ_c is the consumption tax rate, τ_u is the tax rate on undistributed profits, τ_d is the dividend tax rate, and primed variables refer to period $t+1$ values.

The intertemporal first order condition that governs efficient investment shows how changes in expected taxation affect investment:

$$\frac{(1+\tau_{ut})(1-\tau_{dt})}{(1+\tau_{ct})c_t}=\beta E_t\left[\frac{(1-\tau_{dt+1})}{(1+\tau_{ct+1})c_{t+1}}\{(1-\tau_{pt+1})(r_{t+1}-\tau_{kt+1}-\delta)+(1+\tau_{ut+1})\}\right] \tag{63}$$

Table 12 Equilibrium path of recovery from depression in cartel policy model

						Employment		Wage	
	Output	**Consumption**	**Investment**	**Employment**	**Searchers**	**Cartel sector**	**Competitive sector**	**Cartel sector**	**Competitive sector**
1934	0.77	0.85	0.40	0.82	0.07	0.68	0.89	1.16	0.81
1935	0.81	0.85	0.62	0.84	0.11	0.69	0.92	1.19	0.83
1936	0.86	0.85	0.87	0.89	0.06	0.72	0.97	1.20	0.83
1937	0.87	0.86	0.90	0.90	0.04	0.73	0.98	1.20	0.83
1938	0.86	0.86	0.86	0.89	0.06	0.72	0.97	1.20	0.84
1939	0.87	0.86	0.88	0.89	0.04	0.73	0.97	1.20	0.84

Note that dividend taxes and consumption taxes in (65) do not distort investment incentives at the margin in the deterministic version of this model when these tax rates are constant over time. However, expected changes in tax rates will affect investment decisions. An expected increase in these tax rates reduces the expected returns to investment, and leads firms to increase current distributions. Tax rates rose considerably in the mid-1930s, with the dividend tax rate rising from about 14% to about 25%, the corporate profit tax rate rising from about 14% to about 19%, and the newly implemented undistributed tax rate of 5%. McGrattan shows that plausible expectations of these tax rate changes can help account for the fact that business investment remained at 50% or more below trend after 1933.

McGrattan's analysis of the US Great Depression focused on changes in capital income tax rates. Prescott (2004) and Ohanian, Raffo, and Rogerson (2008) analyze how long-run changes in labor income tax rates have affected hours worked more recently. Ohanian et al. (2008) document that hours worked per adult in the OECD vary enormously over time and across countries. Hours worked in many Northern and Western European countries declined by about 1/3 between the 1950s and 2000, including a nearly 40% decline in Germany.

Ohanian et al. use a standard neoclassical growth model with log preferences over consumption, log preferences over leisure, a flat rate labor income tax, and a flat rate consumption tax rate. The economy's technology is a constant returns to scale Cobb–Douglas production function that uses capital and labor, which is given by $Y_t = A_t K_t^{\theta} H_t^{1-\theta}$. Preferences for the representative family are given by:

$$\max \sum \beta^t \{\alpha \ln(c_t - \bar{c} + \lambda g_t) + (1-\alpha)\ln(\bar{h} - h_t)\}. \tag{64}$$

Households value private consumption, c, and public consumption, g. The term $\bar{c}$ is a subsistence consumption term to account for possible nonhomotheticities in preferences that may affect trend changes in hours worked. The parameter $\lambda, 0 < \lambda \leq 1$, governs the relative value that households place on public spending. The specification that government consumption (scaled by the parameter λ) is a perfect substitute for private consumption follows from the fact that much government spending (net of military spending) is on close substitutes for private spending, such as health care.

The first order condition governing time allocation in this economy is standard, and equates the marginal rate of substitution between consumption and leisure to the wage rate, adjusted for consumption and labor income taxes. This first order condition is presented below. Note that the marginal product of labor, $(1-\theta)\frac{Y_t}{H_t}$ is substituted into the equation for the wage rate in (67):

$$\frac{(1-\alpha)}{\bar{h} - h_t} = \frac{(1-\tau_{ht})}{(1+\tau_{ct})} \frac{\alpha}{(c_t + \lambda g_t)} (1-\theta) \frac{Y_t}{H_t}. \tag{65}$$

In the first order condition, τ_h is the labor income tax rate, and τ_c is the consumption tax rate. Ohanian et al. feed McDaniel's (2011) panel data construction of consumption and income tax rates into this first order condition, along with actual labor productivity and consumption data. They choose the value of α by country so that model hours in the first year of the dataset are equal to actual hours for each country. They set $\lambda = 1$, and labor's share of income is set to 0.67. The subsistence consumption term is set to 5% of US consumption in 1956, which represents a small departure from the standard model of homothetic preferences. Ohanian et al. describe the sensitivity of results to alternative values for these parameters.

With these parameter values and data, Ohanian et al. use this equation to construct a predicted measure of hours worked from the model economy, and compare it to actual hours worked by country and over time. Fig. 25 shows actual hours worked and

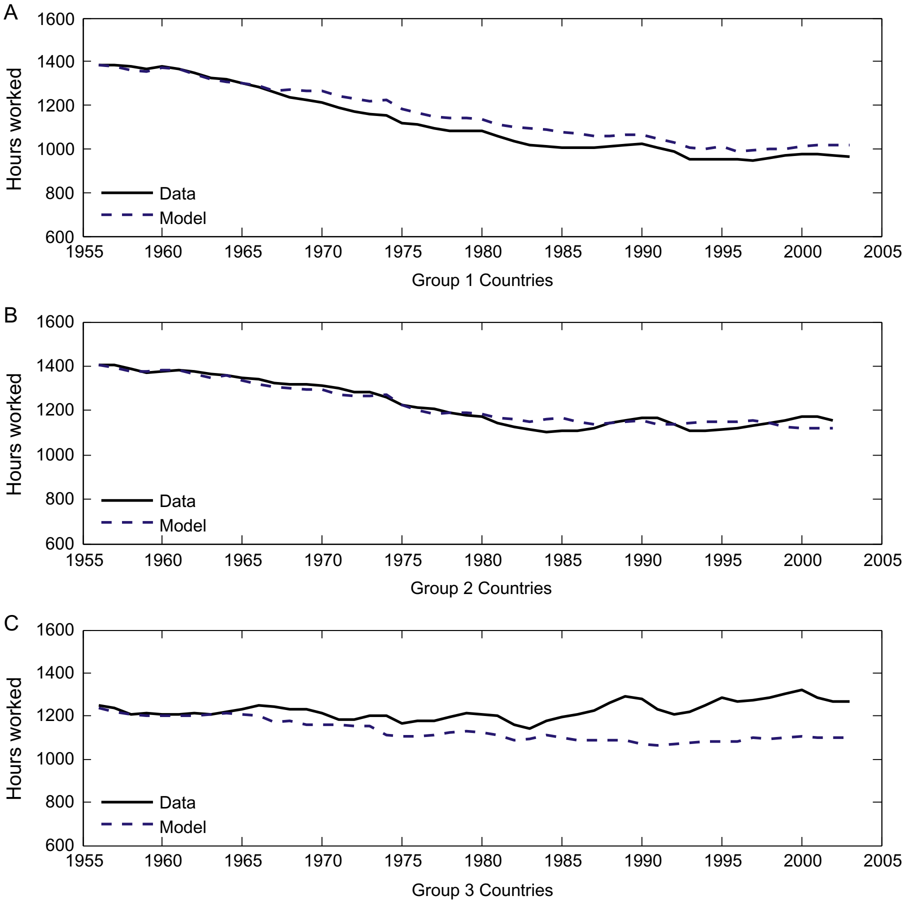

Fig. 25 Comparing OECD hours worked, model and data.

predicted hours worked from the model for 21 OECD countries.[q] Panel (A) of the graph shows results for countries which experienced at least a 25% decline in hours worked per capita. Panel (B) shows results for countries which experienced a decline in hours per capita that range between 10% and 25%. Panel (C) shows results for countries that experienced a decline in hours per capita of less than 10%, or alternatively experienced higher hours.

The figures show that the model economy accounts for much of the secular decline in hours worked, particularly for the countries which experienced the largest hours declines. Ohanian et al. also report that the contribution of tax rate changes to changes in hours worked is not sensitive to other labor market factors that may have affected hours, such as changes in employment protection policies, changes in union density, and changes in unemployment benefits.

These findings indicate that the observed increases in labor and consumption tax rates can account for the large observed declines in hours worked per adult across these countries. These neoclassical findings regarding the impact of tax rates on hours worked stand in contrast to other explanations of the decline in European hours. Other explanations include a preference shift for more leisure, or a preference shift in conjunction with policies that restrict work, and that may have been chosen in order for society to coordinate on a low-work equilibrium (see Blanchard, 2004 and Alesina et al., 2006).[r]

5.6 Summary

Depressions, which are protracted periods of substantial economic decline relative to trend, have been difficult to understand and are often presumed to extend beyond the scope of neoclassical economics. The models developed here show that government policies that depress competition can account for a considerable amount of the Great Depression, and can also account for much of the failure of economic activity to return to trend. More broadly, these models of the US Great Depression successfully confront the frequently cited view of Modigliani (1977) that neoclassical models cannot plausibly account for the behavior of labor markets during Depressions.

Modigliani interpreted the Great Depression as the failure of the market economy to right itself. This view, and associated Keynesian views of the Depression, are based on the idea that business organizations did not expand investment in the 1930s, which in turn kept employment low. The studies discussed here turn that interpretation on its head. Specifically, these new neoclassical studies indicate that the depth and persistence of the Depression was the consequence of government policies that depressed the steady

[q] Ohanian et al. (2008) describe the data sources and data construction in detail. The Group 1 countries are Austria, Belgium, Denmark, France, Finland, Germany, Italy, and Ireland. The Group 2 countries are Japan, the Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, and the United Kingdom. The Group 3 countries are Australia, Canada, Greece, New Zealand, and the United States.

[r] Other neoclassical studies of taxes and labor supply include Erosa, Fuster, and Kambourov (2012) Rogerson (2009), Ragan (2013), Meza (2008), Samaniego (2008), Dalton (2015), and Davis and Henrekson (2005).

state allocation of time to market work. A lower steady state level of market hours reduced the return to capital, which in turn depressed capital accumulation.

Neoclassical models can also account for more recent periods of depressed economic activity. This includes not only the secular decline in market hours worked in much of Northern and Western Europe through higher tax rates, but also the Finish Depression of the early 1990s that reflects the trade impact of the breakup of the USSR. (Gorodnichenko et al., 2012), and tax changes and productivity changes (Conesa et al., 2007). Other studies of recent Depressions include the Korean Crisis of 1998 (Otsu, 2008), and several case studies in Kehoe and Prescott (2007).

The Depression methodology presented in this section has also been used to study the flip side of Depressions, which are Growth Miracles. This includes studies of Ireland's Growth Miracle (see Ahearne et al., 2006, who analyze a standard growth model with TFP, and Klein and Ventura (2015), who study a small open economy model with taxes, labor wedges, and TFP), and Lu (2012), who analyzes the development of some East Asian countries in a neoclassical framework.

6. NEOCLASSICAL MODELING OF LARGE FISCAL SHOCKS: THE US WORLD WAR II ECONOMY

Wartime economies are interesting and important macroeconomic episodes because they feature very large, exogenous changes in government policies, particular fiscal policies, as well as large changes in macroeconomic activity. The World War II economy in the United States represents perhaps the largest fiscal policy shift of any advanced economy. This includes a nearly 400% increase in federal government spending, large increases in income tax rates, and a large increase in the number of men drafted into military service. Moreover, there was a very large resource reallocation from private use to military use that occurred in a very short period of time.

This striking period of policy changes provides information on how large aggregate and sectoral disruptions quantitatively affect a market economy, which provides a powerful test of neoclassical theory. These episodes are also informative about what a number of economists call the *government spending multiplier*, which refers to the change in output as a consequence of a change in government spending. This research area has received considerable attention since the Great Recession, when the United States and other countries increased government spending to expand economic activity (see Barro and Redlick, 2011; Mountford and Uhlig, 2009; Ramey, 2011; and Taylor, 2011).

Neoclassical analysis of fiscal policies and wars has become an active research area.[s] These studies analyze a range of issues, including the welfare costs of different wartime fiscal policies (Ohanian, 1997), the impact of the draft on economic activity

[s] Studies include Ohanian (1993, 1997), Braun and McGrattan (1993), Siu (2008), Mulligan (2005), McGrattan and Ohanian (2010), Burnside, Eichenbaum, and Fisher (2004), Baxter and King (1993), Christiano and Eichenbaum (1992), Doepke et al. (2015), and Monacelli and Perotti (2008).

(Siu, 2008), the behavior of labor productivity and investment (Braun and McGrattan, 1993), and the extent that a neoclassical model can account for aggregate time series, particularly the impact of wars on the incentives to work (Mulligan, 2005 and McGrattan and Ohanian, 2010).

This section develops a neoclassical model of the World War II US economy to study how well a neoclassical model can fit the wartime US data. The model easily can be applied to other episodes with changes in government spending, transfers, and tax rates. The model is from McGrattan and Ohanian (2010), which in turn draws on Braun and McGrattan (1993), Ohanian (1997), and Siu (2008).

There is a representative family, with two types of family members, civilians and draftees. The size of the family is denoted as N. Both types of family members have identical preferences. At date t, a_t is the number of family members in the military, and $(1 - a_t)$ is the number who are civilians. The family optimally chooses consumption of both types, which is denoted as c_{ct} for civilians, and c_{dt}, for draftees. The family also optimally chooses investment in physical capital, i_{pt}, civilian labor input, l_{ct}, and the accumulation of government bonds, b_{t+1}. The inclusion of public debt follows from the fact that there was considerable debt issue during the war. The labor input of draftees is not a choice variable for the family, but rather is set exogenously by the government, and is denoted by $\bar{l}_d$.

The maximization problem for the representative family is:

$$\max E_0 \sum_{t=0}^{\infty} \{(1-a_t)U(c_{ct}, l_{ct}) + a_t U(c_{dt}, \bar{l}_d)\} N_t \tag{66}$$

Maximization is subject to the following constraints:

$$E_t = (1-\tau_{kt})(r_{pt} - \delta)k_{pt} + (1-\tau_{lt})w_t(1-a_t)l_{ct} + R_t b_t + (1-\tau_{lt})w_t a_t \bar{l}_d + T_t \tag{67}$$

$$E_t = (1-a_t)c_{ct} + a_t c_{dt} + i_{pt} + b_{t+1} \tag{68}$$

$$k_{pt+1} = [(1-\delta)k_{pt} + i_{pt}]/(1+\gamma_n) \tag{69}$$

$$N_t = (1+\gamma_n)^t \tag{70}$$

$$c_c, c_d, i_p \geq 0 \tag{71}$$

Note that k_p is the beginning-of-period capital stock, r_p is the rental price of capital, w is the wage rate, τ_k and τ_l are flat rate tax rates on capital income and labor income, respectively, Rb is the value of matured government debt, and T is government transfers. The depreciation rate is δ. The population grows at the constant rate γ_n.

The production technology is given by:

$$Y_t = F(K_{pt}, K_{gt}, Z_t L_t). \tag{72}$$

The production inputs include private capital, labor, and public capital, K_g. Labor-augmenting productivity is denoted as Z, and is given by:

$$Z_t = z_t(1+\gamma_z)^t. \tag{73}$$

Note that z_t is a transient productivity term and γ_z is the long-run growth rate of technology.

Government purchases consist of 3 components. This is a richer specification of government spending than is typically modeled in fiscal policy studies. Government consumption, C_g is the first component, and this is the standard approach to modeling government purchases. It is common to assume that these wartime purchases of goods do not affect marginal utility or private production possibilities. The second component is government investment, I_g which enhances production possibilities by expanding the capital stock that can be used to produce output. This is typically not modeled in the fiscal policy literature, but is modeled here because of the very large government-funded investments in plant and equipment that occurred in World War II. The government made large investments in the aircraft, automotive, and aluminum industries that raised the manufacturing capital stock by 30% between 1940 and 1945. The third component of government purchases is wage payments to military personnel. Government spending is therefore given by:

$$G_t = C_{gt} + I_{gt} + N_t w_t a_t \bar{l} \tag{74}$$

The evolution of the stock of government capital, which is assumed to have the same depreciation rate as physical capital, is given by:

$$K_{gt+1} = (1-\delta)K_{gt} + I_{gt} \tag{75}$$

The period government budget constraint is given by:

$$B_{t+1} = G_t + R_t B_t - \tau_{lt} N_t w_t((1-a_t)l_{ct} + a_t \bar{l}_d) - \tau_{kt}(r_{pt}-\delta)K_{pt} - r_{gt}K_{gt} + T_t, \tag{76}$$

in which T is a residual lump-sum tax.

A competitive firm maximizes profits, which implies that the rental prices for the factors of production are equal to their marginal productivities. Government debt that is accumulated during the war is retired gradually after the war. The exogenous variables are the tax rates on factor incomes, government consumption and government investment, and the productivity shock. The equilibrium definition of this perfectly competitive economy is standard.

The functional form for preferences is given by:

$$\ln(c) + \frac{\psi}{\xi}(1-l)^{\xi} \tag{77}$$

This specification yields a compensated labor supply elasticity of $\frac{1-l}{(l(1-\xi))}$. McGrattan and Ohanian choose $\xi = 0$ (log preferences) as the benchmark specification. The parameter ψ governs the steady state allocation of time for the household, and is chosen so that model steady state hours is equal to the average time devoted to market work between 1946 and 1960. For military time allocation, they choose $\bar{l}$ such that it matches 50 h per week, which is the average hours for soldiers in basic training (see Siu, 2008). Population growth is 1.5% per year, and the growth-rate of technological progress is 2% per year.

Government capital and private capital are modeled as perfect substitutes. This reflects the fact that much of government investment at this time was in the area of manufacturing plant and equipment:

$$Y_t = F(K_{pt}, K_{gt}, Z_t L_t) = (K_{pt} + K_{gt})^{\theta} (Z_t L_t)^{1-\theta} \tag{78}$$

It is straightforward, however, to modify the aggregator between government and private capital to accommodate government capital that is not a perfect substitute for private capital.

There are six exogenous variables in the model: conscription (the draft) (a_t), the tax rate on capital income (τ_{kt}), the tax rate on labor income (τ_{lt}), government consumption (C_{gt}), government investment(I_{gt}), and productivity (z_t). The evolution of the six exogenous variables is governed by a state vector, S_t, which specifies a particular set of values for these exogenous variables. For 1939–46, these exogenous variables are equal to their data counterparts. The model is solved under different assumptions regarding household expectations about the post-1946 evolution of the exogenous variables. The discussion here focuses on the perfect foresight solution to the model that begins in 1939, and McGrattan and Ohanian discuss the other cases in detail.

While the model described here is based on the World War II US economy, it can be tailored to study other episodes, as it includes a number of features that are relevant for wartime economies, including changes in tax rates on factor incomes, changes in conscripted labor, changes in productivity, government debt issue to help pay for the war, government payments to military personnel, and government investment.

Fig. 26 shows the model's exogenous variables. Government consumption, which includes state and local spending, as well as federal spending, rises from about 14% of steady state output in 1940 to 50% of steady state output by 1944. Government investment rises from about 4% of steady state output in 1940 to about 9% by 1942. The tax rates on labor and capital income, which are average marginal tax rates taken from Joines (1981), also rise considerably, with the labor income tax rates rising from about 8% to about 20%, and with the capital income tax rates rising from about 43% to about 63%. The draft reduces potential labor supply significantly, as almost 12% of the working age population is in the military by 1944.

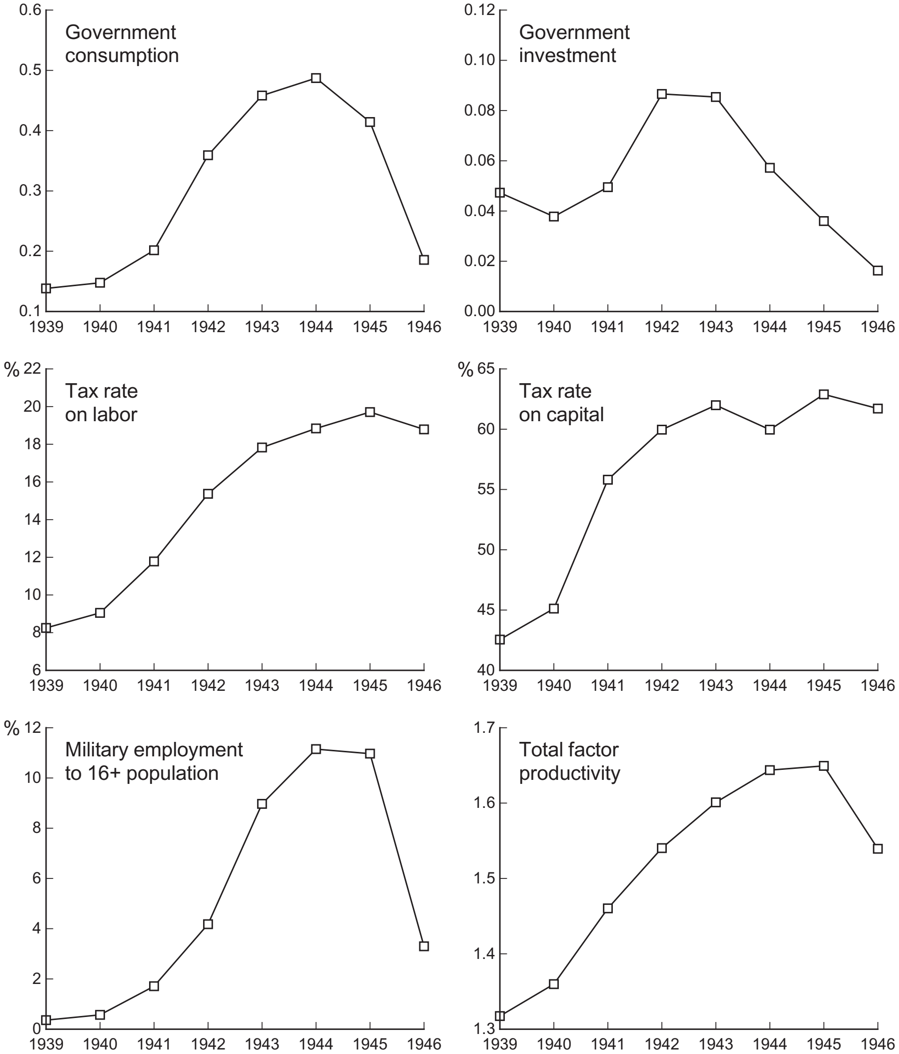

Fig. 26 US government spending, tax rates, draft, and TFP, 1939–46. *Notes*: (1) Government spending series are real and detrended by dividing by the population over 16 and by the growth trend in technology (scaled so the 1946 real detrended level of GNP less military compensation equals 1). (2) Total factor productivity is defined to be $Y/(K^{\theta}L_p^{1-\theta})$, where Y is real, detrended GNP less military compensation, K is real detrended nonmilitary capital stock, L_p is nonmilitary hours worked, and $\theta = 0.38$.

There is a considerable increase in TFP, and there are a number of good reasons why this change actually reflects higher efficiency. This includes the development of federally-funded scientific teams, the development of management science and operations research practices, and a number of technological advances during the 1940s including innovations directly or indirectly fostered by federal R & D expenditures. These include the development of modern airframes, radar, microwave technology, fertilizer, oxygen steel, synthetic rubber, nylon, sulfa drugs and chemotherapy, insecticides, and Teflon and related industrial coatings. Moreover, Herman (2012) describes how business leaders worked together in World War II to mobilize resources and to raise military output through significantly higher efficiency.

The size and diversity of these changes will affect economic activity in a variety of ways. Higher TFP will promote high labor input and output, as will public investment. In contrast, since public investment substitutes for private investment, higher public investment in plant and equipment will tend to reduce private investment. Moreover, rising tax rates and conscription of labor will tend to reduce the incentive to work.

Fig. 27 shows real GNP, real consumption, and real investment, all measured as a percent of trend output. The model output series is very close to actual output, as both increase by more than 50% over the course of the war, and then decline after the war, back to near trend. Model consumption is very flat during the war, and is close to actual consumption. Model investment has a very similar pattern as actual investment. The model investment is somewhat higher than actual investment through 1942, which reflects the perfect foresight solution. Specifically, investment rises considerably in order to build the capital stock by the time that government consumption is high. By 1944, the high level of government investment in plant and equipment, coupled with the enormous resource drain of the war, leads to investment declining significantly. Fig. 28 shows the behavior of total hours worked, and nonmilitary hours, which is the choice variable

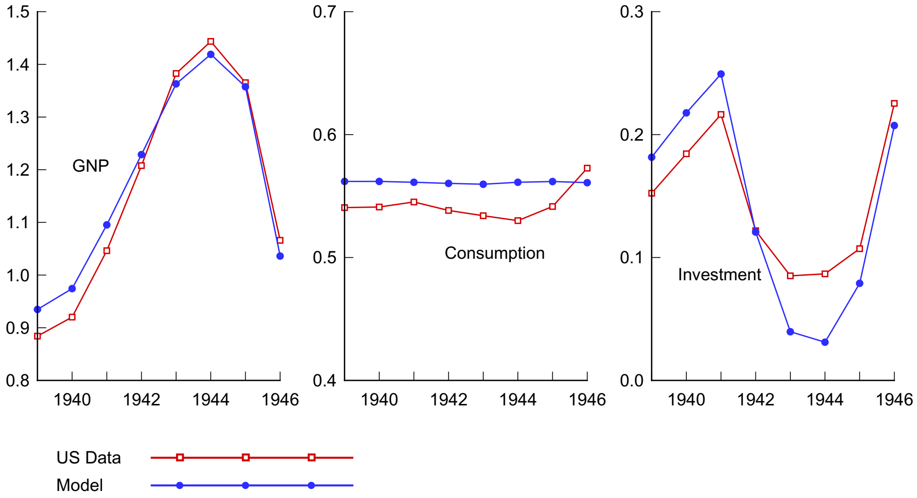

Fig. 27 Real detrended GNP, private consumption, and private investment. *Note*: Data series are divided by the 1946 real detrended level of GNP less military compensation.

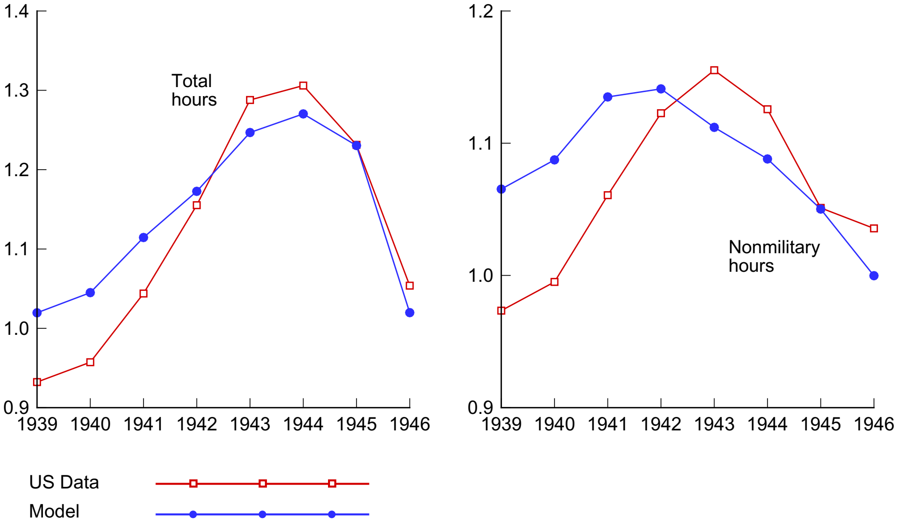

Fig. 28 Per capita total and nonmilitary hours of work, 1939–46. *Note*: Hours series are divided by the 1946–60 US averages.

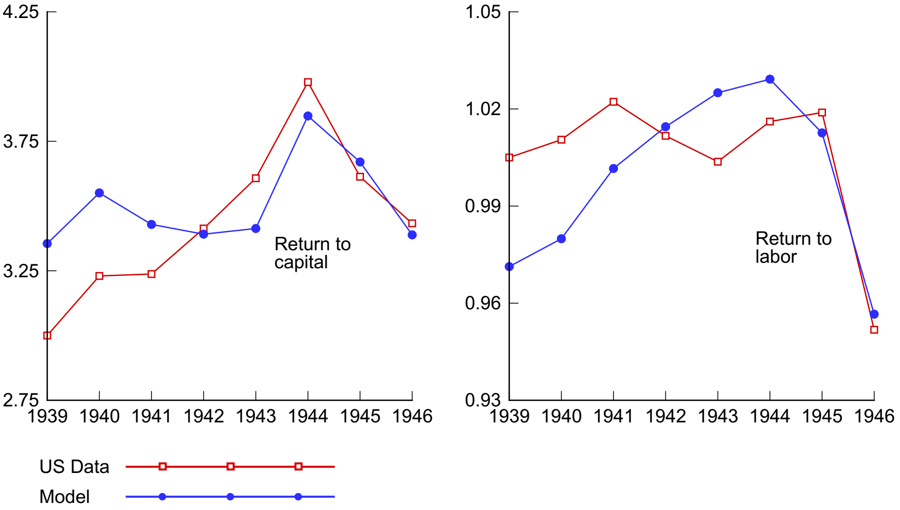

Fig. 29 After-tax returns to capital and nonmilitary labor, 1939–46. *Note*: Return to capital is equal to $100(1-\tau_k)(\theta Y/K-\delta)$. Return to labor is after-tax nonmilitary labor productivity normalized by the 1946–60 US averages.

for the family. Both hours series rise significantly in the data and in the model. The nonmilitary hours in the model rises earlier than in the data, and this again partially reflects the perfect foresight assumption. Fig. 29 shows the after-tax returns to private capital and labor. These are also quite similar to the data.

The dominant factor driving these results is the enormous expansion of government consumption that occurred during the war. This resource drain of wartime government consumption creates a sizeable wealth affect within the model that leads to higher labor input and output, and this effect is much larger than that of any of the other shocks. McGrattan and Ohanian (2010) analyzed the impact of each of the six shocks in the model on hours worked. The impact of just government consumption in the absence of any other shocks raises nonmilitary labor input by about 27% on average between 1943–45. Adding productivity shocks raises this to about a 29% increase. Adding in the draft to these two preceding shocks results in about a 25% increase. Adding in the labor and capital income tax increases has a sizeable depressing effect, and results in an increase in nonmilitary hours of about 10%. Overall, the negative wealth effect arising from government consumption is the dominant factor, followed by the impact of tax increases.

These results shed light on a number of issues that are analyzed in the literature on the macroeconomics of fiscal policy. One issue is regarding the government spending multiplier. A difficulty facing many studies of government spending multipliers is that they are primarily based on peacetime episodes, and episodes even with relatively large peacetime shifts in fiscal policy still involve small changes in fiscal policy compared to policy changes during wartime episodes. Moreover, many of these studies require exogenous changes in fiscal policy, and this can be problematic during peacetime. Consequently, it is challenging to draw sharp conclusions about the size of the multiplier based on peacetime policy changes.

The results from this World War II analysis indicate a multiplier that is considerably less than one. This is informative, not only because the wartime fiscal policy shock is so large, but also because the model explicitly distinguishes between different types of government spending. The analysis conducted here makes it possible to isolate the impacts of different types of spending and taxes on economic activity.

To see that the multiplier from this episode is fairly small, consider the following case in which we account for the impact of all government expenditures, but omit the negative impact of the tax increases and the draft. By omitting these latter two items, we construct the maximum possible effect of fiscal policy, even though tax increases, which depress labor supply, are certainly part of fiscal policy. In this experiment, the World War II episode shows that the multiplier would be about 0.6, reflecting a hypothetical 30% increase in output resulting from government purchases of goods. This multiplier is very similar to Barro and Redlick's (2011) estimates and Mountford and Uhlig's (2009) short-run estimates and is in the lower end of the range of estimates discussed in Ramey (2011).

The results have broader implications regarding neoclassical analyses of large shocks. They indicate that the US economy responded to the enormous wartime economic dislocations, as well as the peacetime reversal of these dislocations, very much along the lines of a simple neoclassical growth model augmented with several large policy changes.

These policy shifts include the massive reallocation of economic activity from peacetime to wartime production, the enormous drain of resources resulting from government purchases, the reduction of the labor endowment through the draft, higher taxes, and government-funded investment. This also includes the rapid unwinding of these unique factors after the war. While this represents just a single episode, this analysis provides a strong test of the neoclassical model in response to large fiscal policy changes.

7. NEOCLASSICAL MODELS OF PRODUCTIVITY SHOCKS

Productivity change is an important feature of the models and the data that we have used to analyze the US historical macroeconomic record in this chapter. This includes a large TFP decline in the Great Depression, a large TFP increase in World War II, and large TFP and equipment-specific productivity fluctuations in the post-Korean War US economy.

There are long-standing questions about the nature and sources of these productivity changes. Much of the profession has viewed TFP declines during downturns, and particularly during depressions, with skepticism, and naturally so. But economists are now analyzing TFP deviations during short-run and longer-run episodes from alternative perspectives than the narrow interpretation that TFP declines reflect a loss of technological know-how and knowledge.

7.1 Resource Misallocation and TFP

Restuccia and Rogerson (2008) analyze the impact of *resource misallocation* on TFP in a competitive economy. The idea is to assess how the misallocation of production inputs across locations affects measured TFP. Their model is related to Hopenhayn and Rogerson (1993), in which there is a representative family and there are different producers, or alternatively, different production locations, each with a decreasing returns to scale technology with potentially different TFP levels, and which are indexed by i. The simplest case of production heterogeneity is the case of a single final good produced at multiple locations, y_i, that is produced with a single production input, labor (h_i). The production relationship at location i is given by:

$$y_i = z_i f(h_i) \tag{79}$$

In this economy, the technology f is twice continuously differentiable, with $f' > 0, f'' < 0$. The term z_i denotes exogenous productivity. Assume that z_i is drawn from the set $\{z_1, z_2, \ldots z_I\}$, and let $\mu(i)$ be the distribution of productivity across these locations.

The efficient allocation of labor requires equating the marginal product of labor across production locations. For the isoelastic technology, $z_i h_i^{\theta}, 0 < \theta < 1$, the efficient allocation of labor between any two locations depends on the differences in productivities at those locations, and the amount of curvature in the production technology:

$$\frac{h_i}{h_j} = \left(\frac{z_i}{z_j}\right)^{\frac{1}{1-\theta}}. \tag{80}$$

We construct an economy-wide measure of TFP by aggregating TFP across all locations. Aggregate TFP in this economy is given by:

$$z = \sum_i z_i^{\frac{1}{1-\theta}} \mu(i)^{1-\theta}. \tag{81}$$

The efficient allocation of labor at any specific location depends on the location's productivity relative to aggregate productivity, as well as the amount of curvature in the technology, and is given by:

$$h_i = \left(\frac{z_i}{z}\right)^{\frac{1}{1-\theta}}. \tag{82}$$

Note that as $\theta \rightarrow 1$, even small differences in productivity generate very large differences in the efficient allocation of production inputs across locations.

Atkeson et al. (1996) use data on differences in worker firing costs and job reallocation rates between the United States and Europe to argue that θ is around 0.85. Restuccia and Rogerson use this value for specifying the level of decreasing returns in their economy, and they study how misallocation of production inputs across locations affects aggregate productivity, z. Resource misallocation means that the marginal product of labor is not equated across production locations, which implies that (82) and (84) are not satisfied.

Restuccia and Rogerson (2008) analyze various government policies that tax the output of some producers, and that subsidize the output of other producers, and they calculate the aggregate productivity and welfare losses from these policies. There is a large literature that has built on Restuccia and Rogerson along many dimensions. This includes the application of misallocation to specific Depressions and Crises (see Oberfield, 2013 and Chen and Irarrazabal, 2013 on the Chilean Depression of the early 1980s, and Sandleris and Wright, 2014 on the Argentinian Depression of 2001), the connection between financial market imperfections and misallocation (see Moll, 2014; Buera and Moll, 2015; and Midrigan and Xu, 2014) and the connection between trade barriers and productivity during the US Great Depression (see Bond et al., 2013). Other studies of misallocation focus on longer-run issues, including studies of the role of misallocation in the development experiences of China and India (Hsieh and Klenow, 2009), entry regulation and productivity (Poschke, 2010), size-dependent policies and productivity (Guner et al., 2008), imperfect information and productivity (David et al., forthcoming), the misallocation of managerial talent and productivity (Alder, 2016), and the magnification of misallocation on productivity in economies with production chains (Jones, 2013).

7.2 Intangible Investments and TFP

Neoclassical models with intangible capital are being developed to construct new measures of TFP. These studies focus on intangible investments that traditionally have not been counted as part of national product. Prior to 2013, the Bureau of Economic Analysis (BEA) counted only software as investment among the intangible categories. In 2013, the BEA implemented a comprehensive revision of the National Income and Product Accounts to include other business purchases that previously were counted as business expenses as investment, including research and development, artistic products, mineral exploration, and intellectual property. The shift of these purchases from an expensed item to business investment increases output. This BEA revision improves the measurement of real output, but the BEA does not currently count other intangible investments in the national accounts, such as marketing, advertising, and organization capital investments. These investment omissions indicate that output is mismeasured, which implies that productivity is also mismeasured.

McGrattan and Prescott (2012, 2014), and McGrattan (2016), go beyond the new NIPA measures of GDP by constructing real output measures that include other expensed items, including advertising, marketing, computer design, management consulting, public relations, and engineering expenses as intangible investment. McGrattan (2016) develops a model of the US economy that includes both tangible and intangible production, with a focus on intersectoral linkages.

McGrattan develops a model with tangible output and intangible output. Intangibles are a nonrival good. There are s sectors that use both tangibles and intangibles. There is a Cobb–Douglas aggregate over consumption goods from the S sectors. The technologies differ in terms of a sector-specific technology shock, and technology share parameters. The outputs for tangibles and intangibles is given by:

$$Y_{st}=(K_{Tst}^{1})^{\theta_S}(K_{Ist})^{\phi_S}(\Pi_l(M_{lst}^{1})^{\gamma_{lS}})(Z_tZ_{st}^{1}H_{st}^{1})^{1-\theta_S-\phi_S-\gamma_S} \tag{83}$$

$$I_{st}=(K_{Tst}^{2})^{\theta_S}(K_{Ist})^{\phi_S}(\Pi_l(M_{lst}^{2})^{\gamma_{lS}})(Z_tZ_{st}^{1}H_{st}^{1})^{1-\theta_S-\phi_S-\gamma_S} \tag{84}$$

Y_s denotes the output of the tangible sector, K_{Ts}^{1} is tangible capital that is used to produce tangible output in sector S, K_{Ts}^{2} is tangible capital used to produce intangible output in sector S, K_{Ist} is intangible capital, which is assumed to be nonrival, M_{ls}^{1} and M_{ls}^{2} are intermediate inputs used to produce tangibles in sector S, and intangibles in sector S, respectively. Z is the aggregate productivity shock and Z_s is a sector-specific productivity shock. H_s^1 and H_s^2 are labor input for tangibles in sector S, and intangibles in sector S, respectively.

McGrattan (2016) uses maximum likelihood to estimate the parameters of the stochastic processes for Z_t and for Z_{st}, and compares two economies, one with intangibles, and another without intangibles. The mismeasurement of productivity in the economy without intangibles generates a large labor wedge, and McGrattan argues that this may account for the empirical labor wedge measured from NIPA data. McGrattan also shows that the economy with intangibles closely accounts for the 2008–14 US economy, despite the fact that the standard measure of TFP based on NIPA data is not highly correlated with hours worked during this period.

Another literature that relates intangible investments to productivity is in the area of organization capital. As noted above, these investments are not counted in the NIPA. Atkeson and Kehoe (2005) study a neoclassical model in which an organization stochastically accumulates intangible knowledge over time. They find that the payments from these intangibles are about one-third as large as the payment from tangible capital, which suggests that organization capital is very large.

7.3 Neoclassical Models of Network Linkages and TFP

The impact of industry and/or sectoral shocks on the aggregate economy motivates a significant component of the real business cycle literature, including the seminal contribution of Long Jr and Plosser (1983), and subsequent research by Dupor (1999) and Horvath (2000). One theme of this research is to provide a theory for aggregate productivity shocks that hit the economy.

This idea is now being developed further in network models, which focus on the idea that production is organized through networks of supply chains, and that small disruptions in networks can have significant aggregate consequences, particularly if there are only a small number of suppliers of a particular input, and if there are no particularly close substitutes for that input. Carvalho (2014) describes much of the recent literature on networks and macroeconomics.

Carvalho describes a simple model of production networks in which individual sectors produce a specialized output. This output is produced using homogeneous labor and intermediate inputs from other sectors. The output of sector i is given by:

$$y_i = (z_i h_i)^{1-\theta} \left(\prod_{i=1}^{n} y_{ij}^{\omega_{ij}} \right)^{\theta}. \tag{85}$$

In this technology, y_i denotes sectoral output, z_i is a sectoral productivity shock, h_i is labor employed in sector i, and the exponents ω_{ij} denote the share of intermediate input j used in producing good i. Note that labor is supplied inelastically by a representative household, so aggregate labor is in fixed supply. For simplicity, preferences are symmetric over the i goods in the household utility function.

The empirical importance of network linkages can be identified from a standard input–output matrix. Since aggregate labor is in fixed supply, aggregate output is a weighted average of the sectoral productivity shocks:

$$\ln(y) = \sum_{i=1}^{n} \nu_i \ln(z_i). \tag{86}$$

In this expression, y is aggregate output and the ν_i are weights that are constructed from the input–output table. Note that measured aggregate productivity in this economy, which is $\frac{y}{h}$, will fluctuate even though there is no aggregate productivity shock. This simple model shows how a single shock to an important sector can have significant aggregate affects that will be observationally equivalent to a one-sector model with an aggregate productivity shock.

8. NEOCLASSICAL MODELS OF INEQUALITY

Neoclassical modeling is also making considerable progress in characterizing and quantifying how technological change has affected income distribution and wage inequality. Neoclassical studies of inequality analyze how biased technological change differentially affects the demand for different types of workers.

Early empirical studies by Katz and Murphy (1992), among others, concluded that skill-biased technological change was responsible for the widening wage gap between highly-educated workers and workers with less education. This conclusion reflects the fact that the relative supply of highly-skilled workers rose considerably, and the relative wage of these workers also rose.

Krusell et al. (2000) develop a neoclassical model to analyze how technological change has affected the relative wage of skilled to less-skilled workers. This relative wage is often called the *skill premium*. Krusell et al. provide an explicit theory of skill-biased technological change, show how to measure this change, and develop a neoclassical model to quantify its effect on inequality through observable variables.

The model features two different types of labor: high-skilled labor, who are workers with 16 or more years of education, and unskilled labor, who have fewer than 16 years of education.[t] Skill-biased technological change in this model is the combination of capital equipment-specific technological change, coupled with different substitution elasticities between the two types of labor. Krusell et al. construct a four factor production function

[t] Note that the term *unskilled* is used here not as a literal description of worker skill, but rather to clearly differentiate the two types of labor from each other.

that allows for different types of labor, and for different types of capital goods. The technology is given by:

$$y_t = A_t k_{st}^{\alpha}[\mu u_t^{\sigma} + (1-\mu)(\lambda k_{et}^{\rho} + (1-\lambda)s_t^{\rho})^{\frac{\sigma}{\rho}}]^{\frac{1-\alpha}{\sigma}} \tag{87}$$

The term A_t is a neutral technology parameter. The inputs are capital structures (k_{st}), unskilled labor input (u_t), which is the product of unskilled hours and unskilled labor efficiency ($\psi_{ut}h_{ut}$), capital equipment (k_{et}), and skilled labor input (s_t), which is the product of skilled labor hours and skilled labor efficiency ($\psi_{st}h_{st}$). These inputs are specified within a nested CES technology in which the curvature parameters σ and ρ govern the substitution elasticities among the inputs. In this technology, rapid growth of capital equipment raises the wage of skilled workers relative to the wage of unskilled workers only if capital equipment is more complementary with skilled labor than with unskilled labor. This requires that $\sigma > \rho$, which Krusell et al. call *capital-skill complementarity*.

It is straightforward to see this requirement of $\sigma > \rho$ by assuming that ψ_{st} and ψ_{ut} are constant, log-linearizing the ratio of the marginal productivities of the two types of labor, and expressing variables in terms of growth rates between periods t and $t + 1$:

$$g_{\pi t} \simeq (1-\sigma)(g_{h_{ut}} - g_{h_{st}}) + (\sigma-\rho)\lambda\left(\frac{k_{et}}{s_t}\right)^{\rho}(g_{k_{et}} - g_{h_{st}}) \tag{88}$$

In (90), g_π is the growth rate of the skill premium, g_{h_u} and g_{h_s} are the growth rates of unskilled and skilled hours, and g_{k_e} is the growth rate of capital equipment. Since the parameter σ is less than one, the first term on the right hand side of (90) shows that the skill premium declines if the growth rate of skilled hours exceeds the growth rate of unskilled hours. Krusell et al. call this first term the *relative quantity effect*. The second term is called the *capital-skill complementarity effect*. This second term shows that the skill premium rises if the growth rate of capital equipment exceeds the growth rate of skilled hours, and if there is relatively more complementarity between skilled labor and equipment ($\sigma > \rho$).

Krusell et al. construct a dataset of skilled and unskilled labor input using data from the Current Population Survey. They use Gordon's (1990) data on equipment prices to construct a measure of the stock of capital equipment, and they use the NIPA measure of capital structures.

