Suppose that the utility function is unbounded below, so that $w_v\left(\theta_{(2)}\right)$ is always interior. Consider the random variable $K'(v_t(\theta^t))$ defined recursively on the probability space $(\Theta^\infty, \mathcal{B}(\Theta^\infty), \pi_\infty)$ starting at $K'(v_0)$. The sequence $\{K'(v_t(\theta^t)), \mathcal{B}(\Theta^t)\}_{t=1,2,\ldots,}$ is a martingale. Indeed, $\{\mathcal{B}(\Theta^t)\}_{t\geq 1}$ is an increasing sequence of σ-algebras, $K'(v_t)$ is measurable with respect to $\mathcal{B}(\Theta^t)$, $\mathbb{E}_0[|K'(v_t)|] = -\mathbb{E}_0[K'(v_t)] = -K'(v_0) < \infty$, and $\mathbb{E}_t[K'(v_{t+1})] = K'(v_t)$ follows from Proposition 5. Hence all the conditions of Definition 1 are satisfied, and Theorem 2 implies that $K'(v_t)$ converges almost surely to a random variable X. That is, for almost all histories $\theta^\infty \in \Theta^\infty$, we have $K'(v_t(\theta^t)) \to X(\theta^\infty)$. The following proposition, the proof of which follows Thomas and Worrall (1990), further characterizes the limit of the sequence:

Proposition 6 *Suppose that the utility function satisfies Assumption 1, shocks satisfy Assumptions 2 and 3, $|\Theta| = 2$, and $T = \infty$.*[j] *If the utility function is unbounded below, then $v_t(\theta^t) \to -\infty$ as $t \to \infty$ with probability 1. If the utility function is bounded below by $\underline{v}$, then the unique invariant distribution of continuation utilities on $\mathbb{V}$ assigns mass 1 to the lower bound $\underline{v}$.*

Proof Suppose that the utility function is unbounded below. Then $K'(v_t(\theta^t))$ is a martingale, and Theorem 2 implies that for almost all θ^∞, $K'(v_t(\theta^t))$ converges to some random variable $X(\theta^\infty)$. We now show that its limit $X(\theta^\infty)$ is equal to 0 almost surely.

Consider a path θ^t such that $K'(v_t(\theta^t)) \to \kappa < 0$. The sequence $v_t(\theta^t)$ thus converges to $\hat{v} > \underline{v}$, solution to $K'(\hat{v}) = \kappa$. With probability 1, the state $\theta_{(2)}$ occurs infinitely often on this path. Take the subsequence composed of the dates $\{t_n\}_{n=1,2,\ldots}$ where the state $\theta_{(2)}$ occurs. We have $\lim_{n\to\infty} v_{t_n-1}\left(\theta^{t_n-1}\right) = \hat{v}$ and $\lim_{n\to\infty} v_{t_n}\left(\theta^{t_n}\right) = \hat{v}$. Since the policy function $w_v(\theta)$ is continuous in v for all $\theta \in \Theta$, we obtain

$$\lim_{n\to\infty} w_{v_{t_n-1}\left(\theta^{t_n-1}\right)}\left(\theta_{(2)}\right) = w_{\hat{v}}\left(\theta_{(2)}\right).$$

But $w_{v_{t_n-1}\left(\theta^{t_n-1}\right)}\left(\theta_{(2)}\right) = v_{t_n}\left(\theta^{t_n-1}, \theta_{(2)}\right) = v_{t_n}\left(\theta^{t_n}\right)$, hence we also have

$$\lim_{n\to\infty} w_{v_{t_n-1}\left(\theta^{t_n-1}\right)}\left(\theta_{(2)}\right) = \hat{v}.$$

This implies that $w_{\hat{v}}\left(\theta_{(2)}\right) = \hat{v}$, which contradicts the inequality $w_{\hat{v}}\left(\theta_{(2)}\right) < \hat{v}$ proved in Proposition 5.

[j] The condition $|\Theta| = 2$ is not important for this proposition. It is easy to show that the martingale property (29) holds for any number of shocks.

Now suppose that the utility function is bounded below by $\underline{v} > -\infty$. In this case $-K'(v_t(\theta^t))$ is a (possibly unbounded) submartingale. Note that the point $\underline{v}$ is absorbing, ie, $u_{\underline{v}}(\theta) = \underline{u}$ and $w_{\underline{v}}(\theta) = \underline{v}$ for all $\theta \in \Theta$. Consider an invariant distribution Ψ of continuation utilities on $\mathbb{V}$, and let $\mathrm{Supp}(\Psi) \subset \mathbb{V}$ denote its support. Let $\mathcal{M}_v$ denote the Markov chain characterizing the law of motion of continuation utilities, starting at v. Define the set $\mathrm{S}_1 \subset \mathrm{Supp}(\Psi)$ consisting of all the continuation utility values v for which $\mathcal{M}_v$ reaches $\underline{v}$ in a finite number of steps with positive probability, and the set $\mathrm{S}_2 = \mathrm{Supp}(\Psi) \setminus \mathrm{S}_1$. By construction of S_1, every state $v \in \mathrm{S}_1 \setminus \{\underline{v}\}$ is transient, so that such a v cannot be in the support of the invariant distribution. Now, for $v \in \mathrm{S}_2$, the Markov chain $\mathcal{M}_v$ defines a sequence $\{v_t(\theta^t)\}_{t,\theta^t}$. By construction of S_2, the process $K'(v_t(\theta^t))$ is a martingale and the previous arguments show that v cannot be in the support of the invariant distribution. Therefore $\mathrm{Supp}(\Psi) = \{\underline{v}\}$. □

The result of Proposition 6 is often referred to as the *immiseration* result. It shows that a feature of the optimal contract is that agents' consumption, c_t^*, goes to 0 with probability 1 as $t \to \infty$. When the utility function is unbounded below, this implies that agents' utility diverges to $-\infty$; otherwise the only invariant distribution is degenerate and assigns probability 1 to $\dfrac{U(0)}{1-\beta}$. Note that the fact that $c_t^* \to 0$ with probability 1 does *not* mean that everyone's consumption converges to zero. As we saw in Proposition 5, an agent with shock realization $\theta_{(1)}$ always gets a strictly higher promised utility (and hence consumption) in the future. Thus there are always some agents (whose measure goes to zero as $t \to \infty$) with strictly positive consumption. In Section 3.1.2 we shut down the intertemporal transfer of resources and show that the immiseration result still holds in this setting. This will imply that in order to provide incentives for agents to reveal their private information, the planner needs to increase inequality without bounds over time. As time goes to infinity this inequality grows until a measure 0 of agents consume the entire endowment of the economy.

The intuition for this result is as follows. To provide agents with incentives to reveal information in the current period, the principal needs to commit to increasing inequality (in promised utilities and therefore consumption) in the future. When the interest rate is equal to the discount factor, as we assumed in this section, there are no offsetting forces and inequality under the optimal contract grows over time. In the infinite period economy it approaches an extreme level as $t \to \infty$, where only a measure zero of agents have positive consumption. We revisit this result in subsequent sections, especially in Sections 2.4.3 and 3.2.

2.4.3 Existence of a Nondegenerate Invariant Distribution

In this section we show in a simple example that there can exist a nondegenerate invariant distribution of utilities if additional constraints are imposed. We study the case where the planner is required to promise future utilities in a compact set $[\underline{w}, \bar{w}]$, with $\underline{v} < \underline{w} < \bar{w} < \bar{v}$. In Section 3.2 we show how similar constraints can emerge from more sophisticated political economy arguments, but for now we simply impose[k]

$$w(\theta) \in [\underline{w}, \bar{w}], \forall \theta \in \Theta \tag{37}$$

in problem (23). It is easy to see that the solution to the modified Bellman equation continues to satisfy the results of Lemma 1 except for the fact that $K'(v)$ is now strictly negative and finite on the set $[\underline{w}, \bar{w}]$.

Lemma 2 *Suppose that all the assumptions of Proposition 5 are satisfied and in addition the constraint (37) is imposed. Then there are no absorbing points:* $w_v(\theta_{(1)}) > w_v(\theta_{(2)})$ *for all* $v \in [\underline{w}, \bar{w}]$.

Proof Suppose $w_v(\theta_{(1)}) = w_v(\theta_{(2)}) = v \in [\underline{w}, \bar{w})$ for some v, implying (from (19) and (27)) that $u_v(\theta_{(1)}) = u_v(\theta_{(2)}) = (1-\beta)v$. Thus $K(v) = \underline{K}(v) \equiv -\frac{1}{1-\beta}C((1-\beta)v)$, where $\underline{K}(v)$ was defined in the proof of Lemma 1. Subtracting Eqs. (30) from (32) (written as an inequality because of the condition $w_v(\theta_{(1)}) \geq \underline{w}$), we obtain

$$K'(v) \leq -\frac{1}{\theta_{(1)}} C'((1-\beta)v) = \frac{1}{\theta_{(1)}} \underline{K}'(v).$$

But $\theta_{(1)} < 1$ contradicts the fact that $K(v') \geq \underline{K}(v')$ for all $v' > v$. For $v = \bar{w}$, a similar reasoning with Eqs. (31) and (33) (written as an inequality because of the condition $w_v(\theta_{(2)}) \leq \bar{w}$) implies that $K'(w_v(\theta_{(2)})) \geq \frac{1}{\theta_{(2)}} \underline{K}'(w_v(\theta_{(2)})) + \frac{\xi_v}{\pi(\theta_{(2)})}\left(1 - \frac{\theta_{(1)}}{\theta_{(2)}}\right)$ and leads to the same conclusion. □

We show next that a nondegenerate long-run distribution of utilities and consumption exists.

Proposition 7 *Suppose that all the assumptions of Proposition 5 are satisfied and in addition the constraint (37) is imposed. Then there exists a unique invariant and nondegenerate distribution* Ψ *of utilities, and for any initial measure* Ψ_0 *on the state space,* $\mathcal{T}^n(\Psi_0)$ *converges to* Ψ^* *as* $n \to \infty$ *at a geometric rate that is uniform in* Ψ_0.

Proof The result follows from Theorem 11.12 in Stokey et al. (1989), which holds if condition M (p. 348 in Stokey et al., 1989) is satisfied. To show this condition, it is

[k] Our arguments here adapt Atkeson and Lucas (1995) and Phelan (1995). See also Farhi and Werning (2007) and Hosseini et al. (2013).

sufficient to prove that there exists $\underline{\varepsilon} > 0$ and an integer $N < \infty$ such that, for all $v \in [\underline{w}, \bar{w}]$, $P^N(v, \underline{w}) \geq \underline{\varepsilon}$, where P denotes the transition matrix of the Markov chain $\mathcal{M}$ that characterizes the law of motion of continuation utilities; that is, the probability of reaching $\underline{w}$ in N steps starting from any v is at least as large than $\underline{\varepsilon}$.

To show this we proceed in two steps. First, we prove that if the continuation utility v in the current period is close enough to $\underline{w}$, receiving a high taste shock $\theta_{(2)}$ implies that the promised utility in the next period is $\underline{w}$. That is, there exists $\varepsilon > 0$ such that, for all $v \leq \underline{w} + \varepsilon$, we have $w_v(\theta_{(2)}) = \underline{w}$. Suppose by contradiction that this is not the case, and consider a sequence $v_n > \underline{w}$ with $\lim_{n \to \infty} v_n = \underline{w}$, such that $w_{v_n}(\theta_{(2)}) > \underline{w}$ for all n. The martingale property (29) then writes

$$K'(v_n) = \pi(\theta_{(1)}) K'(w_{v_n}(\theta_{(1)})) + \pi(\theta_{(2)}) K'(w_{v_n}(\theta_{(2)})).$$

Letting $n \to \infty$ in this equation imposes $w_{\underline{w}}(\theta_{(1)}) = w_{\underline{w}}(\theta_{(2)}) = \underline{w}$, which contradicts Lemma 2.

Second, we prove that there exists $\delta > 0$ such that, for any $v > \underline{w} + \varepsilon$, receiving a high taste shock $\theta_{(2)}$ implies that the promised utility in the next period, $w_v(\theta_{(2)})$, is smaller than $v - \delta$. To show this, note that since $w_v(\theta_{(2)})$ is continuous in v, it is either bounded away from the 45 degree line for $v \geq \underline{w} + \varepsilon$, or $w_v(\theta_{(2)}) = v$ for some $v \in [\underline{w} + \varepsilon, \bar{w}]$. By the martingale property, the latter implies that $w_v(\theta_{(1)}) = v$, contradicting Lemma 2.

These results imply that there exists $N < \infty$ such that, for any $v \in [\underline{w}, \bar{w}]$, the promised utility after a sequence of N high taste shocks $\theta_{(2)}$, starting from v, is $\underline{w}$. This implies that $\underline{\varepsilon} < \pi(\theta_{(2)})^N$ is a uniform lower bound on the probability of being at $\underline{w}$ in N steps. Thus condition M is satisfied in Stokey et al. (1989), which concludes the proof. □

The immiseration result does not hold in the case where expected discounted utilities are constrained by (37), because the lower bound $\underline{w} > \underline{v}$ acts as a reflective (rather than absorbing) barrier (Lemma 2), creating a form of mean reversion that leads to a nondegenerate invariant distribution.

2.4.4 A Simple Example

In this section we address one remaining issue of our analysis. Proposition 4 showed that the allocation generated by the policy functions of our Bellman equation is the solution to the original problem (9) as long as it satisfies the limiting conditions (25) and (26). These conditions are trivially satisfied if the utility function is bounded, but many convenient functional forms assume an unbounded utility. In this section we analyze a simple example with unbounded utility in which we can easily verify conditions (25) and (26). This example also leads to a characterization of the solution to the Bellman equation "almost" in closed form.

We assume a logarithmic utility function $U(c) = \ln c$. Similar arguments can be applied to CRRA and CARA preferences. Note that $(\mathbf{u}, \mathbf{v}) \in \Gamma(v_0)$ if and only if

$(\mathbf{u}-(1-\beta)v_0, \mathbf{v}-v_0) \in \Gamma(0)$, where $\Gamma(\cdot)$ is defined in (16). We can thus rewrite the dual planner's problem (21) as

$$K(v_0) = \max_{(\mathbf{u},\mathbf{v})\in\Gamma(v_0)} \mathbb{E}_0\left[-\sum_{t=1}^{\infty}\beta^{t-1}\exp(u_t)\right]$$
$$= \max_{(\tilde{\mathbf{u}},\tilde{\mathbf{v}})\in\Gamma(0)} \mathbb{E}_0\left[-\sum_{t=1}^{\infty}\beta^{t-1}\exp(\tilde{u}_t+(1-\beta)v_0)\right] = \exp((1-\beta)v_0)K(0).$$

This implies that if $\{u_0(\theta), w_0(\theta)\}_{\theta\in\Theta}$ is the solution to the Bellman equation (23) for $v=0$, then $\{u_0(\theta)+(1-\beta)v, w_0(\theta)+v\}_{\theta\in\Theta}$ is the solution to (23) for any v. This property allows us to establish bounds on the left hand sides of (25) and (26). If we start with some initial v_0 and generate $(\mathbf{u},\mathbf{v})$ using the policy functions $(u_v(\theta), w_v(\theta))$ of the Bellman equation (23) as described in Section 2.3, we have

$$v_t(\theta^t) = w_{v_{t-1}(\theta^{t-1})}(\theta_t) = v_{t-1}\left(\theta^{t-1}\right) + w_0(\theta_t)$$
$$= w_{v_{t-2}(\theta^{t-2})}(\theta_{t-1}) + w_0(\theta_t) = v_{t-2}\left(\theta^{t-2}\right) + w_0(\theta_{t-1}) + w_0(\theta_t)$$
$$= \cdots = v_1\left(\theta^1\right) + w_0(\theta_2) + \cdots + w_0(\theta_t) = v_0 + \sum_{s=1}^{t} w_0(\theta_s).$$

Let $\underline{A} \equiv \min_\Theta\{w_0(\theta)\}$ and $\bar{A} \equiv \max_\Theta\{w_0(\theta)\}$, so that $\underline{A} \le w_0(\theta) \le \bar{A}$ for all $\theta \in \Theta$. Then $\beta^t(v_0+t\underline{A}) \le \beta^t v_t(\theta^t) \le \beta^t(v_0+t\bar{A})$ for all t, θ^t. Since $\lim_{t\to\infty}\beta^t t = 0$, this implies that $\lim_{t\to\infty}\beta^t v_t(\theta^t) = 0$ for all $\theta^\infty \in \Theta^\infty$, which implies both (25) and (26).

Since the value function K is homogeneous, it is easy to find it "almost" in closed form. Our arguments established that $K(v) = a\exp((1-\beta)v)$ for some $a < 0$. The parameter a can then be found as a fixed point of the equation

$$a = \max_{(\vec{u},\vec{w})\in B(0)} \sum_{\theta\in\Theta} \pi(\theta)[-\exp(u(\theta)) + \beta a \exp((1-\beta)w(\theta))].$$

The arguments used in this example can be extended to utility functions in the CRRA or CARA classes by observing that if $(\mathbf{u},\mathbf{v}) \in \Gamma(v_0)$ then $\left(\frac{1}{|v_0|}\mathbf{u}, \frac{1}{|v_0|}\mathbf{v}\right) \in \Gamma\left(\frac{v_0}{|v_0|}\right)$.

2.5 Autocorrelated Shocks

2.5.1 General Approach

We now address the case where the taste shocks θ follow a first-order Markov process. The goal of this section is to derive a recursive formulation for the planner's dual problem. We assume that the probabilities of the first period types $\theta_1 \in \Theta$ are given by $\pi\left(\theta_1 \middle| \theta_{(1)}\right)$, ie, as if the type realization in period 0 was the seed value

$\theta_{(1)}$. This assumption carries no loss of generality and simplifies the exposition. Fernandes and Phelan (2000) show how to write a recursive formulation of the planner's problem in this environment.

We define the analogue of the temporary incentive-compatibility constraint (10) in the case where shocks are first-order Markov as follows. For all $\theta^{t-1},\theta,\hat{\theta}$,

$$\theta U\left(c_t\left(\theta^{t-1},\theta\right)\right) + \beta \sum_{s=1}^{T-t} \sum_{\theta^{t+s}\in\Theta^{t+s}} \beta^{s-1}\pi_{t+s}\left(\theta^{t+s}\middle|\theta^{t-1},\theta\right)\theta_{t+s}U\left(c_{t+s}\left(\theta^{t-1},\theta,\theta_{t+1}^{t+s}\right)\right)$$

$$\geq \ \theta U\left(c_t\left(\theta^{t-1},\hat{\theta}\right)\right) + \beta \sum_{s=1}^{T-t} \sum_{\theta^{t+s}\in\Theta^{t+s}} \beta^{s-1}\pi_{t+s}\left(\theta^{t+s}\middle|\theta^{t-1},\theta\right)\theta_{t+s}U\left(c_{t+s}\left(\theta^{t-1},\hat{\theta},\theta_{t+1}^{t+s}\right)\right). \tag{38}$$

The one-shot-deviation result of Proposition 2 extends to the problem with persistent shocks:

Lemma 3 *Suppose that either T is finite, or U is bounded. Suppose moreover that the shocks θ follow a first-order Markov process. An allocation $\mathbf{c}$ satisfies (8) if and only if it satisfies (38).*

Proof Suppose that (8) is violated for some strategy $\boldsymbol{\sigma}'$ but (38) holds. If $\boldsymbol{\sigma}'$ involves misreporting at finitely many nodes, the arguments of Proposition 2 apply directly. If T is infinite and $\boldsymbol{\sigma}'$ recommends lying at infinitely many nodes, we have, by the previous result,

$$\sum_{t=1}^{\infty}\sum_{\theta^t\in\Theta^t}\beta^{t-1}\pi_t(\theta^t)\theta_t U(c_t(\theta^t)) \geq \sum_{t=1}^{\infty}\sum_{\theta^t\in\Theta^t}\beta^{t-1}\pi_t(\theta^t)\theta_t U(c_t(\sigma'^t(\theta^t)))$$

$$\ldots - \beta^T\left[\sum_{s=1}^{\infty}\sum_{\theta^{T+s}\in\Theta^{T+s}}\beta^{s-1}\pi_{T+s}\left(\theta^{T+s}\right)\theta_{T+s}\left(U\left(c_{T+s}\left(\sigma'^{T+s}\left(\theta^{T+s}\right)\right)\right) - U\left(c_{T+s}\left(\theta^{T+s}\right)\right)\right)\right].$$

Since the utility is bounded, the second line converges to zero as $T \to \infty$, which establishes that if $\mathbf{c}$ satisfies (38) then it satisfies (8). □

We follow Section 2.3 and redefine our maximization problem with respect to $u_t(\theta^t)$ rather than $c_t(\theta^t)$. We now emphasize the main differences that persistent shocks introduce. As in Section 2.3, we start by assuming that T is finite.