They estimate the parameters of the nonlinear production function with data from 1963 to 1992 using two-step simulated pseudo-maximum likelihood. They fit the model using the equations that measure the deviation between model and data for total labor's share of income, and the ratio of skilled labor income to unskilled labor income. The third equation in the criterion function measures the deviation between the rate of return to investment in structures to equipment. They estimate substitution elasticities of about 1.67 between unskilled labor and equipment, and of about 0.67 between skilled labor and

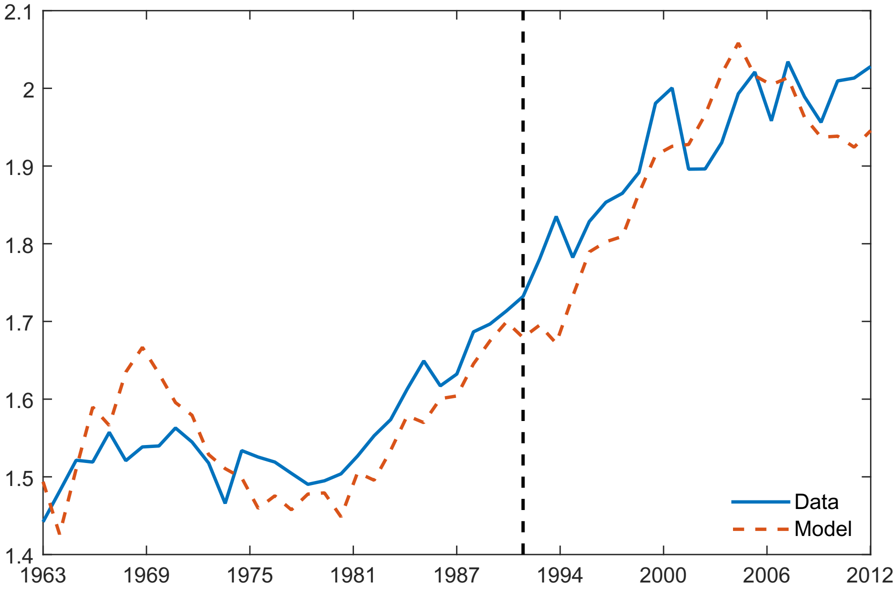

Fig. 30 Comparing college skill premium, model and data.

equipment, which provides strong support for capital-skill complementarity. They find that the model accounts for much of the movements in the skill premium over the 1963–92 period.

Given that the Krusell et al. data end in 1992, Ohanian and Orak (2016) analyze this same model, but extend the dataset through 2013 to assess the contribution of capital-skill complementarity to wage inequality for the last 20 years. Fig. 30 shows the skill premium in the model and in the data from 1963 to 2013. To compare the analysis to Krusell et al., Ohanian and Orak also estimate the model from 1963 to 1992. The dashed line in Fig. 30 corresponds to the end of the estimation period for the parameters (1992). Although Ohanian and Orak use the same sample period to estimate the parameters, they use revised data in the estimation. They find very similar elasticities to those in Krusell et al. Ohanian and Orak estimate an elasticity of about 1.78 between unskilled labor and equipment, and about 0.69 between skilled labor and equipment. The figure shows that the model accounts for the major changes in the skill premium, including the very large rise that has occurred in the last 30 years.[u]

The Krusell et al. model also fits aggregate labor share very well up until the mid-2000s. After that, the model overpredicts labor's share. This finding led Orak (2016) to analyze the same type of production function with different substitution possibilities

[u] Krusell et al. normalize the skill premium to 1 in 1963, and report fluctuations relative to the normalized value. To show the actual level of the skill premium, Ohanian and Orak estimate the model with normalized data as in Krusell et al. and then reconstruct the levels data. See Ohanian and Orak for details.

between capital equipment and different types of skills, but with three types of labor, as opposed to two types of labor. The labor types in Orak are classified based on occupational tasks, as in Autor et al. (2003), rather than on education levels, as in Krusell et al.

Orak specifies the three types of labor based on whether an occupation primarily performs cognitive tasks, manual tasks, or routine tasks. He estimates a relatively high elasticity of substitution between capital equipment and workers who perform routine tasks, and he estimates lower substitution elasticities between equipment and cognitive workers, and between equipment and manual workers. He finds that this augmented neoclassical model can account for much of the recent and significant decline in labor's share of income.

9. NEOCLASSICAL MACROECONOMICS: CRITICAL ASSESSMENTS AND FUTURE DIRECTIONS

This section discusses the open questions in the area of neoclassical macroeconomics, and presents our views on interesting future avenues for research that will address these questions. Perhaps the major open question for neoclassical models—and which is also a major question for other classes of macroeconomic models—is accounting for fluctuations in hours worked. The multisector models developed in this chapter account for considerably more of the fluctuations in hours worked than the standard one-sector neoclassical model, but there are also changes in hours that these models do not capture. Below, we describe the research areas that we view as important and promising in addressing this issue and others.

9.1 Biased Technological Change and the Labor Market

Analysis of biased technological change, and its impact on both aggregate variables and on labor market outcomes of workers with different skill levels, is an interesting avenue for future research. The home production results from the model motivated by Greenwood et al. (2005) indicate interesting trend changes in hours worked from the early 1980s through the 1990s, which coincide with the increase in women's hours worked. Important future research will further connect this demographic increase in hours worked with general equilibrium models of home production.

More broadly, it will be important to further develop models in the area of directed technological change and the shape of the production function, as in Acemoglu (2002) and Jones (2005), the relationship between technologies and secular sectoral shifts, as in Lee and Wolpin (2006), human capital accumulation and technological change, as in Heckman et al. (1998), and demographic shifts, technological change, and wage shifts as in Jeong et al. (2015). A related area is studying movements in factor income shares, as in Karabarbounis and Neiman (2014) and Orak (2016), and the impact of factor endowments on how societies choose among biased technologies, as in Caselli and Coleman (2006).

All of these research areas are in relatively early stages of development, and merit additional analysis. Research in this area can also be combined with broader empirical studies of time allocation, including the analysis and documentation of home and market time allocation, as in Aguiar and Hurst (1997) and Aguiar et al. (2013), and studies of the allocation of time across rich and poor countries, as in Bick et al. (2016).

9.2 Neoclassical Analyses of the Great Recession and Its Aftermath

Several open questions remain about the Great Recession and its aftermath. This includes accounting for macroeconomic aggregates from 2008 and onwards, particularly for hours worked. The results presented in this chapter indicate that neoclassical models with standard measures of equipment-specific productivity shocks, and TFP shocks, and without any policy components, miss some features of the Great Recession. McGrattan (2016) argues that output mismeasurement resulting from the omission of intangible investments in GDP has important implications for measured TFP and labor wedge measures during the Great Recession. Further research in this important area is needed.

There are also interesting aspects of economic policies during this period that merit additional analysis. Mulligan (2012, 2013) argues that changes in social insurance programs and the Affordable Care Act depressed labor by implicitly raising tax rates on labor. Kydland and Zarazaga (2016) study how expectations of different types of tax policies may have contributed to the weak recovery from the Great Recession. Baker et al. (2015) measure the evolution of economic policy uncertainty during the Great Recession. These uncertainty measures can be used in models in which uncertainty can depress an economy, as in Bloom (2009) and Fernández-Villaverde et al. (2015). These factors may have implications for understanding changes in hours worked in recent years.

9.3 The Effect of Policy Changes and Institutions on Macroeconomic Performance

An important area for future research is quantifying the impact of observed departures from competitive markets on economies. Cole and Ohanian (2004) developed and applied a particular methodology in their study of cartelization and unionization in the US Great Depression. This approach was also applied by Lahiri and Yi (2009) in evaluating the affect of noncompetitive policies in West Bengal Indian development. A similar approach has been used by Cheremukhin et al. (2013, 2015) to study the impact of Lenin's policies and institutions on economic development in the USSR at that time, and to study the impact of Mao's policies and institutions on Chinese development in the 1940s and 1950s. Alder (2016) uses a related approach to analyze the contribution of labor union hold-up and imperfect competition on the decline of America's Rust Belt region in the postwar United States. Similar methods also can be used to study the recent evolution of the post-Soviet Union economies, to study recent Indian and Chinese development patterns (see Dekle and Vandenbroucke (2012) for a neoclassical study of recent trends in China's economy), and to study long-run Latin American development (see Cole et al., 2005 for a long-run analysis of Latin America). As better data becomes available, these methods can also be used to study how policies and institutions have affected the stagnation and development of very poor countries. Future research along these lines will allow us to understanding the relative importance of various noncompetitive policies across countries, and will be an important input in developing growth-enhancing policies in poor countries.

9.4 Analyses of TFP

Since productivity is central in neoclassical growth models, advancing our understanding of changes in TFP is another important area for future research. In the last 10 years, progress in evaluating TFP has been made along three different research lines: resource misallocation, intangible investments, and network economies. Advancements in misallocation analysis of TFP will be facilitated by the assessment of how actual economic policies have affected resource allocation and productivity loss. Continued advances in computing power will facilitate the analysis of network economies and intersectoral linkages in the study of TFP. The continued expansion of intangible investments into NIPA data will advance our understanding of intangibles investment and TFP.

An area that to our knowledge has not been studied in detail is to link changes in what Decker et al. (2014) call "business dynamism" to aggregate measures of TFP. Specifically, Decker et al. document lower rates of resource reallocation in the United States, and also a lower rate of successful start-ups that have occurred over time. This decline has coincided with a secular decline in productivity growth. Analyzing theoretical and empirical connections between these observations has the potential to advance our understanding of secular movements in productivity.

9.5 Taxes and Macroeconomic Activity

The impact of tax and fiscal policies on economic activity in neoclassical models is another interesting area for future work, and may advance our understanding of changes in hours worked. Research in this area has been constrained by the availability of data on tax rates and hours worked. Constructing tax rates along the lines of McDaniel's (2011) tax measurements for the OECD can in principle be extended to other countries. In terms of hours worked, Ohanian and Raffo (2011) construct panel data on hours in the OECD, and similar data constructions can be made for other countries.

10. CONCLUSIONS

This chapter presented aggregate data and a series of neoclassical models to show how the historical evolution of the US economy reflects much longer-run changes in economic activity than previously recognized, and that much of this evolution is plausibly interpreted as the consequences of long-run shifts in technologies and government policies.

This chapter shows that neoclassical models can shed light on relatively stable periods of aggregate economic activity, such as the post-Korean War US economy, but also on very turbulent periods that are typically considered to be far beyond the purview of neoclassical economics, including the Great Depression and World War II. Moreover, neoclassical analysis not only provides insights into purely aggregate issues, but also sheds light on how technological change has affected individual labor market outcomes.

Future macroeconomic analyses of fluctuations should shift from the standard practice of narrowly studying business cycle frequencies, and to include the quantitatively important lower frequency component of fluctuations that dominates much of the US historical economic record. We anticipate that neoclassical research along these lines will continue to advance the profession's knowledge in a number of areas reflecting both longer-run events and business cycle fluctuations. This includes Depressions, Growth Miracles, the macroeconomic effects of various types of government regulatory and fiscal policies, the sources and nature of productivity shocks, the effects of biased technological change on the macroeconomy and on individual labor market outcomes, and understanding cyclical and longer-run fluctuations in hours worked.

ACKNOWLEDGMENTS

We thank John Cochrane, Jesus Fernández-Villaverde, Kyle Herkenhoff, Per Krusell, Ed Prescott, Valerie Ramey, John Taylor, Harald Uhlig, seminar participants at the Handbook of Macroeconomics Conference, and at the 2015 Federal Reserve Bank of Saint Louis Policy Conference for comments. Adrien D'Avernas Des Enffans, Eric Bai, Andreas Gulyas, Jinwook Hur, and Musa Orak provided excellent research assistance.

Abstract

In modern economies, sharp increases in unemployment from major adverse shocks result in long periods of abnormal unemployment and low output. This chapter investigates the processes that account for these persistent slumps. The data are from the economy of the United States, and the discussion emphasizes the financial crisis of 2008 and the ensuing slump. The framework starts by discerning driving forces set in motion by the initial shock. These are higher discounts applied by decision makers (possibly related to a loss of confidence), withdrawal of potential workers from the labor market, diminished productivity growth, higher markups in product markets, and spending declines resulting from tighter lending standards at financial institutions. The next step is to study how driving forces influence general equilibrium, both at the time of the initial shock and later as its effects, persist. Some of the effects propagate the effects of the shock—they contribute to poor performance even after the driving force itself has subsided. Depletion of the capital stock is the most important of these propagation mechanisms. I use a medium-frequency dynamic equilibrium model to gain some notions of the magnitudes of responses and propagation.

Beginning in 2008, output and employment in the United States dropped well below its previous growth path. Eight years later, unemployment is back to normal, but output remains below the growth path. Japan has been in a persistent slump for two decades. And many of the advanced economies of Europe are in slumps, several quite deep. This chapter reviews the macroeconomics of slumps taking the American experience as a leading example.

The adverse shock that launches a slump generally triggers a rapid contraction of output and employment, with a substantial jump in unemployment. This phase—the recession—is usually brief. It ended in mid-2009 in the recent case. The recovery from the trough often lasts many years. The slump is the entire period of substandard output and employment and excess unemployment. In the recent U.S. case, the slump lasted

Table 1 Unemployment in the four serious slumps since 1948

		Ratio of later unemployment rate to peak rate, by number of years later			
Peak year	**Peak rate**	**1**	**2**	**3**	**4**
1975	8.5	0.91	0.84	0.72	0.69
1982	9.7	0.99	0.77	0.74	0.72
1992	7.5	0.92	0.81	0.75	0.72
2010	9.6	0.93	0.84	0.77	0.65

from late 2008 until around the end of 2014. Dating the end of a slump is challenging because some of the state variables accounting for depressed output, notably the capital stock, take many years to return to normal. Output in 2014 was well below its earlier trend path.

Persistent slumps did not begin with the one that originated from the financial crisis of 2008. The Great Depression remains much the deepest and longest slump in the American record since the beginning of national income accounting. Table 1 shows that the persistence of unemployment was about equally high in the four major slumps that occurred after the introduction of the household unemployment survey in 1948. Normal unemployment in the United States, measured as its average over the period starting in 1948, is 6.0%. In all four slumps, unemployment remained above normal 3 years following the peak of unemployment, and in only one slump, the milder one associated with the recession of 1990–91, did unemployment drop below normal 4 years after the peak of unemployment.

Other accounts of persistent shortfalls in output and employment, focusing on the financial crisis and its aftermath, include Kocherlakota (2013), Christiano et al. (2016), Christiano et al. (2010), Benigno and Fornaro (2015), Petrosky-Nadeau and Wasmer (2015), Gertler et al. (2008), Mian and Sufi (2010), Reifschneider et al. (2013), Hall (2013, 2014).

1. THE SLUMP FOLLOWING THE 2008 FINANCIAL CRISIS

This section provides the factual foundation for the chapter by describing events in the U.S. economy around the time of the 2008 crisis, through to 2014. I provide plots of key macroeconomic variables with brief discussions. The rest of the chapter considers the ideas and models that seem most relevant to understanding those events.

Fig. 1 shows that real GDP fell dramatically right after the crisis and remained below its prior growth path even 6 years after the crisis. Plainly the crisis had a persistent effect on the total output of goods and services. Fig. 2 shows that real consumption expenditures behaved similar to real GDP, with no sign of regaining its earlier growth path over the

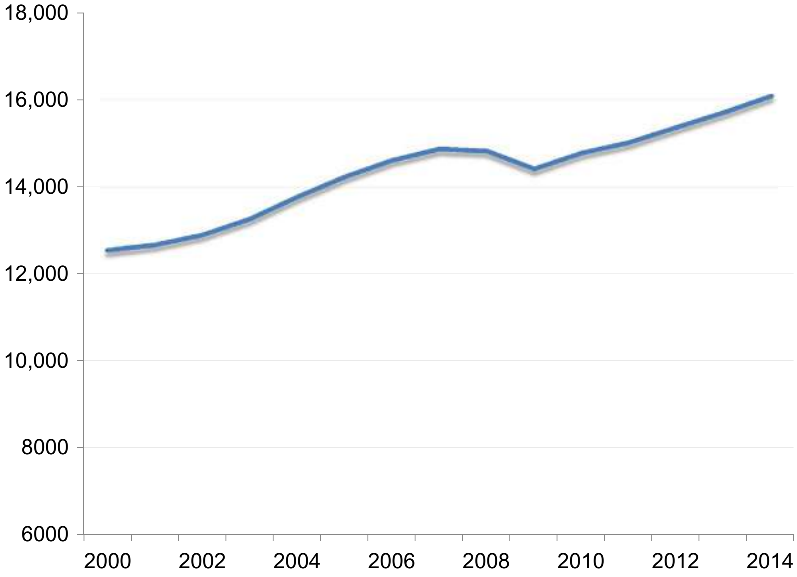

Fig. 1 Real GDP, 2000–14, billions of 2009 dollars.

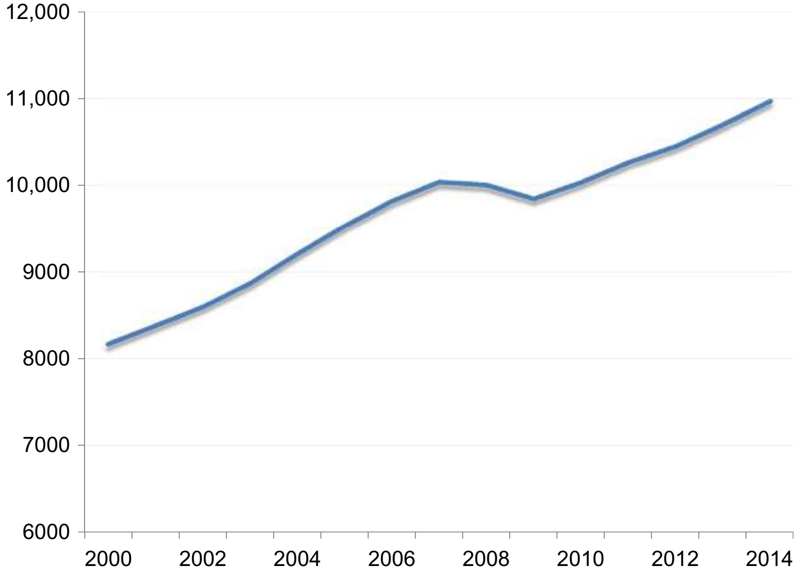

Fig. 2 Real consumption expenditure, 2000–14, billions of 2009 dollars.

period following the 2008 crisis. Fig. 3 shows persistent shortfalls from the growth path of employment. Fig. 4 shows that unemployment rose to a high level and returned to its long-run average of 5.8% at the end of 2014, 6 years after the crisis. The unemployment rate is the only major macroeconomic indicator that returned to normal within the 6-year

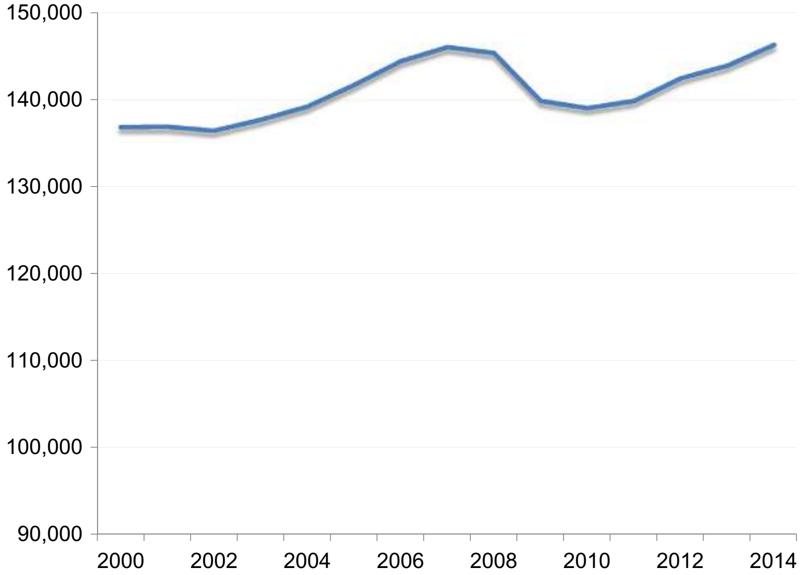

Fig. 3 Employment, 2000–14, thousands of workers.

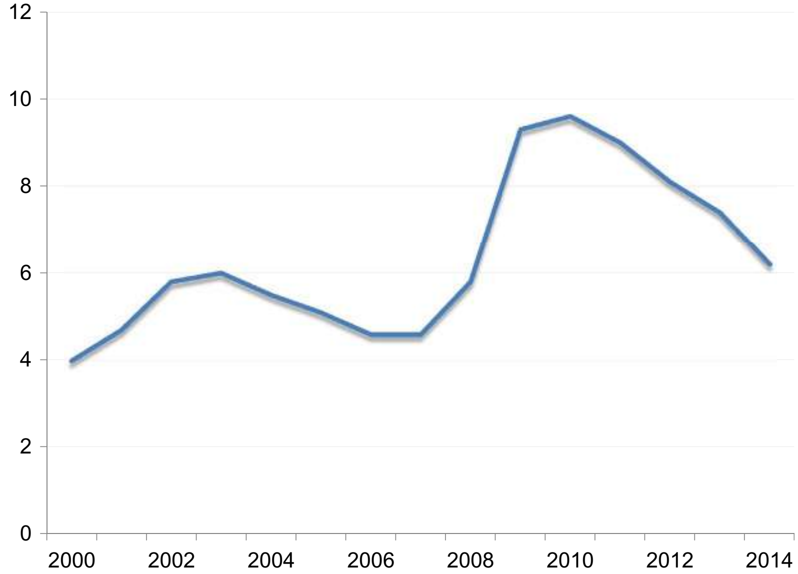

Fig. 4 Unemployment, 2000–14, percent of labor force.

period considered here. Fig. 5 shows that the labor force shrank after the crisis, relative to the working-age population, and that no recovery of the labor force occurred during the recovery. Fig. 6 shows that average real compensation per household, which had grown briskly through 2000, flattened before the crisis, fell sharply just after the crisis, and only

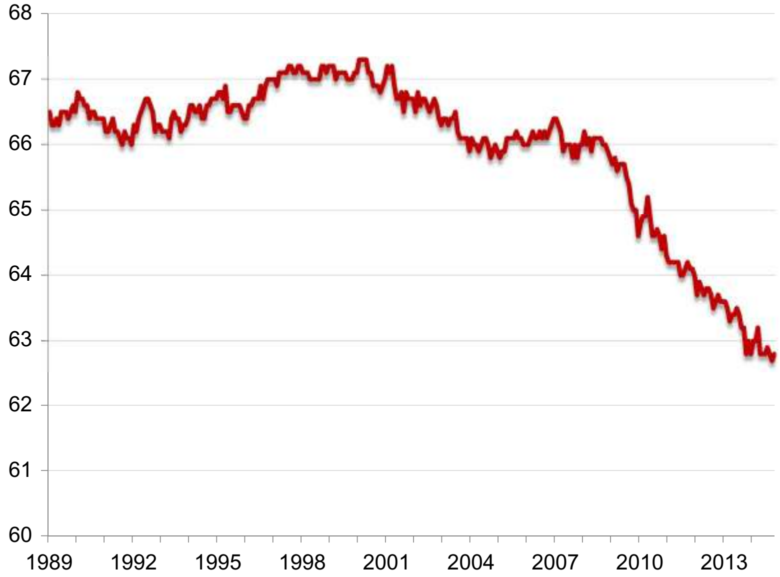

Fig. 5 Percent of working-age population in the labor force, 2000–14.

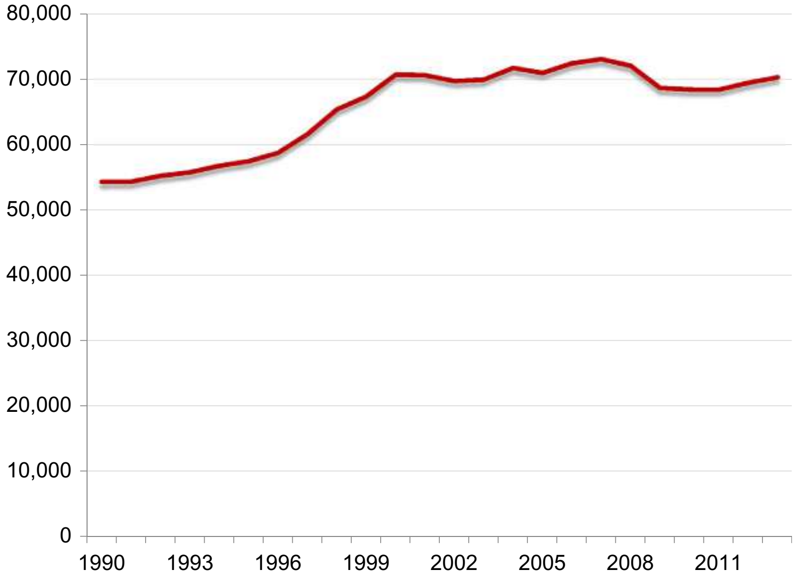

Fig. 6 Average real earnings per household, 2009 dollars, 1990–2014.

regained its previous level in 2014. Fig. 7 shows that the business capital stock—in the sense of an index of capital services available to private businesses—grew much less rapidly than normal immediately after the crisis. Its growth rate returned closer to normal, but left a considerable shortfall in capital relative to trend, as of 2014. Fig. 8 shows that

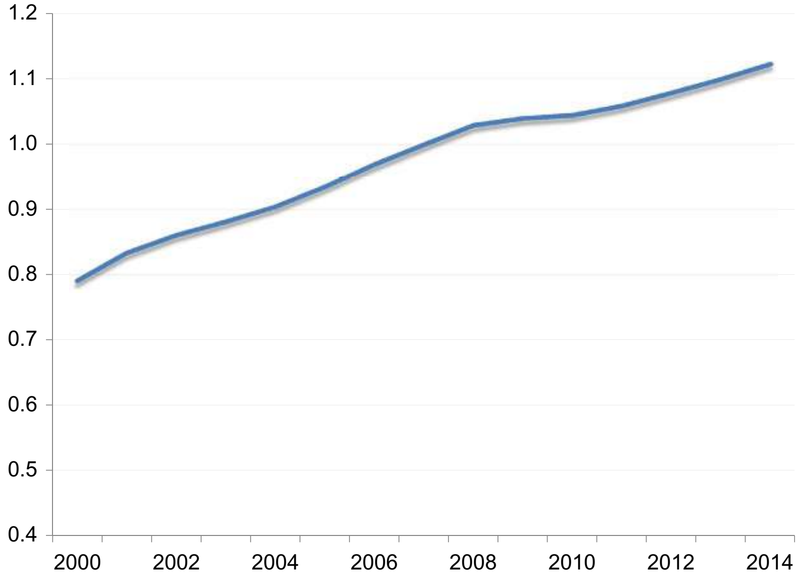

Fig. 7 Index of capital services, 2007 = 1, 2000–14.

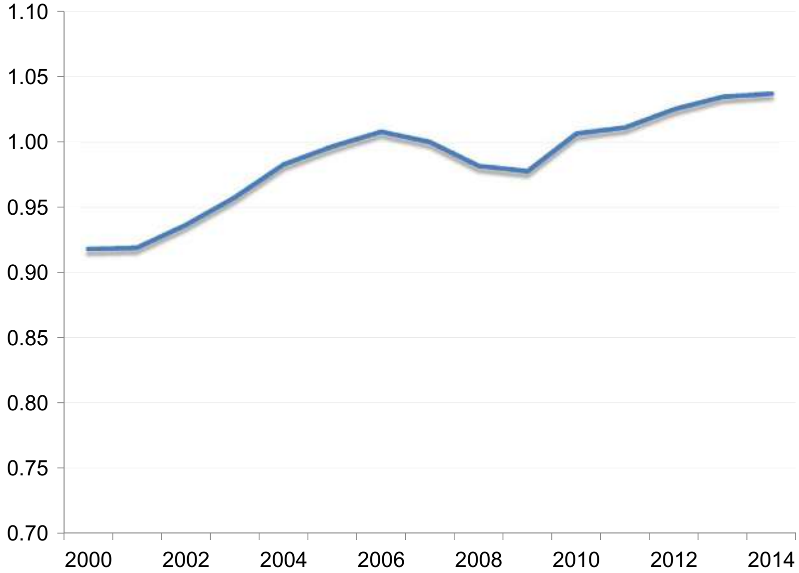

Fig. 8 Index of total factor productivity, 2007 = 1, 2000–14.

private business total factor productivity grew rapidly from 1989 through 2006. A dip in productivity began in 2007. Though productivity grew at normal rates during the recovery, it did not make up for the cumulative decline just after the crisis. Fig. 9 shows the index of the share of the total income generated in the U.S. economy that accrues to

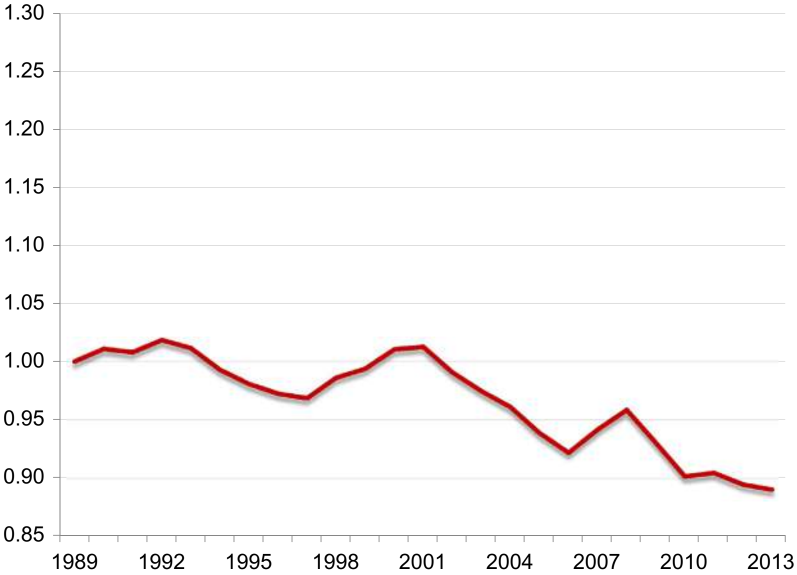

Fig. 9 Labor share.

workers, including fringe benefits. It tends to have a high level in recession years, to fall during the first half of the ensuing expansion, then to rise back to a high level at the next recession. But superimposed on that pattern is a general decline that cumulates to about 10% over the period. Like the general declining trend in earnings, the decline in the share seems to have started around 2000.

2. DRIVING FORCES

I use the term *driving force* to mean either an exogenous variable or an endogenous variable that is taken as an input to a macro model. An example of the latter case is a rise in the discount rate for investment and job creation, triggered by a financial crisis. There is no claim that the discount increase is exogenous. Rather, the hypothesis is that a process outside the model—say a collapse of house prices—influences the model through a higher discount rate. The same process outside the model may enter the model through more than one driving force. For example, the collapse of housing prices may also affect consumption demand by lowering borrowing opportunities of constrained households.

Here I provide an informal review of the driving forces that macroeconomics has identified to account for persistent slumps.

2.1 Labor-Force Participation

A discovery in recent U.S. experience has been the importance of a major decline in labor-force participation. In past slumps, participation remained close to unchanged—the economy has not had a consistent tendency for the labor force to shrink when job finding became more difficult. As of 2015, the U.S. labor market had returned to normal tightness, as measured by job-finding and job-filling rates, yet a large decline in participation starting around 2000 has not reversed. The decline in participation is an important contributor to the divergent behavior of output and employment, on the one hand, and labor-market tightness, on the other hand. Judged by the latter, the slump triggered by the financial crisis of 2008 is over, yet output and employment are far below the paths expected just prior to the crisis.

Movements in participation not directly tied to labor-market tightness need to be added to the list of phenomena associated with episodic slumps. Even if a major shock did not cause a subsequent decline in participation, if a decline happens to occur during a slump, the shortfall in employment and output will be negatively affected.

Elsby et al. (2013) is a recent investigation of the decline in participation. Autor (2011) describes the disability benefits that may be a contributor to that decline.

2.2 The Capital Wedge

A key fact in understanding the slump following the financial crisis is the stability of business earnings. Fig. 10 shows the earnings of private business (the operating surplus from the NIPAs, revenue less noncapital costs) as a ratio to the value of capital (plant, equipment, software, and other intangibles, from the Fixed Assets account of the NIPAs). Earnings fell in 2007 from their normal level of just over 20%, but recovered most of the way by 2010, when output and employment remained at seriously depressed levels.

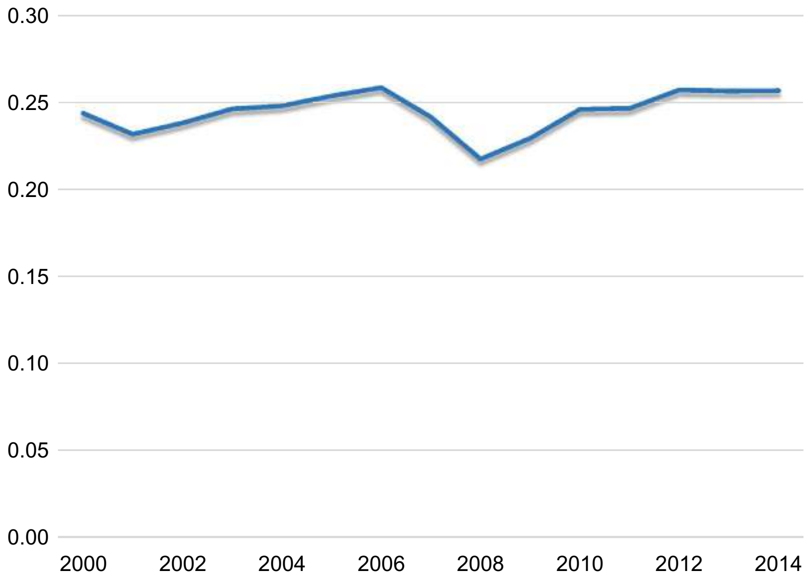

Fig. 10 Business earnings as a ratio to the value of capital.

A basic question is why investment fell so much despite the continuing profitability of business activities. Macroeconomics has gravitated toward an analysis of wedges as ways of describing what seem to be failures of incentives. The capital wedge is the difference between the measured return to investment and the financial cost of investment. I take the latter to be the risk-free real interest rate. The risk premium is one component of the wedge between the return to business capital and the risk-free interest rate. Other components are taxes, financial frictions, and liquidity premiums. To measure the total wedge, I calculate the annual return to capital and subtract the 1-year safe interest rate from it. Later, I decompose the total wedge into one component, interpreted as an extra discount on risky capital earnings not explained by finance theory, and a second, interpreted as an extra premium on safe returns not explained by finance theory.

The calculation of the return to capital uses the following thought experiment: A firm purchases one extra unit of investment. It incurs a marginal adjustment cost to install the investment as capital. During the year, the firm earns incremental gross profit from the extra unit. At the end of the year, the firm owns the depreciated remainder of the one extra unit of installed capital. Installed capital has a shadow value measured by Tobin's q.

Installation incurs a marginal cost at the beginning of the period of $\kappa(k_t/k_{t-1} - 1)$. Thus the shadow value of a unit of installed capital at the beginning of the year is

$$q_t = \kappa\left(\frac{k_t}{k_{t-1}} - 1\right) + 1 \tag{1}$$

units of capital. From its investment of a unit of capital at the beginning of year t together with the marginal installation cost—with a total cost of $q_t p_{k,t}$—the firm's nominal return ratio is the gross profit per unit of capital π_t/k_t plus the depreciated value of the capital in year $t + 1$, all divided by its original investment:

$$1 + r_{k,t} = \frac{1}{q_t p_{k,t}}\left[\frac{\pi_t}{k_t} + (1 - \delta_t) q_{t+1} p_{k,t+1}\right]. \tag{2}$$

Gross profit includes pretax accounting profit, interest payments, and accounting depreciation. In principle, some of proprietors' income is also a return to capital—noncorporate business owns significant amounts of capital—but attempts to impute capital income to the sector result in an obvious shortfall in labor compensation measured as a residual. The reported revenue of the noncorporate business sector is insufficient to justify its observed use of human and other capital. Note that business capital as measured in the NIPAs now includes a wide variety of intangible components in addition to plant and equipment.

The implied wedge between the return to capital and the risk-free real interest rate $r_{f,t}$ is the difference between the nominal rate of return to capital and the 1-year safe nominal interest rate:

$$r_{k,t} - r_{f,t}. \tag{3}$$

This calculation is on the same conceptual footing as the investment wedge in Chari et al. (2007), stated as an interest spread. Note that the wedge is in real units—the rate of inflation drops out in the subtraction.

Fig. 11 shows the values of the business capital wedge for two values of the adjustment cost parameter κ, calculated from Eq. (3), combining plant, equipment, and intellectual property. On the left, κ is taken as 0 and on the right, as 2. The former value accords with the evidence in Hall (2004) and the latter with the consensus of other research on capital adjustment costs. The value $\kappa = 2$ corresponds to a quarterly parameter of 8.

The two versions agree about the qualitative movements of the wedge since 1990, but differ substantially in volatility. The wedge was roughly steady or falling somewhat during the slow recovery from the recession of 1990, rose to a high level in the recession of 2001, declined in the recovery, and then rose to its highest level after the crisis. The two calculations agree that the wedge remained at a high level of about 18% per year through 2013.

Hall (2011a) discusses the surprising power of the financial wedge over general economic activity. The adverse effect of the wedge on capital formation cuts market activity in much the same way as taxes on consumption or work effort.

One branch of the recent literature on the propagation of financial collapse into a corresponding collapse of output and employment emphasizes agency frictions in businesses and financial intermediaries. The simplest model in the case of an intermediary—completely dominant in this literature though not obviously descriptive of the actual U.S. economy—grants the intermediary the opportunity to abscond with the investors' assets. Absconding takes place if the intermediary's continuation value falls short of the value of absconding, taken to be some fraction of the amount stolen from the investors. If the intermediary's equity falls on account of a crisis—for example, if mortgage-backed securities suffer a large capital loss—the investors need to restore the intermediary's incentive to perform by granting a larger spread between the lending rate the intermediary earns and the funding rate it pays to the investors. Hence spreads rise after a financial crisis. This view is consistent with the actual behavior of the spread between the return to capital and the risk-free rate.

The same type of agency friction can occur between a nonfinancial business and its outside investors. Depletion of the equity in the business will threaten the investors' capital. They need to raise the rents earned by the business to increase the continuation values of the insiders, and again spreads will rise.

Gertler and Kiyotaki (2011) cover this topic thoroughly in a recent volume of the *Handbook of Monetary Economics*. Brunnermeier et al. (2012) is another recent survey. Key contributions to the literature include Bernanke et al. (1999), Kiyotaki and Moore (2012), Gertler and Karadi (2011), Brunnermeier and Sannikov (2014), and Gertler and Kiyotaki (2011). See also Krishnamurthy and Vissing-Jorgensen (2013), He and Krishnamurthy (2015), Adrian et al. (2012), and Korinek and Simsek (2014).

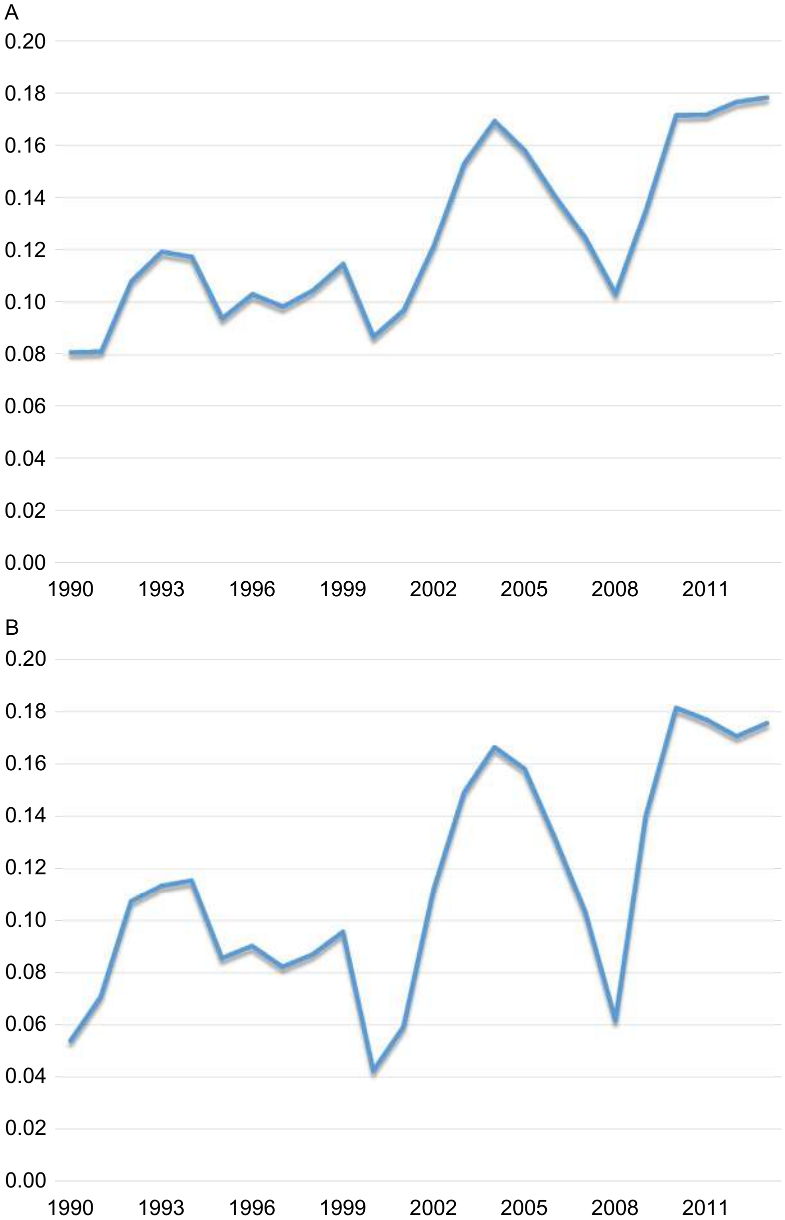

Fig. 11 The capital wedge for two values of the adjustment cost κ. (A) $\kappa = 0$ and (B) $\kappa = 2$.

2.3 Discounts and Confidence

A second branch of the literature linking financial collapse to rising spreads considers widening risk premiums in crises and ensuing slumps. Cochrane (2011) discusses the high volatility of the risk premium in the stock market, measured as the discount rate less

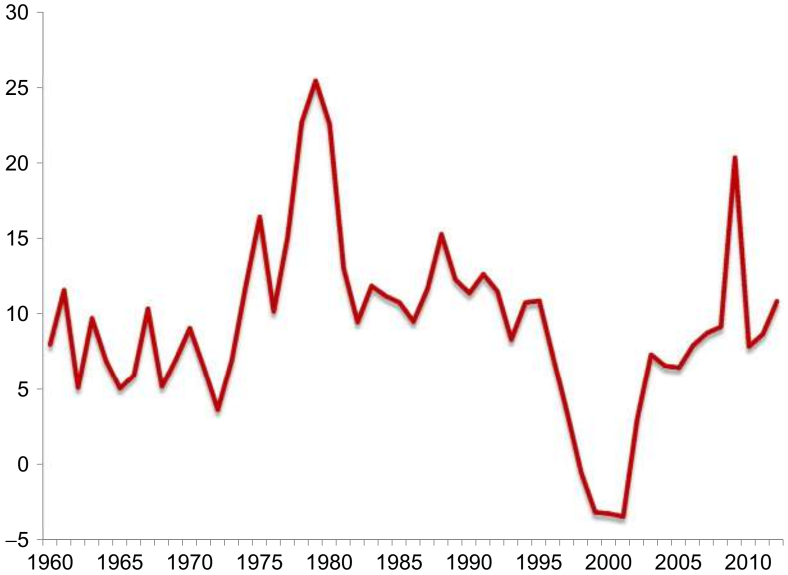

Fig. 12 The S&P Risk Premium, 1960 through 2012.

the risk-free rate. Lustig and Verdelhan (2012) document the tendency for discounts to rise in slumps.

A basic property of the stock market is that, when the level of the stock market is low, relative to a benchmark such as dividends, discounts are higher—see Campbell and Shiller (1988). Normalized consumption is another reliable predictor of returns. Fig. 12 shows the equity premium for the S&P stock-price index from a regression of annual returns on those two variables (see Hall, 2015 for further discussion and details of its construction). The risk premium spiked in 2009. Notice that it is not nearly as persistent as the slump itself—the premium was back to normal well before unemployment fell back to normal and long before investment recovered.

Macroeconomics and finance are currently debating the explanation for the high volatility of discounts. In principle, high discounts arise when the marginal utility of future consumption is high. Generating this outcome in a model is a challenge. Marginal utility would need to be highly sensitive to consumption to generate observed large movements in discounts from the modest expected declines in consumption that occur even in severe contractions. Contractions in consumption appear to be almost completely surprises. If a model implied that occasional drops in consumption occurred as surprises, and consumption then grew faster than normal to regain its previous growth path, the discount rate would *fall* after a crisis because marginal utility would be lower in the future.

Fig. 13 shows the history of the growth of real consumption of nondurable goods per person from 2001 through 2014. The largest decline was in 2009, at 2.5%, about 3.5% below its normal growth. With a coefficient of marginal utility with respect to

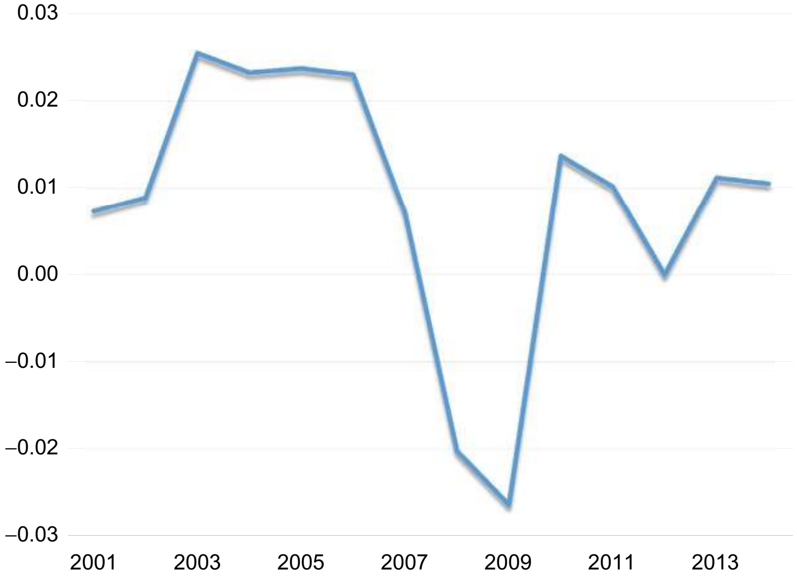

Fig. 13 Growth rate of real consumption of nondurable goods per person.

consumption of 2 (elasticity of intertemporal substitution of 0.5), the effect on marginal utility would be a substantial 7%. But this applies to a fully foreseen decline. The process for consumption change is close to white noise, so the hypothesis of a large negative expected change seems untenable.

Bianchi et al. (2012) propose a mechanism to overcome the problem that expected increases in marginal utility are inconsistent with the observed behavior of consumption. They disconnect discounts from rational expectations of changes in marginal utility by invoking ambiguity aversion. Investors form discounts based on their perceptions of a bad-case realization of marginal utility. During periods when investors have unusually pessimistic views, discounts are high.