Finite-period economy

In this section we consider the case $T < \infty$. For any history $\theta^t \in \Theta^t$ and any $\theta' \in \Theta$, define $v_t(\theta^t|\theta')$ as

$$v_t(\theta^t|\theta') \equiv \sum_{s=1}^{T-t} \sum_{\theta^{t+s} \in \Theta^{t+s}} \beta^{s-1} \pi_{t+s}\left(\theta_{t+1}^{t+s}|\theta'\right)\theta_{t+s} u_{t+s}\left(\theta^t, \theta_{t+1}^{t+s}\right), \tag{39}$$

where $\left(\theta^t, \theta_{t+1}^{t+s}\right)$ denote the histories θ^{t+s} whose first t elements are θ^t. This allows us to write (38) as

$$\theta u_t\left(\theta^{t-1}, \theta\right) + \beta v_t\left(\theta^{t-1}, \theta|\theta\right) \geq \theta u_t\left(\theta^{t-1}, \hat{\theta}\right) + \beta v_t\left(\theta^{t-1}, \hat{\theta}|\theta\right), \forall \theta^{t-1}, \theta, \hat{\theta}. \tag{40}$$

Unlike the case of i.i.d. shocks, considered in Section 2.3.1, the continuation utility of an agent who reports θ^t depends not only on the history of reports but also on the true period-t shock θ'_t of the agent. The economic intuition for this result is that when shocks are autocorrelated, the realization of the shock θ'_t is informative about the realization of future shocks from period $t+1$ onward. Repeated substitution allows us to rewrite v_t as

$$v_t(\theta^t|\theta') = \sum_{\theta \in \Theta} \pi(\theta|\theta')[\theta u_{t+1}(\theta^t, \theta) + \beta v_{t+1}(\theta^t, \theta|\theta)], \forall \theta^t, \theta', \tag{41}$$

with the convention that $v_T\left(\theta^T|\theta'\right) = 0$ if T is finite. The initial utility v_0 is given by

$$v_0 = \sum_{\theta \in \Theta} \pi\left(\theta|\theta_{(1)}\right)[\theta u_1(\theta) + \beta v_1(\theta|\theta)]. \tag{42}$$

Let $\mathbf{v} = \left\{v_t\left(\theta^t|\theta'_t\right)\right\}_{t \geq 1, \theta^t \in \Theta^t, \theta'_t \in \Theta}$. The set $\Gamma(v_0)$ is now defined as the set of allocations $(\mathbf{u}, \mathbf{v})$ that satisfy (40)–(42). The direct extension of the arguments of Section 2.3 implies that the optimal incentive-compatible allocation (ie, the solution to the primal problem (9)) exists and is a solution to the dual maximization problem

$$\widetilde{K}_0(v_0) \equiv \max_{(\mathbf{u}, \mathbf{v}) \in \Gamma(v_0)} \left[-\sum_{t=1}^{T} \sum_{\theta^t \in \Theta^t} \beta^{t-1} \pi_t\left(\theta^t|\theta_{(1)}\right) C(u_t(\theta^t))\right]. \tag{43}$$

This problem can be written recursively following the same ideas as we used to obtain the Bellman equation (18), with two differences: (i) the state space is larger when the shocks are autocorrelated, and (ii) the space of feasible values for the state variables is now more difficult to characterize. We show both of these differences using backward induction arguments.

The need for the larger state space can be seen already from the incentive constraints. Each history of reports θ^t has an associated $|\Theta|$-dimensional *vector* of "promised utilities" $v_t(\theta^t|\cdot) = \left\{v_t\left(\theta^t|\theta_{(j)}\right)\right\}_{j=1}^{|\Theta|}$, where for each j, $v_t\left(\theta^t|\theta_{(j)}\right)$ is the promised utility allocated to the agent who reported history θ^t and whose true type in period t was actually $\theta_{(j)}$. Moreover, the expectation over the future realizations of shocks in period $t+1$ depends on the period-t realized shock θ'_t. Therefore the state space has dimensionality $|\Theta| + 1$. We now describe the recursive construction of the value function $K_{t-1}\left(v\left(\theta_{(1)}\right), \ldots, v\left(\theta_{(|\Theta|)}\right), \theta_-\right)$

and its domain $\mathcal{V}_{t-1} \times \Theta$. Let $\mathcal{V}_{T-1}$ be the space of all vectors $v(\cdot) \in \mathbb{R}^{|\Theta|}$ with the property that there exists some $u \in \mathbb{U}$ such that $v(\theta_{(i)}) = u \sum_{\theta \in \Theta} \pi(\theta | \theta_{(i)}) \theta$ for all $i \in \Theta$. Let $K_{T-1}(v(\cdot), \theta) = -C(u)$ for all such $v(\cdot) \in \mathcal{V}_{T-1}$. This definition simply captures the fact that in the last period the principal cannot provide any insurance against the period-T shocks (by incentive compatibility (40)), and K_{T-1} is then (minus) the cost of the feasible promises that the principal can make in period $T - 1$. For $0 \leq t \leq T-2$ define K_t recursively as

$$K_t(v(\cdot), \theta_-) = \max_{\{u(\theta), w(\theta|\cdot)\}_{\theta \in \Theta}} \sum_{\theta \in \Theta} \pi(\theta|\theta_-)[-C(u(\theta)) + \beta K_{t+1}(w(\theta|\cdot), \theta)] \tag{44}$$

subject to the promise-keeping constraints

$$v(\theta_{(j)}) = \sum_{\theta \in \Theta} \pi(\theta | \theta_{(j)})[\theta u(\theta) + \beta w(\theta|\theta)], \forall j \in \{1, \ldots, |\Theta|\}, \tag{45}$$

the incentive-compatibility constraints

$$\theta u(\theta) + \beta w(\theta|\theta) \geq \theta u(\hat{\theta}) + \beta w(\hat{\theta}|\theta), \forall \theta, \hat{\theta} \in \Theta, \tag{46}$$

and

$$u(\theta) \in \mathbb{U}, \quad w(\theta|\cdot) \in \mathcal{V}_{t+1}, \quad \forall \theta \in \Theta. \tag{47}$$

The domain of K_t is $\mathcal{V}_t \times \Theta$, where $\mathcal{V}_t$ is defined as the set of all $v(\cdot) \in \mathbb{R}^{|\Theta|}$ with the property that there exist $\{u(\theta), w(\theta|\cdot)\}_{\theta \in \Theta}$ such that the constraints (45), (46), and (47) are satisfied.

So far we defined K_t from purely mathematical considerations by observing that the solution to the maximization problem (43) after any history θ^t could be found independently of any other history $\hat{\theta}^t$, as long as we keep track of the vector $v(\cdot)$ and the realization of the period-t shock θ'_t. It is useful to describe the economic intuition behind these equations. Eq. (46) is simply the incentive constraint, familiar from Section 2.3. Eq. (45) for $\theta_{(j)} = \theta_-$ summarizes the expected utility that an agent with period-$(t-1)$ shock θ_- receives in period t. This equation is the analogue of the promise-keeping constraint (19) in the i.i.d. case. Eq. (45) for $\theta_{(j)} \neq \theta_-$ are auxiliary "threat-keeping" constraints, which allow us to keep track of the incentives provided in the previous period. Since allocations are incentive compatible, no agent misrepresents his type along the equilibrium path and hence no agent actually obtains utility $v(\theta_{(j)})$ for $\theta_{(j)} \neq \theta_-$. One can think of those $v(\theta_{(j)})$ as threats that the principal chooses in period $t-1$ to ensure that agents do not misrepresent their type. Eq. (45) in period t ensures that the principal's subsequent choices are consistent with that threat. The principal chooses a common allocation for all the agents that report θ_-. This common allocation simultaneously delivers utility $v(\theta_-)$ to the agents with true type θ_- (ie, when expected values are computed using the probabilities $\pi(\theta|\theta_-)$), and $v(\theta_{(j)})$ to the agents with true types $\theta_{(j)}$ (ie, when expected values are computed using the probabilities $\pi(\theta|\theta_{(j)})$) for each $j \in \{1, \ldots, |\Theta|\}$.

The relationship between the function $K_0(v(\cdot),\theta_-)$ defined in (44) and the function $\widetilde{K}_0(v_0)$ defined in (43) is as follows. Observe that there are no auxiliary threat-keeping constraints in the set $\Gamma(v_0)$. It is mathematically equivalent to saying that those constraints are slack. Thus, given our assumption that shocks in period 1 are drawn from $\pi\left(\cdot|\theta_{(1)}\right)$, the relationship between $K_0(v(\cdot),\theta_-)$ and $\widetilde{K}_0(v_0)$ is simply

$$\widetilde{K}_0(v_0) = \max_{v(\cdot)\in\mathcal{V}_0,\, v\left(\theta_{(1)}\right)=v_0} K_0\left(v(\cdot),\theta_{(1)}\right). \tag{48}$$

This gives a simple way to find the solution $(\mathbf{u}^*,\mathbf{v}^*)$ for the primal problem (9). The value of this problem should be such that the feasibility constraint holds with equality, which can be found as a solution to $\widetilde{K}_0(v_0) = -\dfrac{1-\beta^T}{1-\beta}e$. Then from the maximization problem (48) we generate the vector $v_0(\cdot)$. Finally, we use the policy functions to the Bellman equation (44) to generate the solution $(\mathbf{u}^*,\mathbf{v}^*)$, analogous to the i.i.d. case.

Infinite-period economy

We now turn to the recursive formulation in the infinite-period economy, $T=\infty$. Assume for simplicity that the utility function is bounded, ie, $\mathbb{U}=[\underline{u},\bar{u}]$. Let $\mathcal{V}$ be the set of promised utility vectors $v(\cdot)$ for which there exists an allocation $\mathbf{u}$ such that

$$v\left(\theta_{(j)}\right) = \sum_{t=1}^{\infty}\sum_{\theta^t\in\Theta^t}\beta^{t-1}\pi_t\left(\theta^t\middle|\theta_{(j)}\right)\theta_t u_t(\theta^t),\ \forall j\in\{1,\ldots,|\Theta|\}, \tag{49}$$

and for all $t\geq 1$, for all $\theta^{t-1},\theta,\hat{\theta}$,

$$\begin{aligned}&\theta u_t\left(\theta^{t-1},\theta\right)+\beta\left\{\sum_{s=1}^{\infty}\sum_{\theta^{t+s}\in\Theta^{t+s}}\beta^{s-1}\pi_{t+s}\left(\theta^{t+s}\middle|\theta^{t-1},\theta\right)\theta_{t+s}u_{t+s}\left(\theta^{t-1},\theta,\theta_{t+1}^{t+s}\right)\right\}\\ \geq\ &\theta u_t\left(\theta^{t-1},\hat{\theta}\right)+\beta\left\{\sum_{s=1}^{\infty}\sum_{\theta^{t+s}\in\Theta^{t+s}}\beta^{s-1}\pi_{t+s}\left(\theta^{t+s}\middle|\theta^{t-1},\theta\right)\theta_{t+s}u_{t+s}\left(\theta^{t-1},\hat{\theta},\theta_{t+1}^{t+s}\right)\right\}.\end{aligned} \tag{50}$$

For any $\theta_-\in\Theta$ and $v(\cdot)\in\mathcal{V}$, the Bellman equation writes

$$K(v(\cdot),\theta_-) = \max_{\{u(\theta),w(\theta|\cdot)\}_{\theta\in\Theta}}\sum_{\theta\in\Theta}\pi(\theta|\theta_-)[-C(u(\theta))+\beta K(w(\theta|\cdot),\theta)] \tag{51}$$

subject to (45), (46), and $u(\theta)\in\mathbb{U}$, $w(\theta|\cdot)\in\mathcal{V}$ for all θ.

This Bellman equation is a direct extension of the Bellman equation (23) in the i.i.d. case. The need to keep track of a larger number of state variables in the case of general Markov shocks follows from our discussion in the finite period economy. One additional consideration that (51) introduces is that it is defined over a set $\mathcal{V}$, which needs to be found. The work of Abreu et al. (1990) provides a method of finding this set and characterizing its properties.

Proposition 8 *The set $\mathcal{V}$ is nonempty, compact, and convex. It is the largest bounded fixed point of the operator $\mathscr{A}$ defined for an arbitrary compact set $\tilde{\mathcal{V}} \subset \mathbb{R}^{|\Theta|}$ as*

$$\mathscr{A}\tilde{\mathcal{V}} = \left\{ v(\cdot) \text{ s.t. } \exists \{u(\theta), w(\theta|\cdot)\}_{\theta \in \Theta} : (45), (46) \text{ hold and } (u(\theta),\ w(\theta|\cdot)) \in \mathbb{U} \times \tilde{\mathcal{V}},\ \forall \theta \right\}.$$

It is the limit of the monotonically decreasing sequence of compact sets $\{\mathcal{V}_n\}_{n=0,1,\ldots}$ defined as $\mathcal{V}_0 = \left[\frac{\theta_{(1)}}{1-\beta}\underline{u}, \frac{\theta_{(|\Theta|)}}{1-\beta}\bar{u}\right]^{|\Theta|}$ and $\mathcal{V}_n = \mathscr{A}\mathcal{V}_{n-1}$ for $n \geq 1$, so that $\mathcal{V} = \lim_{n\to\infty}\mathcal{V}_n = \bigcap_{n=1}^{\infty}\mathcal{V}_n$.

Proof The set $\mathcal{V}$ is nonempty because any allocation that is independent of the report is incentive compatible. $\mathcal{V}$ is convex since $v_{\mathbf{u}}\left(\theta_{(j)}\right)$ is affine in $\mathbf{u}$ for all $j \in \{1, \ldots, |\Theta|\}$, where $v_{\mathbf{u}}\left(\theta_{(j)}\right)$ is defined by the right hand side of (49). The construction of $\mathcal{V}$ as the largest compact fixed point of the operator $\mathscr{A}$ follows from the results of Abreu et al. (1990). Here we give a simple proof that $\mathcal{V}$ is compact and is a fixed point of $\mathscr{A}$.

Let $\mathcal{U}$ denote the space of allocations $\mathbf{u} = \{u_t(\theta^t)\}_{t\geq 1, \theta^t \in \Theta^t}$, with $u_t(\theta^t) \in [\underline{u}, \bar{u}]$ for all $t \geq 1$, $\theta^t \in \Theta^t$. Since $|\Theta^t| < \infty$ for all $t \geq 1$, $\mathcal{U}$ is the countable product of the compact metric spaces $[\underline{u}, \bar{u}]$. Embedding $\mathcal{U}$ with the product topology, we obtain that $\mathcal{U}$ is a compact metric space (the compactness is a standard result that follows from a diagonalization argument). A sequence $\mathbf{u}^{(n)}$ in $\mathcal{U}$ converges as $n \to \infty$ if and only if all of its projections $u_t^{(n)}(\theta^t)$ converge in $[\underline{u}, \bar{u}]$ as $n \to \infty$.

We now show that $\mathcal{V}$ is compact. Since the utility function is bounded, $v_{\mathbf{u}}$ is bounded and hence $\mathcal{V}$ is bounded. To prove that $\mathcal{V}$ is closed, let $\left\{\vec{v}^{(n)}\right\}_{n=1}^{\infty}$ be a Cauchy sequence in $\mathcal{V}$, and let $\vec{v}^{(\infty)} = \left\{v^{(\infty)}\left(\theta_{(j)}\right)\right\}_{j=1,\ldots,J}$ its limit. Let $\left\{\mathbf{u}^{(n)}\right\}_{n=1}^{\infty}$ be a sequence of allocations such that $v^{(n)}\left(\theta_{(j)}\right) = v_{\mathbf{u}^{(n)}}\left(\theta_{(j)}\right)$ for all $j \in \{1, \ldots, |\Theta|\}$ and all $n \geq 1$. Since $\mathcal{U}$ is compact, $\left\{\mathbf{u}^{(n)}\right\}_{n=1}^{\infty}$ contains a convergent subsequence $\left\{\mathbf{u}^{(\varphi(n))}\right\}_{n=1}^{\infty}$; denote by $\mathbf{u}^{(\infty)}$ its limit. We have $\mathbf{u}^{(\infty)} \in \mathcal{U}$. Since $v_{\mathbf{u}}\left(\theta_{(j)}\right)$ is continuous in $\mathbf{u}$ we get, for all $j \in \{1, \ldots, |\Theta|\}$,

$$v^{(\infty)}\left(\theta_{(j)}\right) = \lim_{n\to\infty} v^{(\varphi(n))}\left(\theta_{(j)}\right) = \lim_{n\to\infty} v_{\mathbf{u}^{(\varphi(n))}}\left(\theta_{(j)}\right) = v_{\mathbf{u}^{(\infty)}}\left(\theta_{(j)}\right).$$

Finally, since $\mathbf{u}^{(n)}$ satisfies the incentive constraints (50), by continuity we obtain that $\mathbf{u}^{(\infty)}$ satisfies (50) as well. Thus $\vec{v}^{(\infty)} \in \mathcal{V}$ and hence $\mathcal{V}$ is closed. Since $\mathcal{V} \subset \mathbb{R}^{|\Theta|}$, we obtain that $\mathcal{V}$ is compact.

Next we show that $\mathcal{V}$ is a fixed point of $\mathscr{A}$, that is $\mathscr{A}\mathcal{V} = \mathcal{V}$. First let $\vec{v} \in \mathcal{V}$. There exists $\mathbf{u} = \{u_t(\theta^t)\}_{t,\theta^t} \in \mathcal{U}$ that satisfies the incentive constraints (50) and delivers $v\left(\theta_{(j)}\right) = v_{\mathbf{u}}\left(\theta_{(j)}\right)$ for all $j \in \{1, \ldots, |\Theta|\}$. Define the allocation rule $\{u(\theta), w(\theta|\cdot)\}_{\theta \in \Theta}$

by $u(\theta) = u_1(\theta)$ and $w\left(\theta\middle|\theta_{(j')}\right) = v_{\mathbf{u}_2^\infty(\theta)}\left(\theta_{(j')}\right)$, where $\mathbf{u}_2^\infty(\theta)$ is the continuation of the allocation $\mathbf{u}$ from period 2 onward given the history $\theta^1 = \theta$. We have $w(\theta|\cdot) \in \mathcal{V}$ for all $\theta \in \Theta$ because the allocation $\mathbf{u}_2^\infty(\theta)$ satisfies the incentive-compatibility condition (50) after all histories. Moreover, we have

$$\begin{aligned} \theta u(\theta) + \beta w(\theta|\theta) &= \theta u_1(\theta) + \beta v_{\mathbf{u}_2^\infty(\theta)}(\theta) \\ \geq \theta u_1\left(\hat{\theta}\right) + \beta v_{\mathbf{u}_2^\infty\left(\hat{\theta}\right)}(\theta) &= \theta u\left(\hat{\theta}\right) + \beta w\left(\hat{\theta}|\theta\right), \end{aligned}$$

where the inequality follows from (50). Hence $\{u(\theta), w(\theta|\cdot)\}_{\theta\in\Theta}$ satisfies (46). Finally, by construction $\{u(\theta), w(\theta|\cdot)\}_{\theta\in\Theta}$ satisfies (45). Thus, $\vec{v} \in \mathscr{A}\mathcal{V}$ and hence $\mathcal{V} \subset \mathscr{A}\mathcal{V}$. For the converse, suppose that $\vec{v} \in \mathscr{A}\mathcal{V}$. Then there exists some allocation rule $\{u(\theta), w(\theta|\cdot)\}_{\theta\in\Theta}$ such that the promise-keeping constraint (45) and the incentive constraints (46) hold and $w(\theta|\cdot) \in \mathcal{V}$ for all θ. Define an allocation $\mathbf{u}$ as follows. Let $u_1(\theta) = u(\theta)$. For each $\theta \in \Theta$, since $w(\theta|\cdot) \in \mathcal{V}$ there exists some allocation $\tilde{\mathbf{u}}\ (\theta)$ such that $v_{\tilde{\mathbf{u}}(\theta)}\left(\theta_{(j)}\right) = w\left(\theta\middle|\theta_{(j)}\right)$ for all $j \in \{1, \ldots, |\Theta|\}$. Define $\mathbf{u}_2^\infty(\theta) = \tilde{\mathbf{u}}\ (\theta)$. The allocation $\mathbf{u}$ constructed in this way is in $\mathcal{U}$, satisfies the incentive constraints (50), and delivers $v_{\mathbf{u}}\left(\theta_{(j)}\right) = v\left(\theta_{(j)}\right)$. Thus, $\vec{v} \in \mathcal{V}$ and hence $\mathscr{A}\mathcal{V} \subset \mathcal{V}$. □

2.5.2 Continuum of Shocks and the First-Order Approach

The previous section provides a general way to characterize recursively the solution to the optimal insurance problem when shocks are Markovian. One practical difficulty in using the Bellman equation (51) in applications is that the dimensionality of the state space grows with the number of shocks. As the number of shocks becomes large, solving problem (51) becomes intractable. To keep the problem manageable, it is useful to have a method that keeps the number of state variables small.

One approach is to guess that only some of the incentive constraints (38) bind at the optimum. In this case all the nonbinding constraints can be dropped, which also eliminates the need to keep track of the corresponding state variables. The natural candidate for binding constraints are the local constraints that ensure that a type θ does not want to mimic the types closest to his. In this section we describe how to construct this relaxed problem and provide sufficient conditions that can be verified ex post to make sure that the dropped incentive constraints are satisfied.[1]

This analysis can be done with a discrete number of shocks, but it becomes particularly simple if instead we allow for a continuum of shocks. In this case applying the envelope theorem to the incentive-compatibility condition gives a simple and

[1] It is important to keep in mind that there is a large class of incentive problems with persistent shocks in which nonlocal incentive constraints bind (see, eg, Battaglini and Lamba, 2015) and thus the relaxed problem may not satisfy the sufficient conditions.

tractable way to derive the Bellman equation. This problem has been analyzed by Kapička (2013) and Pavan et al. (2014); here we follow the exposition of the former.