Angeletos et al. (2014) overcome the problem in a related way. Investors form expectations about the future state of the economy based on biased beliefs about beliefs of other decision makers. When these second-order beliefs are unusually pessimistic, investors believe that their own future consumption will be lower and their future marginal utility higher, and thus apply higher discounts. The authors use the term *confidence* to refer to optimism in second-order beliefs.

In general, if a financial crisis or other salient event causes investors to shift their beliefs toward higher future marginal utility, discounts will rise. To the extent that the mean of future marginal utility rises, the safe real rate will increase along with the discounts applied to risky returns. To harness the mechanism to explain the decline in the safe rate in the Great Slump along with the rise in the risky discount, the change in the distribution of future marginal utility needs to lower the mean but raise the expected product of marginal utility and the payoffs that govern the levels of employment and output.

The spreads between yields on risky and safe bonds of the same maturity are informative about variations in discounts. Philippon (2009) argues that the bond spread may be more informative. Because the difference in the values of a risky bond and a safe bond is sensitive only to shocks that alter payoffs conditional on default, and default is relatively rare for bonds, the bond spread encodes information about the rare, serious events that could account for high discounts on business income and low discounts on safe payoffs. Fig. 14 shows the option-adjusted spread between BBB-rated bonds and Treasurys of the same maturity.

The spread widened dramatically in 2009, supporting the hypothesis that the perceived probability of a collapse of business cash flow had increased substantially. But the widening was transitory. The spread returned to historically normal levels in 2010 and remained there subsequently. It would take a powerful propagation mechanism for the change in perceptions to account for the persistent slump after 2010.

Gilchrist et al. (2014b), figs. 2 and 3, show IRFs for a spread shock, derived from a vector autoregression. These show relatively little persistence in the shock, but substantial persistence in investment and GDP responses. See also Cúrdia and Woodford (2015).

Other contributions relating to discounts and confidence include Kozlowski et al. (2015), Farmer (2012), He and Krishnamurthy (2013), Gourio (2012), Bianchi et al.

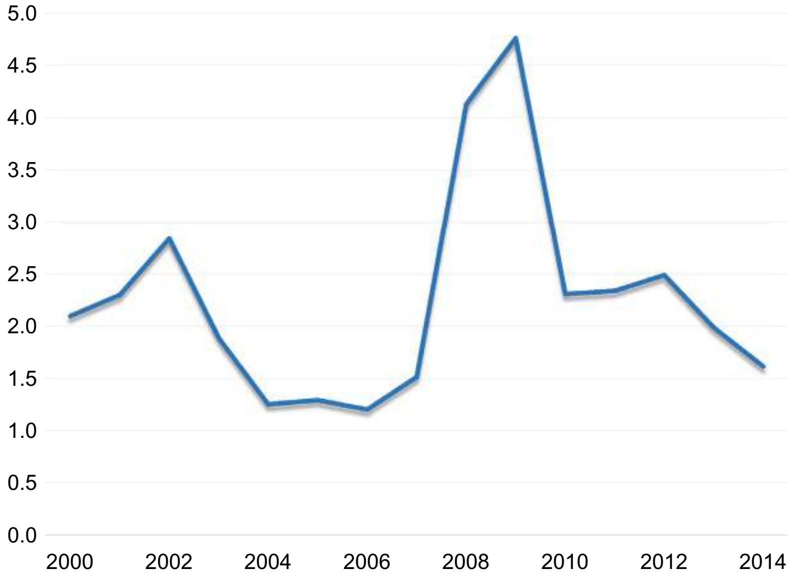

Fig. 14 BBB-treasury bond spread.

(2012), Lustig et al. (2013), and Eckstein et al. (2015). A related topic is the role of fluctuations in uncertainty as a driving force—see Ludvigson et al. (2015) for cites and discussion.

2.4 Productivity

A decline in TFP growth was an important factor in the shortfall of output during the post-crisis U.S. slump. Fernald (2014) makes the case that the productivity slowdown was unrelated to the crisis. Rather, he argues, it was a slowdown only relative to rapid TFP growth in the late 1990s and the early 2000s, associated with adoption of modern information technology. The episode illustrates the importance of TFP growth as a driving force of medium-term fluctuations, even though TFP is not a consistent driver of sharp contractions.

2.5 Product-Market Wedge

Market power in product markets creates a wedge that has been discussed extensively as a driving force of fluctuations, mainly in the context of the new Keynesian model. Rotemberg and Woodford (1999) discuss how sticky product prices result in cyclical fluctuations in markups—in a slump, prices fall less than costs, so market power rises. In almost any modern macro model, the market-power wedge has a negative effect on employment and output. Nekarda and Ramey (2013) question the evidence supporting this view, with respect to shocks apart from productivity. Bils et al. (2014) defend the view, using new evidence.

Gilchrist et al. (2014a) show that firms facing higher financial stress after the crisis raised prices (and thus the wedge) relative to other firms, a finding that supports the idea that the product-market wedge rose in general when overall financial stress worsened. The likely mechanism is different from the one in Rotemberg and Woodford (1999)—it is an idea launched in Phelps and Winter (1970). Financially constrained firms borrow, in effect, by raising prices relative to cost and shedding some of their customer bases.

Chari et al. (2007) provide a comprehensive discussion of wedges in general. See also Gourio and Rudanko (2014).

2.6 Household Deleveraging

Survey data also show a belief that lending standards to households tightened, for mortgages, loans against home equity, and unsecured borrowing (mostly credit cards). Mian and Sufi (2010) use detailed geographic data to argue that household credit restrictions caused declines in consumption. Mian and Sufi (2012), Mian et al. (2013), and Dynan (2012) document the relation between economic activity and household debt. Bhutta (2012) uses household data to show that families did not repay debt more quickly than usual during the slump. Rather, they took on less debt as it became more difficult to qualify for loans, thanks to rising lending standards and declining equity for existing homeowners who prior to 2008 were using cash-out refinancing and home-equity loans. See also Blundell et al. (2008), Petev et al. (2012), and De Nardi et al. (2011).

3. PROPAGATION MECHANISMS

3.1 Capital

The capital stock is an important source of propagation in slumps, a point that has escaped analysis in the cycle-around-trend view of fluctuations. Investment falls sharply in slumps, leaving a depleted capital stock in a slump that lasts several years. Capital depletion also helps account for the divergent behavior of output and labor-market tightness. See Gilchrist et al. (2014b) and Gomme et al. (2011).

3.2 Unemployment Dynamics

In the standard search-and-matching model, calibrated as in Shimer (2005), the unemployment rate is a fast-moving state variable. With job-finding rates around 50% per month even during slumps, unemployment converges to the stationary level dictated by tightness and the job-finding rate within a few months. Unemployment dynamics have essentially nothing to do with the persistence of slumps.

Some facts about the U.S. labor market call this view into question. Hall (1995) observed that research on the experiences of workers who lost jobs after gaining substantial tenure gave a quite different view of unemployment. Davis and von Wachter (2011) summarize more recent results with the same conclusion and emphasize the discord between the quick recovery from job loss implicit in the basic search-and-matching model and the actual experience of workers with three or more years of tenure following job loss. That experience involves an extended period of low employment—much greater loss than a 50% per month reemployment rate—and years of loss of hourly earnings. Jarosch (2014) confirms this view. The aggregate implications are that a wave of layoffs from a major shock, such as the financial crisis, results in an extended period of unemployment and a much longer period of lower productivity of the higher-tenure workers who lose jobs from the shock. Ravn and Sterk (2012) develop a model with two kinds of unemployment to capture this type of heterogeneity among the unemployed.

Some progress has been made in reconciling high monthly job-finding rates with the low recovery from high unemployment following a shock. Hyatt and Spletzer (2013) show that short jobs are remarkably frequent—the distribution of job durations is utterly unlike the exponential distribution with a constant separation hazard usually assumed in search-and-matching models. This finding explains the high job-finding rates found in the CPS—there is a huge amount of churn in the U.S. labor market. Hall and Schulhofer-Wohl (2015) show that job-finding rates over year-long periods are well below what would be expected from monthly job-finding rates. The obvious explanation of this finding is that job-seekers often take interim jobs during much longer spells of mixed unemployment and brief employment.

Shimer (2008) discusses the labor-market wedge as a convenient summary of the effects of labor-market frictions.

Other contributions relating to propagation through unemployment dynamics include Valletta and Kuang (2010b), Cole and Rogerson (1999), Chodorow-Reich and Karabarbounis (2015), Davis and von Wachter (2011), Davis et al. (2012), Petrosky-Nadeau and Wasmer (2013), Fujita and Moscarini (2013), Jarosch (2014), Rothstein (2011), Petrosky-Nadeau and Zhang (2013), Mortensen (2011), Valletta and Kuang (2010a), Sahin et al. (2012), Daly et al. (2011a,b, 2012), Kuehn et al. (2013), Mulligan (2012a), Barnichon and Figura (2012), Estevão and Tsounta (2011), Krueger et al. (2014), Herz and van Rens (2011), Sahin et al. (2012), Farber and Valletta (2013), Kaplan and Menzio (2016), Elsby et al. (2011), Krueger and Mueller (2011), Davis and Haltiwanger (2014), Hall (2012), Fujita (2011), Hagedorn et al. (2013), Mulligan (2012b), Restrepo (2015), Farber (2015), and Ravn and Sterk (2012).

3.3 The Zero Lower Bound

The policy of every modern central bank is to issue two types of debt: reserves and currency. The bank pays interest or collects negative interest on reserves. No direct force constrains the rate on reserves. It is impractical to pay or collect interest on currency. Central banks keep currency and reserves at par with each other by standing ready to exchange currency for reserves or reserves for currency in unlimited amounts. If the bank sets a reserve rate below the negative of the storage cost of currency, owners of reserves will convert them to higher-yielding currency. A number of European central banks have experimented recently with increasingly negative reserve rates.

The lower bound on the real interest rate is the bound on the nominal rate less the expected rate of inflation. Fig. 15 shows three time series relevant for measuring expected inflation. The top line is the median expected rate of inflation over the coming year for the Michigan Survey of Consumers. The line starting in 2007 is the median forecast of the average annual rate of change of the PCE price index over the coming 5 years, in the Survey of Professional Forecasters of the Philadelphia Federal Reserve Bank. The bottom line is the breakeven inflation rate in the 5-year TIPSs and nominal 5-year note—the rate of inflation that equates the nominal yields of the two instruments. See also Fleckenstein et al. (2013) on extracting expected inflation from inflation swaps.

The three measures agree that essentially nothing happened to expected inflation over the period of the post-crisis slump. All recorded a drop around the time of the crisis, but

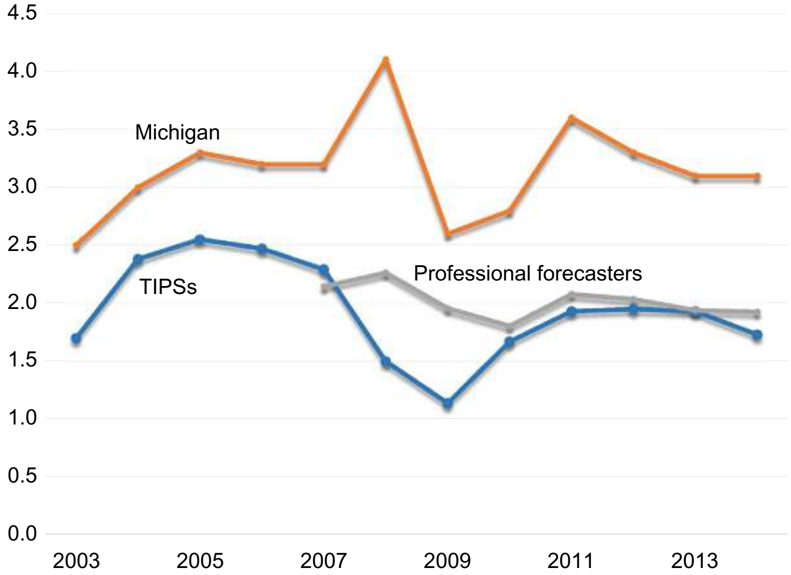

Fig. 15 Inflation expectations and forecasts.

then returned to close to precrisis levels despite high unemployment. This finding pretty much eliminates an idea that permeated macroeconomics over the past 50 years, that slack more or less automatically results in lower inflation. Some combination of factors in 2008 prevented the collapse of the price level that occurred, for example, in the much deeper slump following the contraction of 1929–33.

Had expected inflation declined by the amounts that occurred in the earlier slumps of the past 50 years, the influence of the zero lower bound on the real interest rate would have been more severe. And if deflation at the rate experienced in 1929–33 had occurred, a catastrophe similar to the Great Depression would probably have occurred. Good fortune kept expected inflation at normal levels and avoided high real interest rates and their likely adverse effects on output and employment.

In view of the importance of the inflation rate in determining the real interest rate corresponding to a zero nominal rate, the complete absence of a model of inflation is a considerable shortcoming of current macroeconomic thinking. About the best that macro modeling can do is to take expected inflation as an exogenous constant, currently around 2%. It is common for macroeconomists to say that "inflation is firmly anchored at the Fed's target of two percent" as if that amounted to a model. But it is not—at best it is an observation that expected inflation has remained at about that level despite large changes in output, employment, and other macro variables.

With exogenous, constant inflation, the bound on the nominal interest rate places a bound on the safe real rate at the nominal bound minus the rate of inflation—minus

2% in the recent slump if the nominal bound is zero; minus 3% if the nominal bound is minus 1%.

Stock and Watson (2010) study the joint behavior of inflation and unemployment with conclusions similar to those stated here. Ball and Mazumder (2011) argue in favor of the conventional view that inflation has a stable relation to slack.

3.3.1 Incorporating the Zero Lower Bound in Macro Models

Hall (2011b) discusses the issues in modeling an economy with a safe real rate fixed above the value that would clear the output market under normal conditions. In brief, the high real rate creates the illusion of an opportunity to defer consumption spending when deferral is actually infeasible. Because of the mispricing of the benefit of saving, consumers create congestion as they try to save and defer spending. Congestion arises from the same force that slows traffic on a highway that is underpriced, so more drivers try to use it than its capacity. As a practical matter, the congestion appears to take the form of low job-finding rates and abnormally high unemployment.

Modeling of the congestion resulting from the mispricing of saving is still at a formative stage. To frame the issue, consider a simple frictionless general-equilibrium macro model with a unique equilibrium. The model will describe an equilibrium value of the short-term safe real interest rate. Now implant a central bank in the model with a policy of setting that rate at a value above the equilibrium value. In particular, suppose that the bank's interest rate is elevated by the zero lower bound. What happens in the model? It cannot have an equilibrium—its only equilibrium is ruled out by assumption. One solution in macro theory is to disable one equation. Then the model has one less endogenous variable, the interest rate (made exogenous by the zero lower bound), and one less equation. One example is to drop a clearing condition for the labor market and to interpret the gap between labor supply and labor demand as unemployment. When the central bank sets a rate above equilibrium, labor demand will fall short of labor supply and unemployment will be above its normal level. This approach has some practical appeal and often gives reasonable answers.

A closely related approach is to place the demand gap in the product market. Krugman (1998) and Korinek and Simsek (2014) are examples of that approach. Farhi and Werning (2013) present a general analysis of demand gaps, where any set of prices and wages can be jointly restricted and gaps can occur in any market.

The new Keynesian tradition takes a different and more subtle approach to this issue by adding the price level as another endogenous variable without any corresponding equation. The model has demand gaps in the product market associated with temporarily sticky prices that adjust over time to close the gaps. Eggertsson and Krugman (2012) and Christiano et al. (2011) apply the NK model to the zero lower bound issue. One branch of the NK literature—notably Walsh (2003), Gertler et al. (2008), and, most recently, Christiano et al. (2016)—uses the Diamond–Mortensen–Pissarides framework to describe the labor market, so the only role of demand gaps is in the product market.

Hall (2016) tackles the congestion issue directly, in the DMP setup. Both the output and labor markets suffer from congestion when the central bank elevates the real rate above the market-clearing level. The central bank's acceptance of deposits at the elevated real rate creates an outside option in the product-price bargain that creates slack according to standard DMP principles.

In general, a model that combines the DMP view of unemployment with a real interest rate held above its market-clearing level will incorporate an additional variable, analogous to congestion in the highway case, that changes the DMP unemployment rate and the demand-gap rate until they are equal. To be concrete about that variable, suppose it is matching efficiency. A decline in efficiency increases hiring cost, raises the cost of labor, lowers the demand for labor, and raises demand-gap unemployment. The decline in efficiency lowers the job-finding rate and raises the DMP unemployment rate. The second effect is robust in the DMP model and presumably exceeds the effect on demand-gap unemployment. In equilibrium, unemployment is less than demand-gap unemployment would be at normal matching efficiency but higher than DMP unemployment would be at normal efficiency. The model would need to tie matching efficiency to the spread between the bank's interest rate and the rate that cleared the output and labor markets. Though this mechanism is attractive because matching efficiency did fall after the 2008 crisis, I do not have a model embodying variations in matching efficiency. The model in Hall (2016) is rather more complicated and invokes DMP principles in both product and labor markets.

If the effect of congestion in the labor market on labor demand is small enough to be neglected, the gap between labor supply and labor demand controls unemployment. In this case, the traditional view that ignores DMP-type considerations applies. In that case, the general-equilibrium model simply omits the DMP-based equations. In the background, labor-market congestion fluctuates to bring unemployment into line with the level dictated by product demand. In the model later in this chapter, I take this approach as an interim solution pending development of fully articulated models of congestion induced by above-equilibrium real interest rates.

Michaillat and Saez (2014) build a model of labor- market congestion that differs from the DMP model in one crucial respect—it lacks a resource decision to control the tightness of the market. In the DMP model, recruiting effort determines the tightness of the labor market. Employers expand recruiting effort until the payoff to creating an incremental vacancy equals the expected recruiting cost. In a simple real business-style macro model with a DMP labor market, equilibrium is determinate. By contrast, in the model of Michaillat and Saez, the corresponding basic model is indeterminate. It has a continuum of equilibria indexed by the real interest rate, with tightness depending on that rate. A monetary intervention that sets the real interest rate picks out one of those equilibria.

Adding that monetary intervention to the DMP-based model would make it overdetermined.

This discussion presupposes that the central bank can set any path it chooses for the real interest rate. Friedman (1968) reached the opposite conclusion. In his view, a bank that tried to keep the real rate below the market-clearing level would cause exploding inflation (the case that concerned him in 1967), and a policy aiming to keep the real rate above the market-clearing level presumably would cause exploding deflation. Recent experience does not bear his prediction out—the lower bound froze the safe real rate at around minus 2% because expected inflation remained unchanged at around 2% per year. Our lack of understanding of inflation stands in the way of fully satisfactory modeling of central bank policies that control the real interest rate.

See also Attanasio and Weber (1995), Correia et al. (2010), Eggertsson and Krugman (2012), Cochrane (2014), Hall (2016), and Eggertsson and Mehrotra (2014).

3.3.2 The Zero Lower Bound and Product Demand

The zero lower bound, together with low expected inflation, has prevented central banks from lowering interest rates as much as would seem appropriate. Lower rates should stimulate output and employment. The Federal Reserve and the Bank of Japan have kept rates slightly positive since the crisis, while the European Central Bank did the same until recently, when it pushed the rate just slightly negative. All three economies had combinations of high unemployment and substandard inflation that unambiguously called for lower rates, according to standard principles of modern monetary economics. Under normal conditions, fluctuations in product demand are not a source of important fluctuations in output and employment, because interest rates change as needed to clear those markets. Under almost any view of purposeful monetary policy, the central bank adjusts its policy rate in response to those demand fluctuations. But the zero lower bound is an exception to that principle. Economies with low inflation rates and low equilibrium real interest rates run the danger of episodic slumps when the lower bound is binding.

In the slump that began in 2008, three driving forces for product demand appeared to be important: rising discounts, tightening lending standards to businesses, and tightening lending standards to households. All three of these declines may also reflect the rising importance of another driving force, financial frictions. Other sources could be declining government purchases and transfers and declining export demand. In the recent slump, government purchases fell slightly relative to trend, transfers rose dramatically, and exports fell.

3.3.3 Discounts

As documented elsewhere in this section, discounts applied to future risky cash flows appeared to rise dramatically during and immediately after the financial crisis. Basic principles of investment theory hold that purchases of new capital goods decline when discounts rise. In fact, all three major categories of investment fell sharply: (1) business purchases of new plant, equipment, and intellectual property, (2) residential construction, and (3) autos and other consumer durables. Eggertsson and Krugman (2012) describe how a rise in discounts pushes the economy into a regime where the zero lower bound binds.

3.3.4 Lending Standards to Businesses

Survey data show unambiguously that bank officials believe that they tightened lending standards after the crisis. It remains controversial whether the tightening is an independent driving force or just a symptom of other adverse forces. Chodorow-Reich (2014), using data on individual bank–borrower relationships, argues for a separate role for tightening standards. Tighter standards may also be a driving force for the sharp decline in residential construction, given the dependence of major house-builders on bank lending.

3.3.5 Lending Standards to Households

I noted earlier that rising lending standards and declining equity resulted in cutbacks in consumption because families who had previously financed high consumption levels in part by taking on more and more debt could no longer qualify for those loans.

4. FISCAL DRIVING FORCE AND MULTIPLIER

The multiplier is the derivative of total GDP or a component, such as consumption, with respect to an exogenous shift in product demand. The obvious source of such a shift is government purchases, but the same multiplier describes the propagation of other shifts in product demand, notably those induced by changes in household access to credit.

Ramey (2011a) is a recent survey of the literature on the multiplier, and her chapter in this volume also treats the subject in detail. See also Coenen et al. (2012), Shapiro and Slemrod (2009), Spilimbergo et al. (2009), Hall (2009), Barro and Redlick (2011), Parker et al. (2011), Kaplan and Violante (2014), and Ramey (2011b).

5. OTHER ISSUES

5.1 Decline in the Labor Share

Economists have pursued multiple explanations of the decline, but no consensus has formed. Rognlie (2015) provides a comprehensive discussion of this topic. See also Karabarbounis and Neiman (2014).

5.2 Time Use

Some indication about the changing balance between work and other uses of time comes from the American Time Use Survey, which began in 2003. Table 2 shows the change in

Table 2 Changes in weekly hours of time use, between 2003 and 2013, people 15 and older

	Personal care	Household work	Market work	Education	Leisure	Other
Men	1.3	0.1	−2.5	0.2	1.3	−0.4
Women	1.6	−0.7	−0.8	−0.1	0.8	−0.8

weekly hours between 2003 and 2013 in a variety of activities. For men, the biggest change by far is the decline of 2.5 h per week at work, a big drop relative to a normal 40-h work week. A small part of the decline is attributable to higher unemployment—the unemployment rate was 6.0% in 2003 and 7.4% in 2013. The decline for women is much smaller, at 0.8 h per week. For both sexes, the big increases were in personal care (including sleep) and leisure (mainly video-related activities). Essentially no change occurred in time spent in education. Women cut time spent on housework. See also Aguiar et al. (2013).

6. A MODEL

Many macro-fluctuations models omit slower-moving driving forces and are correspondingly estimated or calibrated to data filtered to remove slower movements. Growth models generally omit cyclical and medium-frequency driving forces. A small literature—notably including Comin and Gertler (2006)—deals explicitly with medium-frequency driving forces and corresponding movements of key macro variables. That paper focuses on technology and productivity. The model developed here considers other medium-frequency driving forces, such as labor-force participation and discounts. Hall (2005) discusses evidence of the importance of medium-frequency movements and argues against the suitability of superimposing a high-frequency business-cycle model on an underlying growth model. Instead, a unified model appears to be a better approach.

The model is inherently nonstationary—its labor force grows randomly and so does productivity. Solution methods widely used for stochastic macro models, either near-exact solutions using projection methods or approximate solutions based on log-linearization, require that models be restated in stationary form. I take a different approach. The model has random driving forces that are functions of a Markov discrete state. Over a finite horizon the model has an event space with a large but finite set of nodes. Models with this structure are widely used in finance and banking. I find essentially exact solutions for the contingent values of continuous state variables and other key macro variables at each node. Finance models, such as the binary option-pricing model, have backward-recursive solutions, but macro models require solving the entire model as a system of simultaneous equations. Recursive models are highly sparse, and solution methods that fully exploit the sparsity are fast.

6.1 Specification

The equations of the model are the familiar first-order conditions for optimization by the decision makers in the model and laws of motion of the state variables, together with initial and terminal conditions. The framework does not require that the model be recursive, though the model here is actually recursive—it can be expressed in equations that consider only three dates: *Now* (for example, k), *Soon* (for example, k'), and *Later* (for example, k''). Each value *Now* branches stochastically into N_t values in the *Soon* period and N_t^2 values in the *Later* period. Here N_t is the number of states in the discrete Markov process in period t. The economy operates for T periods.

The driving forces of the model are:

a: increment to total factor productivity

l: increment to the labor force

d_k: discount or confidence with respect to capital

d_n: discount or confidence with respect to job creation

d_f: discount or flight to safety factor with respect to safe 1-year returns (found to be negative, implying a safety premium)

z: product-market wedge arising from market power

g: government purchases of goods and services, serving as a proxy for shifts in product demand arising from forces not considered explicitly in the model

The continuous state variables are:

k: physical capital stock (endogenous)

A: total factor productivity (exogenous)

L: labor force (exogenous)

Endogenous variables that are functions of the state variables are:

y: output

n: employment

c: consumption

q: Tobin's q, the value of installed capital

r': the realized return to holding installed capital from now to later

r_f: the safe real interest rate from now to later, known now

m: the stochastic discounter, not including d_k, d_n, and d_f

x: the marginal revenue product of labor

6.2 States

An integer-valued state s governs the outcomes of random influences on the economy. It follows a Markov process:

$$\text{Prob}[s'|s] = \pi_{s,s'}. \tag{4}$$

6.3 Technology

Output at the beginning of a period combines labor and capital services according to a Cobb–Douglas technology:

$$y' = A' n^{1-\alpha} k^{\alpha}. \tag{5}$$

Installation of capital incurs quadratic adjustment costs. The marginal cost of adjustment, q, is

$$q' = \kappa\left(\frac{k'}{k} - 1\right) + 1. \tag{6}$$

Total factor productivity evolves as

$$A' = \exp(a_{s'})A. \tag{7}$$

Here $a_{s'}$ is a state-dependent log-increment to TFP. The law of motion of the capital stock is

$$k' = (1-\delta)k + y' - c' - g'. \tag{8}$$

Here δ is the rate of depreciation of capital.

6.4 Financial Markets

The realized rate of return to holding capital is

$$r_k' = \frac{\alpha \frac{y'}{z'k} + (1-\delta)q'}{q} - 1. \tag{9}$$

Here z is a product-marked wedge. The economy's normal stochastic discount factor is

$$m' = \beta\left(\frac{c'}{c}\right)^{-1/\sigma}. \tag{10}$$

The pricing condition for the return to capital is

$$\mathbb{E}[(1 + r_k')m'] - d_k = 1. \tag{11}$$

Here d_k is a distortion of the discounter for the return to capital, interpreted as loss of confidence or increased pessimism, that lowers the perceived present value of the future payoff to capital.

The pricing condition for the risk-free rate is

$$\mathbb{E}\ [(1 + r_f)m'] - d_f = 1. \tag{12}$$

Here d_f is a distortion of the discounter for the safe real return, whose negative value is interpreted as a liquidity premium or flight to safety premium.

6.5 The Zero Lower Bound

The model does not embody a bound on the short safe interest rate. Rather, it identifies conditions when the rate is low—generally negative. Times of negative rates are times when the lower bound would be binding, and the model's equilibrium would not actually hold. As noted earlier, macroeconomics has yet to provide a coherent account of equilibrium with a binding lower bound. All the literature simply assumes that a demand gap implies output and employment gaps, without further explanation of why economic behavior results in gaps. The predictions of the demand-gap model may well be correct—the point is that models do not meet normal standards of explanation imposed on modeling other economic phenomena. See Hall (2016) for further discussion of this point.

6.6 Initial and Terminal Values of the Capital Stock

The capital stock grows stochastically along with growth in TFP, A, and the labor force, L. I calculate the initial capital stock and the stock at each terminal node as

$$k^* = (1-u^*)L\left(\frac{\alpha A}{r^*+\delta}\right)^{1/(1-\alpha)}. \qquad (13)$$

Here u^* is the normal unemployment rate. The quantity r^* is the constant discount rate equivalent to actual stochastic discounting, including the extra discount d_k. I pick the value of r^* that generates roughly constant growth of capital. If r^* is below that level, the capital stock grows more rapidly at first until it reaches the stochastic turnpike path, then shrinks back to the terminal condition toward the end. The stock sags below its initial level and grows extra-rapidly at the end of the period if r^* is too high.

6.7 The Labor Market

The model incorporates the idea that hiring is a form of investment, as in the Diamond–Mortensen–Pissarides model of the labor market. As with other forms of investment, the discount rate influences hiring, as discussed with citations in Hall (2015). The equation also takes the marginal revenue product of labor as the measure of the benefit of a hire—subject to variation through changes in market power as in Rotemberg and Woodford (1999), stated in DMP terms in Walsh (2003).

DMP employment depends on the present value of the ratio, $x'/\bar{x}'$ of the actual future marginal revenue product of labor to the normal level based on future technology A' and current capital k. The numerator is

$$x' = (1-\alpha)A'\left(\frac{k}{z'n}\right)^{\alpha} \qquad (14)$$

and the denominator is

$$\bar{x}' = (1-\alpha)A'\left(\frac{k}{\bar{n}}\right)^{\alpha}. \tag{15}$$

There is a downward distortion, d_n, in the discounted value of the ratio. Employment is

$$\begin{aligned} n &= \bar{n}\left[\frac{\mathbb{E}(m'x')}{\mathbb{E}(m'\bar{x}')}\exp(-d_n)\right]^{\omega} \\ &= \bar{n}\left[\left(\frac{\bar{n}}{zn}\right)^{\alpha}\exp(-d_n)\right]^{\omega}. \end{aligned} \tag{16}$$

The value of d_n implied by the data is

$$d_n = -\left(\alpha + \frac{1}{\omega}\right)\log\frac{n}{\bar{n}} - \alpha\log z. \tag{17}$$

Given d_n, the resulting solution is

$$\log\frac{n}{\bar{n}} = -\left(\frac{\omega}{1+\alpha\omega}\right)(\alpha\log z + d_n). \tag{18}$$

The labor force evolves as

$$L' = \exp(l_{s'})L. \tag{19}$$

Unemployment is

$$n = (1-u)L. \tag{20}$$

6.8 Timing

Timing is easiest to understand in the nonstochastic case, where $N_t = 1$ for all periods t. In period 1, capital is at its specified initial value k_I. No consumption occurs in period 1. In period T, capital is at its specified terminal value, k_T. No employment occurs. Consumption c_T is an unknown to be determined. Thus there are $T-2$ values of capital to be determined, k_2 through k_{T-1}, and $T-1$ values of consumption, c_2 through c_T. Given candidate values for these, and the exogenous variables A_t and L_t, one can calculate corresponding candidate values of the other variables, y_t, q_t, $r_{k,t}$, $m_{t,t+1}$, x_t, n_t, and u_t. The $T-1$ residuals of the material balance condition

$$\epsilon_{M,t} = k' - [y' + (1-\delta)k - c' - g'], t = 1 : T-1 \tag{21}$$

and the $T-2$ residuals of the Euler equation

$$\epsilon_{E,t} = \mathbb{E}_t(1 + r_{k,t+1})(m_{t,t+1} - d_t) - 1, t = 2 : T-1 \tag{22}$$

define a system of equations

$$\epsilon(x) = 0. \tag{23}$$

Here $\epsilon(x)$ is the combined vector of the $2T-3$ residuals and x is a vector of the $2T-3$ unknown values of k_t and c_t. A standard nonlinear equation solver finds a solution, which is the dynamic stochastic contingent equilibrium of the model.

6.9 Summary

Equations with a zero on the right-hand side enter the solution with discrepancies ϵ which are driven to zero by Newton's method:

$$\text{Prob}[s'|s] = \pi_{s,s'}, \tag{24}$$

$$k' - (1-\delta)k - y' + c' + g' = 0, \tag{25}$$

$$A' = \exp(a)A, \tag{26}$$

$$L' = \exp(l)L, \tag{27}$$

$$y' = A'n^{1-\alpha}k^{\alpha}, \tag{28}$$

$$q' = \kappa\left(\frac{k'}{k} - 1\right) + 1, \tag{29}$$

$$r_k' = \frac{\alpha\dfrac{y'}{zk} + (1-\delta)q'}{q} - f' - 1, \tag{30}$$

$$m' = \beta\left(\frac{c'}{c}\right)^{-1/\sigma}, \tag{31}$$

$$x' = (1-\alpha)\frac{y'}{zn}, \tag{32}$$

$$\mathbb{E}[(1+r_k')(m'-d)] - 1 = 0, \tag{33}$$

$$r_f = \frac{1}{\mathbb{E}m'} - 1, \tag{34}$$

$$n = (1-u)L, \tag{35}$$

$$\log\frac{n}{\bar{n}} = \left(\frac{\omega}{1+\alpha\omega}\right)\left(\alpha\log\frac{k}{z\bar{k}} - d_n\right). \tag{36}$$

7. APPLICATION TO THE U.S. ECONOMY

7.1 States of the Economy

The model operates at an annual frequency. I constructed its states by the *k*-cluster method with six clusters, based on the following variables measured over the period from 1953 through 2014:

- TFP growth, from Fernald (2012), without utilization adjustment
- The discount implicit in the S&P stock-market index, measured as the expected real return based on the Livingston survey
- The annual growth rate of the civilian labor force
- The unemployment rate

Table 3 shows the discrete states of the model, in terms of the values of the four variables. It also shows the classification of years by state. Each of the four variables defining the states has six state-dependent values. In a row in the table, *Low* refers to the two lowest values of a variable across the states, *Med* to the middle two values, and *High* to the upper two values. Table 4 shows the state-contingent values of the variables that define the states. The states are:

1. Strong economy with low discount, low unemployment, high growth of labor force, and high productivity growth
2. Strong economy with medium TFP growth
3. Mediocre economy with low TFP growth
4. Mediocre economy with high discount and low TFP growth
5. Slump with average TFP growth
6. Slump with high TFP growth

Table 3 The states of the model

State	TFP growth	Discount	Labor-force growth	Unemployment	Years in state
1	Low	Low	High	High	1955, 1957, 1959, 1960, 1964, 1966, 1968, 1969, 1972, 1995, 1996, 1997, 1999, 2000, 2006
2	Low	Low	High	Med	1953, 1956, 1962, 1965, 1973, 1978, 1988, 1989, 1998
3	Med	Med	Med	Low	1954, 1958, 1963, 1967, 1971, 1977, 1979, 1980, 1985, 1986, 1987, 1990, 1991, 1993, 1994, 2007, 2013, 2014
4	High	Med	Med	Low	1961, 1970, 1974, 1975, 1981, 1982, 1983, 2001, 2002, 2004, 2005, 2008
5	High	High	Low	Med	2003, 2009
6	Med	High	Low	High	1976, 1984, 1992, 2010, 2011, 2012

Table 4 State-contingent values of the variables defining the states

	State-contingent value (%)			
State	**Discount**	**Unemployment**	**Labor-force growth**	**TFP growth**
1	2.79	4.67	1.68	2.00
2	−1.84	4.81	1.79	1.80
3	5.40	6.22	1.48	0.43
4	10.73	6.63	1.40	0.27
5	20.74	7.63	0.52	0.92
6	3.94	8.22	1.03	2.42

Table 5 Transition matrix and ergodic distribution

		To state						
		1	**2**	**3**	**4**	**5**	**6**	**Ergodic probability**
From state	1	0.33	0.27	0.20	0.20	0.00	0.00	0.25
	2	0.33	0.11	0.44	0.11	0.00	0.00	0.13
	3	0.35	0.12	0.35	0.12	0.00	0.06	0.30
	4	0.08	0.08	0.08	0.42	0.17	0.17	0.20
	5	0.00	0.00	0.00	0.50	0.00	0.50	0.03
	6	0.00	0.00	0.67	0.00	0.00	0.33	0.10

Table 5 shows the annual transition matrix among the four states together with the ergodic probabilities of the states. Fig. 16 illustrates the persistence of the six states. It shows the expected value of the unemployment rate starting in each of the six states and evolving toward the ergodic distribution over a 10-year period. For example, the curve labeled 6 shows unemployment starting at the state-contingent level for state 6, which is over 8%. The rate falls quickly, dropping slightly below its ergodic value before converging back to that value. In the first few years, the dynamics of these impulse response functions differ, corresponding to the differences in the rows of the transition matrix. In later years, the paths are similar, because they are all controlled by the largest eigenvalue of the transition matrix.

The model starts in period 1 with initial values of TFP and the labor force both equal to one. In the base case, the distribution of the state in period 2 is the ergodic distribution. For 4 years, the transition matrix governs the succeeding states. In year 5, the economy has $6^4 = 1296$ possible configurations. For the next 10 years, the economy continues to evolve, but no further random events occur. The exogenous variables—TFP and the labor force—grow at constant rates equal to the average of the state-contingent rates, weighted by the ergodic distribution. The model has $1+6+36+216+1296+10\times 1296=14{,}515$ nodes, each with distinct values of all the variables of the model.

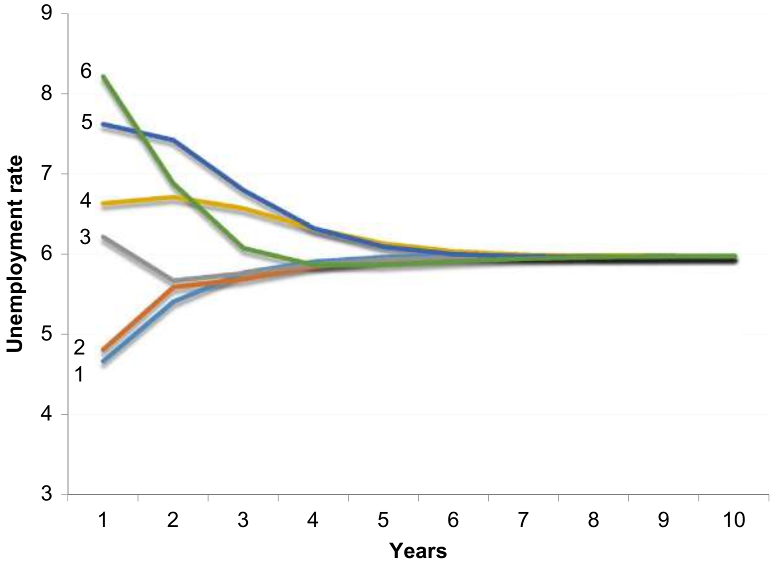

Fig. 16 Persistence of the states.

7.2 State-Based Driving Forces

Two of the variables used to define the states are also treated as driving forces in the model. These are the increments to TFP and the labor force. Another two driving forces are calculated from the data. These are the discount shock for capital, calculated as the residual in the pricing condition for capital,

$$d_k = \mathbb{E}[(1 + r_k')m'] - 1, \tag{37}$$

averaged over states to measure the expectation, and the discount shock for job creation, calculated as

$$d_n = -\left(\alpha + \frac{1}{\omega}\right)\log\frac{n}{\bar{n}}. \tag{38}$$

I also calculate the values of the discount shock for the safe 1-year interest rate, as

$$d_f = \mathbb{E}[(1 + r_f)m'] - 1, \tag{39}$$

but this value does not feed back into the rest of the model, so it is not a driving force, provided no bound on the rate is binding. Table 6 shows the state-contingent values of the driving forces.

TFP growth varies substantially across the economy's states. It is generally higher in the better, lower-numbered, states, but is highest in state 6. The reason is that most of the

Table 6 Values of the driving forces

	State-contingent value (%)				
State	TFP growth	Labor-force growth	Capital discount	Liquidity discount	Labor discount
1	2.00	1.68	15.01	−1.09	−0.81
2	1.80	1.79	14.93	−1.23	−0.72
3	0.43	1.48	13.39	−2.25	0.17
4	0.27	1.40	12.14	−0.90	0.44
5	0.92	0.52	12.98	−4.87	1.08
6	2.42	1.03	14.25	−3.05	1.46

years classified into state 6 are in the later years of slumps, when the economy is recovering. Historically, recoveries enjoyed high measured TFP growth because of improving utilization (recall that the model uses Fernald's TFP measure without his utilization adjustment). Labor-force growth, a driving force omitted from most models of fluctuations, also shows substantial variability across states, in a pattern similar to TFP. The capital discount is high, definitely in excess of almost all measures of the equity premium. The reason is that it includes factors that cause the return to capital to exceed the payout to owners that are not normally included in the equity premium. These include corporate taxes and agency frictions. The capital discount is higher in the favorable, lower-numbered states, again with the exception of state 6, so it is not much of a contributor to the business cycle. The table shows the calculated values of the liquidity discount, though it is not actually a driving force. The negative of the discount is a safety premium, associated with liquidity services and, in the bad states, a flight to safety. The most negative value of the discount is in the rare state 5 when the economy is in an unusually bad condition. That fact is important for the model's message about the conditions when the zero lower bound on the safe rate will matter. Finally, the labor discount, calculated from the unemployment rate, naturally tracks unemployment perfectly, because the other determinant of unemployment in the model, the product-market wedge, is taken to be the same in all states, for want of a reliable basis for computing it.

Two additional driving forces are present in the model, but do not have empirical counterparts. These are the product-market wedge, z, and the variable g, interpreted as a shift in product demand. The product-market wedge plays a central role in the new Keynesian model, but the measurement has proven controversial. Shifts in product demand resulting from tightening financial constraints on consumption have played a big role in understanding the financial crisis of 2008 and its aftermath, but again measurement of the shifts has proven controversial. The model tracks the effects of z and g, but its base case does not include their actual movements as driving forces in the economy. They both play important roles in the application of the model to the crisis of 2008 and the ensuing slump.

7.3 Parameters

Table 7 shows the parameter values used in the model. All are standard except for r_k^*, which is special to this framework, to ensure that the model's initial and terminal capital are close to its turnpike level of capital in relation to TFP and the size of the labor force.

7.4 Equilibrium

An equilibrium of the model is a complete set of values of the variables at every node. Fig. 17 provides some basic information about the equilibrium—it shows the means and standard deviations of the two exogenous variables, TFP and the size of the labor force, and two key endogenous variables, consumption and the unemployment rate, in each year. The distributions are conditional on the state of the economy in the first year. The standard deviations are calculated across the nodes for each year. Each should be interpreted as the standard deviation of the corresponding variable, conditional on the state of the economy in year 1, defined by the initial values of TFP, the labor force, and the capital stock. Because the capital stock is chosen to start the economy on its (stochastic) turnpike path, the subsequent values of the variables are distributed symmetrically around the path as time passes. Some of the variables grow and some have stable distributions around constant means. The upper left graph shows the distribution of TFP, A, which is close to a random walk. Its mean grows smoothly and its standard deviation fans out, rising approximately as the square root of the year number. The size of the labor force, L, shown in the upper right, behaves similarly, but its growth rate is somewhat higher and its conditional standard deviation is smaller. The variables in the lower part of Fig. 17 are not defined in period 1, but, again, the figures show the distributions conditional on the state of the economy in period 1. The conditional standard deviation of consumption, shown in the lower left, evolves by the same square-root principle as the ones for TFP and the labor force. The unemployment rate, shown in the lower right, has a stationary distribution along the turnpike path.

Table 7 Parameter values

Parameter	Interpretation	Value
α	Elasticity of output with respect to capital	0.35
δ	Depreciation rate of capital	0.1
β	Household discount ratio	0.95
σ	Intertemporal elasticity of substitution	0.5
κ	Capital adjustment parameter	2
u^*	Normal unemployment rate	0.0596
ω	Elasticity of employment function with respect to present value of a worker's contribution	4
rk^*	Effective discount rate for initial and terminal capital	0.3

Table 8 compares the volatility of some of the model's variables to the volatility of the corresponding data. In the case of variables that share the random-walk character of TFP and the labor force, the table describes rates of growth. The left column shows the standard deviations of the variables in the original annual data. The middle column shows the standard deviation, calculated using the model's ergodic distribution, of the state-contingent averages calculated from the original annual data. The right column shows

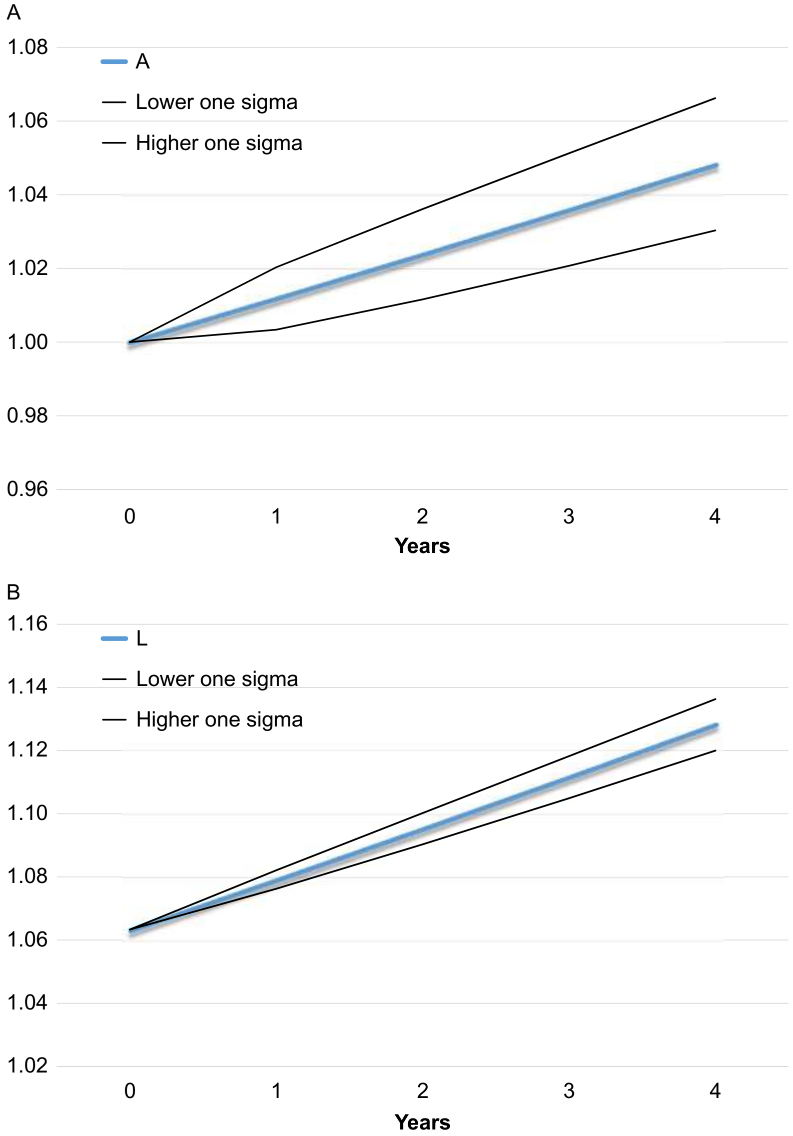

Fig. 17 Distributions of four variables in equilibrium. (A) TFP, (B) labor force,

(Continued)

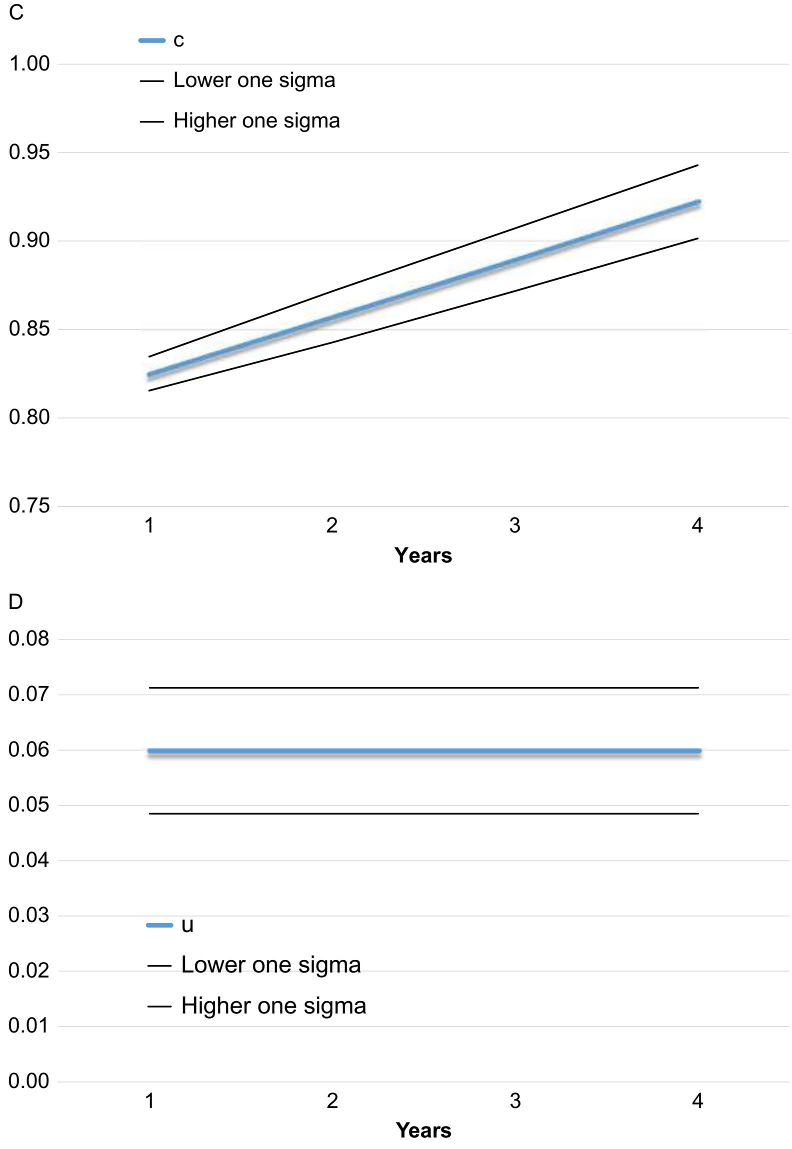

Fig. 17—Cont'd (C) consumption, and (D) unemployment rate.

the standard deviations in year 5 of the equilibrium. Comparison of the middle to the left column shows the success of the state setup in capturing the volatility of the corresponding variable. By necessity, the state setup falls short of full success. In most cases, the standard deviation across the states, weighted by the ergodic distribution, is around half of the actual standard deviation. Employment, unemployment, output, consumption,

Table 8 Standard deviations of selected variables in the data and in the model's equilibrium

	Standard deviation		
Variable	**Data**	**State-based data**	**Model**
TFP growth	1.65	0.83	0.84
Labor-force growth	0.81	0.27	0.27
Capital wedge	NA	1.42	1.42
Employment wedge	1.02	0.73	0.73
Output growth	2.19	1.34	1.18
Consumption growth	1.81	1.04	1.17
Investment growth	8.88	5.32	4.63
Return to capital	3.81	1.05	1.63
Unemployment	1.59	1.13	1.14

and investment do better than half, while labor-force growth and the return to capital fall short. Comparison of the right column to the middle column of Table 8 shows the success of the model in matching its target, the state-contingent values in the middle. For TFP growth, labor-force growth, the capital wedge, and the employment wedge, the match is perfect by construction. The match is reasonably good for the other variables.

7.5 Effects of the Driving Forces

The popular vector autoregression framework emphasizes *shocks* as the starting point for dynamic macro models. Shocks are uncorrelated with each other contemporaneously and uncorrelated with all lagged variables. See Ramey's chapter "Macroeconomic shocks and their propagation" in this handbook for a discussion of these assumptions. The framework of this chapter is different. Each year, a new value of the underlying state, s, occurs. Its probability distribution is known from the transition probabilities of the Markov process, but the realization from that distribution is a shock. The realization determines the new values of the driving forces. These movements are mutually correlated. Because the model incorporates the hypothesis of rational expectations, adjusted by the known state-dependent distortions, the model incorporates the notion that rational actors respond to the surprise elements of current realizations.

In this framework, it is interesting but challenging to answer questions about the separate effects of the driving forces. Because those forces are correlated, the variance decomposition often presented along with a VAR model is not available—potentially large components of the variance of a given endogenous variable arise from the covariance of a pair of driving forces, so their distinct contributions are not defined. The position of the VAR modeler, as Ramey explains, is that shocks must be uncorrelated, because otherwise they would not have distinct contributions. The approach in this chapter is that driving forces are fundamental and that their correlation is a matter of measurement, not assumption.

One way to understand the roles of the driving forces is to consider a set of counterfactual economies, each with only one driving force. Table 9 shows the results of that exercise. The top row shows the standard deviations of annual output growth for the base case, with all four driving forces in action, and for the four counterfactuals, with single driving forces. Table 10 shows the correlation matrix of the driving forces, based on the state-contingent values, using the ergodic probabilities (the one-period-ahead correlation matrix is state dependent). Two correlations stand in the way of even an approximate allocation of explanatory role: The capital wedge is correlated 0.83 with TFP growth and the labor wedge is correlated −0.89 with the labor-force growth.

Table 9 suggests that all four driving forces have important roles in economic fluctuations. An economy with only TFP fluctuations has substantial fluctuations in all of the variables except unemployment. An economy with only labor-force fluctuations has moderate volatility of investment growth—but recall that this driving force is not well captured by the states of the model, so this finding probably understates the importance of labor-force fluctuations. An economy with only a capital wedge has some volatility of consumption, quite a bit of volatility of the return to capital, and a lot of volatility of investment. An economy with only a labor wedge has substantial volatility of all the variables.

In addition to the ambiguities associated with the correlation among the four observed driving forces, the results in Table 9 need to be interpreted in the light of

Table 9 Standard deviations of selected variables in counterfactual economies with single driving forces

	All driving forces	TFP growth only	Labor-force growth only	Capital wedge only	Labor wedge only
Output growth	1.18	0.84	0.15	0.09	0.73
Consumption growth	1.17	0.80	0.12	0.44	0.41
Investment growth	4.63	1.18	0.71	2.64	3.26
Return to capital	1.63	0.62	0.26	0.84	1.03
Unemployment	1.14	0.00	0.00	0.00	1.14

Table 10 Correlations of driving forces

	TFP growth	Labor-force growth	Capital wedge	Labor wedge
TFP growth	1.00			
Labor-force growth	0.15	1.00		
Capital wedge	0.83	−0.03	1.00	
Labor wedge	−0.28	−0.89	−0.18	1.00

the inability to measure other driving forces, notably fluctuations in product demand. The large role of the labor wedge in the table may actually reflect effects operating through shifts of consumption and investment from forces not included in the model. A later section of this chapter on the forces unleashed by the 2008 crisis shows the potential importance of the product demand and product-market-wedge driving forces.

The model takes a simplified view of the role of confidence, ambiguity aversion, and other factors that may discourage economic activity in ways not included in traditional macro models. Both the capital wedge and the labor wedge are modeled as extra discounts that have adverse effects, but the labor wedge appears to be much the more important of the two. In the model, a decline in confidence and the corresponding increase in the labor discount d_n have a direct effect on job creation through the mechanisms associated with the DMP model. Lower job creation results in lower job-finding rates and higher unemployment. The result enters the rest of the economy as an adverse shift in net labor supply resulting in declines in output, shared between consumption and investment. As Table 9 shows, in the base model, there is no effect on unemployment from other driving forces—the rise in unemployment in bad times is entirely assigned to a decline in confidence among businesses that cuts back their job-creation flows. Obviously this property is an oversimplification, but the macro-labor research community has made more progress recently in demonstrating the near-irrelevance of driving forces of unemployment such as productivity than in finding driving forces to account for fluctuations in unemployment as responses to other forces. The later section on the crisis shows how the product-market wedge influences unemployment.

8. CRISIS AND SLUMP

This section explores the model's properties when the driving forces are tuned to data from the years 2009 through 2012, the years of the maximum effects of the crisis of late 2008 and its aftermath. This exercise assigns those 4 years to an altered state 5 with more negative effects, including values of the two driving forces not measured for the base model covering all the years starting in 1953. Table 11 shows the values for the six driving

Table 11 Values of driving forces hypothesized for crisis slump

Driving force	Value in state 5
TFP growth	0.92
Labor-force growth	0.10
Capital discount	16.70
Liquidity discount	−6.00
Labor discount	1.96
Product-market wedge	3.00
Product demand	−5.00

forces. TFP growth retains its value from the base case, which was close to actual growth over 4 years. Labor-force growth is much lower than normal, just above zero. The capital discount is well above its actual value in any state in the base case, reflecting the belief that agency frictions and a loss of confidence occurred during the immediate post-crisis years. The liquidity discount for the safe 1-year interest rate is lower than in any state in the base case, reflecting an unusual flight to safety after the crisis. The labor discount is 0.4 percentage points higher than in state 5 in the base case, corresponding to an unemployment rate (with no product-market wedge) around 9%, that actually occurred after the crisis. The product-market wedge is taken at the hypothetical value of 3% and the product demand shift at minus 5%.

Table 12 shows the average effects of the driving forces over 4 years of adverse shocks, in comparison to an economy that stayed all 4 years in a different version of state 5 in which the driving forces all had the average of their values from the base case. Thus the figures in the table are the effects of the crisis in the sense of the differences in the outcomes between an economy with the special crisis driving forces and one with driving forces typical of the U.S. economy historically in normal times. The left column shows the average with all the crisis-specific driving forces in action. The rise of 4.54 percentage points of unemployment resembles the actual behavior of the economy. The decline in output is substantial but falls short of the actual decline of about 10%. But the *positive* numbers for consumption and investment are dramatically the opposite of the actual sharp decline in consumption and collapse of investment. This result is not a failure of the model, but rather a consequence of the model's implication of a huge decline in the safe interest rate. This decline could not have occurred, because of the zero lower bound. The story of the table is that the decline in the interest rate unhindered by the lower bound would have brought about an increase in interest-sensitive consumption and investment that would more than offset the direct decline in the spending shift g and the adverse effects of other driving forces.

Table 12 Effects of crisis shocks on key variables, averaged over 4 years

	Driving force						
Variable	**All**	**Capital discount**	**Labor discount**	**Safe rate discount**	**Labor force**	**Product-market wedge**	**Spending shift**
Unemployment, percentage points	4.54	0.00	2.98	0.00	0.00	1.61	0.00
Consumption, %	0.23	0.32	−1.33	0.00	−1.72	−0.71	2.51
Output, %	−3.30	−0.26	−1.84	0.00	−1.30	−1.00	0.53
Investment, %	1.47	−0.57	−0.51	0.00	0.43	−0.28	1.77
Safe interest rate, percentage points	−11.37	−1.48	−0.33	−4.48	−0.88	−0.17	−3.20

The right panel of Table 12 breaks down the effects by the driving forces. Because the model is nonlinear, the sum of the effects on the right side is slightly different from the combined effect on the left. The increase in the capital discount had no effect on unemployment, moved a small amount of spending from investment to consumption, lowered output modestly, and depressed the safe interest rate. The rise in the labor discount raised unemployment substantially and cut output by 1.84%, 1.33% of output from consumption and 0.51% from investment. The rise in the liquidity-safety premium for the short rate had an effect only on that rate, as there is no direct feedback from changes in that rate induced by changes in the premium in the model. The adverse effect of the crisis on the labor force cut output by 1.30%. Consumption fell by 1.72% of normal output, while investment rose by 0.43%. The rise in the product-market wedge accounted for 1.61 percentage points of the rise in unemployment, by raising market power and lowering the marginal revenue product of labor and thus cutting the incentive to create jobs. The spending shift, modeled as a decline in government purchases, resulted in increases of 2.51% of output in consumption and 1.77% in investment, thanks to the income effect of lower implied taxes and the induced decline in the safe short rate of 3.20 percentage points.

8.1 The Zero Lower Bound

Obviously the main lesson of Table 12 is the central importance of the zero lower bound for the severity of the post-crisis slump in the U.S. economy. Although the model does not implement a lower bound on the safe real rate, the results are informative about the incidence of the bound and, to some extent, about the magnitude of adverse effects that would have resulted from the bound. During the slump following the 2008 crisis, the short safe nominal rate was essentially zero, at its bound as perceived by the Federal Reserve, and the expected inflation rate was around two percent—see Fig. 15—so the corresponding bound on the real rate is around minus 2%.

In the model, the normal value of the safe real rate during the years after 2008 is about 3%. According to the lower left figure in Table 12, with all driving forces active at the levels in Table 11, the rate would have been about 11% lower, or minus 8%. Most macroeconomists would probably agree that the effects of a monetary force that raised the safe real rate 8 percentage points above its equilibrium would be severely contractionary. More than half of that is the direct result of the depression of the safe rate on account of the flight to safety hypothesized in the crisis-slump scenario. The other big negative force is the downward shift in product demand, shown in the lower right corner of Table 12. The model supports the idea that the collapse of house prices and tightening of bank lending battered the economy by discouraging consumption and investment. The third-biggest contributor to the decline in the safe rate was the capital discount, good for about 1.5 percentage points of decline. The labor discount, on the other hand, had only a small effect—it is a supply effect. Whereas demand effects are more than fully offset by the decline in the safe rate, reductions in supply cannot be offset that way.

9. PERSISTENCE

Effects lasting longer than the driving forces themselves operate through the model's state variables. It has two exogenous state variables, TFP and the labor force, and one endogenous state variable, the capital stock.

9.1 Exogenous Persistence

In the model, each shock to the labor force has permanent effects. Where the shocks operate through births and immigration, this property is a reasonable approximation. Whether the substantial decline in the labor-force participation of existing individuals that occurred during the slump will ultimately reverse itself is an open question. As of early 2016, there was no sign that the return to essentially normal conditions in the labor market would result in a restoration of any of the large decline that accompanied the slump. Fig. 18 shows the path of the labor force as a percent of its initial normal value in the hypothetical crisis slump studied in the previous section. With four consecutive large incremental shortfalls in the labor force during years 1–4, the cumulative shortfall in the labor force in year 4 is about 6%. Though the labor-force growth rate returns to normal in year 5, the cumulative shortfall continues to become larger, because the growth process is multiplicative and is always at a lower base, post-crisis.

9.2 Endogenous Persistence

Endogenous persistence occurs through the capital stock. The effect of the capital discount is concentrated on investment, as shown in Table 12. An increase in that discount

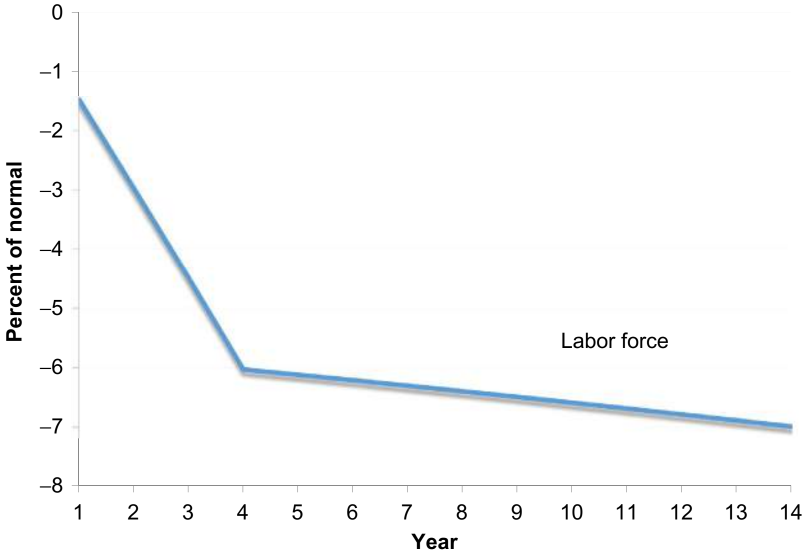

Fig. 18 Persistence of a labor-force shock.

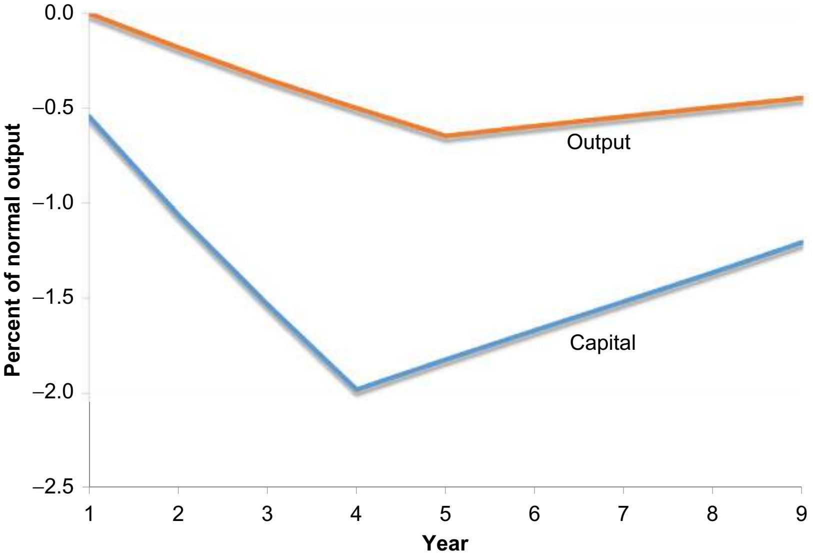

Fig. 19 Persistent effects of an elevation of the capital discount.

causes businesses to place a lower value on the future payoff to capital formation, so capital falls further and further below its normal growth path during a period of higher discount. The effects on output and other variables persist beyond the time when the discount declines back to normal. The capital stock returns only gradually to its normal growth path. Fig. 19 shows the effects of the 4-year period of increased capital discount described in Table 11 on the capital stock and on output. The figure shows the difference between the expected values of those variables conditional on the crisis values of the capital discount and the expected values with normal, noncrisis values of the discount. The effects on both variables cumulate during the 4 years with the higher crisis discount and then begin to return toward zero. Five years after the end of the crisis values, the effects remain strong.

Similar results apply to the other driving forces that have negative effects on investment in Table 11. These are the labor discount, which cuts investment by reducing the effective supply of labor, and the product-market wedge, which lowers the marginal revenue product of capital.

10. CONCLUDING REMARKS

This chapter is complementary to Ramey's chapter in this volume. Most of her discussion relates to empirical evidence from VARs and other econometric specifications, or to the properties of new Keynesian structural models, though she does also consider structural models more closely affiliated with the tradition of the real business-cycle model. She focuses extensively on monetary shocks—departures of monetary policy from its usual relation to current developments in the economy. No monetary shocks occur in the economy considered in this chapter. The central bank never pushes the short rate away from its equilibrium value to restore inflation to its target rate. In the context of the literature that includes monetary policy and monetary nonneutrality, the model here reveals the values of the interest rate and other variables that would prevail in the absence of sticky prices and wages. Both chapters consider government purchases as a driving force. In the empirical work Ramey considers, the focus is on the purchases multiplier, as revealed by the empirical relation between output and purchases. She finds that the multiplier is around one but with considerable dispersion across studies. In this chapter, Table 12 shows a multiplier of 0.53, the value in the row for output and the column for the spending shift. The lower value may be the result of the model's assumption of full monetary response to government purchases, letting the interest rate track the change in its equilibrium value. The sample period for the model includes times when, for example, monetary policy kept the interest rate constant in the face of an increase in purchases, which would considerably amplify the response of output. On the tax side of fiscal policy, Ramey considers taxes as explicit driving forces. Taxes have a role in this chapter because they are one of the sources of historical shifts in the capital discount. But I do not consider tax changes as special driving forces of the post-crisis slump. Ramey's chapter includes a detailed treatment of the measurement of technology shifts and their effects, as measured in empirical work. To measure TFP growth, she concludes in favor of measures with utilization adjustments. This chapter uses Fernald's measure without that adjustment. She also discusses, in detail, measures of technological change apart from TFP, relating to investment. She briefly mentions oil-price changes, credit conditions, policy uncertainty, fluctuations in the labor force, and the labor wedge as additional driving forces. She does not mention the product-market wedge as a driving force.

The importance of total factor productivity as a determinant of medium-term growth and economic performance is widely agreed among macroeconomists today, and is confirmed in the results of this chapter—Table 9 shows that, historically, movements of TFP by themselves would account for a standard deviation of output around 75% of the total of all driving forces. A decline in productivity growth occurred during the slump that began in 2008 and contributed to the shortfall in output, consumption, and capital formation during the slump. Whether the crisis of 2008 contributed to the decline in productivity growth is unresolved.

On the other hand, fluctuations in the size of the work force relative to the working-age population—the labor-force participation rate—are about as big as fluctuations in productivity and have similar effects. Research on medium-run fluctuations has neglected this driving force, even though research on participation itself has been extensive. The continuation during the recent slump of a major decline in participation that began in 2000—and is not the result of demographic shifts—worsened the slump. The evidence seems to point in the direction that the decline in participation was not the result of the crisis and resulting explosion of unemployment.

Evidence from financial markets appears to confirm the proposition that discounts applied to risky investments rose as a result of the crisis even as the safe rate fell to zero. In normal times, without the zero lower bound, higher discounts result in lower output and employment. There is an interesting unresolved question about the role of discount increases when the real rate is held fixed by the zero lower bound on the nominal interest rate and the immovability of inflation.

Models that attribute some of the depth and persistence of the response of the economy to financial shocks hold that the shocks cause increases in agency frictions within financial intermediaries or nonfinancial businesses. Financial wedges develop to ensure that managers deprived of equity still have continuation values sufficient to prevent misconduct. The evidence of widening wedges between the return to capital and the safe short rate is convincing, as is the sharp but transitory rise in the spreads between risky private bonds and Treasurys of the same maturity. The model in this chapter assigns a moderate but important role to financial frictions, as part of the driving force called the capital discount.

The new Keynesian model has called attention to the product-market wedge—the markup of price over cost—as the transmission mechanism of shocks to economic activity. With sticky prices, an increase in demand raises cost but not price, so the markup declines. The economy expands because the product-market wedge functions like a tax wedge in depressing activity and the decline in markups relieves that adverse effect. An interesting debate has yet to resolve the issue of the importance of the product-market wedge in the depth and persistence of slumps.

Finally, the model confirms earlier findings about the multiplier effects of shifts in product demand. As an important cause of declining consumption demand, household deleveraging has been assigned a major role in the recent slump and is an obvious candidate for explaining the persistence of the slump. In the model, an exogenous decline in product demand results in a large decrease in the interest rate, which stimulates consumption and investment. Rather than collapsing, the economy undergoes a large reallocation of resources. But with the zero lower bound in effect, the reallocation fails to occur. Instead, output and employment fall. As yet, the profession has not come forth with a well-founded model of that failure.

ACKNOWLEDGMENTS

Chapter prepared for the *Handbook of Macroeconomics*, John Taylor and Harald Uhlig, eds. The Hoover Institution supported this research. The research is also part of the National Bureau of Economic Research's Economic Fluctuations and Growth Program. I thank Gauti Eggertsson, Wouter den Haan, and Cosmin Ilut for illuminating conference discussions, and Valerie Ramey and the editors for comments. Complete backup for all of the calculations is available from my website, stanford.edu/~rehall

Abstract

In this chapter, we discuss a number of challenges for structural macroeconomic models in the light of the Great Recession and its aftermath. It shows that a benchmark DSGE model that shares many features with models currently used by central banks and large international institutions has difficulty explaining both the depth and the slow recovery of the Great Recession. In order to better account for these observations, the chapter analyses three extensions of the benchmark model. First, we estimate the model allowing explicitly for the zero lower bound constraint on nominal interest rates. Second, we introduce time variation in the volatility of the exogenous disturbances to account for the non-Gaussian nature of some of the shocks. Third and finally, we extend the model with a financial accelerator and allow for time variation in the endogenous propagation of financial shocks. All three extensions require that we go beyond the linear Gaussian assumptions that are standard in most policy models. We conclude that these extensions go some way in accounting for features of the Great Recession and its aftermath, but they do not suffice to address some of the major policy challenges associated with the use of nonstandard monetary policy and macroprudential policies.

1. INTRODUCTION

In this chapter, we discuss new challenges for structural macroeconomic models used at central banks in light of the Great Recession in United States and other advanced economies. This recession has had widespread implications for economic policy and economic performance, with historically low nominal interest rates and elevated unemployment levels in its aftermath. The fact that the intensification of the crisis in the fall of 2008 was largely unexpected and much deeper than central banks predicted and that the subsequent recovery was much slower, has raised many questions about the design of macroeconomic models at use in these institutions. Specifically, the models have been criticized for omitting key financial mechanisms and shocks stemming from the financial sector.

We start by analyzing the performance of a benchmark macroeconomic model during the Great Recession. The model we use—the well-known Smets and Wouters (2007) model—shares many features with the models currently used by central banks. When we analyze this model estimated over the precrisis period we find, confirming previous results in Del Negro and Schorfheide (2013), that actual GDP growth was outside the predictive density of the model during the most acute phase of the recession. To account for the depth of the recession, the model needs a cocktail of extremely unlikely shocks that mainly affect the intertemporal decision of households and firms to consume or invest such as risk-premium and investment-specific technology shocks. We then proceed to document that these shocks are non-Gaussian, and strongly related to observable financial variables such as the Baa-Aaa and term spread, suggesting the importance of including financial shocks and frictions to account for large recessions. Moreover, in order to account for the slow recovery, restrictive monetary policy shocks reflecting a binding lower bound on the nominal interest rate, negative investment shocks, and positive price mark-up shocks are needed. This configuration of shocks explains the slow recovery and the missing disinflation following the great recession.

To try to better account for these observations, we proceed to amend the benchmark model along three dimensions. First, we take the zero lower bound (ZLB henceforth) explicitly into account when estimating the model over the full sample. We do this using two alternative approaches. First, we implement the ZLB as a binding constraint on the policy rule with an expected duration that is determined endogenously by the model in each period. Second, we impose the expected duration of the ZLB spells during the recession to be consistent with external information derived from overnight index swap rates. Importantly, we find that the variants of the model estimated subject to the ZLB constraint typically feature a substantially higher degree of nominal stickiness in both prices and wages which helps to understand the inflation dynamics during the recession period and the subsequent slow recovery. In addition, an important characteristic of these variants of the model is a substantially higher response coefficient on the output gap in the policy rule. Incorporating the ZLB in the estimation and simulation of the model does not materially affect the median forecast of output and inflation in 2008Q3 as the probability of hitting the lower bound is estimated to be low before the crisis. It does, however, tilt the balance of risks towards the downside in the subsequent periods as the likelihood of monetary policy being constrained increases.

Second, in order to account for the non-Gaussian nature of the shocks driving most recessions, we allow for time-varying volatility in some of the shocks. In line with the previous literature, we find that the empirical performance of the model improves a lot when two regime change processes are allowed in the variance of the shocks. One of those regime switches captures the great moderation period from the mid-1980s to the mid-2000s, when overall macroeconomic volatility was much lower than both before and after this period. The other regime switching process captures the higher volatility of the risk-premium, the monetary policy, and the investment-specific technology shocks in recession periods. This regime switching process can account for the non-Gaussian nature of those shocks and also helps widening the predictive density of output growth at the end of 2008 as the probability of a financial recession increases.

Finally, we proceed to examine how the performance and properties of the basic model can be improved by introducing a financial accelerator mechanism and explicit shocks stemming from the financial sector. This exercise is initiated by embedding a variant of the Bernanke et al. (1999) financial accelerator into the workhorse model and estimating it under the standard assumption that the financial sector excerpts a time-invariant influence on business cycles: that is, we follow, eg, Christiano et al. (2003a), De Graeve (2008) and Queijo von Heideken (2009), and assume that the parameters characterizing the financial frictions are constant and that shocks stemming from the financial bloc are Gaussian. In this specification, we do not find that the financial accelerator adds much propagation of other macroeconomic shocks, and that movements in the Baa-Aaa spread we add as observable is mostly explained by the exogenous shock stemming from the financial sector. Driven by this result, and because of the non-Gaussian features of the smoothed shocks in the benchmark model, we examine if the performance of this augmented model can be improved by allowing for regime switching in the sensitivity of the external finance premium to the leverage ratio, which one may think of as risk-on/risk-off behavior in the financial sector. We find that allowing for regime switching in the sensitivity of external finance premium to the leverage ratio introduces a high degree of skewness in the predictive density of the spread and makes the model put nonzero probability in the predictive density on the observed 2008Q4 output growth outcome. Moreover, when we follow Del Negro and Schorfheide (2013) and condition on the actual spread outcome during the fourth quarter of 2008—which is reasonable since the spread reached its quarterly mean in the beginning of October—the model's ability to account for the severe growth outcome further improves. This result indicates that if we appropriately could integrate the nonlinear accelerator dynamics from financial frictions in our models, we may obtain a more realistic predictive density in line with reduced form time-varying volatility models.

The three extensions discussed in this chapter go some way to address some of the challenges faced by the benchmark DSGE model in accounting for the Great Recession and its aftermath. They all involve going beyond the linear Gaussian-modeling framework. However, they do not suffice to fully address some of the major empirical policy challenges. These new challenges stem from the fact that, following the crisis and hitting the zero lower bound, central banks have implemented a panoply of nonstandard monetary policy measures such a Large-Scale-Asset-Purchases and other credit easing policies. Basic extensions of the benchmark model with financial frictions (such as a financial accelerator) are not sufficient to be able to fully analyze the effectiveness of those policies and their interaction with the standard interest rate policy. Similarly, the financial crisis has given rise to the new macroprudential policy domain that aims at containing systemic risk and preserving financial stability. Current extensions of the benchmark model are often not rich enough to analyze the interaction between monetary and macroprudential policy. Being able to do so will require incorporating of a richer description of both solvency (default) and liquidity (bank runs) dynamics with greater complexity in terms of both nonlinearities and heterogeneity.

The rest of the chapter is structured as follows. Section 2 provides an incomplete survey of the macroeconomic models used by central banks and other international organizations. Following this survey, Section 3 presents the prototype model—the estimated model of Smets and Wouters (2003). This model shares many features of models in use by central banks. The section also discusses the data and the estimation of this model on precrisis data. In Section 4, we use this model estimated on precrisis data to analyze the crisis episode, which gives us valuable insights into the workings of the model. We also compare the performance of our structural model to a reduced-form benchmark VAR, which is estimated with Bayesian priors. As this analysis points to some important shortcomings of the benchmark model, we augment the baseline model in Section 5 along the three dimensions discussed earlier.

Finally, Section 6 sums up by discussing some other new and old challenges for structural macro models used in policy analysis and presents some conclusions. Appendices contain some technical details on the model, methods, and the data used in the analysis.

2. COMMON FEATURES OF CENTRAL BANK MODELS

In this section, we provide an incomplete survey of the key policy models currently in use at central banks and other key policy institutions like the IMF, European Commission, and the OECD. We aim at determining the similarity between models, and assess if—and how—they have been changed in response to the recession and developments since then.

A good starting point for the discussion is the paper by Coenen et al. (2012). Wieland et al. (2012) provides a complementary and very useful overview of policy models in use at central banks. An additional advantage with the paper by Wieland et al. is that they have pulled together an archive with well-know estimated macroeconomic models (both policy and academic) that can conveniently be used to run and compare various diagnostic shocks using a Matlab graphical user interface.[a] We nevertheless base our discussion on Coenen et al., as they focus exclusively on models in use at policy institutions. Coenen et al. studies the effects of monetary and fiscal shocks in the key policy models in use at the Bank of Canada (BoC-GEM), the Board of Governors of the Federal Reserve System (with two models, FRB-US and SIGMA), the European Central Bank (NAWM), the European Commission (QUEST), the International Monetary Fund (GIMF), and the OECD (OECD Fiscal). Out of the seven models, six are dynamic

[a] Taylor and Wieland (2012) use the database to compare the responses to monetary policy shocks. Wieland and Wolters (2013) study the forecasting behavior for a large set of models in the database.

stochastic general equilibrium (DSGE) models, while one–the FRB-US—is based on the polynomial adjustment cost (PAC) framework. Hence, an overwhelming majority of key policy institutions today use DSGE models as the core policy tool.[b] The switch from traditional backward-looking macroeconometric models (see, eg, Rudebusch and Svensson, 1999) to DSGEs occurred amid the forceful critique by Lucas (1976) and Sims (1980) of such models, and was made feasible due to the progress in the solution and estimation of such models (see, eg, Blanchard and Kahn, 1980 and Fair and Taylor, 1983) as well as the contribution of Christiano et al. (2005) who showed that such models, carefully specified, could feature a realistic monetary policy transmission mechanism. As pointed out by Clarida et al. (1999), Woodford (2003) and Galí (2008), these models assigns an important role to expectations for macroeconomic stabilization, and this view was embraced by policy makers at central banks. However, although macroeconomic models have been used in scenario analysis and affected policy making more generally, it is probably fair to say that the models impact on the short- and medium-term economic projections have been limited, see, eg, Iversen et al. (2016).

As outlined in detail in tables 1 and 2 by Coenen et al. (2012), the DSGE models share many similarities to the seminal models of Christiano et al. (2005) (CEE henceforth) and Smets and Wouters (2003, 2007). They typically feature imperfect competition in product and labor markets as vehicles to introduce sticky prices and wages. They also include important real rigidities like habit formation, costs of adjusting investment and variable capital utilization. Monetary policy is generally determined by a simple Taylor-type policy rule which allows for interest rate smoothing, but although they share many similarities with the academic benchmark models of CEE and Smets and Wouters (2007) (SW07 henceforth), policy models often embed some additional features. One such important feature is that they have a significant share of financially constrained households, ranging between 20% and 50%. In some models these are hand-to-mouth households, who take their labor income as given and determine consumption residually from a period-by-period budget constraint. In other models these are liquidity-constrained households, who face the same period-by-period budget constraint but solve an intertemporal decision problem between consumption and work effort. An additional difference between the policy models and the academic style ones is that the former generally has a much more detailed fiscal sector with many distortionary taxes, types of government spending and various transfers from the government to the households.[c]

[b] Other prominent institutions that have adopted estimated DSGE model as their core policy tool include Bank of England (COMPASS, see Burgess et al., 2013), Norges Bank (NEMO, see Brubakk et al., 2006), Sveriges Riksbank (RAMSES, see Adolfson et al., 2013), Federal Reserve Bank of New York (Del Negro et al., 2013), and the Federal Reserve Bank of Chicago (Brave et al., 2012).

[c] These results are broadly in line with the findings of Wieland et al. (2012).

Another interesting observation is that neither CEE nor SW07 include frictions in financial markets or a detailed banking sector in their models.[d] Four of the seven policy models included financial frictions prior to the crisis. By asking the policy institutions that were part of this study about their development efforts since then, it is clear that efforts have been made towards better integration of financial markets, with a focus on the interaction between banks and the firms in the economy. For instance, following the crisis, financial frictions following the approach of Bernanke et al. (1999) have been introduced in (at least) two of the three models that did not feature them before.[e]

The key lesson we draw from this is that while the crisis has had some impact on improving the modeling of the financial sector in DSGE models, it has not so far had a material impact on the type of models used at key policy institutions, which still share many features of the basic model developed by CEE.

3. A BENCHMARK MODEL

In this section, we show the benchmark model environment, which is the model of Smets and Wouters (2007). The SW07-model builds on the workhorse model by CEE, but allows for a richer set of stochastic shocks. In Section 3.4, we describe how we estimate it using aggregate times series for the United States.

3.1 Firms and Price Setting

3.1.1 Final Goods Production

The single final output good Y_t is produced using a continuum of differentiated intermediate goods $Y_t(f)$. Following Kimball (1995), the technology for transforming these intermediate goods into the final output good is

$$\int_0^1 G_Y\left(\frac{Y_t(f)}{Y_t}\right) df = 1. \tag{1}$$

As in Dotsey and King (2005), we assume that $G_Y(\cdot)$ is given by a strictly concave and increasing function:

[d] The CEE, but not the SW07-model, includes a working capital—or cost channel—of monetary policy whereby firms have to borrow at the policy rate to finance the wage bill. This channel allows the CEE model to account for the "Price-puzzle" (ie, that inflation rises on impact following a hike in the policy rate) that often emerges for monetary policy shocks in identified VAR models.

[e] We are grateful to Günter Coenen (ECB) and John Roberts (Federal Reserve Board) for providing very helpful responses to our questionnaire.

$$G_Y\left(\frac{Y_t(f)}{Y_t}\right)=\frac{\phi_t^p}{1-(\phi_t^p-1)\epsilon_p}\left[\left(\frac{\phi_t^p+(1-\phi_t^p)\epsilon_p}{\phi_t^p}\right)\frac{Y_t(f)}{Y_t}+\frac{(\phi_t^p-1)\epsilon_p}{\phi_t^p}\right]^{\frac{1-(\phi_t^p-1)\epsilon_p}{\phi_t^p-(\phi_t^p-1)\epsilon_p}} \\ +\left[1-\frac{\phi_t^p}{1-(\phi_t^p-1)\epsilon_p}\right], \tag{2}$$

where $\phi_t^p \geq 1$ denotes the gross markup of the intermediate firms. The parameter ϵ_p governs the degree of curvature of the intermediate firm's demand curve. When $\epsilon_p=0$, the demand curve exhibits constant elasticity as with the standard Dixit–Stiglitz aggregator. When ϵ_p is positive the firms instead face a quasi-kinked demand curve, implying that a drop in the good's relative price only stimulates a small increase in demand. On the other hand, a rise in its relative price generates a large fall in demand. Relative to the standard Dixit–Stiglitz aggregator, this introduces more strategic complementary in price setting which causes intermediate firms to adjust prices less to a given change in marginal cost. Finally, notice that $G_Y(1)=1$, implying constant returns to scale when all intermediate firms produce the same amount of the good.

Firms that produce the final output good are perfectly competitive in both product and factor markets. Thus, final goods producers minimize the cost of producing a given quantity of the output index Y_t, taking the price $P_t(f)$ of each intermediate good $Y_t(f)$ as given. Moreover, final goods producers sell the final output good at a price P_t, and hence solve the following problem:

$$\max_{\{Y_t,\, Y_t(f)\}} P_tY_t-\int_0^1 P_t(f)\,Y_t(f)df, \tag{3}$$

subject to the constraint in (1). The first order conditions (FOCs) for this problem can be written

$$\begin{aligned}\frac{Y_t(f)}{Y_t}&=\frac{\phi_t^p}{\phi_t^p-(\phi_t^p-1)\epsilon_p}\left(\left[\frac{P_t(f)}{P_t}\frac{1}{\Lambda_t^p}\right]^{-\frac{\phi_t^p-(\phi_p-1)\epsilon_p}{\phi_t^p-1}}+\frac{(1-\phi_t^p)\epsilon_p}{\phi_t^p}\right)\\ P_t\Lambda_t^p&=\left[\int P_t(f)^{-\frac{1-(\phi_t^p-1)\epsilon_p}{\phi_t^p-1}}df\right]^{-\frac{\phi_t^p-1}{1-(\phi_t^p-1)\epsilon_p}}\\ \Lambda_t^p&=1+\frac{(1-\phi_t^p)\epsilon_p}{\phi_p}-\frac{(1-\phi_t^p)\epsilon_p}{\phi_t^p}\int\frac{P_t(f)}{P_t}df,\end{aligned} \tag{4}$$

where Λ_t^p denotes the Lagrange multiplier on the aggregator constraint in (1). Note that when $\epsilon_p=0$, it follows from the last of these conditions that $\Lambda_t^p=1$ in each period t, and the demand and pricing equations collapse to the usual Dixit–Stiglitz expressions, ie,

$$\frac{Y_t(f)}{Y_t} = \left[\frac{P_t(f)}{P_t}\right]^{-\frac{\phi_t^p}{\phi_t^p-1}}, P_t = \left[\int P_t(f)^{\frac{1}{1-\phi_t^p}} df\right]^{1-\phi_t^p}.$$

3.1.2 Intermediate Goods Production

A continuum of intermediate goods $Y_t(f)$ for $f \in [0, 1]$ is produced by monopolistic competitive firms, each of which produces a single differentiated good. Each intermediate goods producer faces the demand schedule in Eq. (4) from the final goods firms through the solution to the problem in (3), which varies inversely with its output price $P_t(f)$ and directly with aggregate demand Y_t.

Each intermediate goods producer utilizes capital services $K_t(f)$ and a labor index $L_t(f)$ (defined later) to produce its respective output good. The form of the production function is Cobb–Douglas:

$$Y_t(f) = \varepsilon_t^a K_t(f)^\alpha [\gamma^t L_t(f)]^{1-\alpha} - \gamma^t \Phi,$$

where γ^t represents the labor-augmenting deterministic growth rate in the economy, Φ denotes the fixed cost (which is related to the gross markup ϕ_t^p so that profits are zero in the steady state), and ε_t^a is a total productivity factor which follows a Kydland and Prescott (1982) style process:

$$\ln \varepsilon_t^a = \rho_a \ln \varepsilon_{t-1}^a + \eta_t^a, \eta_t^a \sim N(0, \sigma_a). \tag{5}$$

Firms face perfectly competitive factor markets for renting capital and hiring labor. Thus, each firm chooses $K_t(f)$ and $L_t(f)$, taking as given both the rental price of capital R_{Kt} and the aggregate wage index W_t (defined later). Firms can without costs adjust either factor of production, thus, the standard static first-order conditions for cost minimization implies that all firms have identical marginal costs per unit of output.

The prices of the intermediate goods are determined by nominal contracts in Calvo (1983) and Yun (1996) staggered style nominal contracts. In each period, each firm f faces a constant probability, $1 - \xi_p$, of being able to reoptimize the price $P_t(f)$ of the good. The probability that any firm receives a signal to reoptimize the price is assumed to be independent of the time that it last reset its price. If a firm is not allowed to optimize its price in a given period, this is adjusted by a weighted combination of the lagged and steady state rate of inflation, ie, $P_t(f) = (1+\pi_{t-1})^{\iota_p}(1+\pi)^{1-\iota_p} P_{t-1}(f)$ where $0 \le \iota_p \le 1$ and π_{t-1} denotes net inflation in period $t - 1$, and π the steady state net inflation rate. A positive value of the indexation parameter ι_p introduces structural inertia into the inflation process. All told, this leads to the following optimization problem for the intermediate firms

$$\max_{\tilde{P}_t(f)} \mathrm{E}_t \sum_{j=0}^{\infty} (\beta\xi_p)^j \frac{\Xi_{t+j} P_t}{\Xi_t P_{t+j}} \left[\tilde{P}_t(f)\left(\Pi_{s=1}^j (1+\pi_{t+s-1})^{\iota_p} (1+\pi)^{1-\iota_p}\right) - MC_{t+j}\right] Y_{t+j}(f),$$

where $\widetilde{P}_t(f)$ is the newly set price and $\beta^j \frac{\Xi_{t+j} P_t}{\Xi_t P_{t+j}}$ the stochastic discount factor. Notice that given our assumptions, all firms that reoptimize their prices actually set the same price.

As noted previously, we assume that the gross price-markup is time varying and given by $\phi_t^p = \phi^p \varepsilon_t^p$, for which the exogenous component ε_t^p is given by an exogenous ARMA (1,1) process:

$$\ln \varepsilon_t^p = \rho_p \ln \varepsilon_{t-1}^p + \eta_t^p - \vartheta_p \eta_{t-1}^p, \eta_t^p \sim N(0, \sigma_p). \tag{6}$$

3.2 Households and Wage Setting

Following Erceg et al. (2000), we assume a continuum of monopolistic competitive households (indexed on the unit interval), each of which supplies a differentiated labor service to the production sector; that is, goods-producing firms regard each household's labor services $L_t(h)$, $h \in [0, 1]$, as imperfect substitutes for the labor services of other households. It is convenient to assume that a representative labor aggregator combines households' labor hours in the same proportions as firms would choose. Thus, the aggregator's demand for each household's labor is equal to the sum of firms' demands. The aggregated labor index L_t has the Kimball (1995) form:

$$L_t = \int_0^1 G_L\left(\frac{L_t(h)}{L_t}\right) dh = 1, \tag{7}$$

where the function $G_L(\cdot)$ has the same functional form as does (2), but is characterized by the corresponding parameters ϵ_w (governing convexity of labor demand by the aggregator) and a time-varying gross wage markup ϕ_t^w. The aggregator minimizes the cost of producing a given amount of the aggregate labor index L_t, taking each household's wage rate $W_t(h)$ as given, and then sells units of the labor index to the intermediate goods sector at unit cost W_t, which can naturally be interpreted as the aggregate wage rate. From the FOCs, the aggregator's demand for the labor hours of household h—or equivalently, the total demand for this household's labor by all goods-producing firms—is given by

$$\frac{L_t(h)}{L_t} = G_L'^{-1}\left[\frac{W_t(h)}{W_t} \int_0^1 G_L'\left(\frac{L_t(h)}{L_t}\right) \frac{L_t(h)}{L_t} dh\right], \tag{8}$$

where $G_L'(\cdot)$ denotes the derivative of the $G_L(\cdot)$ function in Eq. (7).