Let the taste shocks θ_t in each period belong to an interval $\Theta = \left(\underline{\theta}, \overline{\theta}\right) \subset \mathbb{R}_{+}^{*}$, with $\overline{\theta} < \infty$. We assume that the stochastic process for the shocks θ_t is Markov with continuous density $\pi(\theta_t|\theta_{t-1})$. We use $\pi_s(\cdot|\theta_t)$ to denote the p.d.f. of histories θ_{t+1}^{t+s} given that the shock θ_t occurred in period t, that is,

$$\pi_s\left(\theta_{t+1}^{t+s}|\theta_t\right) = \pi(\theta_{t+s}|\theta_{t+s-1}) \times \cdots \times \pi(\theta_{t+1}|\theta_t).$$

Assume as in the previous section that these probabilities are generated from the seed value $\theta_0 = \theta_{(1)}$. We make the following assumptions:

Assumption 4 Assume that the density $\pi(\theta|\cdot)$ is uniformly Lipschitz continuous for all θ, and that the derivatives $\hat{\pi}(\theta|\theta_-) \equiv \dfrac{\partial \pi(\theta|\theta_-)}{\partial \theta_-}$ exist and are uniformly bounded.

These assumptions can be substantially relaxed (see Kapička, 2013; Pavan et al., 2014 for more general treatments of the problem), but they considerably simplify our analysis. To simplify the integrability conditions, we further assume in this section that the utility function is bounded.

Having a continuum of shocks does not change the arguments leading to the recursive characterization of the constraints (40), (41), with the only difference that the sum over a finite number of shock realizations in Eq. (41) is now replaced by an integral. Constraints (41) and (40) can be written as

$$v_t\left(\theta^{t-1}, \hat{\theta}_t|\theta_t\right) = \int_{\Theta}\left[\theta' u_{t+1}\left(\theta^{t-1}, \hat{\theta}_t, \theta'\right) + \beta v_{t+1}\left(\theta^{t-1}, \hat{\theta}_t, \theta'|\theta'\right)\right]\pi(\theta'|\theta_t)d\theta', \forall \theta^t, \hat{\theta}_t, \tag{52}$$

and

$$\theta_t u_t\left(\theta^{t-1}, \theta_t\right) + \beta v_t\left(\theta^{t-1}, \theta_t|\theta_t\right) = \max_{\hat{\theta}\in\Theta}\left\{\theta_t u_t\left(\theta^{t-1}, \hat{\theta}\right) + \beta v_t\left(\theta^{t-1}, \hat{\theta}|\theta_t\right)\right\}, \forall \theta^{t-1}, \theta_t. \tag{53}$$

Lemma 4 *Suppose Assumption 4 is satisfied and the utility function is bounded. Then the function $v_t\left(\theta^{t-1}, \theta_t|\cdot\right)$ is differentiable with respect to the realized period-t type θ for each history of reports $\theta^t = \left(\theta^{t-1}, \theta_t\right)$ and its derivative evaluated at θ_t is given by*

$$\hat{v}_t(\theta^t) = \int_{\Theta}[\theta' u_{t+1}(\theta^t, \theta') + \beta v_{t+1}(\theta^t, \theta'|\theta')]\hat{\pi}(\theta'|\theta_t)d\theta'. \tag{54}$$

Moreover, if an allocation is incentive compatible, then for all $t \geq 1$, $\theta^t \in \Theta^t$,

$$\theta_t u_t\left(\theta^{t-1},\theta_t\right) + \beta v_t\left(\theta^{t-1},\theta_t|\theta_t\right) = \int_{\underline{\theta}}^{\theta_t} \left\{u_t\left(\theta^{t-1},\theta\right) + \beta \hat{v}_t\left(\theta^{t-1},\theta\right)\right\} d\theta + \nu\left(\theta^{t-1}\right), \tag{55}$$

where $\nu\left(\theta^{t-1}\right) = \lim_{\theta \to \underline{\theta}}\left\{\theta u_t\left(\theta^{t-1},\theta\right) + \beta v_t\left(\theta^{t-1},\theta|\theta\right)\right\}$.

Proof Let $S_{t+1}(\theta^t,\theta') = \theta' u_{t+1}(\theta^t,\theta') + \beta v_{t+1}(\theta^t,\theta'|\theta')$. Then

$$\begin{aligned}\frac{v_t\left(\theta^{t-1},\theta_t|\theta+\Delta\theta\right) - v_t\left(\theta^{t-1},\theta_t|\theta\right)}{\Delta\theta} &= \int_\Theta S_{t+1}(\theta^t,\theta')\frac{\pi(\theta'|\theta+\Delta\theta) - \pi(\theta'|\theta)}{\Delta\theta}d\theta' \\ &\xrightarrow[\Delta\theta \to 0]{} \int_\Theta S_{t+1}(\theta^t,\theta')\hat{\pi}(\theta'|\theta)d\theta',\end{aligned}$$

where the last step follows from the Dominated Convergence Theorem, noting that $S_{t+1}(\theta^t,\theta')$ and $\left|\frac{\pi(\theta'|\theta+\Delta\theta) - \pi(\theta'|\theta)}{\Delta\theta}\right|$ are bounded by the uniform Lipschitz continuity of $\pi(\theta'|\cdot)$. Hence $v_t\left(\theta^{t-1},\theta_t|\cdot\right)$ is differentiable, and it is Lipschitz continuous on $\left[\eta,\overline{\theta}\right)$ for all $\eta > \underline{\theta}$ since $\hat{\pi}(\theta'|\theta)$ is uniformly bounded.

Let $\hat{S}_t\left(\theta^{t-1},\hat{\theta}_t|\theta_t\right) = \theta_t u_t\left(\theta^{t-1},\hat{\theta}_t\right) + \beta v_t\left(\theta^{t-1},\hat{\theta}_t|\theta_t\right)$. Then $\hat{S}_t$ is differentiable in θ_t on $\left(\eta,\overline{\theta}\right)$ (denote by $\hat{S}_{\theta,t}$, its derivative) and Lipschitz in θ_t on $\left[\eta,\overline{\theta}\right)$. Hence it is absolutely continuous and has a bounded derivative with respect to θ_t on $\left(\eta,\overline{\theta}\right)$. Since the allocation is incentive compatible, $\hat{S}_t\left(\theta^{t-1},\hat{\theta}_t|\theta_t\right)$ is maximized at $\hat{\theta}_t = \theta_t$. By Theorem 2 in Milgrom and Segal (2002), $\hat{S}_t\left(\theta^{t-1},\theta_t|\theta_t\right)$ can be represented as an integral of its derivative:

$$\begin{aligned}\hat{S}_t\left(\theta^{t-1},\theta_t|\theta_t\right) &= \int_\eta^{\theta_t} \hat{S}_{\theta,t}\left(\theta^{t-1},\theta,\theta\right)d\theta + \hat{S}_t\left(\theta^{t-1},\eta|\eta\right) \\ &= \int_\eta^{\theta_t}\left\{u_t\left(\theta^{t-1},\theta\right) + \beta\hat{v}_t\left(\theta^{t-1},\theta|\theta\right)\right\}d\theta + \hat{S}_t\left(\theta^{t-1},\eta|\eta\right).\end{aligned}$$

Take the limit as $\eta \to \underline{\theta}$ to get expression (55). □

We can now define a relaxed problem by replacing the temporarily incentive-compatibility constraints (53) by the envelope condition (55) for all histories. This substantially simplifies the analysis, as the latter constraint only depends on the lifetime utility and marginal lifetime utility of the truthteller, rather than the continuation utility of all possible types as in Section 2.5. In the recursive formulation of the planner's problem, the choice variables are the current utility $u(\theta)$, the continuation utility of the truthtelling agent $w(\theta)$, and the marginal change in the continuation utility of the truthtelling agent

$\hat{w}(\theta)$. The state variables are the reported taste shock realization θ_- in the previous period, the promised utility v of an agent who truthfully announced θ_- last period, and the marginal promised utility $\hat{v}$ of an agent who truthfully announced θ_- last period.

We now show the recursive formulation of the relaxed problem in an infinite-period economy. Let $\hat{\mathcal{V}}(\theta_-)$ denote the set of lifetime utility and marginal lifetime utility pairs $(v,\hat{v}) \in \mathbb{R}^2$ for which there exist values $\{u(\theta), w(\theta), \hat{w}(\theta)\}_{\theta \in \Theta}$ such that the following conditions hold:

(i) the envelope condition:

$$\theta u(\theta) + \beta w(\theta) = \int_{\underline{\theta}}^{\theta} \{u(\theta') + \beta \hat{w}(\theta')\} d\theta' + \lim_{\theta' \to \underline{\theta}} \{\theta' u(\theta') + \beta w(\theta')\}, \forall \theta \in \Theta, \tag{56}$$

(ii) the promise-keeping constraint:

$$v = \int_{\Theta} \{\theta' u(\theta') + \beta w(\theta')\} \pi(\theta' | \theta_-) d\theta', \tag{57}$$

(iii) the marginal promise-keeping constraint:

$$\hat{v} = \int_{\Theta} \{\theta' u(\theta') + \beta w(\theta')\} \hat{\pi}(\theta' | \theta_-) d\theta', \tag{58}$$

(iv) $(w(\theta), \hat{w}(\theta)) \in \hat{\mathcal{V}}(\theta)$ for all $\theta \in \Theta$.

Note that in general $\hat{\mathcal{V}}(\theta)$ depends on the realized value of θ. It can be characterized along the lines of Proposition 8.

For any $\theta_- \in \Theta$ and pair $(v,\hat{v}) \in \hat{\mathcal{V}}(\theta_-)$, the Bellman equation writes

$$K(v,\hat{v},\theta_-) = \sup_{(\vec{u},\vec{w},\vec{\hat{w}})} \int_{\Theta} \{-C(u(\theta)) + \beta K(w(\theta), \hat{w}(\theta), \theta)\} \pi(\theta | \theta_-) d\theta \tag{59}$$

subject to (56)–(58) and $u(\theta) \in \mathbb{U}$, $(w(\theta), \hat{w}(\theta)) \in \hat{\mathcal{V}}(\theta)$ for all $\theta \in \Theta$.