The utility function of a typical member of household h is

$$\mathrm{E}_t \sum_{j=0}^{\infty} \beta^j \left[\frac{1}{1-\sigma_c}\left(C_{t+j}(h) - \varkappa C_{t+j-1}\right)\right]^{1-\sigma_c} \exp\left(\frac{\sigma_c - 1}{1+\sigma_l} L_{t+j}(h)^{1+\sigma_l}\right), \tag{9}$$

where the discount factor β satisfies $0 < \beta < 1$. The period utility function depends on household h's current consumption $C_t(h)$, as well as lagged aggregate consumption per capita, to allow for external habit persistence (captured by the parameter $\varkappa$). The period utility function also depends inversely on hours worked $L_t(h)$.

Household h's budget constraint in period t states that expenditure on goods and net purchases of financial assets must equal to the disposable income:

$$\begin{aligned} &P_t C_t(h) + P_t I_t(h) + \frac{B_{t+1}(h)}{\varepsilon_t^b R_t} + \int_s \xi_{t,t+1} B_{D,t+1}(h) - B_{D,t}(h) \\ &= B_t(h) + W_t(h)L_t(h) + R_t^k Z_t(h) K_t^p(h) - a(Z_t(h))K_t^p(h) + \Gamma_t(h) - T_t(h). \end{aligned} \tag{10}$$

Thus, the household purchases part of the final output good (at a price of P_t), which is chosen to be consumed $C_t(h)$ or invest $I_t(h)$ in physical capital. Following Christiano et al. (2005), investment augments the household's (end-of-period) physical capital stock $K_{t+1}^p(h)$ according to

$$K_{t+1}^p(h) = (1-\delta)K_t^p(h) + \varepsilon_t^i \left[1 - S\left(\frac{I_t(h)}{I_{t-1}(h)}\right)\right] I_t(h). \tag{11}$$

The extent to which investment by each household turns into physical capital is assumed to depend on an exogenous shock ε_t^i and how rapidly the household changes its rate of investment according to the function $S\left(\frac{I_t(h)}{I_{t-1}(h)}\right)$, which we assume satisfies $S(\gamma) = 0, S'(\gamma) = 0$ and $S''(\gamma) = \varphi$ where γ is the steady state gross growth rate of the economy. The stationary investment-specific shock ε_t^i follows the process:

$$\ln \varepsilon_t^i = \rho_i \ln \varepsilon_{t-1}^i + \eta_t^i, \eta_t^i \sim N(0, \sigma_i).$$

In addition to accumulating physical capital, households may augment their financial assets through increasing their nominal bond holdings (B_{t+1}), from which they earn an interest rate of R_t. The return on these bonds is also subject to a risk-shock, ε_t^b, which follows

$$\ln \varepsilon_t^b = \rho_b \ln \varepsilon_{t-1}^b + \eta_t^b, \eta_t^b \sim N(0, \sigma_b). \tag{12}$$

Fisher (2015) shows that this shock can be given a structural interpretation.

We assume that agents can engage in friction-less trading of a complete set of contingent claims to diversify away idiosyncratic risk. The term $\int_s \xi_{t,t+1} B_{D,t+1}(h) - B_{D,t}(h)$ represents net purchases of these state-contingent domestic bonds, with $\xi_{t,t+1}$ denoting the state-dependent price, and $B_{D,t+1}(h)$ the quantity of such claims purchased at time t.

On the income side, each member of household h earns labor income $W_t(h)L_t(h)$, capital rental income of $R_t^k Z_t(h) K_t^p(h)$, and pays a utilization cost of the physical capital equal to $a(Z_t(h))K_t^p(h)$ where $Z_t(h)$ is the capital utilization rate. The capital services provided by household h, $K_t(h)$ thereby equals $Z_t(h)K_t^p(h)$. The capital utilization adjustment function $a(Z_t(h))$ is assumed to satisfy $a(1) = 0$, $a'(1) = r^k$, and $a''(1) = \psi/(1-\psi) > 0$, where $\psi \in [0, 1)$ and a higher value of ψ implies a higher cost of changing the utilization rate. Finally, each member also receives an aliquot share $\Gamma_t(h)$ of the profits of all firms, and pays a lump-sum tax of $T_t(h)$ (regarded as taxes net of any transfers).

In every period t, each member of household h maximizes the utility function in (9) with respect to consumption, investment, (end-of-period) physical capital stock, capital utilization rate, bond holdings, and holdings of contingent claims, subject to the labor demand function (8), budget constraint (10), and transition equation for capital (11).

Households also set nominal wages in Calvo-style staggered contracts that are generally similar to the price contracts described previously. Thus, the probability that a household receives a signal to reoptimize its wage contract in a given period is denoted by $1 - \xi_w$. In addition, SW07 specify the following dynamic indexation scheme for the adjustment of wages for those households that do not get a signal to reoptimize: $W_t(h) = \gamma(1+\pi_{t-1})^{\iota_w}(1+\pi)^{1-\iota_w} W_{t-1}(h)$. All told, this leads to the following optimization problem for the households

$$\max_{\tilde{W}_t(h)} \mathrm{E}_t \sum_{j=0}^{\infty} (\beta\xi_w)^j \frac{\Xi_{t+j}P_t}{\Xi_t P_{t+j}} \left[\tilde{W}_t(h)\left(\Pi_{s=1}^{j}\gamma(1+\pi_{t+s-1})^{\iota_w}(1+\pi)^{1-\iota_w}\right) - W_{t+j}\right] L_{t+j}(h),$$

where $\tilde{W}_t(h)$ is the newly set wage and $L_{t+j}(h)$ is determined by Eq. (7). Notice that with our assumptions all households that reoptimize their wages will actually set the same wage.

Following the same approach as with the intermediate-goods firms, we introduce a shock ε_t^w to the time-varying gross markup, $\phi_t^w = \phi^w \varepsilon_t^w$, where ε_t^w is assumed being given by an exogenous ARMA(1,1) process:

$$\ln \varepsilon_t^w = \rho_w \ln \varepsilon_{t-1}^w + \eta_t^w - \vartheta_w \eta_{t-1}^w, \eta_t^w \sim N(0, \sigma_w). \tag{13}$$

3.3 Market Clearing Conditions and Monetary Policy

Government purchases G_t are exogenous, and the process for government spending relative to trend output in natural logs, ie, $g_t = G_t/(\gamma^t Y)$, is given by the following exogenous AR(1) process:

$$\ln g_t = \left(1-\rho_g\right) \ln g + \rho_g\left(\ln g_{t-1} - \rho_{ga} \ln \varepsilon_{t-1}^a\right) + \eta_t^g, \eta_t^g \sim N\left(0, \sigma_g\right).$$

Government purchases neither have any effects on the marginal utility of private consumption, nor do they serve as an input into goods production. The consolidated government sector budget constraint is

$$\frac{B_{t+1}}{R_t} = G_t - T_t + B_t,$$

where T_t are lump-sum taxes. By comparing the debt terms in the household budget constraint in Eq. (10) with the equation earlier, one can see that receipts from the risk shock are subject to iceberg costs, and hence do not add any income to the government.[f] We acknowledge that this is an extremely simplistic modeling of the fiscal behavior of the government relative to typical policy models, and there might be important feedback effects between fiscal and monetary policies that our model does not allow for.[g] As discussed by Benigno and Nisticó (2015) and Del Negro and Sims (2014), the fiscal links between governments and central banks may be especially important today when central banks have employed unconventional tools in monetary policy. Nevertheless, we maintain our simplistic modeling of fiscal policy throughout the chapter, as it allows us to examine the partial implications of amending the benchmark model with more elaborate financial markets modeling and the zero lower bound constraint more directly.

The conduct of monetary policy is assumed to be approximated by a Taylor-type policy rule (here stated in nonlinearized form)

$$R_t \;= \max\left(0, R^{1-\rho_R} R_{t-1}^{\rho_R} \left(\frac{\Pi_t}{\Pi}\right)^{r_\pi(1-\rho_R)} \left(\frac{Y_t}{Y_t^{pot}}\right)^{r_y(1-\rho_R)} \left(\frac{Y_t}{Y_t^{pot}} \Big/ \frac{Y_{t-1}}{Y_{t-1}^{pot}}\right)^{r_{\Delta y}(1-\rho_R)} \varepsilon_t^r\right), \tag{14}$$

where Π_t denotes the is gross inflation rate, Y_t^{pot} is the level of output that would prevail if prices and wages were flexible, and variables without subscripts denote steady state values. The policy shock ε_t^r is supposed to follow an AR(1) process in natural logs:

$$\ln \varepsilon_t^r = \rho_r \ln \varepsilon_{t-1}^r + \eta_t^r, \eta_t^r \sim N(0, \sigma_r). \tag{15}$$

Total output of the final goods sector is used as follows:

$$Y_t = C_t + I_t + G_t + a(Z_t) - K_t,$$

where $a(Z_t) - K_t$ is the capital utilization adjustment cost.

3.4 Estimation on Precrisis Data

We now proceed to discuss how the model is estimated. To begin with, we limit the sample to the period 1965Q1–2007Q4 to see how a model estimated on precrisis data fares during the recession. Subsequently, we will estimate the model on data spanning the crisis.

[f] But even if they did, it would not matter as the government is assumed to balance its expenditures each period through lump-sum taxes, $T_t = G_t + B_t - B_{t+1}/R_t$, so that government debt $B_t = 0$ in equilibrium. Furthermore, as Ricardian equivalence (see Barro, 1974) holds in the model, it does not matter for equilibrium allocations whether the government balances its debt or not in each period.

[g] See, eg, Leeper and Leith (2016) and Leeper et al. (2015).

3.4.1 Solving the Model

Before estimating the model, we log-linearize all the equations of the model. The log-linearized representation is provided in Appendix A. To solve the system of log-linearized equations, we use the code packages Dynare (see Adjemian et al. (2011) and RISE (see Maih (2015)) which provides an efficient and reliable implementation of the method proposed by Blanchard and Kahn (1980).

3.4.2 Data

We use seven key macroeconomic quarterly US time series as observable variables: the log difference of real GDP, real consumption, real investment and the real wage, log hours worked, the log difference of the GDP deflator and the federal funds rate. A full description of the data used is given in Appendix C. The solid blue line in Fig. 1 shows the data for the full sample, which spans 1965Q1–2014Q2.[h] From the figure, we see the extraordinary large fall in private consumption, which exceeded the fall during the recession in the early 1980s. The strains in the labor market are also evident, with hours worked per capita falling to a postwar bottom low in early 2010. Finally, we see that the Federal reserve cut the federal funds rate to near zero in 2009Q1 (the FFR is measured as an average of daily observations in each quarter). Evidently, the zero bound was perceived as an effective lower bound by the FOMC committee, and they kept it as this level during the crisis and adopted alternative tools to make monetary policy more accommodating (see, eg, Bernanke, 2013). Meanwhile, inflation fell to record lows and into deflationary territory by late 2009. Since then, inflation has rebounded close to the new target of 2% announced by the Federal Reserve in January 2012.

The measurement equation, relating the variables in the model to the various variables we match in the data, is given by:

$$Y_t^{obs} = \begin{bmatrix} \Delta\ \ln GDP_t \\ \Delta\ \ln CONS_t \\ \Delta\ \ln INVE_t \\ \Delta\ \ln W_t^{real} \\ \ln HOURS_t \\ \Delta\ \ln PGDP_t \\ FFR_t \end{bmatrix} = \begin{bmatrix} \ln Y_t - \ \ln Y_{t-1} \\ \ln C_t - \ \ln C_{t-1} \\ \ln I_t - \ \ln I_{t-1} \\ \ln(W/P)_t - \ \ln(W/P)_{t-1} \\ \ln L_t \\ \ln \Pi_t \\ \ln R_t \end{bmatrix} \approx \begin{bmatrix} \overline{\gamma} \\ \overline{\gamma} \\ \overline{\gamma} \\ \overline{\gamma} \\ \overline{l} \\ \overline{\pi} \\ \overline{r} \end{bmatrix} + \begin{bmatrix} \widehat{y}_t - \widehat{y}_{t-1} \\ \widehat{c}_t - \widehat{c}_{t-1} \\ \widehat{\imath}_t - \widehat{\imath}_{t-1} \\ \widehat{w}_t^{real} - \widehat{w}_{t-1}^{real} \\ l_t \\ \pi_t \\ \widehat{R}_t \end{bmatrix} \tag{16}$$

where ln and Δ ln stand for log and log-difference, respectively, $\overline{\gamma} = 100(\gamma - 1)$ is the common quarterly trend growth rate to real GDP, consumption, investment and wages, $\overline{\pi} = 100\pi$ is the quarterly steady state inflation rate and $r = 100\left(\beta^{-1}\gamma^{\sigma_c}(1+\pi) - 1\right)$ is the

[h] The figure also includes a red-dashed line, whose interpretation will be discussed in further detail within Section 4.

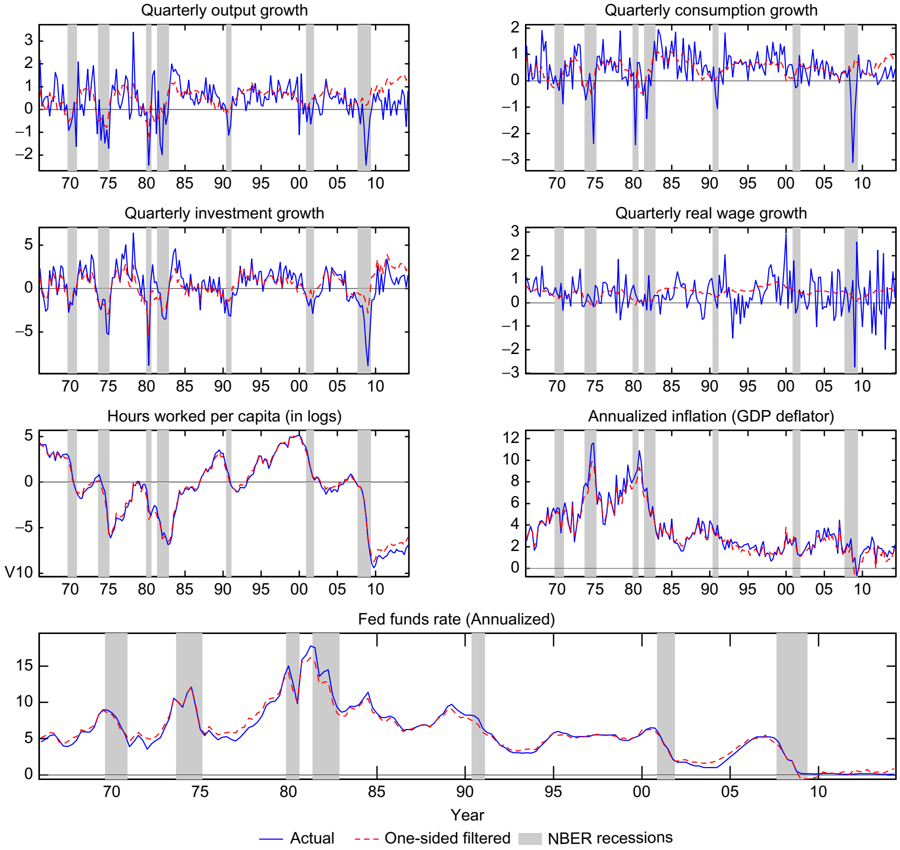

Fig. 1 Actual and filtered data in model estimated on precrisis data.

steady state nominal interest rate. Given the estimates of the trend growth rate and the steady state inflation rate, the latter will be determined by the estimated discount rate. Finally, $\bar{l}$ is steady state hours worked, which is normalized to be equal to zero.

Structural models impose important restrictions on the dynamic cross-correlation between the variables but also on the long run ratios between the macroaggregates. Our transformations in (16) impose a common deterministic growth component for all quantities and the real wage, whereas hours worked per capita, the real interest rate and the inflation rate are assumed to have a constant mean. These assumptions are not necessarily in line with the properties of the data and may have important implications for the estimation results. Some prominent papers in the literature assume real quantities to follow a stochastic trend, see, eg, Altig et al. (2011). Fisher (2006) argues that there is a stochastic trend in the relative price of investment and examines to what extent shocks that can explain this trend matter for business cycles. There is also an ongoing debate on whether hours worked per capita should be treated as stationary or not, see, eg, Christiano et al. (2003b), Galí and Pau (2004), and Boppart and Krusell (2015). Within the context of policy models, it is probably fair to say that less attention and resources have been spent to mitigate possible gaps in the low frequency properties of models and data, presumably partly because the jury is still out on the deficiencies of the benchmark specification, but also partly because the focus is on the near-term behavior of the models (ie, monetary transmission mechanism, forecasting performance, and historical decomposition) and these shortcomings do not seriously impair the model's behavior in this dimension.

3.4.3 Estimation Methodology

Following SW07, Bayesian techniques are adopted to estimate the parameters using the seven US macroeconomic variables in Eq. (16) during the period 1965Q1–2007Q4. Bayesian inference starts out from a prior distribution that describes the available information prior to observing the data used in the estimation. The observed data is subsequently used to update the prior, via Bayes' theorem, to the posterior distribution of the model's parameters which can be summarized in the usual measures of location (eg, mode or mean) and spread (eg, standard deviation and probability intervals).[i]

Some of the parameters in the model are kept fixed throughout the estimation procedure (ie, having infinitely strict priors). We choose to calibrate the parameters we think are weakly identified by the variables included in $\widetilde{Y}_t$ in (16). In Table 1, we report the parameters we have chosen to calibrate. These parameters are calibrated to the same values as had SW07.

The remaining 36 parameters, which mostly pertain to the nominal and real frictions in the model as well as the exogenous shock processes, are estimated. The first three columns in Table 2 shows the assumptions for the prior distribution of the estimated parameters. The location of the prior distribution is identical to that of SW07. We use the beta distribution for all parameters bounded between 0 and 1. For parameters assumed to be positive, we use the inverse gamma distribution, and for the unbounded parameters,

Table 1 Calibrated parameters

Parameter	**Description**	**Calibrated value**
δ	Depreciation rate	0.025
ϕ_w	Gross wage markup	1.50
g_y	Government G/Y ss-ratio	0.18
ϵ_p	Kimball curvature GM	10
ϵ_w	Kimball curvature LM	10

Note: The calibrated parameters are adapted from SW07.

[i] We refer the reader to Smets and Wouters (2003) for a more detailed description of the estimation procedure.

Note: Data for 1965Q1–1965Q4 are used as presample to form a prior for 1966Q1, and the log-likelihood is evaluated for the period 1966Q1–2007Q4. A posterior sample of 250, 000 postburn-in draws was generated in the Metropolis-Hastings chain. Convergence was checked using standard diagnostics such as CUSUM plots and the potential scale reduction factor on parallel simulation sequences. The MCMC marginal likelihood was numerically computed from the posterior draws using the modified harmonic estimator of Geweke (1999).

we use the normal distribution. The exact location and uncertainty of the prior can be seen in Table 2, but for a more comprehensive discussion of our choices regarding the prior distributions we refer the reader to SW07.

3.4.4 Posterior Distributions of the Estimated Parameters

Given these calibrated parameters in Table 1, we obtain the joint posterior distribution mode for the estimated parameters in Table 2 on precrisis data in two steps. First, the posterior mode and an approximate covariance matrix, based on the inverse Hessian matrix evaluated at the mode, is obtained by numerical optimization on the log posterior density. Second, the posterior distribution is subsequently explored by generating draws using the Metropolis-Hastings algorithm. The proposal distribution is taken to be the multivariate normal density centered at the previous draw with a covariance matrix proportional to the inverse Hessian at the posterior mode; see Schorfheide (2000) and Smets and Wouters (2003) for further details. The results in Table 2 shows the posterior mode of all the parameters along with the approximate posterior standard deviation obtained from the inverse Hessian at the posterior mode. In addition, it shows the mean along with the 5th and 95th percentiles of the posterior distribution, and finally, the last column reports the posterior mode in the SW07 paper.

There two important features to notice with regards to the posterior parameters in Table 2. First, the policy- and deep-parameters are generally very similar to those estimated by SW07, reflecting a largely overlapping estimation sample (SW07 used data for the 1965Q1–2004Q4 period to estimate the model). The only noticeable difference relative to SW07 is that the estimated degree of wage and price stickiness is somewhat more pronounced (posterior mode for ξ_w is 0.79 instead of 0.73 in SW07, and the mode for ξ_p has increased from 0.65 (SW07) to 0.69). The tendency of an increased degree of price and wage stickiness in the extended sample is supported by Del Negro et al. (2015b), who argue that a New Keynesian model similar to ours augmented with financial frictions points towards a high degree of price and wage stickiness to fit the behavior of inflation during the Great Recession. Second, the estimated variances of the shocks are somewhat lower (apart from the wage markup shock). Given that SW07 ended their estimation in 2004, and the so-called "Great Moderation" was still in effect from 2005 into the first half of 2007, the finding of reduced shock variances is not surprising.

4. EMPIRICAL PERFORMANCE OF BENCHMARK MODELS DURING THE GREAT RECESSION

We will now assess the performance of our benchmark DSGE model during the great recession in a number of dimensions. First and foremost, we study the forecasting performance of the model during the most intense phase of the recession, ie, the third and fourth quarters of 2008. In addition, we look into what the model has to say about the speed of recovery in the economy during the postcrisis period. In this exercise, we benchmark the performance of the DSGE model against a standard Bayesian VAR, which includes the same set of variables.

Second, we examine how the model interprets the "Great Recession", and assess the plausibility of the shocks the model needs to explain it. We do this from both a statistical and economic viewpoint.

4.1 Forecasting Performance of Benchmark Models During the Recession

We now use the DSGE model estimated on data up to 2007Q4 to forecast for the out-of-sample data. We start to make forecasts for 1, 2, …, 12 quarters ahead in the third and fourth quarter of 2008, conditional on observing data up to and including 2008Q3 and 2008Q4, respectively. Forecasts starting in these quarters are of particular interest as output plummeted in 2008Q4 (about -9.75% at an annualized quarterly rate) and in 2009Q1 (roughly -5.75% at an annualized rate). To provide a benchmark for the DSGE forecasts, we also report the forecasts of a Bayesian vector autoregressive (BVAR) model estimated on the same sample. While both models have been estimated for the same time series stated in Equation (16), we only show results for a subset of variables; the federal funds rate, output growth and price inflation (where inflation and output growth have been transformed into yearly rates by taking four-quarter averages). Warne et al. (2015) study how the predictive likelihood can be estimated, by means of marginalization, for any subset of the observables in linear Gaussian state-space models. Our exposition later is less formal and focuses on the univariate densities.[j]

The BVAR uses the standard Doan–Litterman–Sims (Doan et al., 1984) prior on the dynamics and an informative prior on the steady state following the procedure outlined in Villani (2009). We select the priors on the steady state in the BVAR to be consistent with those used in the DSGE model, which facilitates comparison between the two models. In both the DSGE and the BVAR, the median projections and 50%, 90%, and 95% uncertainty bands are based on 10, 000 simulations of respective model in which we allow for both shock and parameter uncertainty.[k]

In Fig. 2, the left column shows the forecasts in the DSGE conditional on observing data up to 2008Q3. As can be seen in the upper left panel, the endogenous DSGE model forecast predicted yearly GDP growth (four quarter change of log-output) to be about unchanged, whereas actual economic activity fell dramatically in the fourth quarter. Moreover, the 95% uncertainty band suggests that the large drop in output was

[j] We perform these forecasts on *ex post* data, collected on September 25th 2014 (see Appendix C).

[k] For an extensive comparison of the forecasting performance of the Smets and Wouters model along with a comparison to a BVAR and Greenbook forecasts on real-time data, see Edge and Gürkaynak (2010) and Wieland and Wolters (2013). Adolfson et al. (2007a, d) examine the forecasting properties of an open economy DSGE model on Swedish data.

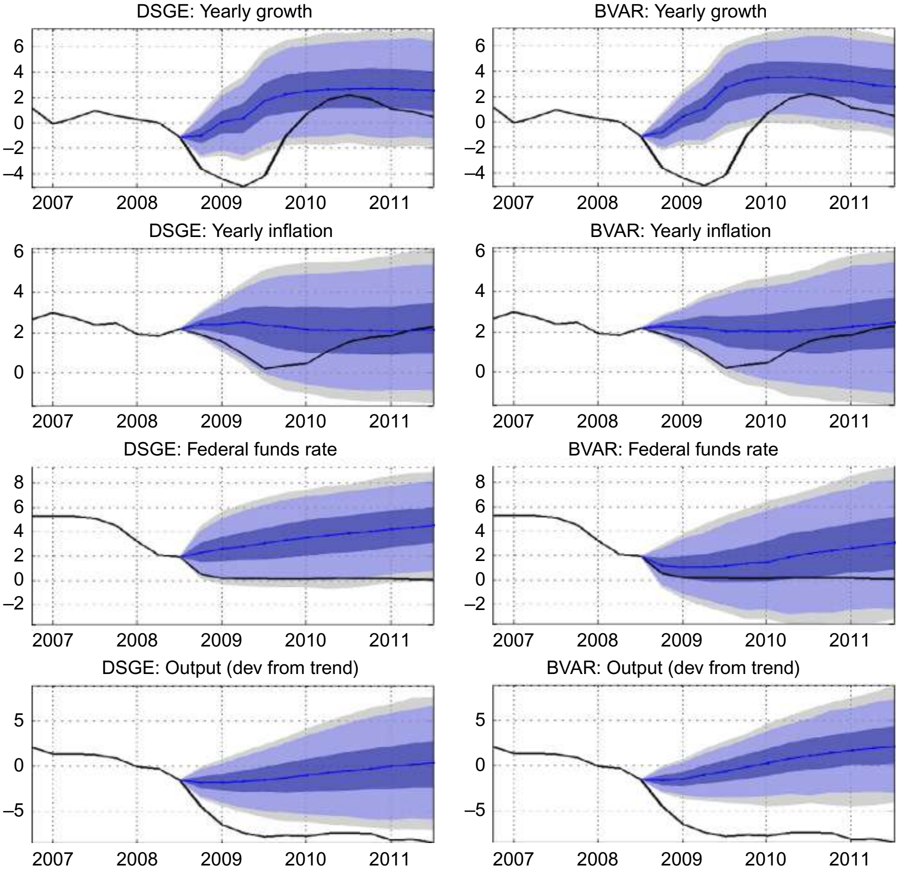

Fig. 2 Forecast 2008Q4–2011Q3 conditional on state in 2008Q3.

completely unexpected from the point of the view of the DSGE model. Thus, in line with Del Negro and Schorfheide (2013), our estimated model carries the implication that the "Great Recession" as late as of observing the outcome in 2008Q3 was a highly unlikely tail event. Turning to yearly inflation and the federal funds rate in the middle and bottom left panels, we also see that they fell considerably more than predicted by the model, but their decline are within or close to the 95% uncertainty bands of the linearized DSGE model and hence, cannot be considered as tail events to the same extent as the Great Recession.

Turning to the results for the BVAR, which are reported in the right column in Fig. 2, we see that the forecast distribution in the BVAR for yearly GDP growth is both quantitatively and qualitatively very similar to that in the DSGE model. Hence, the Great Recession was also a highly unlikely tail event according to the BVAR model. Given that the BVAR and the DSGE are both linearized models, the relatively high degree of similarity of the two model forecasts is not completely surprising. We also see that the uncertainty bands for the output roughly are equally sized in the DSGE as those in the BVAR model. This finding is neither obvious nor trivial as the DSGE model does not have a short-lag BVAR representation. The BVAR, on the other hand, does not impose nearly as many cross-restrictions on the parameter space as the DSGE model. Hence, allowing for parameter uncertainty will tend to increase the uncertainty bands considerably more in the BVAR relative to the DSGE model (the BVAR has around 190 free parameters, while the DSGE has 36). On net, these two forces appear to cancel each other out.

Moreover, as is clear from Fig. 3, the high degree of coherence between the DSGE and BVAR output growth forecasts also holds up when conditioning on the state in 2008Q4 and using the estimated models to make predictions for 2009Q1, 2009Q2, …, 2011Q4. For yearly inflation and the federal funds rate, the forecasts conditional on the state in 2008Q3 are very similar, as can be seen in the middle rows in Fig. 2.

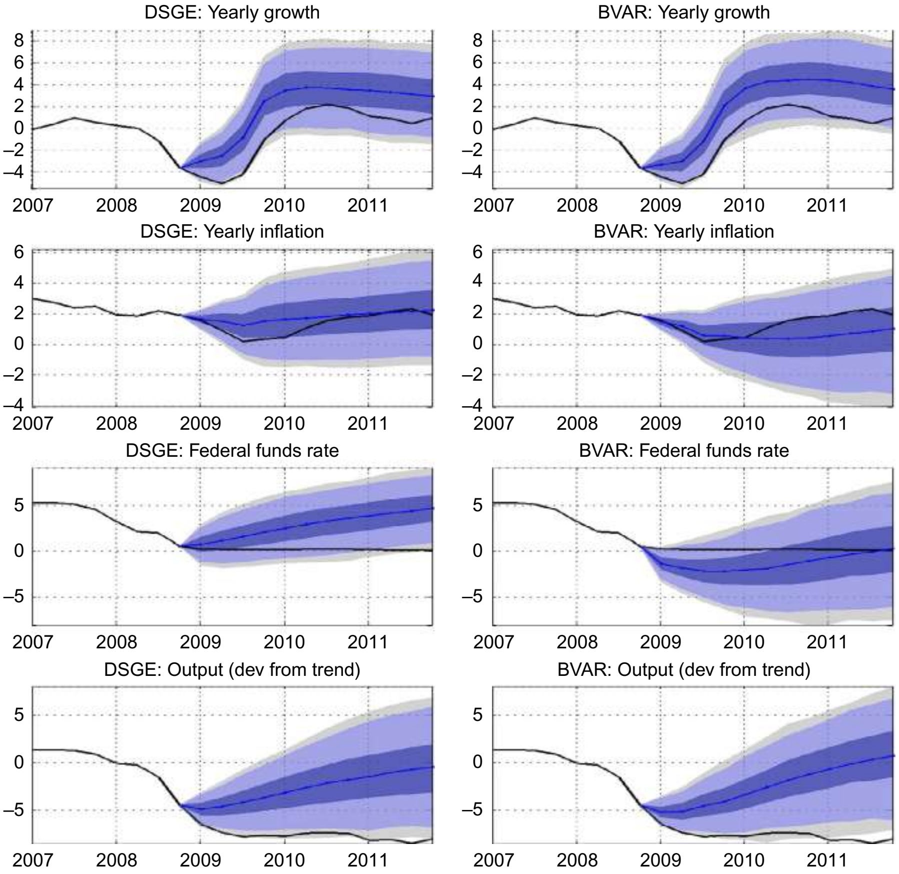

Fig. 3 Forecast 2009Q1–2011Q4 conditional on state in 2008Q4.

However, for the forecast made conditional on the state in 2008Q4 (Fig. 3), the DSGE and BVAR forecasts differ substantially, at least qualitatively. In this period, the BVAR predicts a prolonged period with near-zero inflation and a federal funds rate well below zero for 2 years, whereas the modal outlook in the DSGE model is that inflation would quickly return to near 2% and that the federal funds rate should therefore be increased steadily throughout the forecast horizon. The zero lower bound is not much of a concern in the DSGE model, while the BVAR suggests that it should be a binding constraint longer than 2 years.

Apart from failing to predict the crisis in the first place, both the BVAR and the DSGE model also have a clear tendency to forecast a quick recovery. For the benchmark DSGE model, this feature is evident already from Fig. 1. In this figure, the red-dotted line shows the one-sided filtered Kalman projections of the observed variables; that is, the projection for period t given all available information in period $t-1$. By comparing the one-sided filtered Kalman projections against the outcome (the blue-solid line) it is evident that the benchmark DSGE model predicts that growth in output, consumption and investment would pick up much quicker than they did following the recession. Hence, consistent with the findings in Chung et al. (2012), the benchmark DSGE model consistently suggests a V-shaped recovery and that better times were just around the corner, whereas the outcome is consistent with a much more slower recovery out of the recession as is evident from Figs. 2 and 3. Fig. 4 shows sequential BVAR forecasts 1, 2, …, 12 quarters ahead for the period 2008Q3–2014Q1 conditional on observing the state up to the date in which the forecasts start. In line with the results for the DSGE model, the results in this figure indicate that the BVAR also tends to predict a quick recovery of economic activity. Consistent with this reasoning, the forecasts for the level of output (as deviation from the deterministic trend), shown in the bottom row in Figs. 2 and 3, display that both the DSGE and the BVAR models overestimate the speed of recovery out of the recession.[l]

The slow recovery following the recession is consistent with the work by Reinhart and Rogoff (2009) and Jordà et al. (2012), who suggest that recoveries from financial crises are slower than recoveries from other recessions. The empirical observation by Reinhart and Rogoff has also been corroborated in subsequent theoretical work by Queralto (2013) and Anzoategui et al. (2015).[m] As our benchmark equilibrium model does not include the mechanisms of Queralto, it has a hard time accounting for the slow recovery following the recession, both in terms of the level and the growth rate of GDP. Our benchmark models—both the DSGE and the BVAR—rely on significant influence of adverse

[l] For both the BVAR and the DSGE model, the series for detrended output is the smoothed estimate from the DSGE model. When we construct the forecast of detrended output in the BVAR, we accumulate the projected quarterly growth rate of output after subtracting the estimated steady state growth rate in each period.

[m] Notwithstanding these results, Howard et al. (2011) argue out that the finding pertains to the level of economic activity, and not the growth rate (which is what we focused on in Fig. 1).

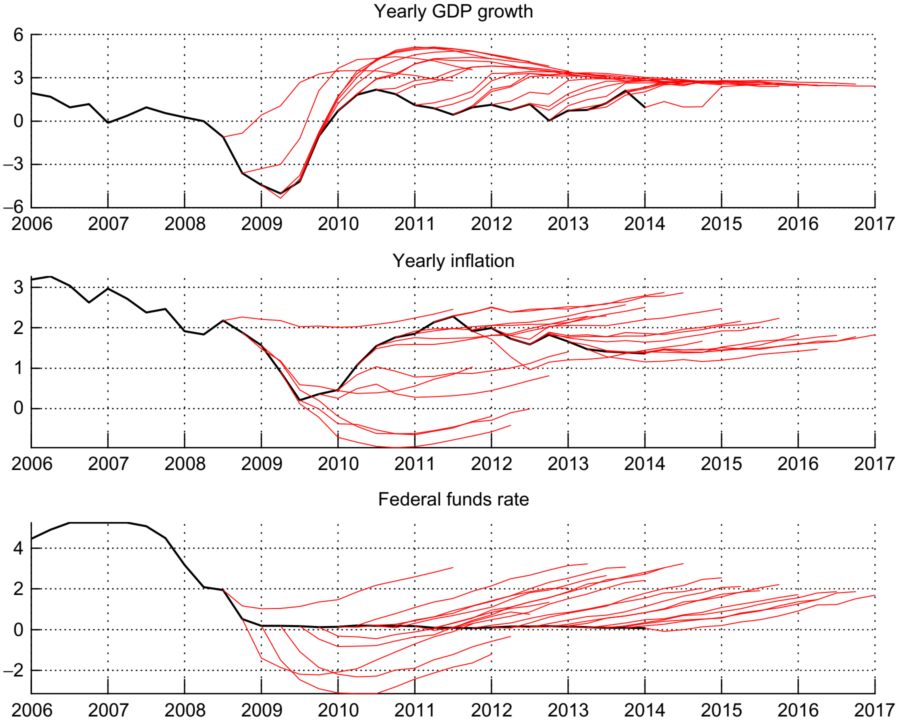

Fig. 4 Sequential BVAR forecasts 2008Q3–2014Q1.

exogenous shocks which weighs on economic activity during the recovery. While this might be deemed to be a significant weakness of these models, it should be noted that some major negative events may have contributed to hold back the recovery; eg, the European debt crisis which intensified in May 2010, and the showdown between the Republicans and democrats in the congress which created significant uncertainty in the US economy according to estimates by Fernández-Villaverde et al. (2011). With these events in mind, it is not entirely implausible that the models need some adverse shocks to account for the slow recovery.

4.2 Economic Interpretation of the Recession

As indicated in the previous section, both the DSGE and BVAR models are dependent on major adverse shocks to account for the recession. In this section, we examine what shocks are filtered out as the drivers of the recession and its aftermath. We will focus entirely on the benchmark DSGE, as it would be hard to identify all the shocks in the BVAR model. We extract the smoothed shocks through the Kalman filter by using the model estimated on the precrisis period for the full sample (without reestimating the parameters).

In Fig. 5, the left column shows the two-sided smoothed Kalman filtered innovations—eg, η_t^a for the technology shock in Eq. (5)—for the seven shock processes in

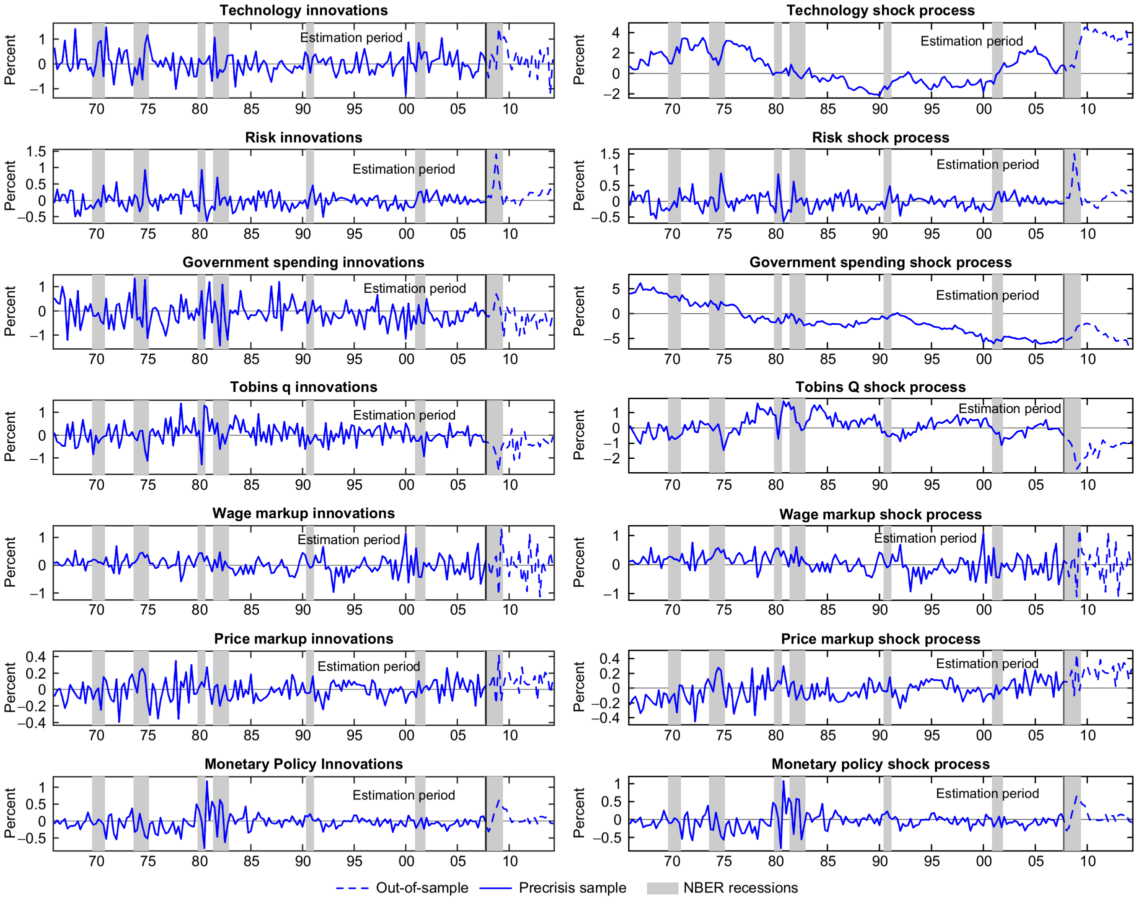

Fig. 5 Smoothed innovations and shocks in model estimated on precrisis data.

the model using the posterior mode parameters. In the right column, we show the two-sided smoothed shock processes in levels—eg, ε_t^a for the technology shock in Eq. (5). The blue solid-line indicates the in-sample period, and the blue-dotted line the out-of-sample period. The grey bars are NBER dated recessions.

Before analyzing the role various shocks played during the crisis and its aftermath, it is insightful to discuss if there are any signs in the precrisis shocks about what events might have been causal for the crisis itself. As is clear from the left column in the figure, there is nothing that stands out in the innovations between 2000 and the burst of the crisis. There were a string of positive innovations to technology during 2003–2005, which led to a run-up in technology (right upper panel) during this period. To the extent that households and firms expected this positive development to continue and were taken off-guard by the adverse outcomes 2006 and onward, this could have been a contributing factor to the crisis. Christiano et al. (2010b) argue that over-optimistic expectations of future technology have been associated with credit cycles that have contributed to boom-bust cycles in the real US economy in a model with a more elaborate financial sector.[n] Our benchmark model does not include a financial sector and thus, cannot be used to assess this possibility explicitly. Loose monetary policy have also been argued as a possible driver for the crisis, see, eg, Taylor (2007). Our estimated model lend some, but limited, support to this view; although the estimated policy rule suggest that monetary policy was on average expansionary between 2002 and 2006, the magnitude of the deviations are not very large though, as seen from the lower panels in Fig. 5. Based on the shock decomposition, it is therefore hard to argue that the Fed's conduct of monetary policy was causal for the crisis.[o]

With this discussion in mind, we now turn to the crisis and its aftermath. As is clear from Fig. 5, the key innovations happened to technology, investment specific technology (the Tobin's Q-shock), and the risk-premium shock during the most intense phase of the recession. More specifically, the model filters out a very large positive shock to technology (about 1.5% as shown in the upper left panel, which corresponds to a 3.4 standard error shock) in 2009Q1. In 2008Q4 and 2009Q1, the model also filters out two negative investment specific technology shocks (about −1 and −1.5%—or 2.0 and 3.7 standard errors—respectively). The model moreover filters out a large positive risk shocks in

[n] The focus of Christiano et al. is what monetary policy should do to mitigate the inefficient boom-bust cycle. They do not consider the role macroprudential regulation could play to mitigate the cycle.

[o] The main reason why our policy shocks are much smaller in magnitude than those computed by Taylor is that we consider a more elaborate policy rule with considerable interest rate smoothing ($\rho_R = 0.82$, see Table 2). One could argue about whether one should allow for interest rate smoothing or whether this persistence should be attributed to the exogenous monetary policy shock (ie, a higher ρ_r in the process for ε_t^r in Eq. (15). In our estimated model, however, the log marginal likelihood strongly favors a high degree of interest rate smoothing and low persistence of the exogenous policy shocks (ie, a combination of high ρ_R and low ρ_r).

2008Q3–Q4, and in 2009Q1 (0.5%, 1.5%, and 0.5%, respectively, equivalent to 1.9, 6.0, and 2.8 standard errors). These smoothed shocks account for the bulk of the sharp decline in output, consumption and investment during the acute phase of the crisis at the end of 2008 and the beginning of 2009. Our finding of a large positive technology shock in the first quarter of 2009 may at first glance be puzzling, but can be understood from Figs. 1 and 3. In these, we see that output (as deviation from trend) fell less during the recession than did hours worked per capita. Hence, labor productivity rose sharply during the most acute phase of the recession. The model replicates this feature of the data by filtering out a sequence of positive technology shocks. These technology shocks will stimulate for output, consumption and investment. The model thus needs some really adverse shocks that depresses these quantities even more and causes hours worked per capita to fall, and this is where the positive risk premium and investment specific technology shocks come into play. These shocks cause consumption (risk premium) and investment (investment specific)—and thereby GDP—to fall. Lower consumption and investment also causes firms to hire less labor, resulting in hours worked per capita to fall.

Another shock that helps account for the collapse in activity at the end of 2008 is the smoothed monetary policy shock shown in the bottom left panel (expressed at a quarterly rate). This shock becomes quite positive in 2008Q4 and 2009Q1; in annualized terms it equals roughly 150 (1.6 standard errors) and 250 (2.8 standard errors) basis points in each of these quarters, respectively. As the actual observations for the annualized federal funds rate is about 50 and 20 basis points, these sizable policy shocks suggests that the zero lower bound is likely to have been a binding constraint, at least in these quarters. This finding is somewhat different from those of Del Negro and Schorfheide (2013) and Del Negro et al. (2015b), who argued that the zero lower bound was not a binding constraint in their estimated models.

The large smoothed innovations translate into very persistent movements in some of the smoothed shock processes, reported in the right column in Fig. 5. For the simple AR(1) shock processes, the degree of persistence is governed by the posterior for ρ. As can be seen from Table 2, the posterior for $\rho_a(\rho_b)$ is very high (low), whereas the posterior for ρ_i is somewhere in between. It is therefore not surprising that the technology process is almost permanently higher following the crisis, whereas the risk shock process quickly recedes towards steady state. Our finding of a very persistent rise in the exogenous component of total factor productivity (TFP) is seemingly at odds with Christiano et al. (2015), who reports that TFP fell in the aftermath of the recession. Christiano et al. (2015) and Gust et al. (2012) also report negative innovations to technology in 2008 (see fig. 5 in their paper). While a closer examination behind the differences in the results would take us too far, we note that our findings aligns very well with Fernald (2012). Specifically, our smoothed innovations to technology are highly correlated with the two TFP measures computed by Fernald (2012), as can be seen from Table 3. The table shows the correlations between our technology innovations η_t^a, shown in the left column

Table 3 Correlations between smoothed and actual TFP shocks

	Sample period	
TFP measure	**Precrisis: 66Q1–07Q4**	**Full: 66Q1–14Q2**
$\text{Corr}\left(\Delta\text{Raw}, \eta_t^a\right)$	0.483	0.522
$\text{Corr}\left(\Delta\text{Corrected}, \eta_t^a\right)$	0.602	0.608

Note: "ΔRaw" denotes the first difference of the quarterly unadjusted measure in Fernald (2012), while "ΔCorrected" is the first difference Fernald's capacity utilization adjusted TFP measure. In the model, the smoothed estimates of the innovations η_t^a (see Eq. (5)) are used. This series is depicted in the upper left column of Fig. 5.

in Fig. 5, and the period-by-period change in the raw and utilization-corrected measure of TFP by Fernald. From the first column in the table, we learn that the correlation between our innovations and his raw measure is almost 0.5 for the estimation sample period. As we are studying first differences and innovations, this correlation must be considered quite high. Even more reassuring for our model is that the correlation between our smoothed innovation series and Fernald's utilization adjusted series is as high as 0.6. When extending the sample to include the crisis and postcrisis period, we see that these correlations remain high; if anything, they become slightly higher. We believe this lends support for our basic result that weak TFP growth was not a key contributing factor to the crisis.