We finally discuss when the relaxed problem gives the solution to the original problem. The envelope condition (55) is necessary but not sufficient for an allocation to be temporarily incentive compatible. A sufficient condition is given in Proposition 9:

Proposition 9 *Suppose that an allocation* $\mathbf{u}$ *satisfies the envelope condition (55) and, in addition,*

$$u_t(\theta^{t-1}, \hat{\theta}_t) + \beta \hat{v}_t(\theta^{t-1}, \hat{\theta}_t | \theta_t) \tag{60}$$

is increasing in $\hat{\theta}_t$ *for all* t, θ^{t-1} *and almost all* θ_t, *where* $\hat{v}_t(\theta^{t-1}, \hat{\theta}_t | \theta_t) \equiv \frac{\partial}{\partial \theta} v_t(\theta^{t-1}, \hat{\theta}_t | \theta_t)$. *Then* $\mathbf{u}$ *is incentive compatible.*

Proof Fix t, θ^{t-1}, and let $S_t(\theta^{t-1}, \theta_t) \equiv \hat{S}_t(\theta^{t-1}, \theta_t | \theta_t)$. An allocation is temporarily incentive compatible if $S_t(\theta^{t-1}, \theta_t) \geq \hat{S}_t(\theta^{t-1}, \hat{\theta}_t | \theta_t)$ for all $\theta^{t-1}, \theta_t, \hat{\theta}_t$. Eq. (55) shows that $S_t(\theta^{t-1}, \cdot)$ is differentiable for almost all $\theta \in \Theta$ with

$$\frac{\partial}{\partial \theta} S_t(\theta^{t-1}, \theta) = u_t(\theta^{t-1}, \theta) + \beta \hat{v}_t(\theta^{t-1}, \theta).$$

We thus have

$$\begin{aligned} & S_t(\theta^{t-1}, \theta_t) - S_t(\theta^{t-1}, \hat{\theta}_t) \\ & = \int_{\hat{\theta}_t}^{\theta_t} \frac{\partial}{\partial \theta'} S_t(\theta^{t-1}, \theta') \, d\theta' = \int_{\hat{\theta}_t}^{\theta_t} \left\{ u_t(\theta^{t-1}, \theta') + \beta \hat{v}_t(\theta^{t-1}, \theta' | \theta') \right\} d\theta' \\ & \geq \int_{\hat{\theta}_t}^{\theta_t} \left\{ u_t(\theta^{t-1}, \hat{\theta}_t) + \beta \hat{v}_t(\theta^{t-1}, \hat{\theta}_t | \theta') \right\} d\theta' = \hat{S}_t(\theta^{t-1}, \hat{\theta}_t | \theta_t) - S_t(\theta^{t-1}, \hat{\theta}_t), \end{aligned}$$

where the inequality follows from the monotonicity of (60), and the last equality follows from the differentiability of $\hat{S}_t(\theta^{t-1}, \hat{\theta}_t | \theta_t)$, with $\frac{\partial}{\partial \theta} \hat{S}_t(\theta^{t-1}, \hat{\theta}_t | \theta) = u_t(\theta^{t-1}, \hat{\theta}_t) + \beta \hat{v}_t(\theta^{t-1}, \hat{\theta}_t | \theta)$. We obtain that $\mathbf{u}$ is temporarily incentive compatible. □

If the shocks are i.i.d., the second term in expression (60) drops out and the proposition is equivalent to a simple requirement that $u_t(\theta^t)$ is increasing in θ_t, and one can show that this requirement is necessary as well. In the static setting, u satisfies the Spence–Mirrlees condition and this sufficient condition reduces to the familiar necessary and sufficient condition that allocations are monotonic (see Myerson, 1981). Unfortunately, in the dynamic model with persistent shocks, the monotonicity condition on (60) is not necessary, and moreover there is no one-to-one mapping between marginal lifetime utilities and allocations. Moreover, in practice condition (60) is difficult to verify directly, and we have to either try to derive weaker sufficient conditions, or check ex post (possibly numerically) in specific applications whether the solution to the relaxed problem is indeed an optimal allocation.

2.6 Hidden Storage

We now suppose that agents have access to a storage technology, a problem analyzed by Allen (1985) and Cole and Kocherlakota (2001).[m] The model is the same as in Sections 2.3 and 2.4 (with i.i.d. and discrete types), except that individuals can now store nonnegative amounts of goods at rate R. The planner cannot observe these private savings.

[m] See also Werning (2002), Golosov and Tsyvinski (2007), Farhi et al. (2009), and Ales and Maziero (2009).

The planner is still able to both borrow and lend at the same rate R as the agents.[n] We show that allowing for hidden private storage dramatically changes the optimal social insurance contract: in this environment, no social insurance can be provided.

To understand the argument, suppose first (following Allen, 1985) that agents can both borrow *and* lend at rate R. In this case, agents can always perfectly smooth across time their consumption. Hence they always report the shocks that yield the highest net present value of transfers, regardless of their true history. Consequently, incentive compatibility requires that the planner gives all individuals the same present value of transfers, which must then be equal to the present value of the endowment, $e + e/R$. Therefore, the planner simply gives the economy's endowment to the agents, who self-insure from then on. In particular, there is no transfer of resources *across* households, ie, no risk sharing is possible.

Now suppose (following Cole and Kocherlakota, 2001) that the agent can only privately save, but *not* borrow, at the interest rate R. Assume for simplicity that the horizon lasts two periods (see Cole and Kocherlakota, 2001 for a generalization to $T \leq \infty$ periods).[o] We still denote by $\mathbf{c} = \{c_1(\theta_1), c_2(\theta_1, \theta_2)\}$ the agent's consumption, but now the transfers from the planner to the agent may be different and are denoted by $\boldsymbol{\tau} = \{\tau_1(\theta_1), \tau_2(\theta_1, \theta_2)\}$. Denote by $k(\theta_1)$ the agent's private storage, and by K the public saving or borrowing. An efficient allocation is defined as a tuple $\{\mathbf{c}, \boldsymbol{\tau}, k, K\}$ that solves:

$$\max_{\{\mathbf{c},\boldsymbol{\tau},k,K\}} \sum_{\theta_1\in\Theta} \pi(\theta_1)\left\{\theta_1 U(c_1(\theta_1)) + \sum_{\theta_2\in\Theta} \beta\pi(\theta_2)\theta_2 U(c_2(\theta_1,\theta_2))\right\} \tag{61}$$

subject to the planner's feasibility constraints: $\forall \theta_1, \theta_2 \in \Theta$,

$$\begin{aligned} &\sum_{\theta_1\in\Theta} \pi(\theta_1)\tau_1(\theta_1) + K = e, \\ &\sum_{(\theta_1,\theta_2)\in\Theta^2} \pi(\theta_1)\pi(\theta_2)\tau_2(\theta_1,\theta_2) = e + RK, \end{aligned} \tag{62}$$

the agent's resource constraints: $\forall \theta_1, \theta_2 \in \Theta$,

$$\begin{aligned} &c_1(\theta_1) + k(\theta_1) = \tau_1(\theta_1), \\ &c_2(\theta_1,\theta_2) = \tau_2(\theta_1,\theta_2) + Rk(\theta_1), \\ &k(\theta_1) \geq 0, \end{aligned} \tag{63}$$

and the incentive-compatibility constraints: $\forall \hat{\theta}_1, \hat{\theta}_2 \in \Theta$, $\forall \hat{k} \geq 0$,

[n] This definition of feasibility is that of Ljungqvist and Sargent (2012) rather than that of Cole and Kocherlakota (2001), who assume that the planner cannot borrow.

[o] The results of this section extend to finite horizons if the utility function has non-increasing absolute risk aversion, and to the infinite horizon if the utility function is bounded.

$$\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U(\tau_1(\theta_1)-k(\theta_1))+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U(\tau_2(\theta_1,\theta_2)+Rk(\theta_1))\right\}$$
$$\geq\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U\left(\tau_1\left(\hat{\theta}_1\right)-\hat{k}(\theta_1)\right)+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U\left(\tau_2\left(\hat{\theta}_1,\hat{\theta}_2\right)+R\hat{k}(\theta_1)\right)\right\}. \tag{64}$$

We first note that there is no loss to having the planner do all the (public plus private) saving publicly, since the agent and the planner have the same rate of return R.

Lemma 5 *Given any incentive-compatible and feasible allocation* $\{\mathbf{c},\boldsymbol{\tau},k,K\}$, *there exists another incentive-compatible and feasible allocation* $\{\mathbf{c},\boldsymbol{\tau}^0,0,K^0\}$.

Proof Define the transfers $\tau_1^0(\theta_1)=\tau_1(\theta_1)-k(\theta_1)$, $\tau_2^0(\theta_1,\theta_2)=\tau_2(\theta_1,\theta_2)+Rk(\theta_1)$, and the public saving $K^0=K+\sum_{\theta_1\in\Theta}\pi(\theta_1)k(\theta_1)$. The allocation $\{\mathbf{c},\boldsymbol{\tau}^0,0,K^0\}$ with $\mathbf{c}=\boldsymbol{\tau}^0$ clearly satisfies the planner's and the households budget constraints, and hence is feasible. We now show that it is incentive compatible. Indeed, suppose that there exists $\left(\hat{\theta}_1,\hat{\theta}_2,\hat{k}\right)$ such that

$$\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U\left(\tau_1^0\left(\hat{\theta}_1\right)-\hat{k}(\theta_1)\right)+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U\left(\tau_2^0\left(\hat{\theta}_1,\hat{\theta}_2\right)+R\hat{k}(\theta_1)\right)\right\}$$
$$>\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U\left(\tau_1^0(\theta_1)\right)+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U\left(\tau_2^0(\theta_1,\theta_2)\right)\right\}.$$

Then the strategy $\left(\hat{\theta}_1,\hat{\theta}_2,\left\{k(\theta_1)+\hat{k}(\theta_1)\right\}\right)$ dominates $(\theta_1,\theta_2,k(\theta_1))$, so that $\{\mathbf{c},\boldsymbol{\tau},k,K\}$ is not incentive compatible. □

Next, note that the incentive constraint in period 2 imposes that the second-period transfers are independent of the report $\hat{\theta}_2$ (otherwise the agent would always report the type that yields the highest transfer regardless of his true type). Thus we can rewrite the transfers from the planner to the agent as $\tau_1(\theta_1),\tau_2(\theta_1)$.

The possibility of hidden storage in the incentive constraints (64) makes the planner's problem (61)–(64) difficult to solve directly. In a first step, we thus consider a simpler planner's problem with a larger constraint set: we suppose that the agent can only lie upward by one notch. Thus we analyze the following relaxed problem:

$$\max_{\{\tau_1(\theta_1),\tau_2(\theta_1)\}}\quad\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U(\tau_1(\theta_1))+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U(\tau_2(\theta_1))\right\} \tag{65}$$

subject to

$$\sum_{\theta_1\in\Theta}\pi(\theta_1)\tau_1(\theta_1)+K=e,$$
$$\sum_{\theta_1\in\Theta}\pi(\theta_1)\tau_2(\theta_1)=e+RK, \tag{66}$$

and, for all $\hat{k}\geq 0$ and σ such that $\sigma\left(\theta_{(j)}\right)\in\left\{\theta_{(j)},\theta_{(j+1)}\right\}$ for all $j\in\{1,\ldots,|\Theta|-1\}$ and $\sigma\left(\theta_{(|\Theta|)}\right)=\theta_{(|\Theta|)}$,

$$\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1U(\tau_1(\theta_1))+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2U(\tau_2(\theta_1))\right\}$$
$$\geq\sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1U\left(\tau_1(\sigma(\theta_1))-\hat{k}(\theta_1)\right)+\sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2U\left(\tau_2(\sigma(\theta_1))+R\hat{k}(\theta_1)\right)\right\}. \tag{67}$$

We start by analyzing the relaxed problem (65). We do this in two steps. First, we show:

Lemma 6 *Consider any allocation that solves (65), say* $\{\mathbf{c},\boldsymbol{\tau},0,K\}$. *It must satisfy*

$$\theta_{(j)}U'\left(c_1\left(\theta_{(j)}\right)\right)=\beta R\sum_{\theta_{(j')}\in\Theta}\pi\left(\theta_{(j')}\right)\theta_{(j')}U'\left(c_2\left(\theta_{(j)},\theta_{(j')}\right)\right), \tag{68}$$

for all $j\in\{1,\ldots,|\Theta|\}$.

Proof Suppose first by contradiction that there exists $i\in\{1,\ldots,|\Theta|\}$ such that

$$\theta_{(i)}U'\left(c_1\left(\theta_{(i)}\right)\right)<\beta R\sum_{\theta_{(j')}\in\Theta}\pi\left(\theta_{(j')}\right)\theta_{(j')}U'\left(c_2\left(\theta_{(i)},\theta_{(j')}\right)\right).$$

Then, by saving $\hat{k}\left(\theta_{(i)}\right)>0$, agent $\theta_{(i)}$ raises his ex ante discounted utility, which contradicts the incentive constraint. Thus, because of the availability of private saving, individuals can only be borrowing constrained and not saving constrained.

Next, suppose that there exists $i\in\{1,\ldots,|\Theta|\}$ such that

$$\theta_{(i)}U'\left(c_1\left(\theta_{(i)}\right)\right)>\beta R\sum_{\theta_{(j')}\in\Theta}\pi\left(\theta_{(j')}\right)\theta_{(j')}U'\left(c_2\left(\theta_{(i)},\theta_{(j')}\right)\right). \tag{69}$$

We then construct an alternative incentive-compatible and feasible allocation $\left\{\tilde{\mathbf{c}},\tilde{\boldsymbol{\tau}},0,\tilde{K}\right\}$ that yields strictly higher ex ante utility than $\{\mathbf{c},\boldsymbol{\tau},0,K\}$. Specifically, let

$$\tilde{\tau}_1\left(\theta_{(i)}\right) = \tau_1\left(\theta_{(i)}\right) + \varepsilon_1,$$
$$\tilde{\tau}_2\left(\theta_{(i)}\right) = \tau_2\left(\theta_{(i)}\right) - \varepsilon_2,$$
$$\tilde{K} = K - \pi\left(\theta_{(i)}\right)\varepsilon_1,$$

where $(\varepsilon_1, \varepsilon_2)$ are chosen such that

$$\theta_{(i)} U\left(\tilde{\tau}_1\left(\theta_{(i)}\right)\right) + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tilde{\tau}_2\left(\theta_{(i)}\right)\right)$$
$$= \theta_{(i)} U\left(\tau_1\left(\theta_{(i)}\right)\right) + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tau_2\left(\theta_{(i)}\right)\right),$$

and

$$\theta_{(i)} U'\left(\tilde{\tau}_1\left(\theta_{(i)}\right)\right) \geq \beta R \sum_{\theta_{(j')} \in \Theta} \pi\left(\theta_{(j')}\right)\theta_{(j')} U'\left(\tilde{\tau}_2\left(\theta_{(i)}\right)\right). \tag{70}$$

That is, the alternative allocation slightly raises the transfer to agent $\theta_{(i)}$ in period 1 and slightly lowers it in period 2, in a way that makes him indifferent between the initial and the perturbed allocation, and by an amount small enough that he is still (weakly) borrowing constrained.

Since (69) holds, by the envelope condition we have $\varepsilon_2 > R\varepsilon_1$. Therefore this alternative allocation frees up resources, ie,

$$\sum_{\theta_1 \in \Theta} \pi(\theta_1)\tilde{\tau}_2(\theta_1) < e + R\tilde{K}.$$

These resources can be used to raise agents' ex ante utility in the following way: we can give them in period 2 to the household that reports the lowest taste shock θ_1. This does not violate any incentive constraints, since by assumption agents can only lie upward, and this does not lead to any private storage since the additional consumption is given in the second period.

We finally show that the alternative allocation $\left\{\tilde{\mathbf{c}}, \tilde{\boldsymbol{\tau}}, 0, \tilde{K}\right\}$ is incentive compatible. First, the incentive compatibility is satisfied for individual $\theta_{(i)}$, since his payoffs from truthtelling and from lying are unchanged by construction, and (70) ensures that he still finds it optimal to not privately store ($\hat{k} = 0$).

Thus it remains to prove that agent $\theta_{(i-1)}$ does not want to lie upward. Intuitively, the perturbation is constructed so that the planner borrows (ie, reduces public saving K) at rate R, and then offers a loan ε_1 to the borrowing constrained individual at his shadow interest rate $\varepsilon_2/\varepsilon_1 > R$ (which generates extra resources). Now, the individuals who lie have a lower actual taste shock than their report (ie, $\theta_{(i-1)} < \hat{\theta}_{(i)}$), and hence a lower shadow interest rate than that of the thruthteller $\theta_{(i)}$: they are less desperate to consume a bit more today in exchange for a larger consumption loss ε_2 tomorrow. They are thus made strictly worse off by the planner's loan if they lie.

To show this formally, define, for any $\theta \in \mathbb{R}_+$,

$$Z(\theta) = \max_{k \geq 0} \left\{ \theta U\left(\tau_1\left(\theta_{(i)}\right) - k\right) + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tau_2\left(\theta_{(i)}\right) + Rk\right) \right\},$$

$$W(\theta) = \max_{k \geq 0} \left\{ \theta U\left(\tau_1\left(\theta_{(i)}\right) + \varepsilon_1 - k\right) + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tau_2\left(\theta_{(i)}\right) - \varepsilon_2 + Rk\right) \right\}.$$

By construction of the perturbed allocation, we have $Z\left(\theta_{(i)}\right) = W\left(\theta_{(i)}\right)$. We want to show that $Z\left(\theta_{(i-1)}\right) > W\left(\theta_{(i-1)}\right)$ (so that agent $\theta_{(i-1)}$ finds it even worse to lie than he did before the planner perturbed the allocation). Suppose by contradiction that $W\left(\theta_{(i-1)}\right) \geq Z\left(\theta_{(i-1)}\right)$. Then by the mean value theorem, we have $W'(\theta) \leq Z'(\theta)$ for some $\theta \in \left(\theta_{(i-1)}, \theta_{(i)}\right)$. This can be written as

$$U\left(\tau_1\left(\theta_{(i)}\right) - k_W(\theta) + \varepsilon_1\right) \leq U\left(\tau_1\left(\theta_{(i)}\right) - k_Z(\theta)\right),$$

where $k_W(\theta)$ and $k_Z(\theta)$ denote the argmax of $W(\theta)$ and $Z(\theta)$, respectively. This equation leads to $k_W(\theta) - \varepsilon_1 \geq k_Z(\theta) \geq 0$, which in turn implies $k_W\left(\theta_{(i-1)}\right) \geq k_W(\theta) \geq \varepsilon_1$, as we can easily show by differentiating the relevant first-order condition that $k_W(\cdot)$ is weakly monotonic. Therefore, we have

$$\begin{aligned} W\left(\theta_{(i-1)}\right) &= \theta_{(i-1)} U\left(\tau_1\left(\theta_{(i)}\right) - \left\{k_W\left(\theta_{(i-1)}\right) - \varepsilon_1\right\}\right) \\ &\quad + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tau_2\left(\theta_{(i)}\right) + Rk_W\left(\theta_{(i-1)}\right) - \varepsilon_2\right) \\ &< \theta_{(i-1)} U\left(\tau_1\left(\theta_{(i)}\right) - \left\{k_W\left(\theta_{(i-1)}\right) - \varepsilon_1\right\}\right) \\ &\quad + \beta \sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)} U\left(\tau_2\left(\theta_{(i)}\right) + R\left\{k_W\left(\theta_{(i-1)}\right) - \varepsilon_1\right\}\right) \\ &\leq Z\left(\theta_{(i-1)}\right), \end{aligned}$$

where the first inequality uses the fact that $\varepsilon_2 > R\varepsilon_1$, and the second inequality invokes the fact (shown above) that $k_W\left(\theta_{(i-1)}\right) - \varepsilon_1 \geq 0$. Therefore, we have proved by contradiction that the agent $\theta_{(i-1)}$ does not want to lie upward and take the planner's loan at the implied rate $\varepsilon_2/\varepsilon_1 > R$ at which agent $\theta_{(i)}$ is indifferent. □

The second step consists in showing that all agents receive the same present value of transfers:

Lemma 7 *For all $\theta_1 \in \Theta$,*

$$\tau_1(\theta_1) + \frac{1}{R}\tau_2(\theta_1) = \left(1 + \frac{1}{R}\right)e. \tag{71}$$

Proof The planner's intertemporal budget constraint writes

$$\sum \pi(\theta_1)\left(\tau_1(\theta_1)+\frac{1}{R}\tau_2(\theta_1)\right)=\left(1+\frac{1}{R}\right)e.$$

Thus, to prove the result, it is sufficient to show that for all $j \in \{1,\ldots,|\Theta|-1\}$, we have $\psi_j = \psi_{j+1}$, where we denote

$$\psi_j \equiv \tau_1\left(\theta_{(j)}\right)+\frac{1}{R}\tau_2\left(\theta_{(j)}\right).$$

Suppose first by contradiction that there exists $i \in \{1,\ldots,|\Theta|-1\}$ such that $\psi_i < \psi_{i+1}$. Define, for any (θ,ψ),

$$\tilde{Z}(\theta,\psi)=\max_{k\in\mathbb{R}}\left\{\theta U(\psi-k)+\beta\sum_j \pi\left(\theta_{(j)}\right)\theta_{(j)}U(Rk)\right\},$$

If agent $\theta_{(i)}$ reports his true type $\theta_{(i)}$, he reaches utility $\tilde{Z}\left(\theta_{(i)},\psi_i\right)$, since we know from the previous lemma that his consumption is optimally smoothed across periods. If instead he lies and reports $\theta_{(i+1)}$, he reaches utility $\tilde{Z}\left(\theta_{(i)},\psi_{i+1}\right)$ (and in particular will still be able to perfectly smooth his consumption), because his constraint $k \geq 0$ does not bind (since it does not bind for individuals with the higher taste shock). Thus agent $\theta_{(i)}$ is strictly better off lying upward, which contradicts incentive compatibility.