For the two markup shocks, we notice that they are not nearly as highly correlated as the technology shock although the estimated AR(1) coefficients for these processes are quite high (0.89 for the price markup shock, and 0.97 for the wage markup shock, see Table 2). The reason why their correlation is so low is the estimated MA(1) coefficients, ϑ_p and ϑ_w in Eqs. (6) and (13) are rather high, ie, 0.72 and 0.92, respectively. Despite the generally low correlation of the price shock process during the precrisis period, we see that its outcome is driven by a sequence of positive innovations during the crisis period. This finding is in line with Fratto and Uhlig (2014), who found that price markup shocks played an important role to avoid an even larger fall in inflation during the crisis, and contributed to the slow decline in employment during the postcrisis recovery.[p] The wage markup shock process does not display any clear pattern after the precrisis period, but it is clear that its variance has increased since the end of the 1990s suggesting that the model provides a less accurate description of wage-setting behavior in the US labor market since

[p] The prominent role of the price and wage markup for explaining inflation and behavior of real wages in the SW07-model have been criticized by Chari et al. (2009) as implausibly large. Galí et al. (2011), however, shows that the size of the markup shocks can be reduced substantially by allowing for preference shocks to household preferences.

then. However, it should be kept in mind that this finding may not necessarily remain if alternative wage series are used.[q]

The historical decompositions in Fig. 6 summarizes the impact of the various shocks on the output growth, inflation, federal funds rate and output as deviation from a trend during 2007Q1–2014Q2 in the benchmark model estimated on data up to 2007Q4 (see Table 2). Notice that the scale on the left- and right-axes are not the same (except for the two-sided-smoothed output as deviation from trend): the left axis shows the

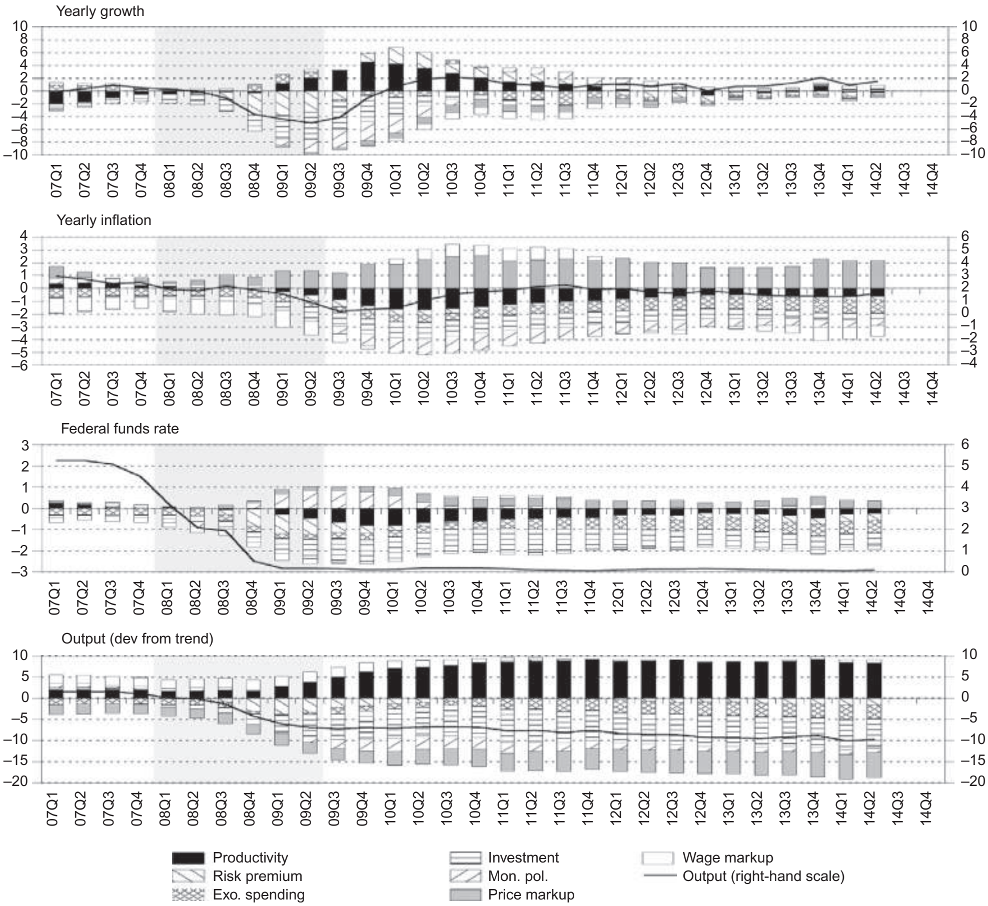

Fig. 6 Historical decompositions of yearly output growth (four-quarter change), yearly inflation (four-quarter change), fed funds rate, and output (deviation from trend). Left axis shows the contributions of the shocks (bars) to fluctuations around the steady state and right axis shows actual outcomes (in levels).

[q] Because of potential measurement problems pertaining to Galí et al. (2011) and Justiniano et al. (2013b) use two series for real wage growth when estimating their DSGE model.

contributions of the various shocks to fluctuations around the steady state, whereas the right axis shows evolution of each variable in levels. Thus, for each period the sum of the bars on the left axis plus the steady state value for each variable (not shown) equals the actual outcome (thin line). For output as deviation from trend, the steady state value is nil, why the sum of the bars directly equals the smoothed values.

As seen from the figure, the risk premium, the investment specific technology and the monetary policy shocks are the key drivers behind the decline in output during the recession period, whereas TFP as discussed earlier had some offsetting impact on output. However, all four shocks contributed to the gradual decline in inflation. The nominal interest rate would clearly have dropped below zero in absence of the zero bound constraint. The slow recovery is attributed to the persistence of the shocks that were responsible for the recession, but also captures new unexpected headwinds along with positive innovations to markups in prices and wages. Interestingly, the negative impact of the risk premium shock is relatively short lived. To a large extent this of course reflects that the model is not rich enough to propagate financial shocks sufficiently, but it is also conceivable that this partly captures the stimulus coming from the nonconventional monetary policy actions. The continuously low interest rate is consistent with the weak state of the economy during this period; output (as deviation from trend) is well below its precrisis trend and inflation persistently below its targeted rate, and sustained subpar growth (slow or nonexistent recovery in output as deviation from trend). As the precrisis model features a moderate degree of price and wage stickiness, inflation would have fallen persistently into negative territory in the absence of other shocks. This is counter-factual relative to the data, and the missing deflation in the model estimated on precrisis data is accounted for by inflationary markup shocks.

While the smoothed shocks—that the model needs to explain the crisis period—are not too surprising given the model's specification, it is nevertheless clear that the benchmark model needs a highly unlikely combination of adverse shocks in 2008Q4 and 2009Q1 to account for the most intense phase of the recession. Therefore, we now discuss the statistical properties of the shocks and examine if they correlate with some key observable financial variables not included in our set of observables.

4.3 Statistical Properties of the Innovations and Their Relation to Financial Indicators

Table 4 provides an overview of the statistical properties of the estimated structural shocks and of the forecast errors for the seven observed macro variables. Most of the forecast errors display a significant amount of kurtosis, a feature that they inherit from the underlying macro variables. For the structural shocks, the problems are mostly concentrated in two shocks—the monetary policy and the risk premium shock—that display highly significant deviations from the underlying Gaussian assumption. The structural innovations in the policy rate and the risk premium are characterized by a highly skewed

and fat-tailed distribution.[r] We identified the large disturbances in these shocks already in the previous section as crucial drivers of the recent recession, but Table 4 illustrates that both processes were already affected by non-Gaussian innovations in the precrisis model as well. As observed in Fig. 5, these negative outliers occur mostly during the recession periods.

This feature implies that the predictive density of linear Gaussian DSGE models underestimates systematically the probability of these large recession events. This observation is important because it means that the model considers the strong economic downturns that we typically observe during recession periods as extremely unlikely tail events.[s] Linear Gaussian models may therefore be inappropriate instruments for analyzing policy questions related to risk scenario's or stress test exercises.

[r] The innovations in the structural shocks are also characterized by a significant ARCH effect illustrating the systematic time-varying volatility structures.

[s] This observation is consistent with the findings presented by Chung et al. (2012).

It is also interesting to note that the two structural shocks that generate most of the extreme events are directly related to the intertemporal decisions and to the developments in the monetary and the financial sector of the economy. The non-Gaussian nature of financial returns, spreads and risk premiums is widely documented in the financial literature. Therefore, it appears like a natural hypothesis to assume that the non-Gaussian shocks that are identified in our macro model reflect the influence—or the feedback—from financial disruptions to the rest of the economy. To support this argument, we calculate the correlations between our estimated structural innovations and a set of popular financial returns and spreads. We selected seven measures related to the different segments of the financial sector and for which long time series are available: the Baa-Aaa spread, the term spread, the Ted spread, the return on the S&P index, the return on the Fama-French financial sector portfolio, the change in the Shiller house price index and the VOX index. Table 5 summarizes the correlation between these seven financial indicators and our seven structural innovations. The strongest correlations in this table—exceeding 0.3 in absolute terms—are observed between our identified risk premium innovation and the Baa-Aaa and Term spreads, and between the monetary policy innovation and the Term and Ted spreads.

To see the strong linkages between some of the smoothed shocks and the financial variables in an alternative way, we regress the structural innovations on this set of financial

Note: * indicates significance at 5%. The financial indicators do not have a significant effect on the other nonreported innovations.

observables. The results of these multivariate regressions are shown in Table 6. In contemporaneous regressions, the significant coefficients are again only apparent in the risk premium, monetary policy and—at a slightly weaker significance level—for the investment specific technology innovation. The most interesting feature of the regression results is that the remaining unexplained variation (ie, the regression residuals) are basically normally distributed. Thus, shock outliers seem to coincide with periods of clear financial stress as measured by our observed financial indicators. Also noteworthy is that in Granger causality regression tests, none of the financial indicators carry significant predictive power for the structural innovations. Because financial variables can essentially be observed in real time; however, they can still provide timely indications of big structural innovations. Including these variables in our list of observables can therefore be very useful to improve the model now-cast and the conditional forecast performance.[t] Even so, this strategy will probably not improve the out-of-sample prediction performance of our linearized models *ex ante* to the observation of financial stress signals. It might also require non-Gaussian and nonlinear models to exploit this information from financial variables more efficiently in our macro models.

[t] See Del Negro and Schorfheide (2013) for strong evidence in this direction.

5. AUGMENTING THE BENCHMARK MODEL

As the analysis in Section 4 suggested that the benchmark model suffers from some important shortcomings, we study in this section to which extent its performance can be improved by allowing for zero lower bound on policy rates, time-varying volatility of the shocks, and by introducing financial frictions and a cost-channel into the model. The modeling of financial frictions follows the basic approach in the seminal work of Bernanke et al. (1999). In contrast to the analysis in Section 3.4, we estimate the different perturbations of the model on data including the crisis period in this section.

5.1 Assessing the Impact of the Zero Lower Bound

We assess the impact of imposing the zero lower bound (ZLB) in the estimation in two alternative ways. These procedures differ in the way the duration of the ZLB spells is determined. In our first approach, the incidence and duration of the ZLB spells are endogenous and consistent with the model expectations. In the second approach, we model them as "exogenous" and require the model to match information from the market-based overnight index swap rates following Del Negro et al. (2015b). In both approaches, we make use of the same linearized model equations (stated in Appendix A), except that we impose the nonnegativity constraint on the federal funds rate. To do this, we adopt the following policy rule for the federal funds rate

$$\begin{aligned}\widehat{R}_t^* &= \rho_R \widehat{R}_{t-1} + (1-\rho_R)(r_\pi \widehat{\pi}_t + r_y(\widehat{ygap}_t)) + r_{\Delta y}\Delta(\widehat{ygap}_t) \quad , \\ \widehat{R}_t &= \max\left(-\bar{r}, \widehat{R}_t^* + \widehat{\varepsilon}_t^r\right).\end{aligned} \tag{17}$$

The policy rule in (17) assumes that the interest rate set by the bank, $\widehat{R}_t$, equals $\widehat{R}_t^* + \widehat{\varepsilon}_t^r$ if unconstrained by the ZLB. $\widehat{R}_t^*$, in turn, is a shadow interest rate that is not subject to the policy shock $\widehat{\varepsilon}_t^r$. Note that $\widehat{R}_t$ in the policy rule (17) is measured as percentage point deviation of the federal funds rate from its quarterly steady state level ($\bar{r}$), so restricting $\widehat{R}_t$ not to fall below $-\bar{r}$ is equivalent to imposing the ZLB on the nominal policy rate.[u] In its setting of the shadow or notional rate we assume that the Fed is smoothing over the lagged actual interest rate, as opposed to the lagged notional rate $\widehat{R}_{t-1}^*$. We made this assumption to preserve the property that $\widehat{\varepsilon}_t^r$ is close to white noise. Smoothing over the notional rate in (17) would cause the policy shock to become highly persistent, with an AR(1) coefficient roughly equal to ρ_R.[v]

[u] See (16) for the definition of $\bar{r}$. If writing the policy rule in levels, the first part of (17) bee replaced by (14) (omitting the policy shock), and the ZLB part would bee $R_t = \max\left(1, R_t^* \varepsilon_t^r\right)$.

[v] To see this, replace $\hat{R}_{t-1}$ with $\hat{R}_{t-1}^*$ in the first equation in (17) and then substitute $\hat{R}_t = \hat{R}_t^* + \hat{\varepsilon}_t^r$ from the second equation to write the unconstrained policy rule with the actual policy rate $\hat{R}_t$. Then, the residual will be $\hat{u}_t^r \equiv \hat{\varepsilon}_t^r - \rho_R \hat{\varepsilon}_{t-1}^r$. Hence, the residual $\hat{u}_t^r$ will be roughly white noise in this case when $\hat{\varepsilon}_t^r$ has an AR (1)-root ρ_R.

To impose the policy rule (17) when we estimate the model, we use the method outlined in Hebden et al. (2010). This method is convenient because it is quick even when the model contains many state variables, and we provide further details about the algorithm in Appendix A.[w] In a nutshell, the algorithm imposes the nonlinear policy rule in Eq. (17) through current and anticipated shocks (add factors) to the policy rule. More specifically, if the projection of $\widehat{R}_{t+h}$ in (17) given the filtered state in period t in any of the periods $h = 0, 1, \ldots, T$ for some sufficiently large nonnegative integer T is below $-\bar{r}$, the algorithm adds a sequence of anticipated policy shocks $\widehat{\varepsilon}^{r}_{t+h|t}$ such that $\mathrm{E}_t\widehat{R}_{t+h} \geq 0$ for all $h = \tau_1, \tau_1 + 1, \ldots, \tau_2$. If the added policy shocks put enough downward pressure on the economic activity and inflation, the duration of the ZLB spell will be extended both backwards (τ_1 shrinks) and forwards (τ_2 increases) in time. Moreover, as we think about the ZLB as a constraint on monetary policy, we further require all current and anticipated policy shocks to be *positive* whenever $\widehat{R}^{*}_{t} < -\bar{r}$. Imposing that all policy shocks are strictly positive whenever the ZLB binds, amounts to think about these shocks as Lagrangian multipliers on the nonnegativity constraint on the interest rate, and implies that we should not necessarily be bothered by the fact that these shocks may not be normally distributed even when the ZLB binds for several consecutive periods $t, t + 1, \ldots, t + T$ with long expected spells each period (h large).

We will subsequently refer to this method as "Endogenous ZLB duration", as it implies that both the incidence and the duration of the ZLB is endogenous determined by the model subject to the criterion to maximize the log marginal likelihood. In this context, it is important to understand that the nonnegativity requirement on the current and anticipated policy shocks for each possible state and draw from the posterior, forces the posterior itself to move into a part of the parameter space where the model can account for long ZLB spells which are contractionary to the economy. Without this requirement, DSGE models with endogenous lagged state variables may experience sign switches for the policy shocks, so that the ZLB has a stimulative rather than contractionary impact on the economy even for fairly short ZLB spells as documented by Carlstrom et al. (2012).[x] As discussed in further detail in Hebden et al., the nonnegativity assumption for all states and draws from the posterior also mitigates the possibility of multiple equilibria (indeterminacy). Finally, it is important to point our that when the ZLB is not a binding constraint, we assume the contemporaneous policy shock $\widehat{\varepsilon}^{r}_{t}$ in Eq. (17) can be either negative or positive; in this case we do not use any anticipated policy shocks as monetary policy is unconstrained.

[w] Iacoviello and Guerrieri (2015) have subsequently shown how this method can be applied to solve DSGE models with other types of asymmetry constraints.

[x] This can be beneficial if we think that policy makers choose to let the policy rate remain at the ZLB although the policy rule dictated that the interest rate should be raised ($\hat{R}^{*}_{t}$ is above $-\bar{r}$). In the case of the United States, this possibility might be relevant in the aftermath of the crisis and we therefore subsequently use an alternative method which allows for this.

However, a potentially serious shortcoming of the method we adapt to assess the implications of the ZLB is that it relies on perfect foresight and hence does not explicitly account for the role of future shock uncertainty as in the work of Adam and Billi (2006) and Gust et al. (2012). Even so, we implicitly allow for parameter and shock uncertainty by requiring that the filtered current and anticipated policy shocks in each time point are positive for all parameter and shock draws from the posterior whenever the ZLB binds. More specifically, when we evaluate the likelihood function and find that $\mathrm{E}_t\widehat{R}_{t+h}<0$ in the modal outlook for some period t and horizon h conditional on the parameter draw and associated filtered state, we draw a large number of sequences of fundamental shocks for $h=0, 1, \ldots, 12$ and verify that the policy rule (17) can be implemented for all possible shock realizations through positive shocks only. For those parameter draws this is not feasible, we add a smooth penalty to the likelihood which is set large enough to ensure that the posterior will satisfy the constraint.[y] As we document below, the nonnegativity constraint on the anticipated policy shocks in the face of parameter and fundamental shock uncertainty has considerable implications for the estimation of the model, and shock and parameter uncertainty is therefore partly accounted for in our estimation procedure.[z]

To provide a reference point for the ZLB estimations we start out by estimating the model for the full sample period, but disregarding the existence of the ZLB. The posterior mode and standard deviation in this case are shown in the first two columns in Table 7, and labeled “No ZLB model”. The only difference between these results and those reported in Table 2 is that the sample period has been extended from 2007Q4 to 2014Q2. By comparing the results, a noteworthy difference is that the estimated degree of wage and price stickiness has increased even further relative to the precrisis sample. The posterior mode for the sticky wage parameter (ξ_w) has increased from 0.79 to 0.83, and the sticky price parameter (ξ_p) from 0.69 to 0.75. Relative to the SW07 posterior mode, ξ_w has increased from 0.73 to 0.83 and ξ_p from 0.65 to 0.75. These increases are substantial, considering that the sample has been expanded with less than 10 years and that these parameters affect the slope of the wage and price pricing curves in a nonlinear fashion, implying an even sharper reduction in the slope coefficients for the forcing variables

[y] For example, it turns out that the model in 2008Q4 implies that the ZLB would be a binding constraint in 2009Q1 through 2009Q3 in the modal outlook. For this period we generated 1000 shock realizations for 2009Q1,2009Q2, …, 2011Q4 and verified that we could implement the policy rule (17) for all forecast simulations of the model through nonnegative current and anticipated policy shocks. For the draws with adverse shocks, the duration of the ZLB was prolonged substantially during the forecast horizon, with expected ZLB spells close to 4 years occurring. We provide further details in Appendix B how the likelihood function is constructed when we impose the ZLB in the estimations.

[z] Alternatively, we could implement this type of restriction by using a stochastic filter in which the prediction is calculated by integrating over a simulated forecast distribution. Parameter values that generate explosive paths and positive outliers typical for sign reversal realizations would be punished automatically in the likelihood evaluation.

Note: See notes to Table 2. The "No ZLB model" neglects the presence of the zero lower bound in the estimations, whereas the "Endogenous ZLB duration" allows the duration of the ZLB to be endogenous as described in the main text. Finally, the "OIS-based ZLB duration" imposes the duration of the ZLB in each point in time according to OIS rates for the federal funds rate between 2008Q4 and 2011Q2.

(wage markup and marginal costs, respectively) in the linearized price and wage equations. Evidently, the much higher degree of price and wage stickiness is only partly driven by the fact that prices and real wages fell modestly relative to output during the Great Recession (as can be seen in Fig. 1); even before the recession materialized there was already a strong trend in the data towards higher stickiness parameters, consistent with the findings by Del Negro et al. (2015b).[aa] Even so, we note that our estimated full sample model without the ZLB still features a much lower degree of price and wage stickiness than the policy model recently estimated by Brave et al. (2012).[ab]

In Fig. 7, we plot conditional forecast distributions for selected variables for the "No ZLB model" posterior in Table 7. In the left column, the forecast is conditional on the state in 2008Q3, whereas in the other two columns it is conditional on the filtered state in 2008Q4. Similarly to the results for the precrisis models in Fig. 2, the results in the left column shows that the severe drop in economic activity in 2008Q4 was outside the 95th percent uncertainty bands, even though the model is estimated on the full sample. This thus should be considered as an in-sample exercise. However, the median forecast conditional on the state in 2008Q4 is very accurate for yearly output growth and output (as deviation from trend) and the actual outcome is well within the uncertain bands for these variables, even disregarding the ZLB. For the federal funds rate, we see that the median forecast for the federal funds rate falls only slightly below nil for three quarters (2009Q1–2009Q3). This seemingly suggest that the ZLB was not much of a binding constraint during the Great Recession, consistent with the finding and interpretation in Del Negro et al. (2015b). This interpretation, however, ignores the fact that the forecast distribution for the federal funds rate has considerable mass below nil. Shifting this part of the distribution to 0 and above may therefore change the median outlook considerably.

To examine this possibility, the third column in Fig. 7 reports the forecast distribution when sampling parameters and shocks from the posterior distribution for the "No ZLB model" in Table 7, but with the unconstrained policy rule replaced by the policy rule in (17). This means that the actual and expected federal funds rate will respect the ZLB during the forecast horizon. Importantly, the 1000 different shock realizations used to construct the forecast distribution in the ZLB case are identical to those used to construct the unconstrained forecast distribution. Given the state in 2008Q4 the only difference between the results in the second and third column is that the federal funds rate is

[aa] This finding implies that the lower slope does not seem to be related to aggregate volatility, consistent with the findings by Vavra (2013).

[ab] As different models make alternative assumptions about strategic complements in price and wage setting, we have the reduced form coefficient for the wage and price markups in mind when comparing the degree of price and wage stickiness. In our benchmark model this coefficient equals 0.012 at the posterior mode for the New Keynesian Phillips curve which is similar to the estimate of Del Negro et al. (2013) (0.016). The estimate of Brave et al. (2012); however, the mode is as low as 0.002.

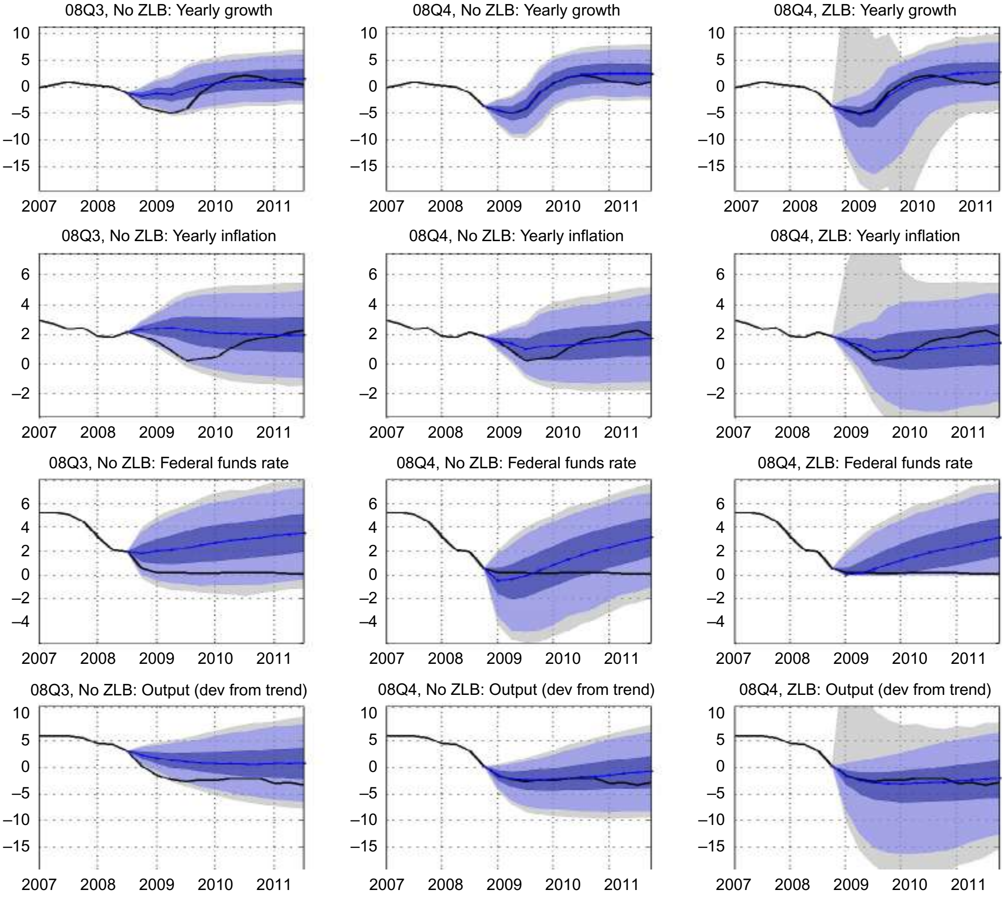

Fig. 7 Forecast 2009Q1–2011Q4 conditional on state in 2008Q4 for model estimated through 2014Q2 without imposing the ZLB.

constrained from falling below zero. As can be seen from the panels for output growth and output as deviation from trend, imposing the ZLB on the federal funds rate widens their uncertainty bands downwards quite notably. For output as deviation from trend, the lower 95th percentile shifts down from roughly −10% to nearly −20% in 2010. Hence, in the absence of unconventional monetary policies and coordination between monetary and fiscal policy (ie, fiscal stimulus when the economy enters a long-lived liquidity trap), the baseline model suggests that the ZLB may be associated with large economic costs.

On the other hand, the upper-95th percent bands for these variables are also much higher when the federal funds rate is constrained to fall below zero conditional on the given state in 2008Q4. For detrended output, the upper 95th percentile is above 10% in 2009. For yearly inflation, the upper 95th percentile is above 6%. Despite these elevated upper uncertainty bands for output growth, detrended output and inflation, the upper 95th percentile for the federal funds rate is lower than the corresponding percentile in the unconstrained policy rate distribution. This seemingly goes against the specification of the policy rule in (17) as the systematic part of the policy rule governing $\widehat{R}_t^*$ calls for a high policy rate whenever inflation, output growth and the output gap is high. The reason why this does not happen in the conditional ZLB distribution in Fig. 7 is that the model estimated without the imposed ZLB constraint needs large *negative* current and anticipated policy shocks $\widehat{\varepsilon}^r_{t+h|t}$ to satisfy $\mathrm{E}_t\widehat{R}_{t+h} \geq 0$. In essence, when the economy is hit by some really adverse shocks in these simulations and the policy rate is constrained to respond to these shocks for a sufficiently long period, inflation expectations and economic activity fall to such a large extent that a sequence of *negative* instead of *positive* policy shocks $\widehat{\varepsilon}^r_{t+h|t}$ for $h = 0, 1, \ldots, \tau_2$ are needed to prevent the federal funds rate to fall below nil. As discussed in Hebden et al. (2010) and Carlstrom et al. (2012), the switch in signs of the policy shocks only happens in the relatively few draws for which the policy rate is expected to be constrained by the lower bound for a very prolonged period of time (ie, τ_2 is large). This also explains why the upper 95th percentiles for inflation and output shifts up so much while the 90th percentile is roughly unchanged relative to the unconstrained distribution. The 90th percentile is associated with simulations of favorable fundamental shocks and parameter draws for which no large negative policy shocks are needed to prevent the policy rate to fall below nil.

We believe this result—that the ZLB can trigger adverse shocks to have sharply expansionary effects on the economy—is an unpalatable feature of the model. Therefore when we reestimate the model subject to the ZLB constraint on the federal funds rate, we believe it is crucial to impose the additional constraint—discussed in the beginning of this section—that the parameters of the economy have to be such that all current and expected policy shocks used to impose the policy rule in (17) are positive whenever the ZLB binds. By imposing this constraint, we ensure that the reestimated model does not feature any sign reversals of the policy shocks even for the most long-lived liquidity traps in our forecast distributions.

The estimation results for this variant of the model are reported in Table 7 and labeled "Endogenous ZLB duration". We use this label because both the incidence and duration of the ZLB spells are endogenous estimation outcomes in the model, and do not necessarily conform with other commonly used measures of the expected future path of the federal funds rate such as overnight index swap (OIS, henceforth) rates. By comparing the results with the "No ZLB model", we see that imposing the ZLB in the estimations have quite important implications for the posterior distribution. First of all the degree of price and wage stickiness is elevated even further, and the estimated parameters imply a slope of the New Keynesian Phillips curve of 0.006. This is somewhat lower than the median estimates of literature which cluster in the range of about 0.009–0.014, but well within standard confidence intervals provided by empirical studies (see, eg, Adolfson et al., 2005;

Altig et al., 2011; Galí and Gertler, 1999; Galí et al., 2001; and Lindé, 2005). In addition, the higher degree of nominal wage stickiness makes marginal costs even more sticky in the ZLB model. Together these features makes inflation and inflation expectations more slow to react to various shocks and therefore allow the model to cope with long spells at the ZLB without triggering indeterminacy problems (ie, switches in signs for the policy shocks). This finding is consistent with Erceg and Lindé (2010), who argue that a low slope of the Phillips curve is consistent with the development during the recent crisis where inflation and inflation expectations have fallen very moderately despite large contractions in output. It is also consistent with many recent papers which have estimated similar DSGE models, see, eg, Brave et al. (2012) and Del Negro et al. (2015b).

In addition to the higher degree of wage and price stickiness, there are two other important differences. Firstly, the coefficient on the output gap in the policy rule (Eq. (17)), r_y, is about twice as high as in the "No ZLB model". To the extent the output gap becomes significantly negative during the Great Recession, this will tend to push down the path of the federal funds rate and extend the duration of the ZLB. Secondly, the persistence coefficient in the risk premium shock process, ρ_b, increases sharply from 0.40 to 0.85. However, since the posterior mode for σ_b is reduced from 0.19 to 0.10, the unconditional variance for the risk-premium shock nevertheless falls slightly (from 0.044 to 0.039) in the ZLB model. Therefore the higher persistence does not imply a significantly larger role for the risk-premium shocks (apart from expectational effects). Even so, the likelihood prefers naturally more persistence in the shock process of the risk premium above a repeated set of positive innovations to explain the duration of the crisis and the slow pace of the recovery, but this shift in the posterior distribution of the parameters goes with a cost during the tranquil periods. This time variation in the role of the financial wedge over periods with more or less financial stress will be further discussed in Section 5.3.

Fig. 8 shows the forecast distribution (given the state in 2008Q4) in the "Endogenous ZLB duration" variant of the model. The left column gives the results when the ZLB is counterfactually neglected, whereas the right column shows the results when the ZLB is imposed. As expected, we see that the forecast distribution in the variant of the model which counterfactually neglects the ZLB features symmetric uncertainty bands around the modal outlook, and is a little bit too optimistic about the outlook for output relative to the model which imposes the ZLB (right column). More surprisingly is that the modal outlook for 2008Q4 in the model estimated and imposing ZLB constraint (right column in Fig. 8) differs very little to the modal outlook in the "No ZLB model" which completely neglects the ZLB (the middle column in Fig. 7). Obviously, a key difference is that the median path of the federal funds rate is constrained by the lower bound in 2009, but below nil in the unconstrained version of the model. Still, the quantitative difference for the median projection is small. The most noticeable difference between the No ZLB model and the model estimated under

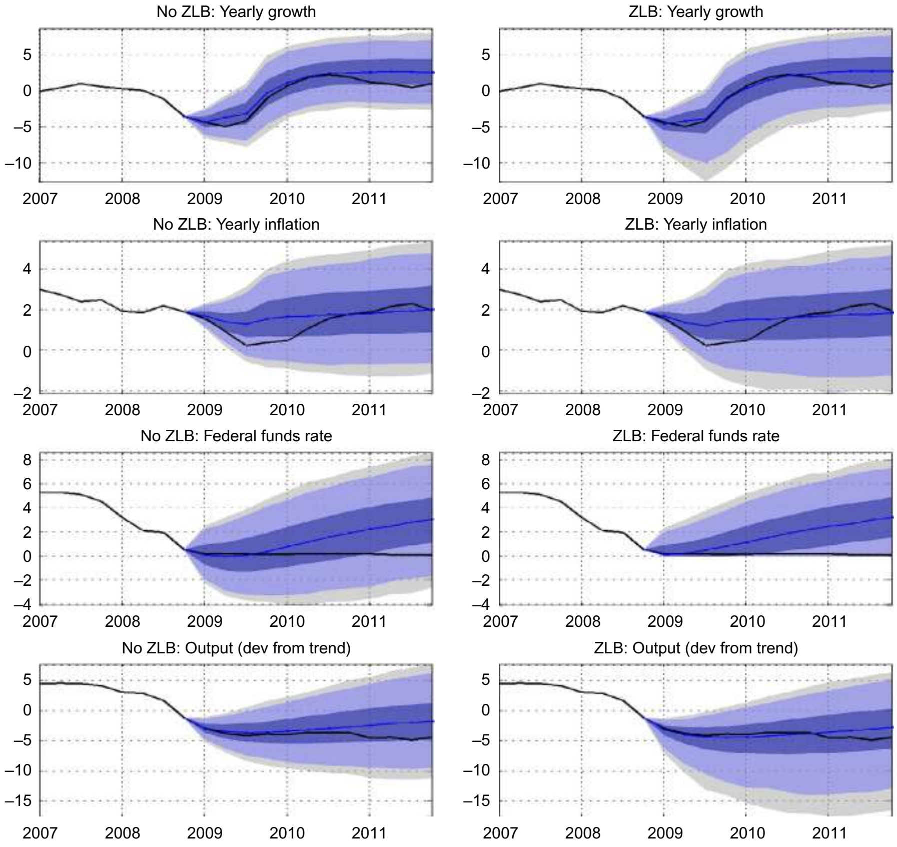

Fig. 8 Forecast 2009Q1–2011Q4 conditional on state in 2008Q4 for model estimated through 2014Q2 when imposing the ZLB.

the ZLB is the uncertainty bands: they are wider and downward skewed in the model that imposes the ZLB constraint (the right column of Fig. 8) compared to the No ZLB model that neglects the presence of the ZLB constraint.

However, the forecast distributions in the "No ZLB model"(the right column in Fig. 7)—which enforces the ZLB *ex post*—differs dramatically to the forecast distributions in the model estimated under the ZLB constraint (the right column in Fig. 8). The higher degree of wage and price stickiness in the model estimated under the ZLB constraint insulate the economy from the disaster scenarios and the indeterminate equilibria, and therefore shrink the uncertainty bands considerably. Overall this suggests that taking the ZLB into account in the estimation stage may be of key importance in assessing its economic consequences, and that it is not evident that models estimated on precrisis data can be useful for policy analysis when the economy enters into a long-lived liquidity trap. In such situations, the precrisis policy models may feature too much flexibility in price and wage setting, and, eg, yield implausibly large fiscal multipliers as noted by, eg, Erceg and Lindé (2010).

Another interesting feature of the model which neglects the ZLB and the variant of the model which is constrained to imposing Equation (17) through positive current and anticipated policy shocks is that the former has a higher log-marginal likelihood (-1146.7 vs -1152). This implies that imposing the ZLB on the model is somewhat costly in terms of data coherence. However, as suggested by the small differences in the conditional forecast distributions in Figs. 7 (middle column) and 8 (right column), it is not evident if this difference in log marginal likelihood is important from an economic viewpoint, although it is large enough to be sizable in terms of a Bayesian posterior odds ratio.

As the model is endogenously determining the incidence and duration of the ZLB spell, it is interesting to note that according to the model, the ZLB is expected in 2008Q4 to be a binding constraint from 2009Q1 to 2009Q3 in the modal outlook. The expected positive policy shocks we use to impose the ZLB partially substitute for the exceptionally huge risk premium shocks that drive the economy to the ZLB in the first place.[ac] The constraint is then expected to be binding during 2009 with a maximum duration of five quarters given the state in 2009Q1, and from 2010Q2 and onward, the model expects the interest rate to lift off already in the next quarter. The short duration of the ZLB spells is consistent with the findings of Chung et al. (2012). The fact that the federal funds rate has remained at the ZLB since then is by the model explained either as a result of expansionary monetary policy actions—forward guidance—or as standard policy reactions to unexpected headwinds. The filtered shocks suggest a dominant role for the second interpretation.

As noted previously, an alternative to letting the DSGE model determine the expected duration of the ZLB in each time period is to use OIS data for the federal funds rate as observables when estimating the model. By doing so, we follow Del Negro et al. (2015b) and require that the expected federal funds rate in the model matches the OIS data in each point in time when the ZLB is binding, ie, from 2008Q4 and onward. We use OIS data (acquired from the Federal Reserve Board) for 1, 2, …, 12 quarters' expected federal funds rates, and require the model to match those rates exactly through anticipated policy shocks following the general idea outlined by Maih (2010). The appealing feature of Maih's algorithm is that it does not require us to include standard

[ac] This high substitutability between anticipated monetary shocks that capture the effect of the ZLB on the one hand and the risk premium shock on the other hand, implies that it is very difficult to quantify accurately the precise impact of the ZLB on growth during the crisis. For instance, when a lagged shadow rate is used in the monetary policy rule instead of the lagged actual rate, the anticipated monetary policy shocks needed to impose the ZLB becomes much larger and more of the recession would then be attributed to the ZLB constraint while the contribution of the exogenous risk premium shock would decline significantly in the decomposition.

deviations for each of the anticipated policy shocks we use to fit the OIS data, and that the log-marginal likelihood can be compared to the models which does not condition on OIS data.

Before we turn to the results in Table 7, there are two additional important pieces of information. First, as we interpret the OIS data as expected means of future federal funds rates, we set them equal to nil in each point in time whenever they are lower than 50 basis points. We do this as our OIS estimation procedure does not explicitly account for future shock uncertainty, and the projected path of the interest rate from the model should therefore be viewed as a modal outlook (which will be lower than the mean of the forecast distribution when the ZLB binds). Second, because the Federal Reserve did not use explicit time-dependent forward guidance until August 2011, we restrict all anticipated policy shocks to be positive prior to this date. After this date we do not impose any signs on the anticipated policy shocks, because credible forward guidance—or a "lower for longer policy"—in the spirit of Reifschneider and Williams (2000) and Eggertsson and Woodford (2003), which extends the duration of the ZLB, is better viewed as expansionary than contractionary policy. Specifically, we allow the model to explain the sharp flattening of the OIS curve between the second and third quarter in 2011 with negative policy shocks, and do not impose this flattening to be associated with a noticeable deterioration in the economic outlook. According to the data, however, the magnitude of these expansionary "forward guidance" shocks are modest: interpreting the long ZLB spells as a deliberate "lower for longer" decision by the policy makers would further boost the predicted recovery by the model which goes against the observed slow and disappointing recovery in growth following the crisis.[ad]

The results when imposing the incidence and duration of the ZLB to adhere with OIS rates are shown in the left panel in Table 7, labeled "OIS-based ZLB duration." Relative to the posterior "Endogenous ZLB duration," for which the incidence and duration of the ZLB is determined endogenously in the model, we see that the degree of price stickiness is elevated further (from 0.83 to 0.89), and now implies a slope of the Phillips curve (ie, direct sensitivity of current inflation to marginal cost) of 0.003. This is substantially lower than, eg, the estimate in Altig et al. (2011), but still higher than Brave et al. (2012). To square this estimate with the microliterature is a challenge, and probably requires a combination of firm-specific capital (as in Altig et al., 2011),

[ad] There is a growing literature on the effectiveness of forward guidance. While Andrade et al. (2015) argue mainly on theoretical grounds that forward guidance may not be effective when agents have heterogeneous beliefs, Campbell et al. (2012), Williams (2014), and Del Negro et al. (2015a) argue on empirical grounds that forward guidance have had some positive impact. Even so, Del Negro, Giannoni and Patterson recognize that forward guidance may be too potent in a standard New Keynesian model relative to what the empirical evidence supports, and therefore integrate perpetual youth structure into the model to reduce its effectiveness. By and large, our estimated model produces results that are in line with their findings and suggests that forward guidance have had some, but limited, impact on the economy.

firm-specific labor (as in Woodford, 2003), and a higher sensitivity of demand to relative prices (ie, higher Kimball parameter ε_p). Apart from the higher stickiness we also see an elevated role for the risk-premium shock in this model (ρ_b rises sharply from 0.85 to 0.97, whereas the std of the innovations only falls moderately from 0.10 to 0.08), and that the degree of habit formation consumption ($\varkappa$) and investment adjustment costs (φ) rises somewhat. Finally, the response coefficient for the output gap in the policy rule is increased further, and is now 3× higher than in the model which neglects the presence of the ZLB.

The reason why these parameters are further changed relative to the "No ZLB model" is that the OIS data generally imposes longer-lived ZLB episodes than the model endogenously produces. In order to be able to explain those episodes with *positive* anticipated policy shocks through 2011Q2 the model needs to make dynamics more sluggish and explain the rebound in inflation during 2010 with temporary shocks. However, enforcing this sluggish dynamics on the model is rather costly in terms of log-marginal likelihood, which falls from -1152 in the model with endogenous ZLB duration to -1175.2 for the OIS-based ZLB duration. This is a sizable drop and a possible interpretation is that the SW07-model despite imposing the ZLB constraint, was more optimistic about the recovery than market participants during this episode.

There are of course other possibilities as to why the ZLB episodes in the model are short-lived relative to what OIS data suggest. They include that; (i) the model miss-measures the size and persistence of the relevant output gap, (ii) the model-consistent or rational expectation hypothesis fails to capture the stickiness and persistence in expectations that might be caused by learning dynamics or information filtering issues, (iii) the steady state natural real rate has fallen (eg, due to lower trend growth) and this has caused the (gross) steady state nominal interest rate R in Eq. (14) to fall; *ceteris paribus* this calls for an extended ZLB duration, and (iv), the Federal Reserve decided to respond more vigorously to the negative output gap (ie, r_y in Eq. (14) increased) from the outset of the Great Recession and thereafter.[ae] Yet other possibilities is that our model above misses out on time-varying volatility of the shocks and omits financial frictions and the cost channel of monetary policy. We explore these latter possibilities below.

5.2 Allowing for Time-Varying Volatility

As documented earlier, the prototype linear Gaussian model with constant volatility does not provide a realistic predictive density for the forecast, in particular around severe recession periods or periods of high financial and monetary stress. A large share

[ae] To the extent that these mechanisms are at work, they should be picked up in our estimated model as expansionary monetary policy shocks due to the presumption in our analysis that the Fed before and after the crisis (ie, upon exit from the ZLB) adheres to the same Taylor-type policy rule (Eq. (17)), and that agents form their expectations accordingly.

of the research effort on DSGE models since the financial crisis and the Great recession has tried to overcome these weaknesses of the basic DSGE setup. By now, most models used in academia and in policy institutions contain financial frictions and financial shocks in an effort to introduce stronger amplification mechanisms in the model. As we will discuss in the next section, however, to the extent that even the modified models adopt a Gaussian linear framework, they still depend on extremely large shocks to predict important recessions. The explicit modeling of the nonlinear macrofinance interactions is complex and ambitious and the research in that direction has not yet been integrated in empirical macro models. A technically feasible avenue to improve the predictive densities of the linear DSGE model is to allow for a more complicated stochastic structure. Here we illustrate this approach by considering a Markov Switching (MS) stochastic structure following Liu et al. (2013).[af] By allowing for such a shock structure, the hope is that the estimated model can capture the phenomena that the economic outlook is sometimes very uncertain (ie, the economy is filtered to be in the high volatility regime), without necessarily destroying its ability to provide reasonably narrow forecast uncertainty bands in normal times (ie, in the low volatility regime).

Low frequency changes in the shock variances have been analyzed by Fernández-Villaverde and Rubio-Ramírez (2007) and Justiniano and Primiceri (2008) via stochastic volatility processes. Chib and Ramamurthy (2014) and Curdia et al. (2014) show that a Student's *t*-distribution for the innovations is also strongly favored by the data as it allows for rare large shocks. The latter authors makes the point that the time variation in shock variances should contain both a low and a high frequency component.

To capture these insights, we consider a version of the benchmark model in which we allow for two independent Markov Switching processes in the shock variances. Each Markov process can switch between a low and a high volatility regime. One process affects the volatility of all the structural innovations with exception of the wage markup shock, based on the observation that the wage markup and the observed real wage variable has a completely different volatility profile compared to the other shocks and variables as shown in Figs. 1 and 5. The second Markov process is restricted to the non-Gaussian structural shocks as identified in Table 6 in Section 4.3: this process affects the volatility in the monetary policy, the risk premium and the investment specific innovations. The volatility in these three shocks is scaled by both the common (σ_c) and the monetary/financial volatility factor (σ_{mf}). The typical process for these three shocks is now written as follows:

$$\widehat{\varepsilon}_t = \rho\widehat{\varepsilon}_{t-1} + \sigma_{mf}\left(s_{mf}\right)\cdot\sigma_c(s_c)\cdot\sigma\cdot\eta_t,\ \eta_t \sim N(0,1).$$

[af] We use the RISE toolbox to implement this exercise, see Maih (2015).

The estimated transition probabilities are summarized by the following matrices:

$$Q_c\begin{pmatrix} low \\ high \end{pmatrix} = \begin{bmatrix} 0.95 & 0.07 \\ 0.05 & 0.93 \end{bmatrix} \quad Q_{mf}\begin{pmatrix} low \\ high \end{pmatrix} = \begin{bmatrix} 0.92 & 0.46 \\ 0.08 & 0.54 \end{bmatrix}.$$

The relative volatility of the two regimes are estimated as:

$$\sigma_c\begin{pmatrix} low \\ high \end{pmatrix} = \begin{bmatrix} 1 \\ 1.74 \end{bmatrix} \quad \text{and} \quad \sigma_{mf}\begin{pmatrix} low \\ high \end{pmatrix} = \begin{bmatrix} 1 \\ 2.33 \end{bmatrix}.$$

In Fig. 9, we plot the smoothed regime probabilities for the model estimated over the complete sample. A filtered probability near unity (zero) implies that the economy is filtered to be in the high (low) volatility regime.

The common volatility process captures the great moderation phenomena. The high volatility regime is typically preferred during most of the 1970s and the first half of the 1980s, while the low volatility regime is active during the great moderation and is interrupted by the financial crisis and the resulting Great Recession. Both regimes are estimated to be persistent and the relative volatility during the high volatility regime is almost twice as high as in the low volatility regime. The monetary/financial volatility process captures the increase in the volatility during most of the recession periods and in the late 1970s- and early 1980s-episode of increased monetary policy uncertainty. The expected duration of this high volatility/financial stress regime is relatively short lived with a quarterly transition probability of 0.46%. The estimated parameters that describe the regimes and the regime probabilities are very stable when estimating the model for the precrisis period or for the complete sample (not shown).

Table 8 shows that the estimated log marginal likelihood of our model with switching volatility outperforms the log marginal likelihood of the homoscedastic Gaussian models by far. In this sense, our results confirm the results in the literature based on stochastic

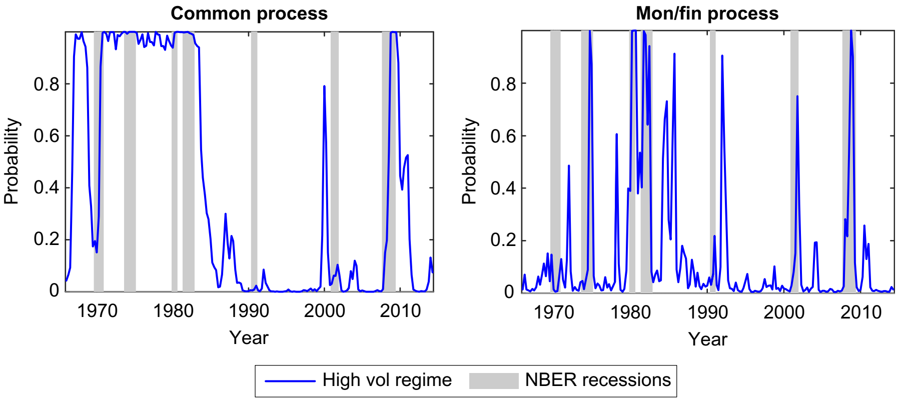

Fig. 9 Smoothed probabilities of the two volatility Markov processes.

Table 8 Log marginal likelihood of alternative regime switching specifications

	Sample period	
	Precrisis: 66Q1–07Q4	**Full sample: 66Q1–14Q2**
No regime switching (RS)	−961.8	−1146.7
RS in common process	−894.6	−1060.9
RS in mon/fin process	−911.8	−1082.1
RS in common and mon/fin process	−881.7	−1046.0

Note: None of the models in this table are estimated subject to the ZLB on policy rates.

volatility or *t*-distributed shocks. In contrast with Liu et al. (2013) and in support of the results of Curdia et al. (2014), we find strong evidence in favor of a setup that allows for multiple sources of volatility changes. The time-varying volatility structure requires sufficient flexibility to account for a common low frequency trend on the one hand, and a more cyclical high frequency process that controls mainly the monetary and financial shocks on the other hand.[ag]

Accounting for the non-Gaussian stochastic structure drastically improves the log marginal likelihood of our models, but leaves the estimated parameters, ie, the central forecasts and identified innovations, relatively unaffected. Most of the gains are realized because the predictive densities attribute appropriate probabilities to the extreme tail events: the large downturns in recessions and the corresponding sharp responses in policy rates. To illustrate this property, we consider the predictive forecast distribution with the precrisis model conditional on data up to 2008Q3, and we calculated the percentile interval that contains the 2008Q4 realized output growth observation (see Fig. 10). For our baseline precrisis model, the realized 2008Q4 growth rate falls completely outside of the simulated predictive densities based on 10,000 draws with parameter and shock volatility, as is clear from the left panel in the figure (see also Fig. 2). In contrast, in the model with Markov Switching volatility, almost 1% of the simulated forecasts fall below the 2008Q4 realization, as shown in the figure's right panel.[ah] The Markov

[ag] Our restrictive setup of two processes improve the log marginal likelihood by 115 for the complete sample. More flexible structures could easily improve this result but this goes with a cost because these setups are less robust, are computational much more intensive and lack an intuitive interpretation of the regimes. Curdia et al. report a gain of 154 in the log marginal likelihood for a setup that contains a combination of shock specific stochastic volatility and *t*-distributed innovations.

[ah] We want to emphasize that it is not the case that we are more content with this model just because it gives a positive probability that the great recession could indeed happen. As pointed out earlier, our rationale for going in this direction is that the models with regime switching in shock variances and the propagation of financial frictions (see analysis in the next section) improves the statistical properties of the model (as suggested by the strong improvement in log marginal likelihood) and makes sense from an economic viewpoint (supporting the widely held belief that financial frictions are key to understand the crisis).

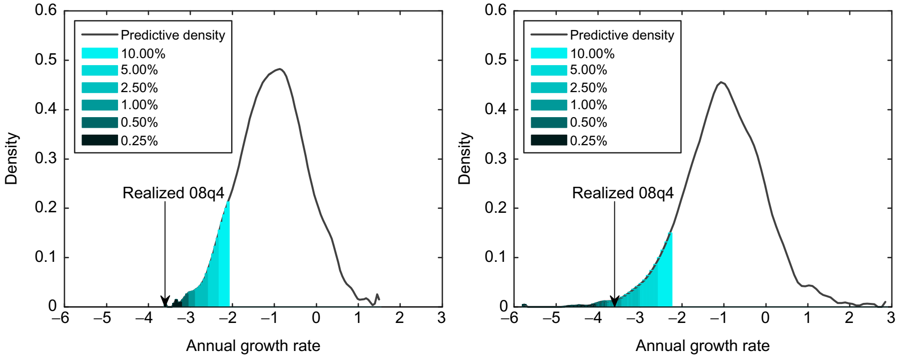

Fig. 10 Distributions for output growth (four-quarter change) in 2008Q4 given state in 2008Q3 in models with constant volatility (left panel) and time-varying volatility (right panel).

Switching volatility structure, by allowing for a mixture of normal distributions, gives more probability to the tails in general. In addition, the probability of the high volatility regimes in both the high and the low frequency Markov processes increased already by 2008Q3 because the magnitude of the realized shocks preceding the fourth quarter observation were relatively large.

5.3 Augmenting the Model with Financial Frictions and a Cost Channel

We incorporate a financial accelerator mechanism into the benchmark model in Section 3 following the basic approach of Bernanke et al. (1999). Thus, the intermediate goods producers rent capital services from entrepreneurs rather than directly from households. Entrepreneurs purchase physical capital from competitive capital goods producers (at price $\widehat{Q}_t^k$, and resell it back at the end of each period), with the latter employing the same technology to transform investment goods into finished capital goods as described by Eq. (11). To finance the acquisition of physical capital ($\widehat{\bar{k}}_t$), each entrepreneur combines his net worth ($\widehat{NW}_t^e$) with a loan from a bank, for which the entrepreneur must pay an external finance premium due to an agency problem. We follow Christiano et al. (2008) by assuming that the debt contract between entrepreneurs and banks is written in nominal terms (rather than real terms as in Bernanke et al., 1999). Banks, in turn, obtain funds to lend to the entrepreneurs by receiving deposits from households, with households bearing no credit risk (reflecting assumptions about free competition in banking and the ability of banks to diversify their portfolios). In equilibrium, shocks that affect entrepreneurial net worth—ie, the leverage of the corporate sector—induce fluctuations in the corporate finance premium.[ai]

[ai] For further details about the setup, see Bernanke, Gertler and Gilchrist, and Christiano, Motto and Rostagno. Excellent expositions are also provided by Christiano et al. (2007) and Gilchrist et al. (2009).

When estimating the model with the financial friction mechanism embedded, we add one more observable variable, the widely-used Baa-Aaa corporate credit spread (see Appendix C for exact definition and data sources). This spread plays a key role in the Bernanke–Gertler–Gilchrist framework. Since we also want to learn about the importance of shocks originating in the financial sector, and because we need as many shocks as observables to avoid stochastic singularity, we also add a "net worth" shock to the set of estimated shocks. We derive this shock by allowing the survival probability of the entrepreneurs to vary over time. Hence, this shock will enter in the accumulation equation for the entrepreneurs net worth. An alternative would have been to allow for a shock directly in the equation which relates the spread (or equivalently, the external finance premium) to the entrepreneurs leverage ratio following, eg, Del Negro and Schorfheide (2013) or Christiano et al. (2008). We preferred, however, not to add a shock directly in the spread equation in an attempt to elevate the endogenous propagation of the financial accelerator mechanism.[aj] Even so, the equation for the external finance premium,

$$\mathrm{E}_t\widehat{R}^e_{t+1} - \widehat{R}^b_t = \chi\left(\widehat{Q}^k_t + \widehat{\bar{k}}_t - \widehat{NW}^e_t\right), \tag{18}$$

still contains a shock because we assume that the financing rate of the banks, $\widehat{R}^b_t$, is not the risk-free rate set by the central bank, but rather the sum of the policy rate $\widehat{R}_t$ and the risk-premium shock $\widehat{\varepsilon}^b_t$.

As recent research by Christiano et al. (2015) and Gilchrist et al. (2015) emphasize the importance of firms financing conditions for their price setting behavior, we also embed a cost channel into the model. Specifically, we assume that firms have to borrow short to finance their wage bill following Christiano et al. (2005). As shown in the CEE paper, the working capital channel can cause inflation to rise following a tightening of monetary policy if firms financing costs rise sufficiently. To allow for sharp increases in firms financing costs, we assume that the relevant financing rate is the expected nominal return on capital for the entrepreneurs as opposed to the risk-free policy rate. However, instead of imposing that all firms borrow to finance their entire wage bills as in CEE, we estimate a parameter, ν, which determines the share of firms that are subject to working capital, so that the expression for log-linearized marginal costs becomes

$$\widehat{mc}_t = (1-\alpha)\ \left(\widehat{w}_t + \widehat{R}^f_t\right) + \alpha\ \ \widehat{r}^k_t - \widehat{\varepsilon}^a_t,$$

[aj] Christiano et al. (2008) embed a complete banking sector into their model and estimate it using 17× series and an equal number of shocks. A benefit, however, of our more modest perturbation of the model size and number of observables matched is that it allows for a straightforward comparison with the findings in the benchmark SW07-model.

where $\widehat{R}_t^f$ is the effective working capital interest rate given by

$$\widehat{R}_t^f = \frac{\nu R}{\nu R + 1 - \nu} \mathrm{E}_t \widehat{R}_{t+1}^e, \tag{19}$$

in which $\mathrm{E}_t \widehat{R}_{t+1}^e$ is the nominal expected return on capital for the entrepreneurs. From Eq. (19), we notice that $\widehat{R}_t^f = \mathrm{E}_t \widehat{R}_{t+1}^e$ when $\nu = 1$.

The SW07-model embedded with the financial friction mechanism and the cost-channel thus include five additional estimated parameters; ν, the two parameters for the AR(1) process for net worth (ρ_{nw} and σ_{nw}), the monitoring cost parameter μ which indirectly determines the sensitivity of the external finance premium to the entrepreneurs leverage ratio (χ in Eq. (18), and a constant ($\bar{c}_{sp}$) which captures the mean of the credit spread. Estimation results for three specifications of the model are provided in Table 9; first we have the "Precrisis sample" (sample 1966Q1–2007Q4 without the ZLB), second, the full sample (66Q1–14Q2) when imposing the ZLB constraint with endogenous duration, and third we study a variant of the model with the ZLB which allows the key parameter μ to switch stochastically between a high and low value. The adopted priors for the five new parameters are provided in the notes to the table. The priors for the other parameters are the same as before (and already stated in Table 2).

In the precrisis model, the external finance premium delivers only a very modest amplification of the standard shocks. The estimated elasticity of the spread to the net worth ratio is small (with $\mu = 0.033$ and χ in Eq. (18) equals 0.012, implying an annualized spread sensitivity of 0.048), a result that is in line with the estimates reported in Gilchrist et al. (2009). The exogenous risk-premium shock and—to a lower degree—the monetary policy shock are most impacted by the introduction of the FA mechanism because they have the biggest impact on the price of capital and net worth. The net worth channel tends to support the persistence in the response of investment to these shocks. The low sensitivity of the spread to the traditional shocks also implies that most of the fluctuations in the external finance premium are generated by the new exogenous shock that is assumed to hit directly the net worth of the entrepreneurs. This highly volatile shock explains up to 70% of the variance in the spread and one-third of the variance in investment. As such, the net worth shock substitutes for the exogenous risk premium and for the investment-specific technology shock. The latter also captures financial frictions as suggested by Justiniano et al. (2013a). Overall, the impact of the net worth shock on the macrodynamics remains modest and one important reason for this is that the net worth shock typically crowds out private consumption and this clashes with the observed strong comovement between consumption, and investment over the business cycle.[ak]

[ak] This crowding out problem is not present for our reduced form risk-premium shock ε_t^b in Eq. (12), see Fisher (2015) for a structural interpretation of this risk-premium shock.

Log marginal likelihood		Laplace	−897.80	Laplace	−1112.00	Laplace	−1063.00

Note: For the financial friction parameters, we use the same prior as for the other exogenous shocks (stated in Table 2). For μ and $\bar{c}_{sp}$, we use a normal distribution with means 0.25 and 1.00 and standard deviations 0.10 and 0.50, respectively. Finally, for ν we use a beta distribution with mean 0.50 and standard deviation 0.20. The "Precrisis sample" neglects the presence of the ZLB and is estimated on data up to 2007Q4, whereas the "Endogenous ZLB duration" imposes the ZLB as described in Section 5.1, and is estimated up to 2014Q2. "Endog. ZLB dur. with regime switch" also imposes the ZLB, but allows μ to vary stochastically between a low (μ_1) and high (μ_2) value. For μ_1 and μ_2, we use a normal distribution with means 0.025 and 0.25, and standard deviations 0.01 and 0.10, respectively. For the transition probabilities p_{12} and p_{21}, we use a beta distribution with means 0.10 and 0.30 and standard deviations 0.05 and 0.10, respectively.

The direct comparison of the marginal likelihood with the baseline model is complicated because the financial frictions model (FF model henceforth) has an additional observable in the form of the Baa–Aaa spread. When we estimate the FF-model without this additional observable, the log marginal likelihood improves by a factor of 10 when no additional shock is considered and by a factor of 20 when the net worth shock is retained. With a posterior mode for $\mu = 0.2$ in this variant of the model, the estimated sensitivity of the spread to the net worth ratio in this model is much higher, ie, 0.08, or 0.32 in annualized terms. This result is more supportive for an important endogenous amplification effect of the standard shocks through the net worth channel (see also De Graeve (2008) for a similar result). This observation suggests that the use of the Baa–Aaa spread as an observable for the external finance premium in the model can be too restrictive. Baa-Aaa spread is only one specific measure for default risk, and the cost of credit for firms is determined by various risks and constraints in the financial sector.[al]

Not surprisingly, when we evaluate the performance of the FF-model for the complete sample including the 2008Q4–2009Q1 crisis period, the monitoring cost parameter μ and the implied elasticity of the spread to the net-worth ratio doubles. Perhaps surprisingly, the standard error of the exogenous net-worth shock is substantially lower, 0.19 vs 0.27 in the model estimated on precrisis data. We interpret this finding to imply that the endogenous amplification becomes more important when including the crisis period in the estimation sample. As we also impose the ZLB constraint in the estimation of this model, the estimated nominal wage and price stickiness is again very high (0.83 and 0.84, respectively) so that all the expected policy shocks that are required for the model to respect the ZLB constraint are positive. It is also striking that in this full-sample model, the estimated fraction of the wage bill that requires external financing is substantially higher than in the precrisis version, supporting the argument in Christiano et al. (2015) that this channel was important during crisis. The magnitude of this cost channel increases from 0.33 to 0.64, but in both models the uncertainty in the posterior distribution for this parameter is very high. These two observations, the time variation in the role of financial frictions and the potential role of the cost channel for the inflation dynamics, are discussed in more detail below.

5.3.1 A Regime Switching Model with Occasionally More Severe Financial Frictions

Precrisis DSGE models typically neglected the role of financial frictions. This additional transmission mechanism was considered nonvital for forecasting output and inflation during the great moderation period, and by Occam's razor arguments this mechanism was typically left out. However, as our discussion of the in-sample innovations illustrated, there was already strong evidence in our estimated precrisis model for occasionally big

[al] Gilchrist et al. (2009) and Gilchrist and Zakrajsek (2012) present alternative indicators of the default spread that have a stronger predictive power for economic activity than the Baa–Aaa spread.

disturbances that seemed to be highly correlated with financial spreads and return indicators. When looking at these results from a broader perspective that also gives appropriate attention to the potential risks around the central banks forecast, these outliers should not be disregarded. A linear Gaussian approach is not the most efficient framework for handling these issues. The instability in the estimated parameters of our FF-model depending on the estimation sample clearly illustrates these limitations. To more efficiently capture the time-varying relevance of the financial frictions in our model, we therefore consider here a Markov switching setup in which the constraints from the financial frictions can become much more binding occasionally.

In our Regime Switching Financial Friction model (RS-FF), we allow for two possible regimes: one regime (high-FF) with a high monitoring costs—implying a high sensitivity of the spread to the net worth position—and another regime (low-FF) with a low monitoring costs and low sensitivity of spread to leverage.[am] The estimation results for this model is reported last in Table 9, and the data prefer this RS-FF setting compared to the linear FF-model as shown by the gain in the log marginal likelihood of more than 30 in the precrisis context (not shown) and around 50 in the sample with the recent crisis.[an] The transition probabilities and the regime-specific μ parameter are given by:

$$Q_{FF}\begin{pmatrix}\text{low}\\ \text{high}\end{pmatrix}=\begin{bmatrix}0.96 & 0.16\\ 0.04 & 0.84\end{bmatrix}\ \mu_{FF}\begin{pmatrix}\text{low}\\ \text{high}\end{pmatrix}=\begin{bmatrix}0.029\\ 0.084\end{bmatrix}.$$

The estimation results indicate that the elasticity of the spread to the leverage ratio varies between the two regimes by a factor of 2.7. As shown in Fig. 11, the high-FF regime is active mainly around the two recession periods in the 1970s, and its probability increases slightly during all recessions. When evaluated over the more recent period the probability of the high-FF regime starts to rise early in 2008 and remains active during the financial crisis in 2009, but quickly returns to the low-FF regime after 2009. The higher marginal likelihood is due to the time-varying volatility in the spread: in the high-FF regime, the financial friction is strongly binding and the spread reacts more than twice as strong to the leverage ratio. The impact of shocks on investment is also higher but the magnitude of the amplification is moderate up to a factor of 1.5 maximum. The expected period-by-period persistence of the high-FF regime is limited (0.84) and this reduces the impact of spread increases on the discounted value of future expected returns on investment.

As evidenced in Fig. 12, the central forecast of the single-regime precrisis FF-model, conditional on data up to 2008Q3 is completely missing the magnitude of the 2008Q4

[am] Christiano et al. (2014) focus instead on the distribution of the idiosyncratic productivity risk as the source for time-varying financial frictions. Levin et al. (2004) identify the time variation in the bankruptcy cost parameter, the equivalent of our monitoring cost, as the source for the counter-cyclical external premium behavior.

[an] Suh and Walker (2016) also finds support for time-variation in parameters governing financial frictions.

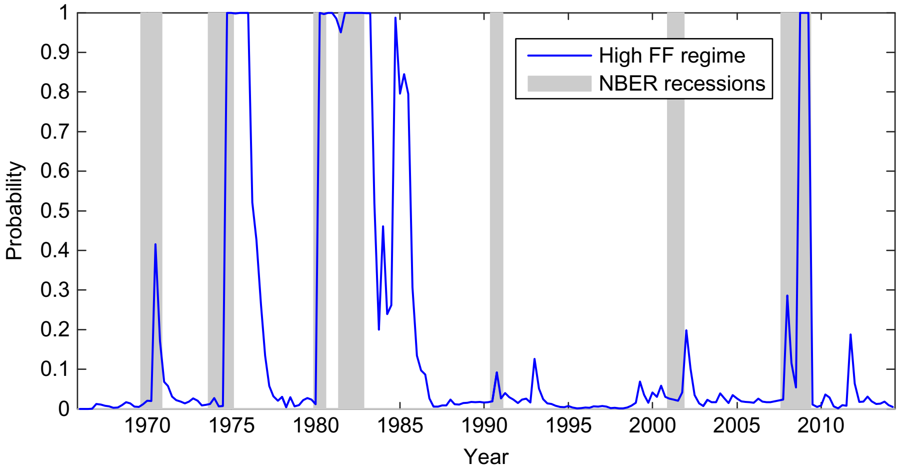

Fig. 11 Markov process in the financial frictions model.

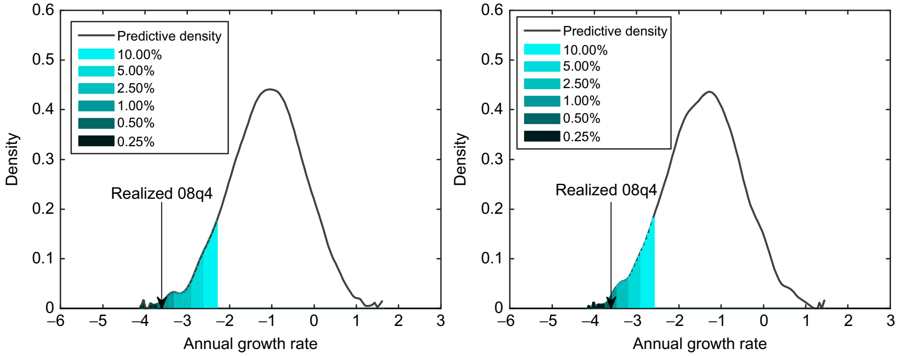

Fig. 12 Distributions for output growth (four-quarter change) in 2008Q4 given state in 2008Q3 in financial friction models with constant parameters (left panel) vs regime switching (right panel).

downturn just as the benchmark SW07-model without financial frictions. By comparing the no-financial friction model—left panel in Fig. 10—with the constant parameter FF-model—left panel in Fig. 12, we see that the distribution around the FF-forecast is more disperse due to the extra volatility that is generated by the spread and the additional net worth shock. As a result, the extreme negative output growth realization of 2008Q4 now falls within the 0.25% interval of the predictive density, which is some improvement relative to the baseline model. The precrisis RS-FF model, shown in the right panel in Fig. 12, further improves on this result because the probability of being in the high friction regime increased in 2008Q3 (56% against an unconditional probability of 20%) and this introduces a high degree of skewness in the predictive density of the spread. While the precrisis FF-model predicts a 1% upper tail for the expected spread above 2.3 percentage points in 2008Q4, this becomes as high as 3 percentage points in the RS-FF model. The probability of the observed 2008Q4 output growth outcome now lies around the 0.5% tail interval, which is still small but at least the *ex post* realized event obtains some nonzero probability in the predictive density. This result indicates that if we appropriately could integrate the nonlinear accelerator dynamics from financial frictions in our DSGE models we may obtain a more realistic predictive density that resembles these from the reduced form time-varying volatility models such as our RS-volatility example in Section 5.2.

Given the important role of the spread in the short run forecast, it is also informative to show how a conditional forecast, conditional on the timely observation of the spread, performs in the crisis period. Therefore, we make a forecast conditional on the 2008Q3 state of the economy as filtered by the precrisis FF-model but now we also provide the model with the information that the spread increased to the exceptionally high observed level of 3.02 percentage points in 2008Q4 (from 1.55 percentage points in 2008Q3). This conditioning is plausible in real time as the spread already in the beginning of the fourth quarter in 2008 (mid-October) had reached 3 percentage points. Fig. 13 shows the unconditional (left panel) and conditional (right panel) forecast distributions for GDP growth in 2008Q4. As seen from the figure, the forecast conditional on the timely information from the spread display a median prediction for annual GDP growth of −2.11% in 2008Q4 and −1.92% in 2009Q1 (not shown), which should to be compared to the observed −3.61% and −4.42% in the actual data and unconditional forecast of −1.05% (left panel in the figure) and 0.06% (not shown).

In the RS-FF model, the result depends very much on the regime in which the economy is finding itself in 2008Q3: the impact of conditioning on the spread is most disturbing when the economy is in the low friction regime. Extreme high spreads are very difficult to reconcile with the low friction regime, with its low elasticity of spread to leverage, and therefore the spreads are translated in huge negative shocks in net worth

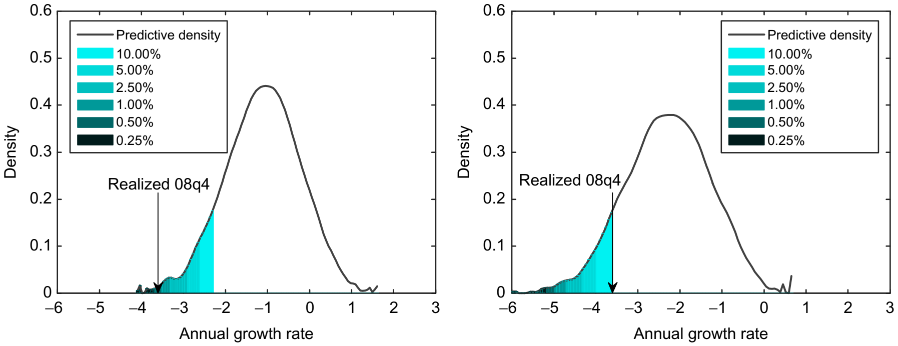

Fig. 13 Distributions for output growth (four-quarter change) in 2008Q4 in constant parameter financial friction model. Left panel is unconditional projection given state in 2008Q3, whereas the right panel is conditional on the spread in 2008Q4.

and/or risk premiums which then also result in worse output growth predictions of −2.53% and −3.01% in 2008Q4 and 2009Q1.[ao] The real-time information on the spread and the presence of the additional transmission mechanism allow the FF-model to considerably improve the accuracy of the central forecast in the crisis period. Our results confirm the findings of Del Negro and Schorfheide (2013), who also compare the predictive performance of a standard SW setup with an augmented SW-FF model. They observe that the relative performance of the two models changes over time. On average the model without financial frictions generates more accurate forecasts, but during the recent financial crisis a SW-FF model—that also exploits the timely information on spread and interest rate—produces better forecasts for output and inflation. Del Negro et al. (2014) built on these results and develop a new method for combining predictive densities from recursively estimated models using time-varying weights. As in our RS-approach, this dynamic linear prediction pooling relies on weights that follow an exogenous process. The next step in this research agenda would be to endogenize the occurrence of financial stress periods during which constraints are reinforced and additional feedback mechanisms are activated.[ap]

5.3.2 The Cost Channel of Financial Spreads and Inflation Dynamics

In Section 4.2, when we discussed the economic interpretation of the great recession through the lense of the baseline SW07-model, we observed that the model requires a series of positive mark up shocks to explain the maintained inflation rate during the period of slow recovery and persistent negative output gap. These positive mark up shocks are necessary despite the high estimate of nominal stickiness in price and wage setting. This trend towards more nominal stickiness was already present in the subsample estimates presented by SW07. The high nominal stickiness also plays a crucial role in the explanation of the recent inflation dynamics by Del Negro et al. (2015b) and Fratto and Uhlig (2014). These positive markup shocks disappear completely in our version of the SW07-model, in which we implement the ZLB, and that features an even higher degree of nominal stickiness. The question arises whether this estimated stickiness parameter should be interpreted effectively as a sign of pure nominal stickiness in the price setting practice or whether it reflects some other mechanism that lowered the responsiveness of inflation to the slack in production capacity.

[ao] This somewhat counter-intuitive result of the RS-FF model is related to the nature of the conditional forecast exercise: conditioning on a given spread observation has larger effects when that observation deviates more from the baseline unconditional forecast. The gain from the RS-FF model is precisely that the unconditional forecast will show larger dispersion in the high-FF regime and lower dispersion in the low-FF regime.

[ap] Various approaches have been developed in this context: Guerrieri and Iacoviello (2013) with occasionally binding constraints, Dewachter and Wouters (2014) with third order nonlinear approximations and Bocola (2013) with a combination of occasionally binding constraints and nonlinear risk premiums.

As noted by Christiano et al. (2015), one mechanism that might contribute to this inflation resilience, in particular during periods of increased financial constraints and high financing costs, is the cost channel. Firms that are financially constrained and that must finance their operations with expensive external capital can experience an increase in their marginal production costs if these financing costs dominate the influence of the other cost components. Related to this cost channel, firms can have other arguments to keep their prices high during periods of financial constraints: high markups can be necessary for firms to generate sufficient cash flow or firms might be forced by their financing constraints to give up on market share (see Gilchrist et al., 2015). Note that this cost channel also plays a crucial role in the explanation of the inflation inertia following a monetary policy shock in Christiano et al. (2005).

Our FF-model contains a parameter that controls the strength of the cost channel. This parameter reflects the fraction of the wage bill that firms have to finance with credit. In this setup, we assume that the external finance premium is also affecting the cost for these intertemporal loans of the firms. In the precrisis model, this fraction of the wage bill on which the financial cost applies is estimated to be quite low (0.33) and the posterior distribution has a large uncertainty margin around this mode. This parameter increases to 0.63 in the complete sample estimation, still with a large uncertainty, but at least there is some indication that the cost channel was more relevant during the recent crisis. To examine the potency of this channel in our model, Fig. 14 plots the impulse response functions of the three shocks that directly affect the external financing costs—the monetary policy shock, the exogenous risk premium shock, and the wealth shock—on the marginal cost and inflation for the two extreme values (zero and one) of the cost channel parameter. Given the large estimation uncertainty around the magnitude of the cost channel parameter, these two extreme values are not completely unlikely and their relevance can probably change depending on the nature of the financial shocks and the constraints. We plot the results for both the precrisis model, with a moderate degree of nominal stickiness, and the full sample ZLB model with a high degree of stickiness.

In both model versions and for all three shocks, it is obvious that marginal cost behaves quite different if the cost channel is fully active compared to a situation in which the cost channel is completely absent. The presence of the cost channel implies that the marginal cost increases at least during the first quarters following each of these shocks. The persistence of this positive effect depends on the type of shock and tends to be shorter for the risk-premium shock and most persistent for the net-worth shock.

The impact on inflation can differ substantially depending on the volatility of the cost shock and on the persistence of the shock relative to the degree of nominal stickiness which determines the degree of forward-lookingness in price setting. In the precrisis model, the exogenous risk-premium shock is highly volatile, but short lived. Combined with the moderate degree of stickiness the cost channel drastically changes the response of inflation to this shock. Inflation rises on impact due to the high risk-premium component

in the financing costs, but the effect is very short lived. In the model with ZLB constraint—with more stickiness—the price setting is more forward looking and the persistence of the shock is crucial. In such a context, the smooth inflation process is dependent on the long-run expected marginal cost. In this case, only the net worth shock has a sufficiently persistent effect on the financing cost to exert a positive impact on inflation; the temporarily high risk free rate and risk premium shock are missing sufficient persistence to have a substantial impact on the inflation dynamics.

From this impulse response analysis, it follows that the cost channel can contribute to the slow response of inflation in a financial crisis context. When the external finance shock for firms are sufficiently high and/or sufficiently persistent, as it is the case for a net worth shock that is expected to have long lasting effects on the financing costs, this inflationary pressure from the cost channel can be quantitatively important. These results illustrate that the financial crisis should not necessarily be viewed as a purely negative aggregate demand shock without an impact on the supply side of the economy. With both aggregate demand and aggregate supply shifting inward by the financial shock, inflation should not necessarily be expected to react that much in a financial crisis situation.

6. STATE OF MACROECONOMIC MODELING: CRITICAL ASSESSMENT AND OUTLOOK

In this section, we conclude by discussing both "new" and "old" challenges for macroeconomic models. As evidenced earlier, the financial crisis has generated new challenges for macroeconomic models used at central banks. When the Great Recession and the financial crisis are included in the estimation sample, we must adjust the specification and empirical estimation strategy of our policy models. Our chapter provides some avenues for moving in that direction, and suggests that the gains of doing so may be considerable. Our suggested modifications have in common of moving away from the standard linear Gaussian setup by including time variation in exogenous and endogenous disturbances. An important short-cut, however, in our adopted Markow Switching framework is that the regime changes are modeled as exogenous events and hence, unrelated to the conduct of policy. At this stage we therefore consider our extensions as a shortcut for truly endogenous nonlinear and state dependent propagation mechanisms. Further progress on the specification of nonlinear methods, solution and filtering techniques, as well as computational techniques, are ongoing for analyzing nonlinear integrated macrofinance models. Together with a broader set of observable variables, these models should allow us to more efficiently identify the nature of shocks, their transmission, and their implications for policy. At this stage, it is important that different theoretical frameworks should be exploited to formulate and validate alternative model specifications.

There were also well-known challenges for central bank models prior to the financial crisis, and they have not been mitigated by the evidence brought forward by the crisis.[aq]

[aq] For instance, the influential work of Del Negro et al. (2007) suggested that workhorse closed economy DSGE models suffered from misspecification problems. Adolfson et al. (2008) confirmed this finding for a standard open economy model.

The balanced growth and the stationarity assumptions provide discipline to the model forecasts, but these long term restrictions often conflict with the observed stochastic trends in many important macro ratios. This mismatch between the theoretical assumptions and the empirical properties can result in overestimation of the persistence in the endogenous frictions and exogenous shocks. It may also be necessary to reevaluate the forecast implications of full information and rational expectations in the models with alternative assumptions about information and expectations formation building on the seminal work of Evans and Honkapohja (2001), Sims (2003, 2010), and Woodford (2014).

Macro models necessarily abstract of many sector details. Recently, a lot of effort have been devoted to model the financial sector. In the standard Smets and Wouters (2007) model analyzed in this chapter, the risk premium shock combines the impact of credit supply conditions, risk aversion, anticipations about future policy actions and the effect of quantitative easing (QE) policies targeting yield curve or risk spreads. Integrating the analysis of financial markets explicitly into general equilibrium is hence of first-order importance, both for firms (the focus of our chapter) and households, eg, along the lines suggested by Iacoviello (2005) and Liu et al. (2013). Other models incorporate an active role for financial institutions in the credit supply process or the asset pricing functions: Christiano et al. (2003a, 2008, 2014), Gerali et al. (2010), and Gertler and Kiyotaki (2010) are inspiring examples. Innovative new macrofinance models, as in, eg, Brunnermeier and Sannikov (2014), He and Krishnamurthy (2012), and Mendoza (2010) suggest that strong endogenous risk and feedback channels between the real and the financial sectors can go a long way in explaining the change in volatility and correlations between tranquil and stress periods. A more explicit recognition of default in both the financial and nonfinancial private sectors as in Clerc et al. (2015) is also an important avenue.

However, other sectors of the economy also have very similar problems in that the exogenous shocks represent a large range of influences that might call for different policy responses depending on the specific underlying distortion or inefficiency. One obvious example is the labor market with very diverging underlying trends in labor participation at intensive and extensive margins, and with shocks and distortions affecting both the labor supply and demand conditions. More work is needed to examine in which dimensions the labor market implications of the standard New Keynesian sticky wage model analyzed by Galí et al. (2011) fall short relative to the data, and if recent work with a more elaborate labor market modeling (see, eg, Gertler et al., 2008; Christiano et al., 2010a; and Christiano et al., 2016) can remedy those shortcomings. Some prominent economists, like Kocherlakota (2009), have recently reiterated that incomplete insurance and heterogeneity in labor and product markets is key for understanding the propagation and welfare costs of business cycles. Thus, the representative agents framework preserved by Gertler et al. and Christiano et al. may not be sufficient in the end, although it represents a clear step forward relative to current generation of policy models.

In a world increasingly integrated through trade of goods and services and more globalized financial markets, policy models also need to be able to account for the impact of foreign shocks. Two old challenges for open economy models is to account for the high degree of observed comovement between real quantities (see, eg, Backus et al., 1992 and Justiniano and Preston, 2010), and the relationship between interest rate differentials and exchange rate movements (ie, the uncovered interest rate parity condition, see, eg, Eichenbaum and Evans, 1995 and Chaboud and Wright, 2005). A voluminous literature deals with these issues, but there is yet no consensus on the "solutions" to these challenges.[ar]

Another key challenge posed for macro models at use in central banks following the crisis is that they have to provide a framework where topical questions can be addressed. First, they have to provide a framework where the central bank can use both conventional monetary policy (manipulating short rates) and unconventional policies (large scale asset purchases (LSAPs) and QE) to affect the economy. A serious treatment of unconventional monetary policy in policy models seems to imply that we have to tackle one old key challenge in macro modeling, namely the failure of the expectations hypothesis (see, eg, Campbell and Shiller, 1991), in favor of environments where the expectations hypothesis does not necessarily hold. One theoretical framework consistent with the idea that large scale asset purchases can reduce term premiums for different maturities and put downward pressure on long-term yields is the theory of preferred habit, see, eg, Andrés et al. (2004) and Vayanos and Vila (2009). Extensions in this direction appear crucial for evaluating the unconventional monetary policy measures during the crisis. Second, apart from analyzing unconventional policies during the crisis, the aftermath of the crisis have brought a renewed focus on financial stability issues, which implies that we need to be able to integrate financial stability considerations into macro models traditionally used for monetary policy analysis only. This involves stress testing exercises and the creation of an environment with an effective role for various macroprudential tools. This requires a more realistic modeling of the interbank market as the one by Boissay et al. (2015). The "3D model" developed by Clerc et al. (2015) and IMF's GIMF model with banks (see Andrle et al., 2015) represent important steps in this direction. Unconventional monetary policy and macroprudential instruments have important distributional effects and this calls for sufficient heterogeneity among agents that are affected by these measures. As mentioned before, the actual and potential budgetary implications of these measures require an explicit modeling of the systematic fiscal reaction function.

[ar] The estimated open economy DSGE model developed by Adolfson et al. (2007b, 2008, 2011) which early on was integrated into operational use at the Riksbank (see Adolfson et al., 2007c) attempted to account for this by modifying the UIP condition following the insights in Duarte and Stockman (2005) and allowing for a common unitroot technology shock.

We believe the benchmark model analyzed in this chapter can serve as the starting point to analyze various extensions for topical questions and policy purposes. Specific model extensions combined with broader set of observed data should help us to better identify the various blocks. This applies equally for the financial, fiscal, labor market and the open economy blocks of the models. Bayesian methodology provides the tools to evaluate and combine these model predictions. In this endeavor, a challenge will be to keep the model size manageable by finding the most parsimonious ways to capture the necessary frictions and shocks, and to understand its implications as the models become increasingly complicated. To keep the models tractable, a critical decision point will be which frictions and shocks that are really needed in the core model, and which features that can be abstracted from in the core model and instead meaningfully analyzed in satellite models. Developing and maintaining empirically validated models with strong theoretical foundations is a daunting task ahead for policy making institutions, even the ones with the most resources.

APPENDICES

A. Linearized Model Representation

In this appendix, we summarize the log-linear equations of the basic SW07-model stated in Section 3. The complete model also includes the seven exogenous shocks $\varepsilon_t^a, \varepsilon_t^b, \varepsilon_t^i, \varepsilon_t^p, \varepsilon_t^w, \varepsilon_t^r$ and g_t, but their processes are not stated here as they were already shown in the main text. Consistent with the notation of the log-linearized *endogenous* variables $\widehat{x}_t = dx_t/x$, the exogenous shocks are denoted with a 'hat', ie, $\widehat{\varepsilon}_t = \ln \varepsilon_t$.

First, we have the consumption Euler equation:

$$\begin{aligned}\widehat{c}_t = & \frac{1}{(1+\varkappa/\gamma)} \mathrm{E}_t \widehat{c}_{t+1} + \frac{\varkappa/\gamma}{(1+\varkappa/\gamma)} \widehat{c}_{t-1} - \frac{1-\varkappa/\gamma}{\sigma_c(1+\varkappa/\gamma)} \\ & (\widehat{R}_t - \mathrm{E}_t \widehat{\pi}_{t+1}) - \frac{(\sigma_c - 1)(w_*^h L/c*)}{\sigma_c(1+\varkappa/\gamma)} (\mathrm{E}_t \widehat{L}_{t+1} - \widehat{L}_t) + \widehat{\varepsilon}_t^b,\end{aligned} \tag{A.1}$$

where $\varkappa$ is the external habit parameter, σ_c the reciprocal of the intertemporal substitution elasticity, $w_*^h L/c_*$ the steady state nominal labor earnings to consumption ratio, and the exogenous risk premium shock $\widehat{\varepsilon}_t^b$ is rescaled so that it enters additive with a unit coefficient.

Next, we have the investment Euler equation:

$$\hat{i}_t = \frac{1}{(1+\overline{\beta}\gamma)} \left(\hat{i}_{t-1} + \overline{\beta}\gamma \mathrm{E}_t \hat{i}_{t+1} + \frac{1}{\gamma^2 \varphi} \widehat{Q}_t^k \right) + \widehat{\varepsilon}_t^q, \tag{A.2}$$

where $\overline{\beta} = \beta\gamma^{-\sigma_c}$, φ is the investment adjustment cost, and the investment specific technology shock $\widehat{\varepsilon}_t^q$ has been rescaled so that it enters linearly with a unit coefficient.

Additionally $i_1 = 1/(1+\beta)$ and $i_2 = i_1/\psi$, where β is the discount factor and ψ is the elasticity of the capital adjustment cost function.

The price of capital is determined by:

$$\widehat{Q}^k_t = -(\widehat{R}_t - \mathrm{E}_t\widehat{\pi}_{t+1}) + q_1\mathrm{E}_t r^k_{t+1} + (1-q_1)\mathrm{E}_t Q^k_{t+1} + \frac{\sigma_c(1+\varkappa/\gamma)}{1-\varkappa/\gamma}\widehat{\varepsilon}^b_t, \tag{A.3}$$

where $q_1 \equiv r^k_*/(r^k_* + (1-\delta))$ in which r^k_* is the steady state rental rate to capital, δ the depreciation rate, and $\widehat{\varepsilon}^b_t$ is multiplied by $\frac{\sigma_c(1+\varkappa/\gamma)}{1-\varkappa/\gamma}$ reflecting the rescaling of this shock in the consumption Euler equation (A.1).

Fourth, we have the optimal condition for the capital utilization rate $\hat{u}_t$:

$$\hat{u}_t = (1-\psi)/\psi\widehat{r}^k_t, \tag{A.4}$$

where ψ is the elasticity of the capital utilization cost function and capital services used in production $(\widehat{k}_t)$ is defined as:

$$\widehat{k}_t = \hat{u}_t + \widehat{\bar{k}}_{t-1}, \tag{A.5}$$

where $\widehat{\bar{k}}_{t-1}$ is the physical capital stock which evolves according to the capital accumulation equation:

$$\widehat{\bar{k}}_t = \kappa_1 \; \widehat{\bar{k}}_{t-1} + (1-\kappa_1)\hat{i}_t + \kappa_2\widehat{\varepsilon}^q_t \tag{A.6}$$

with $\kappa_1 = (1-(i_*/\bar{k}_*)$ and $\kappa_2 = (i_*/\bar{k}_*)\gamma^2\varphi$.

The following optimal capital/labor input condition also holds:

$$\widehat{k}_t = \widehat{w}_t - \; \widehat{r}^k_t + \widehat{L}_t, \tag{A.7}$$

where $\widehat{w}_t$ is the real wage.

The log-linearized production function is given by:

$$\widehat{y}_t = \phi_p \;\; (\alpha\widehat{k}_t + (1-\alpha)\widehat{L}_t + \widehat{\varepsilon}^a_t), \tag{A.8}$$

in which ϕ_p is the fixed costs of production corresponding to the gross price markup in the steady state, and $\widehat{\varepsilon}^a_t$ is the exogenous TFP process.

Aggregate demand must equal aggregate supply:

$$\widehat{y}_t = \frac{c_*}{y_*}\widehat{c}_t + \frac{i_*}{y_*}\hat{i}_t + g_t + \frac{r^k_* k_*}{y_*}\hat{u}_t, \tag{A.9}$$

where g_t represents the exogenous demand component.

Next, we have the following log-linearized price-setting equation with dynamic indexation ι_p:

$$\widehat{\pi}_t - \iota_p\widehat{\pi}_{t-1} = \pi_1\left(\mathrm{E}_t\widehat{\pi}_{t+1} - \iota_p\widehat{\pi}_t\right) - \pi_2\widehat{\mu}^p_t + \widehat{\varepsilon}^p_t, \tag{A.10}$$

where $\pi_1 = \beta$, $\pi_2 = (1 - \xi_p\beta)(1 - \xi_p)/[\xi_p(1 + (\phi_p - 1)\epsilon_p)]$, $1 - \xi_p$ is the probability of each firm being able to reoptimize the price each period, ϵ_p is the curvature of the aggregator function Eq. (2), and the markup shock $\widehat{\varepsilon}_t^p$ has been rescaled to enter with a unit coefficient. The price markup $\widehat{\mu}_t^p$ equals the inverse of the real marginal cost, $\widehat{\mu}_t^p = -\widehat{mc}_t$, which in turn is given by:

$$\widehat{mc}_t = (1-\alpha)\ \ \widehat{w}_t^{real} + \alpha\ \ \widehat{r}_t^k - \widehat{\varepsilon}_t^a. \tag{A.11}$$

We also have the following wage-setting equation allowing for dynamic indexation of wages for nonoptimizing households:

$$\begin{aligned}(1+\overline{\beta}\gamma)\widehat{w}_t^{real} - \widehat{w}_{t-1}^{real} - \overline{\beta}\gamma \mathrm{E}_t\widehat{w}_{t+1}^{real} = {} & \frac{(1-\xi_w\overline{\beta}\gamma)(1-\xi_w)}{[\xi_w(1+(\phi_w-1)\epsilon_w)]} \\ & \left(\frac{1}{1-\varkappa/\gamma}\widehat{c}_t - \frac{\varkappa/\gamma}{1-\varkappa/\gamma}\widehat{c}_{t-1} + \sigma_l\widehat{L}_t - \widehat{w}_t\right) \\ & -(1+\overline{\beta}\gamma\iota_w)\widehat{\pi}_t + \iota_w\widehat{\pi}_{t-1} + \overline{\beta}\gamma\mathrm{E}_t\widehat{\pi}_{t+1} + \widehat{\varepsilon}_t^w,\end{aligned} \tag{A.12}$$

where ϕ_w the gross wage markup, $1 - \xi_p$ is the probability of each household being able to reoptimize its wage each period, ϵ_w is the curvature of the aggregator function (eq. 7), and σ_l determines the elasticity of labor supply given σ_c (see Eq. (9)). The exogenous wage markup shock $\widehat{\varepsilon}_t^w$ has been rescaled to enter linearly with a unit coefficient.

Finally, we have the monetary policy rule:

$$\widehat{R}_t = \rho_R\widehat{R}_{t-1} + (1-\rho_R)\left(r_\pi\widehat{\pi}_t + r_y\widehat{y}_t^{gap} + r_{\Delta y}\Delta\widehat{y}_t^{gap}\right) + \widehat{\varepsilon}_t^r, \tag{A.13}$$

where $\widehat{y}_t^{gap} = \widehat{y}_t - \widehat{y}_t^{pot}$, or in words: the difference between actual output and the output prevailing in the flexible price and wage economy in absence of the inefficient price and wage markup shocks. We solve for $\widehat{y}_t^{pot}$ by setting $\xi_p = \xi_w = 0$ (or arbitrary close to nil) and removing $\widehat{\varepsilon}_t^w$ and $\widehat{\varepsilon}_t^p$ from the system of equations given by (A.1)–(A.13). Note that when we impose the ZLB on the model, Eq. (A.13) is replaced by Eq. (17).

B. The ZLB Algorithm and the Likelihood Function

This appendix provides some details on the ZLB algorithm we use and how the likelihood function takes the ZLB into account. For more details on the ZLB algorithm we refer to Hebden et al. (2010), whereas more details on the computation of the likelihood is provided by Jesper et al. (2016).

B.1 The ZLB Algorithm

The DSGE model can be written in the following practical state-space form,

$$\begin{bmatrix} X_{t+1} \\ Hx_{t+1|t} \end{bmatrix} = A \begin{bmatrix} X_t \\ x_t \end{bmatrix} + Bi_t + \begin{bmatrix} C \\ 0 \end{bmatrix} \varepsilon_{t+1}. \tag{B.1}$$

Here, X_t is an n_X–vector of *predetermined* variables in period t (where the period is a quarter) and x_t is a n_x–vector of *forward-looking* variables. The i_t is generally a n_i–vector of (policy) *instruments* but in the cases examined here it is a scalar—the central bank's policy rate—giving $n_i = 1$. The ε_t is an n_ε-vector of independent and identically distributed shocks with mean zero and covariance matrix I_{n_ε}, while A, B, C, and H are matrices of the appropriate dimension. Lastly $x_{t+\tau|t}$ denotes $\mathrm{E}_t x_{t+\tau}$, ie, the rational expectation of $x_{t+\tau}$ conditional on information available in period t. The forward-looking variables and the instruments are the *nonpredetermined* variables.[as]

The variables are measured as differences from steady state values, in which case their unconditional means are zero. In addition, the elements of the matrices A, B, C, and H are considered fixed and known.

We let i_t^* denote the policy rate when we disregard the ZLB. We call it the *unrestricted* policy rate. We let i_t denote the actual or *restricted* policy rate that satisfies the ZLB,

$$i_t + \bar{\imath} \geq 0,$$

where $\bar{\imath} > 0$ denotes the steady state level of the policy rate and we use the convention that i_t and i_t^* are expressed as deviations from the steady state level. The ZLB can therefore be written as

$$i_t + \bar{\imath} = \max\{i_t^* + \bar{\imath}, 0\}. \tag{B.2}$$

We assume the unrestricted policy rate follows the (possibly reduced form) unrestricted linear policy rule,

$$i_t^* = f_X X_t + f_x x_t, \tag{B.3}$$

where f_X and f_x are row vectors of dimension n_X and n_x, respectively. From (B.2) it then follows that the restricted policy rate is given by:

$$i_t + \bar{\imath} = \max\{f_X X_t + f_x x_t + \bar{\imath}, 0\}. \tag{B.4}$$

Consider now a situation in period $t \geq 0$ where the ZLB may be binding in the current or the next finite number T periods but not beyond period $t + T$. That is, the ZLB constraint

$$i_{t+\tau} + \bar{\imath} \geq 0, \qquad \tau = 0, 1, \ldots, T \tag{B.5}$$

may be binding for some $\tau \leq T$, but we assume that it is not binding for $\tau > T$,

[as] A variable is predetermined if its one-period-ahead prediction error is an exogenous stochastic process (Klein, 2000). For (B.1), the one-period-ahead prediction error of the predetermined variables is the stochastic vector $C\varepsilon_{t+1}$.

$$i_{t+\tau} + \bar{\imath} > 0, \qquad \tau > T.$$

We will implement the ZLB with anticipated shocks to the unrestricted policy rule, using the techniques of Laséen and Svensson (2011). Thus, we let the restricted and unrestricted policy rate in each period t satisfy

$$i_{t+\tau,t} = i^{*}_{t+\tau,t} + z_{t+\tau,t}, \tag{B.6}$$

for $\tau \geq 0$. The ZLB policy rule in (B.4)—as we explain in further detail later—implies that all current and future anticipated shocks $z_{t+\tau,t}$ in (B.6) must be nonnegative, and that $z_{t,t}$ is strictly positive in periods when the ZLB is binding.

Disregarding for the moment when z_t are nonnegative, we follow Laséen and Svensson (2011) and call the stochastic variable z_t the deviation and let the $(T+1)$-vector $z^t \equiv (z_{t,t}, z_{t+1,t}, \ldots, z_{t+T,t})'$ denote a projection in period t of future realizations $z_{t+\tau}$, $\tau = 0, 1, \ldots, T$, of the deviation. Furthermore, we assume that the deviation satisfies

$$z_t = \eta_{t,t} + \sum_{s=1}^{T} \eta_{t,t-s}$$

for $T \geq 0$, where $\eta^t \equiv (\eta_{t,t}, \eta_{t+1,t}, \ldots, \eta_{t+T,t})'$ is a $(T+1)$-vector realized in the beginning of period t. For $T = 0$, the deviation is given by $z_t = \eta_t$. For $T > 0$, the deviation is given by the moving-average process

$$z_{t+\tau,t+1} = z_{t+\tau,t} + \eta_{t+\tau,t+1}$$
$$z_{t+\tau+T+1,t+1} = \eta_{t+T+1,t+1},$$

where $\tau = 1, \ldots, T$. It follows that the dynamics of the projection of the deviation can be written more compactly as

$$z^{t+1} = A_z z^t + \eta^{t+1}, \tag{B.7}$$

where the $(T+1) \times (T+1)$ matrix A_z is defined as

$$A_z \equiv \begin{bmatrix} 0_{T\times 1} & I_T \\ 0 & 0_{1\times T} \end{bmatrix}.$$

Hence, z^t is the projection in period t of current and future deviations, and the innovation η^t can be interpreted as the new information received in the beginning of period t about those deviations.

Let us now combine the model, (B.1), the dynamics of the deviation, (B.7), the unrestricted policy rule, (B.3), and the relation (B.6). Taking the starting period to be $t = 0$, we can then write the combined model as

$$\begin{bmatrix} \tilde{X}_{t+1} \\ \tilde{H}\tilde{x}_{t+1|t} \end{bmatrix} = \tilde{A} \begin{bmatrix} \tilde{X}_t \\ \tilde{x}_t \end{bmatrix} + \begin{bmatrix} C & 0_{n_X \times (T+1)} \\ 0_{(T+1)\times n_\varepsilon} & I_{T+1} \\ 0_{(n_x+2)\times n_\varepsilon} & 0_{(n_x+2)\times(T+1)} \end{bmatrix} \begin{bmatrix} \varepsilon_{t+1} \\ \eta^{t+1} \end{bmatrix} \tag{B.8}$$

for $t \geq 0$, where

$$\tilde{X}_t \equiv \begin{bmatrix} X_t \\ z^t \end{bmatrix}, \quad \tilde{x}_t \equiv \begin{bmatrix} x_t \\ i_t^* \\ i_t \end{bmatrix}, \quad \tilde{H} \equiv \begin{bmatrix} H & 0_{n_x \times 1} & 0_{n_x \times 1} \\ 0_{1 \times n_x} & 0 & 0 \\ 0_{1 \times n_x} & 0 & 0 \end{bmatrix}.$$

Under the standard assumption of the saddle-point property (that the number of eigenvalues of $\tilde{A}$ with modulus larger than unity equals the number of nonpredetermined variables, here $n_x + 2$), the system of difference equations (B.8) has a unique solution and there exist unique matrices M and F returned by the Klein (2000) algorithm such that the solution can be written:

$$\tilde{x}_t = F\tilde{X}_t \equiv \begin{bmatrix} F_x \\ F_{i^*} \\ F_i \end{bmatrix} \tilde{X}_t \tilde{X}_{t+1} = M\tilde{X}_t + \begin{bmatrix} C\varepsilon_{t+1} \\ \eta^{t+1} \end{bmatrix} \equiv \begin{bmatrix} M_{XX} & M_{Xz} \\ 0_{(T+1)\times n_X} & A_z \end{bmatrix} \begin{bmatrix} X_t \\ z^t \end{bmatrix} + \begin{bmatrix} C\varepsilon_{t+1} \\ \eta^{t+1} \end{bmatrix},$$

for $t \geq 0$, and where X_0 in $\tilde{X}_0 \equiv (X_0', z^{0\prime})'$ is given but the projections of the deviation z^0 and the innovations η^t for $t \geq 1$ (and thereby z^t for $t \geq 1$) remain to be determined. They will be determined such that the ZLB is satisfied, ie, Eq. (B.4) holds. Thus, the *policy-rate projection* is given by

$$i_{t+\tau,t} = F_i M^\tau \begin{bmatrix} X_t \\ z^t \end{bmatrix} \tag{B.9}$$

for $\tau \geq 0$ and for given X_t and z^t.

We will now show how to determine the $(T+1)$-vector $z^t \equiv (z_t, z_{t+1,t}, \ldots, z_{t+T,t})'$, ie, the projection of the deviation, such that policy-rate projection satisfies the ZLB restriction (B.5) and the policy rule (B.4).

When the ZLB restriction (B.5) is disregarded or not binding, the policy-rate projection in period t is given by

$$i_{t+\tau,t} = F_i M^\tau \begin{bmatrix} X_t \\ 0_{(T+1)\times 1} \end{bmatrix}, \qquad \tau \geq 0. \tag{B.10}$$

The policy-rate projection disregarding the ZLB hence depends on the initial state of the economy in period t, represented by the vector of predetermined variables X_t. If the ZLB is disregarded, or not binding for any $\tau \geq 0$, the projections of the restricted and unrestricted policy rates will be the same,

$$i_{t+\tau,t} = i^*_{t+\tau,t} = f_X X_{t+\tau,t} + f_x x_{t+\tau,t}, \qquad \tau \geq 0.$$

Assume now that the policy-rate projection according to (B.10) violates the ZLB for one or several periods, that is,

$$i_{t+\tau,t} + \bar{\imath} < 0, \quad \text{for some } \tau \text{ in the interval } 0 \leq \tau \leq T. \tag{B.11}$$

In order to satisfy the ZLB, we then want to find a projection of the deviation z^t such that the policy-rate projection satisfies (B.5) and

$$i_{t+\tau,t} + \bar{\imath} = \max\{i^*_{t+\tau,t} + \bar{\imath}, 0\} = \max\{f_X X_{t+\tau,t} + f_x x_{t+\tau,t} + \bar{\imath}, 0\} \tag{B.12}$$

for $\tau \geq 0$. This requires that the projection of the deviation satisfies a nonnegativity constraint

$$z_{t+\tau,t} \geq 0, \qquad \tau \geq 0, \tag{B.13}$$

and that the policy-rate projection and the projection of the deviation satisfies the complementary-slackness condition

$$(i_{t+\tau,t} + \bar{\imath}) z_{t+\tau,t} = 0, \qquad \tau \geq 0. \tag{B.14}$$

Notice that the complementary-slackness condition implies that $z_{t+\tau,t} = 0$ if $i_{t+\tau,t} + \bar{\imath} > 0$.

For given X_t, we now proceed under the presumption that there exists a unique projection of the deviation z^t that satisfies (B.9) and (B.12)–(B.14).[at] We call this projection of the deviation and the corresponding policy-rate projection the *equilibrium*projection. This projection of the deviation either has all elements equal to zero (in which case the ZLB is not binding for any period) or has some elements positive and other elements zero. Let

$$\mathcal{T}_t \equiv \{0 \leq \tau \leq T \mid z_{t+\tau,t} > 0\}$$

denote the set of periods for which the projection of the deviation are positive in equilibrium.

For each $\tau \in \mathcal{T}_t$, the solution will satisfy

$$i_{t+\tau,t} + \bar{\imath} = F_i M^\tau \begin{bmatrix} X_t \\ z^t \end{bmatrix} + \bar{\imath} = 0 \quad \text{for} \quad \tau \in \mathcal{T}_t. \tag{B.15}$$

Let $n_{\mathcal{T}_t}$ denote the number of elements of $\mathcal{T}_t$, that is, the number of periods that the ZLB binds. The equation system (B.15) then has $n_{\mathcal{T}}$ equations to determine the $n_{\mathcal{T}}$ elements of z^t that are positive. From the system (B.15), it is clear that the solution for z^t and the set $\mathcal{T}_t$ will depend on X_t as well as the initial situation, and thereby also on the initial innovation ε_t. For other periods (that is $\tau \notin \mathcal{T}_t$), the ZLB will not be binding and the elements in z^t will be zero. The equation system (B.15) and the periods in the set $\mathcal{T}_t$ hence refer to the periods where the ZLB is *strictly* binding, that is, when $z_{t+\tau,t}$ is positive. Furthermore, it is important to notice that the set of periods τ in (B.11), for which the policy-rate projection (B.10) violates the ZLB, is not necessarily the same as the set of periods $\mathcal{T}_t$ for which the ZLB is strictly binding *in equilibrium*. That is because the projections of

[at] This assumption is discussed in further detail in Hebden et al. (2010).

the predetermined and forward-looking variables $X_{t+\tau,t}$ and $x_{t+\tau,t}$, that determine the unrestricted policy rate differ, depending on whether z^t is zero or not. This means that the whole policy-rate path is affected when the ZLB is imposed.

The difficulty in imposing the ZLB is to find the set $\mathcal{T}_t$ for which the ZLB is strictly binding in equilibrium, that is, to find the periods for which the equation system (B.15) applies. Once this is done, solving the equation system (B.15) is trivial. Hebden et al. (2010) outline a simple shooting algorithm to find the set $\mathcal{T}_t$.

B.2 Computation of the Likelihood Function

To compute the likelihood function, we follow the general idea outlined by Maih (2010). Maih's algorithm allows us to add anticipated policy shocks (using the algorithm outlined earlier) to the state space formulation of the model and filter those shocks with the Kalman filter to impose the zero lower bound on policy rates in the estimation. The appealing feature of Maih's algorithm is that it does not require us to include standard deviations for each of the anticipated policy shocks. Thus, the log-marginal likelihood can be directly compared to the models which does not impose the ZLB. For further details on the computation of the likelihood function in the face of the ZLB constraint, we refer to Lindé et al. (2016).

C. Data

In this appendix, we provide the sources on the data we use in the analysis.

C.1 Benchmark Model

The benchmark model is estimated using seven key macroeconomic time series: real GDP, consumption, investment, hours worked, real wages, prices, and a short-term interest rate. The Bayesian estimation methodology is extensively discussed by Smets and Wouters (2003). GDP, consumption and investment were taken from the US Department of Commerce—Bureau of Economic Analysis data-bank—on September 25, 2014. Real gross domestic product is expressed in billions of chained 2009 dollars. Nominal personal consumption expenditures and fixed private domestic investment are deflated with the GDP-deflator. Inflation is the first difference of the log of the implicit price deflator of GDP. Hours and wages come from the BLS (hours and hourly compensation for the nonfarm business, NFB, sector for all persons). Hourly compensation is divided by the GDP price deflator in order to get the real wage variable. Hours are adjusted to take into account the limited coverage of the NFB sector compared to GDP (the index of average hours for the NFB sector is multiplied with the Civilian Employment (16 years and over). The aggregate real variables are expressed per capita by dividing with the population size aged 16 or older. All series are seasonally adjusted. The interest rate is the Federal Funds Rate. Consumption, investment, GDP, wages, and hours are expressed in 100× log. The interest rate and inflation rate are expressed on a quarterly basis during the estimation (corresponding with their appearance in the model), but in the figures the series are reported on an annualized (400× first log difference) or yearly (100× the four-quarter log difference) basis.

C.2 Model with Financial Frictions

The first seven variables are exactly those used to estimate the benchmark model, which are described in Appendix C.1. In addition to those series, this model features an interest rate spread. Following Bernanke et al. (1999), this spread is measured as the difference between the BAA corporate interest rate and the US 10-year government yield.

ACKNOWLEDGMENTS

We thank the editors John B. Taylor and Harald Uhlig, as well as our discussant Jonas Fisher, for very helpful suggestions that significantly improved the chapter. Comments by participants in the Handbook conference at the Becker-Friedman institute in Chicago, the 18th Central Bank Macro Modeling Workshop (hosted by the Reserve Bank of New Zealand in Wellington), and seminars at the ECB and Sveriges Riksbank were also useful. We are heavily indebted to Junior Maih for developing code in RISE which allowed us to estimate models subject to the zero lower bound. A special thank you is also due to Mattias Villani, who allowed us to use his BVAR-code in which we could set steady state priors. Leonard Voltaire and Jessica Radeschnig provided excellent research assistance, but all remaining errors are ours. Frank Smets and Raf Wouters acknowledge financial support from the EU FP7-Project MACFINROBODS, grant 612796. The views, analysis, and conclusions in this chapter are solely the responsibility of the authors and do not necessarily agree with ECB, National Bank of Belgium, or the Sveriges Riksbank, or those of any other person associated with these institutions.

Abstract

We study a modification of the Diamond and Dybvig (1983) model in which the bank may hold a liquid asset, some depositors see sunspots that could lead them to run, and all depositors have incomplete information about the bank's ability to survive a run. The incomplete information means that the bank is not automatically incentivized to always hold enough liquid assets to survive runs. Regulation similar to the liquidity coverage ratio and the net stable funding ratio (that are soon be implemented) can change the bank's incentives so that runs are less likely. Optimal regulation would not mimic these rules.

Keywords

Bank runs, Bank regulation, Liquidity regulation, Net stable funding ratio, Liquidity coverage ratio

1. INTRODUCTION

In September 2009, the leaders of 20 major economies created the Financial Stability Board (FSB) whose purpose is to "coordinate at the international level the work of national financial authorities and international standard setting bodies (SSBs) in order to develop and promote the implementation of effective regulatory, supervisory, and other financial sector policies." Since that time the financial system has undergone a regulatory overhaul.

The term "macroprudential" regulation has become synonymous with much of this effort. As we explain in the next section, what that means in practice remains somewhat elusive. But, there are two tangible changes that are on track to occur over the remainder of this decade. One widely studied set of reforms pertain to the rules regarding capital requirements for banks. Less well-understood is that, through their cooperation via the Basel Committee on Bank Supervision, the major economies have also agreed also to implement by 2019 new rules governing banks' debt structures and requirements to hold certain types of liquid assets.

To date there is a remarkable asymmetry in the economic analysis of the capital and liquidity regulations. The pioneering work of Modigliani and Miller (1958) provides a solid theoretical framework for analyzing capital regulation. Any student taking a first course in corporate finance will encounter this theory, and there is a massive empirical literature that explores the theory's predictions. International regulations governing bank capital were introduced in 1988 and there many empirical examinations of the impact of these regulations. A recent book directed toward the general public, Admati and Hellwig (2013), makes a case for substantially increased capital requirements for commercial banks.

The discussion about regulating liquidity is much less advanced. For example, there is no benchmark theory regarding liquidity provision by intermediaries. Indeed, financial economists even have competing concepts that they have in mind when discussing liquidity, so that there is no generally accepted empirical measure of liquidity economists study. Allen (2014), in his survey of the nascent literature on liquidity regulation, concludes by writing "much more research is required in this area. With capital regulation there is a huge literature but little agreement on the optimal level of requirements. With liquidity regulation, we do not even know what to argue about."

Nonetheless, the global regulatory community has agreed on certain liquidity requirements (Basel Committee on Bank Supervision, 2013a, 2014). Two new concepts, the liquidity coverage ratio (LCR) and the net stable funding ratio (NSFR), have been proposed and banks by 2019 will be compelled to meet requirements for these ratios. Thus, it seems fair to say we are in a situation where practice is ahead of both theory and measurement.

In this chapter, we survey the existing work on liquidity regulation and develop a framework for discussing the regulation. The theory that we propose suggests, in certain parameterizations, regulations bearing some resemblance to the LCR and NSFR can emerge as ones which will improve outcomes relative to an unregulated benchmark. However, the regulations that arise in our model would naturally differ across banks, depending on certain bank characteristics, so they do not mimic exactly the ones that are on track to be implemented.

The critical ingredients in our model are the following. First, we consider banks which are spatially separated and hence do not compete aggressively for deposits. Treating the bank as monopolist simplifies the analysis by allowing us to side-step some complications that arise from having to model the deposit market equilibrium. The model can also be interpreted as a description of the aggregate banking system, which for many financial stability and regulatory discussions, is the object of primary concern, and under this interpretation ignoring the deposit competition is perhaps more natural.

Second, we assume that intermediaries provide liquidity insurance for customers who have uncertain withdrawal needs (or consumption desires). We build on the Diamond and Dybvig (1983), henceforth DD, model of banking in which banks provide this insurance by relying on the law of large numbers to eliminate idiosyncratic customer liquidity needs.

For those familiar with DD, we make two modifications. The first is allowing the bank to invest in a liquid asset that has a rate of return exceeding the return from liquidating illiquid assets and thus is the efficient way to arrange to pay customers that need liquidity. This introduces a trade-off between lending and holding liquidity as in Bhattacharya and Gale (1987), several papers of Allen and Gale (1997), and others.

The other modification to DD is the form of run risk that the banks face. Banks are assumed to have a good assessment of the aggregate needs of their customers for fundamental reasons. But, they also know that some customers will receive a signal about the bank which could lead to a run. The sunspots that we consider are a metaphor for people being concerned with the health of the bank, but not having a fully formed set of beliefs about the bank's solvency status. In making their decisions, we assume that customers are unable to fully evaluate the ability of the bank to honor deposits. Given the complexity of modern banks it seems realistic to presume that most customers cannot precisely determine their bank's maturity mismatch and hence its vulnerability to a run. The imperfect information creates a challenge for the banks because their customers will not necessarily know if the bank is prudently holding liquidity or not, which reduces the incentive to hold liquidity.

In the event that a run does occur, we depart from DD and Ennis and Keister (2006) to allow for the possibility that not all customers seek to withdraw their funds. We believe it is useful to analyze partial runs for two separate reasons. One is that in practice there do seem to be some sticky deposits that do not flee even in times of considerable banking stress. In addition, even before troubles occur it is usually clear which types of deposits are prone to running. So this allows us to talk about policies for different types of withdrawal risk.

Within this environment we can assess the vulnerability of the financial system to runs under different regulatory arrangements. In the baseline case, we assume that banks simply maximize their profits and see which types of equilibria arise. As usual in DD style models, the outcomes depend critically on how depositors form beliefs. It is possible, under certain parameter configurations, that the pure self-interest motives of the banks will sufficient to insure that the system will be run proof even if depositors had no detailed information about a bank's liquidity holdings. In these situations, added liquidity could not influence whether a given depositor would choose to join a run if one was feared.

We describe several reasons why depositors may not be able to use some types of disclosure of a bank's liquidity holdings to determine if the holding is sufficient to allow it to survive a run. To fix ideas, one can consider whether a bank would choose to hold this sufficient amount of liquidity even if its choice between liquid assets and illiquid loans was completely unobservable. In circumstances where depositors cannot be sure about how changes in liquidity holdings impact the robustness of banks to runs, the banks will typically face a tension in deciding how much to fortify themselves against the risk of a run. They can always choose to be sufficiently conservative to be able to withstand a worst case of fundamental withdrawals as well as a panic. But in order to do that, they will engage in very little lending, and the forgone profits from deterring the run will be high. The additional liquidity to survive a run will turn out to be excessive whenever a run is avoided. Hence, it is possible they will make more profits from added lending which would leave them unable to always be able to sustain a run.

We next allow regulatory interventions that place restrictions on present and possibly on future bank portfolio choices. In the baseline setup, the banks have perfectly aligned incentives to prepare to service fundamental aggregate withdrawal needs. So the regulatory challenge is to determine whether a requirement that distorts their private incentives toward being more robust to a run will improve outcomes. We allow for regulation that is inspired by the two impending Basel rules.

One variant requires an initial liquidity position that must be established before depositors make their intentions clear. This can function like the "NSFR" that is proposed as part of the Basel reforms. A second option is a mandate to always hold additional liquid assets beyond those needed for the fundamental withdrawals. This imposes both present and future minimum holdings of liquid assets. This regulation looks like a traditional reserve requirement for the bank but can also be interpreted as a kind of "liquidity coverage" ratio that is part of the Basel reforms.

One point of contention regarding the LCR that has emerged is whether required liquidity can be deployed in the case of a crisis. Goodhart (2008) framed the issue nicely with a now famous analogy of "the weary traveller who arrives at the railway station late at night, and, to his delight, sees a taxi there who could take him to his distant destination. He hails the taxi, but the taxi driver replies that he cannot take him, since local bylaws require that there must always be one taxi standing ready at the station."

One way to interpret the Goodhart conundrum is to recognize that, broadly speaking, there are two ways to think about the purpose behind liquidity regulations. One motivation can be to make sure that banks can better withstand a surge in withdrawals should one occur. From this perspective, mandating that the last cab cannot depart the station seems foolish. Another possible motivation is to design regulations aimed at reducing the likelihood of a withdrawal surge in the first place. Our model helps highlight the potential incentive properties of regulation and can potentially explain why mandating the presence of some unused liquidity could be beneficial.

In studying how private and social incentives for liquidity choices diverge, our main conclusion from analyzing the two Basel-style regulations is that they may improve outcomes relative to the ones that arise from pure self-interest, but each brings potential inefficiencies. Hence, we briefly also describe the solution of the mechanism design problem for a social planner who has less information about withdrawal risk than the bank does and seeks to optimally regulate banks to avoid runs. That solution provides a natural benchmark against which to judge the Basel-style regulations.

The remainder of the chapter is divided into five parts. Section 2 contains our selective overview of previous work. We organize this into three subsections. We begin with an overview of the emerging policy proposals and research regarding macroprudential regulation. We then hone in on the enormous and rapidly growing literature on capital regulation. We provide our perspective on how to group these papers and highlight several recent excellent surveys on the pure effects of capital regulation. We close with a review of the most relevant papers for our questions that motivate us about liquidity regulation.

Section 3 introduces the benchmark model. We explain how it works under complete information. We also derive a generic proposition that holds with incomplete information that describes when the bank's preferred liquidity choice will be sufficient to deter a run. Generically, however, privately chosen levels of liquidity need not be sufficient to deter runs. So this opens the door for regulations that might do so.

In Section 4, we analyze the two types of liquidity regulation that are akin to the ones contemplated under the Basel process. We first demonstrate that a particular type of regulation that requires the bank to hold liquid assets equal to a fixed percentage of deposits at all times can potentially deter runs. This works because the liquidity mandate, combined the bank's self-interest to prepare to service predictable deposit outflows, leads the bank to hold more overall liquidity than it would otherwise. Because depositors understand this, it removes the incentive to run in some cases. We also consider alternative assumptions about depositors' knowledge and the information available to regulators and assess the vulnerability of the bank to runs in these scenarios.

In Section 5, we describe a couple of extensions of the baseline model. The first sketches a mechanism design problem where the regulator does not have all of the bank's information and seeks to implement run-free banking. We fully characterize the solution to this problem in Diamond and Kashyap (2016), here we describe the main findings from this exercise. It turns out that a regulator with sufficient tools can induce the bank to hold the proper amount of liquidity despite the private information advantage possessed by the bank.

We also briefly discuss capital regulation. We explain why, as a tool for managing liquidity problems, capital requirements can be relatively inefficient compared to the other regulations that we have reviewed. Obviously in a richer model where both credit risk and liquidity risk are present, capital, and liquidity regulations can serve different purposes. We describe some of these differences.

Section 6 presents our conclusions. Besides summarizing our findings, we also pose a few open questions that are natural next steps to consider in addressing the issues analyzed in this chapter.

2. LITERATURE REVIEW

Research on financial regulation has exploded since the global financial crisis (GFC), and the number of regulatory interventions and tools has also expanded massively. To review all of this work would require a book. To keep our review manageable, we limit our discussion to focusing on the theoretical underpinnings and rationale behind these changes.[a]

2.1 Macroprudential Regulation

Clement (2010) provides the interesting history of the origins and evolution in the meaning of the phrase "macroprudential." His best estimate is that the term appeared first in 1979 in the documents of the committee that was the fore-runner to the Basel Committee on Bank Supervision. The first public document using the term which he can identify was a report by the committee now known as the Committee on the Global Financial System. It defined macroprudential policy as promoting "the safety and soundness of the broad financial system and payments mechanism."

The phrase took on added prominence when it was the focus of a Sept. 2000 speech by Andrew Crockett (who was then the General Manager of the Bank for International Settlements (Crockett, 2000)). He defined the objective of macroprudential policy to be "limiting the costs to the economy from financial distress, including those that arise from any moral hazard induced by the policies pursued." Crockett's rational for calling for macroprudential policies was his belief that optimal choices for a single institution could create problems for the financial system as a whole. He was explicitly focused on the distinction between the supervisory challenges for monitoring an individual institution and those for protecting the aggregate financial system.

[a] For a diverse set of perspectives on the changing postcrisis regulatory landscape see Čihák et al. (2013), Financial Stability Board (2015), Claessens and Kodres (2014), Basel Committee on Bank Supervision (2013a,b), and Fisher (2015).

Crockett did not offer precise microeconomic foundations for why the private actions of individual actors would not be aligned with social welfare, but he did give a few examples where he saw the potential for divergence. One possibility he cited is that one bank seeking to limit its credit exposures could choose to cut lending to its clients, but if all banks did this a credit crunch could ensue that would trigger a recession. A second example was the possibility of what we would now dub to be a fire-sale where all agents simultaneously cut back on asset exposures due to falling prices and in the course of doing so exacerbate the price decline. A third problem arises if many lenders shorten the maturity of their funding to a particular borrower, then the risk of a run can increase so that they are all more vulnerable.

Our view is that Crockett's spotlight on the divergence between the narrow private interests of individual institutions (or supervisors monitoring a single institution) and the interests of overall society is exactly the right focus for considering macroprudential policies. Indeed, this literature would be well-served to move in the direction where all macroprudential papers start by clarifying why (and when) social and private interests diverge. The challenge for both for researchers and policymakers is the difficulty in formalizing and prioritizing the exact reasons for the divergence. To clearly see the problem, compare three prominent perspectives on macroprudential regulation that have followed Crockett.

First, various BIS documents (eg, Clement, 2010) now interpret Crockett as having identified two types of problems that are to be addressed. One relates to the buildup of risks over time that are often now referred to as the procyclicality of the financial system or the "time dimension" of the macroprudential policy problem. The other relates to the distribution of risks within the financial system, the so-called cross-sectional dimension of the problem. Many official sector documents adopt the convention of separating time-series and cross-sectional macroprudential problems. As Clement (2010) notes, while the BIS work in this area has been relatively precise in the way these issues are discussed, "the usage of the term in the public sphere has on occasion been loose. It is not uncommon for it to be employed almost interchangeably with policies designed to address systemic risk or concerns that lie at the intersection between the macroeconomy and financial stability, regardless of the specific tools used."

In contrast, Hanson et al. (2011) start with a particular view of "how modern financial crises unfold, and why both an unregulated financial system, as well as one based on capital rules that only apply to traditional banks, is likely to be fragile." Their perspective, appealing to the model in Stein (2012), presumes that banks will find it cheaper to fund themselves with short-term debt than equity, so that banks have limited incentives to build strong equity buffers in normal times. If, in a crisis, such banks suffer substantial losses, then the market value of debt claims can fall below the face value, which will deter them from raising new equity (Myers, 1977). Consequently, in this case the banks are likely to comply with capital regulations by shrinking their asset base. Hence, Hanson et al. argue that the goal of macroprudential regulation should be to "control the social costs associated with excessive balance sheet shrinkage on the part of multiple financial institutions hit with a common shock."

A recent survey by the Norges bank staff, Borchgrevink et al. (2014), argues that in fact there are six market failures that can give rise to macroprudential concerns. These are pecuniary externalities, interconnectedness externalities, strategic complementarities, aggregate demand externalities, market for lemons, and deviations from full rationality. Not surprisingly they conclude "Because of the diversity of these categories, policy lessons diverge. There is yet no 'workhorse' model for policy analysis." Though they do argue that capital and liquidity regulation should tuned to aggregate conditions, not just those of individual banks, and that borrowers should be subjected to time-varying policies that aim to force them to internalize the costs of excessive borrowing.[b]

We share the Borchgrevink et al (2014) conclusion that the macroprudential literature at this point remains in sufficient flux that it is too soon to reach firm conclusions about where it will lead. Hence, for the remainder of our analysis we focus on capital and liquidity regulation where the range of issues to be considered can be narrowed and where specific global policies are being implemented.

2.2 Capital Regulation

For an overview of the literature on capital regulation, it is useful to sort papers along two dimensions. The first regards what is assumed regarding the Modigliani–Miller (1958) (henceforth MM) capital structure propositions. As in all models of corporate finance, absent failures of one of the MM propositions any choices regarding capital structure will be inconsequential. There have been four primary MM violations that have drawn attention in the literature.

One concerns that existence of deposit insurance. If certain parts of a bank's capital structure is protected from losses by the government, that can create risk-shifting incentives for equity holders. In many models, bank managers working on behalf of the equity owners face an incentive to gamble after adverse shocks that goes unchecked because depositors are immune from losses that they would suffer if the gamble fails.

A second distortion is concerns over guarantees to protect equity holders of banks from losses. Usually this is couched as a problem of having some banks that are assumed to be "too big" or "too-interconnected" to fail. But, in the recent GFC, there were also

[b] Others have also chosen to organize their analyses around distinctions between the kinds of tools that can be deployed. For example, Aikman et al. (2013) classify tools into three groups: those that operate on financial institutions' balance sheets; those that affect the terms and conditions on financial transactions; and those that influence market structures. While Cerutti et al. (2015) present empirical analyses comparing 12 types of different regulations.

cases in some countries where equity owners of smaller, nonsystemic banks were insulated from losses due to political connections.

A third violation regards the MM assumption of complete financial markets. With incomplete markets, an institution that creates new securities could be valuable. In the banking context, deposits are a leading example of special security that banks might create.

Finally, there are many models where either asymmetric information or moral hazard problems are considered. Some of the prominent examples include the possibility that borrowers know more about their investment opportunities than lenders, or that borrowers can shift the riskiness of their investments after receiving funding.

So unlike much of the research on nonfinancial corporations, the trade-off theory of capital structure, whereby firms prefer debt for its tax advantages and balance those benefits against costs of financial distress, has not figured prominently in the banking research on capital regulation. Rather, regulation is usually justified on the grounds of addressing one of these other four problems. The type of regulation that can be welfare improving will differ depending on which of these other frictions is assumed to be present.

The second important dimension one which the literature can be organized concerns the economic services that banks are assumed to provide.[c] Broadly, there are three types of services that have been modeled. The first presumes that certain financial institutions can expand the amount of credit that borrowers can obtain (say, relative to direct lending by individual savers). The micro-founded theories typically assume that borrowers can potentially default on loans and so any lender has to be diligent in monitoring borrowers (Diamond, 1984). By concentrating the lending with specialized agents, these monitoring costs can be conserved and the amount of credit extended can be expanded.

A second widely posited role for intermediaries is helping people and businesses share risks (Allen and Gale, 1997; Benston and Smith, 1976). There are many ways to formalize how this takes place, but perhaps the simplest is to recognize that because banks offer both deposits and equity to savers, they can create two different types of claims that would be backed by bank assets. These two choices allow savers to hedge some risks associated with lending, and this hedging improves the consumption opportunities for savers. More broadly, these theories suppose that banks help pool and tranche risks.[d]

A third class of models, which complements the second, supposes that the financial system creates liquid claims that facilitate transactions. There are various motivations behind how this can be modeled. In DD style models, an intermediary can cross-insure consumers' needs for liquidity by exploiting the law of large numbers among customers. But doing so exposes banks to the possibility of a run, which can be disastrous for the bank and its borrowers and depositors. Calomiris and Kahn (1991) and Diamond and Rajan (2001)

[c] The next few paragraphs are taken from Kashyap et al. (2014).

[d] For instance, if there are transactions costs associated with buying securities, a bank that makes no loans but holds traded securities could still be valuable.

explain that the very destructive nature of a run is perhaps helpful in disciplining the bank to work hard to honor its claims. So the fragility of runs is potentially important in allowing both high amounts of lending and large amounts of liquidity creation.

Gorton and Winton (2003) give a much more complete review of these three classes of theories and one clear conclusion that emerges is that depending on which of these three services is presumed to be operative, and which of the MM failures are present, one can reach very different conclusions about the efficacy of capital regulation in improving welfare. For instance, in models where liquidity creation is not one of the services provided by banks, the costs of mandating higher amounts of equity financing are often modest. Likewise, the benefits of protecting taxpayers from having to bail out banks or depositors by forcing more equity issuance are potentially substantial.

Rather than reviewing the results from many papers on capital regulation we refer interested readers to several recent surveys including Brooke et al (2015), Martynova (2015), Rochet (2014), and the references therein. Both Brooke et al. and Rochet attempt to compare the macroeconomic costs and benefits of higher levels of required capital and use a variety of calculations to assess them. In both cases, the benefits are presumed to be a reduction in likelihood and potential severity of financial crises (and the associated reductions in output). While the costs of higher capital requirements are the possible potential reductions in lending and losses of output. One humbling observation from both of these papers is that despite drawing on many different types of evidence, empirically estimating the net effects is difficult and there is substantial uncertainty about the overall net effects.

One other important observation is that most of the papers in these reviews are not very informative regarding liquidity regulation or the potential interactions of liquidity and capital regulation because in the environment being analyzed there is no value to liquidity creation (and hence no cost to limiting it). Indeed, Bouwman (2015), in a review article, emphasizes the dearth of research on potential interactions between capital and liquidity regulation and argues that it "is critically important to develop a good understanding of how capital and liquidity requirements interact."

2.3 Liquidity Regulation

As mentioned in Section 1, there are far fewer papers that seek to investigate the purpose and effect of liquidity regulation. Allen (2014) offers a survey of this nascent literature and we share the sentiment of the concluding paragraph of his survey. He writes, "much more research is required in this area. With capital regulation there is a huge literature but little agreement on the optimal level of requirements. With liquidity regulation, we do not even know what to argue about."

It is possible to again use a similar kind of two-way to classification regarding capital regulation to describe much of the thinking on liquidity. Trivially, if the economic services offered by a bank do not include the provision of liquidity, then regulation that focuses on liquidity will not be particularly interesting to consider. It is possible that in such environments regulating liquidity could make sense to achieve other aims, such as supplementing or substituting for capital requirements. However, if maturity transformation is not one of the outputs of the financial system, assessments of the efficacy of liquidity regulation in such models will be incomplete. Put bluntly, if there are no costs to limiting liquidity provision per se, then obviously the cost of regulations that have this effect cannot be fully assessed.

It is worth noting that will most of the literature on liquidity and liquidity regulation label the institutions that undertake this activity as "banks." However, as became evident in the GFC this activity is hardly limited to banks. Fig. 1, reproduced from

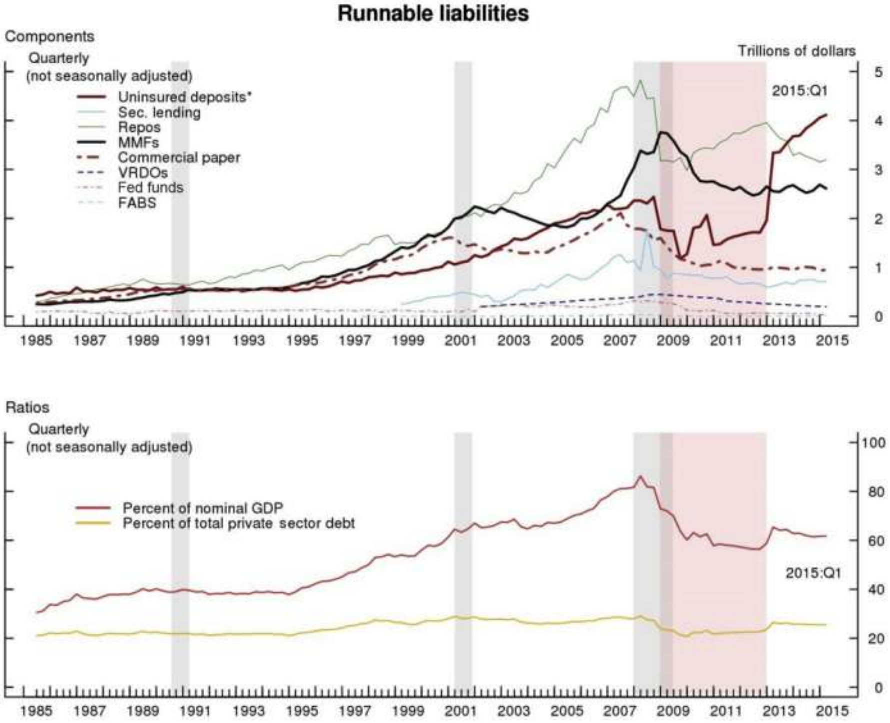

Fig. 1 Bao et al. (2015) estimates of runnable funding in the United States. *Uninsured deposits equal the difference between total deposits and insured deposits. The quarterly insured deposits series between 1985 and 1990 are obtained by interpolating the available annual data. For 2008:Q4–2012:Q4 (*red* (*light gray* in print version)) *shades*, insured deposits increased due to the Transaction Account Guarantee (TAG) program. For 2008:Q4–2009:Q2, some insured deposits were not accounted for because the FDIC did not collect data on insured amounts for those TAG accounts with balances between $100,000 and $250,000. *Note*: The *gray shades*, which overlap the *red* (*light gray* in print version) *shades*, indicate NBER recession dates. Source: *Staff calculations using data from RMA, DTCC, SIFMA, Call Reports, Financial Accounts, M3 monetary aggregates, and Bloomberg Finance LP.*

Bao et al. (2015), shows the total amount of runnable funding inside the US financial system over the past 30 years.

We draw three conclusions from their estimates that are worth bearing in mind throughout the rest of the discussion. First, there has been a sizable increase in the amount maturity transformation over the last 20 years. From 1995 until 2015, the scale of such activity rose by 50% as measured relative to gross domestic product (GDP). Second, as far back as 1985 as much of this activity has occurred outside the banking system as inside it. Third, the decline immediately after the GFC was sizable. The drop in repurchase agreements and money market funds were especially pronounced, but even as a percent of GDP, the level in 2015 is very similar to the level in 2005 (just before the frenzied period ahead of the GFC). Hence, maturity transformation is still happening on a substantial scale even after the GFC and all of the various regulatory reforms that have been introduced.

Given this evidence, we focus only on papers where one of the services of the financial system is to provide liquidity. Among these it is helpful to separate them into papers that model liquidity provision in the same way or similarly to DD, and those that introduce other mechanisms.

Among the DD style models, we focus on three that are closely related to our analysis. Ennis and Keister (2006) have a DD style model (related to Cooper and Ross, 1998) which determines how much liquidity banks need to hold to deter runs. They compute the amount of excess liquidity the bank must hold to buffer it against a run by all depositors, and also determine the optimal amounts to promise depositors. In their model with full information, when depositors desire safe banks, there will be private incentives to hold enough excess liquidity to deter a sunspot-based run. They do not study regulation because there is no need for any under their assumptions, but we will see that some of the same forces that are present in their model arise in ours.

Vives (2014) analyzes a question similar to that in Ennis and Keister (2006): what are the efficient combinations of equity capital and liquidity holdings to make a bank safe when it subject to runs based on private information about its solvency? He studies a global game where a bank can be insolvent or illiquid. The need for regulation is not considered explicitly, but he does examine what capital and liquidity levels would make the bank safer. He finds that capital and liquidity are differentially successful in attending to insolvency and illiquidity. In particular, if depositors are very conservative (and which makes them more inclined to run in the model), increased liquidity holdings which reduce profits by investing more in liquid assets can enhance stability.

Farhi et al. (2009) investigate a DD model where consumers need banks to invest and where the consumers can trade bank deposits. Absent a minimum liquidity regulation, it is profitable to free ride on the liquidity held by other banks, because banks offer rates which subsidize those who need to withdraw their deposit early (which is the spirit of Jacklin, 1987). A floor on liquidity holdings removes the incentive for this free riding.

Among the non-DD models, one that is related is Calomiris et al. (2014). They have a six period model where banks can potentially engage in risk-shifting so that when banks suffer loan losses they may not be able to honor their deposit contracts. Cash is observable and mandating that banks must have minimum levels of cash reserves can limit the risk-shifting.

Santos and Suarez (2015) examine another role for liquidity when runs occur slowly; it allows time to decide if the bank's assets are sufficient to imply solvency absent a run. This channel is foreclosed in our setup with assets which are free of risk.

More generally, our approach is closely related to the mechanism design approach to regulation of monopolists in Baron and Myerson (1982). They also were interested in investigating how regulation could be structured to induce the party being regulated to efficiently use information that is private.

3. BASELINE MODEL

We begin by describing a baseline setup in which the timing and preferences are as in DD. We then modify certain informational assumptions to bound the possible outcomes. Throughout we maintain that there are three dates: $T=0$, 1, and 2. The interest rates that bank must offer are taken as given, motivated by a monopoly bank which must meet the outside option of depositors to attract deposits. Equivalently, the single bank can be thought of as representing the overall banking system.