Suppose next that there exists $i \in \{1,\ldots,|\Theta|-1\}$ such that $\psi_i > \psi_{i+1}$. We then construct an alternative incentive-compatible and feasible allocation that yields strictly higher ex ante utility. Specifically, define the "certainty equivalent" $\overline{\psi}$ by

$$\begin{aligned}&\pi\left(\theta_{(i)}\right)\tilde{Z}\left(\theta_{(i)},\overline{\psi}\right)+\pi\left(\theta_{(i+1)}\right)\tilde{Z}\left(\theta_{(i+1)},\overline{\psi}\right)\\ =\;&\pi\left(\theta_{(i)}\right)\tilde{Z}\left(\theta_{(i)},\psi_i\right)+\pi\left(\theta_{(i+1)}\right)\tilde{Z}\left(\theta_{(i+1)},\psi_{i+1}\right).\end{aligned}$$

Since the utility function U is concave, this alternative allocation frees up resources that can be used to raise ex ante utility, as we already described above. Moreover, it is easy to see that all the incentive constraints remain satisfied: agent $\theta_{(i+1)}$ is now strictly better off when reporting truthfully; agent $\theta_{(i)}$ is now indifferent between reporting truthfully and lying upward, since he gets the same present value of resources for both reports, and his consumption is optimally smoothed when he reports the truth; and agent $\theta_{(i-1)}$ is now strictly worse off if he lies, since his present value of resources at $\theta_{(i)}$ is lower. □

Lemmas 6 and 7 together imply that the relaxed problem (65)–(67) has a unique solution $\{\mathbf{c}^*,\boldsymbol{\tau}^*,0,K^*\}$, with $\boldsymbol{\tau}^* = \mathbf{c}^*$ and $K^* = e - \sum \pi(\theta_1)\tau_1(\theta_1)$, and where $\mathbf{c}^*$ is given by the solution to the problem

$$\max_{\{c_1(\theta_1),c_2(\theta_1,\theta_2)\}} \sum_{\theta_1\in\Theta}\pi(\theta_1)\left\{\theta_1 U(c_1(\theta_1)) + \sum_{\theta_2\in\Theta}\beta\pi(\theta_2)\theta_2 U(c_2(\theta_1,\theta_2))\right\} \tag{72}$$

subject

$$c_1(\theta_1)+\frac{1}{R}c_2(\theta_1,\theta_2)=\left(1+\frac{1}{R}\right)e, \quad \forall(\theta_1,\theta_2)\in\Theta^2. \tag{73}$$

This is because Eqs. (68) and (71) characterize the unique solution to (72)–(73). The solution to the latter problem is the allocation in an economy where each household can borrow *and* lend at the risk-free gross interest rate R, subject to the natural debt limit, with a present value of income equal to the endowment $\left(1+\frac{1}{R}\right)e$.

We finally prove that the solution to the original planner's problem (61)–(64) is the same as the solution to (65)–(67).

Proposition 10 *Any allocation* $\{\mathbf{c},\boldsymbol{\tau},k,K\}$ *is efficient, ie, solves (61)–(64), if and only if* $\mathbf{c}=\mathbf{c}^*$*, where* $\mathbf{c}^*$ *is the solution to problem (72)–(73).*

Proof In the solution to the problem (65)–(67), the agents receive the same net present value of transfers regardless of what taste shock they report. Moreover, telling the truth and not storing is weakly optimal, because the planner already optimally smoothes the consumption of a truthtelling agent, so that lying would not increase the present value of transfers nor improve their allocation over time. Therefore any solution to (65)–(67) is fully incentive compatible in the sense of (64), ie, with respect to the unrestricted set of possible deviations $(\hat{\theta},\hat{k})$.

The conclusion of this section is that in an environment with hidden storage, the optimal transfers that the planner chooses effectively relax the nonnegativity constraint on household storage. However, the optimal transfers offer *no insurance across agents*, as the present value of transfers must equal the economy's endowment *for all* histories $(\theta_1,\theta_2)\in\Theta^2$ (Eq. (73)). As a result, the allocation replicates a self-insurance economy; Cole and Kocherlakota (2001) propose a decentralization of this allocation that can be interpreted as an explicit microfoundation for the models with exogenously incomplete markets, eg, Aiyagari (1994).

2.7 Other Models

The techniques that we introduced in the previous sections in the context of the taste shock model can be easily applied to many more environments. First, Green (1987) and Thomas and Worrall (1990) study a model closely related to the one we analyzed above, in which the agent receives privately observed i.i.d. or persistent endowment (or income) shocks $\theta_t\in\Theta$: in each period $t\geq 1$, the agent observes his income shock θ_t and reports its realization to the planner, who then provides a transfer $\tau_t(\theta^t)$ to the agent. Second, Spear and Srivastava (1987) and Phelan and Townsend (1991) study a moral hazard model in which agents exert a privately observed effort level $\theta_t\in\Theta$ in each period. The output produced from that effort is stochastic and observable to the planner. The case where current effort affects only current output corresponds to the i.i.d. assumption 3 in the taste shock model, while the case where current effort also affects future output corresponds to the taste shock model with persistent types. Third, Thomas and Worrall (1988), Kocherlakota (1996), and Ligon et al. (2002) show that models of limited commitment, in which there is no asymmetry of information but one or both parties are free to walk away from the insurance contract, can be analyzed using similar recursive techniques using promised utilities as state variables; we discuss examples of these models in Section 4.

Here we describe briefly how to apply our recursive techniques to a model of repeated moral hazard. Agents exert an effort level $\theta_t \in \Theta = [0, \infty)$ in each period. The planner does not observe the agent's effort, but only the (random) output produced from that effort, $y_t \in Y = \{y_{(1)}, y_{(2)}\}$, with $0 = y_{(1)} < y_{(2)}$. The flow utility at time t is $U(c_t) - h(\theta_t)$, where the utility from consumption $U(\cdot): \mathbb{R}_+ \to \mathbb{R}$ is differentiable, strictly increasing, and strictly concave, and the disutility of effort $h(\cdot): \mathbb{R}_+ \to \mathbb{R}$ is differentiable, strictly increasing, and strictly convex with $h(0) = 0$ and $h'(0) \geq 0$.

We assume that the probability of output $y_t \in Y$ in period t depends only on the effort $\theta_t \in \Theta$ exerted by the agent in the *current* period.[p] We denote it by $\pi(y_t|\theta_t)$, and we suppose that $0 = \pi(y_{(2)}|0) < \pi(y_{(2)}|\theta) < 1$ for all $\theta > 0$, and $\pi(y_{(2)}|\cdot)$ is twice differentiable with $\pi_\theta(y_{(2)}|\cdot) > 0$. An allocation in this model consists of a sequence $\boldsymbol{\theta} = \{\theta_t(y^{t-1})\}_{t\geq 1}$ (with $y^0 = \varnothing$) describing the effort recommended by the planner to the agent given the observed history of output at the beginning of each period t, and a sequence of utility payments $\mathbf{u} = \{u_t(y^t)\}_{t\geq 1}$ given the observed history of output at the end of each period t. The planner chooses the incentive-compatible allocation $\{\mathbf{c}, \boldsymbol{\theta}\}$ that minimizes the cost of delivering lifetime utility v_0, that is, letting $C \equiv U^{-1}$,

$$\begin{aligned} K(v_0) \equiv \max_{\boldsymbol{\theta}, \mathbf{u}} \quad & \mathbb{E}^{\boldsymbol{\theta}}\left[\sum_{t=1}^{\infty} \beta^{t-1}\{y_t - C(u_t(y^t))\}\right] \\ \text{subject to} \quad & \mathbb{E}^{\boldsymbol{\theta}}\left[\sum_{t=1}^{\infty} \beta^{t-1}\left\{u_t(y^t) - h\left(\theta_t\left(y^{t-1}\right)\right)\right\}\right] = v_0, \\ & \mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[\sum_{t=1}^{\infty} \beta^{t-1}\left\{u_t(y^t) - h\left(\hat{\theta}_t\left(y^{t-1}\right)\right)\right\}\right] \leq v_0, \quad \forall \hat{\boldsymbol{\theta}}, \end{aligned} \tag{74}$$

[p] The analysis of the case where current effort also affects future output is slightly more involved than that of Section 2.5. This is because there is a form of nonseparability of the agent's lifetime utility (incentives in a given period depend no longer only on his current true type and past reports, but also on his past true types) which implies that truthful revelation does not necessarily hold after the agent has deviated from the recommended action in the past; see Example of Section S.5 in Pavan et al. (2014). Thus, after a deviation an agent may prefer to engage in a strategy of infinite deviations, so that one generally cannot restrict attention to one shot deviations in such settings. Fernandes and Phelan (2000) nevertheless show how to modify the arguments of Section 2.5 to write a recursive formulation of this problem.

where the superscripts over expectations $\mathbb{E}^{\boldsymbol{\theta}}$ and $\mathbb{E}^{\hat{\boldsymbol{\theta}}}$ indicate that the probability distributions over the paths of output $\{y^t\}_{t\geq 1}$ depend on the agent's strategies $\boldsymbol{\theta}$ and $\hat{\boldsymbol{\theta}}$ (respectively), that is, for any t and random variable $X_t(y^t)$ we let $\mathbb{E}^{\boldsymbol{\theta}}[X_t] \equiv \sum_{y^t \in Y^t} \pi_t(y^t|\theta^t) X_t(y^t)$. Thus, each expectation in the incentive constraint depends on the agent's effort directly through the cost of effort $h(\theta_t)$, and indirectly through its effect on the probability distribution $\pi_t(y^t|\boldsymbol{\theta})$ over the paths of y^t.

Defining the continuation utility of an obedient (truthtelling) agent up to and after date t as in (11), we can rewrite this problem recursively:

$$
\begin{aligned}
K(v) = \max_{\theta, \vec{u}, \vec{w}} \; & \sum_{y \in Y} \pi(y|\theta)[y - C(u(y)) + \beta K(w(y))] \\
\text{s.t.} \quad & v = \sum_{y \in Y} \pi(y|\theta)[u(y) - h(\theta) + \beta w(y)], \\
& \pi_\theta\left(y_{(2)}|\theta\right)\left[\left(u\left(y_{(2)}\right) - u\left(y_{(1)}\right)\right) + \beta\left(w\left(y_{(2)}\right) - w\left(y_{(1)}\right)\right)\right] - h'(\theta) \leq 0 \\
& \qquad \text{with equality if } \theta > 0,
\end{aligned}
\tag{75}
$$

where the incentive-compatibility constraint is replaced by a first-order condition, assuming for simplicity that this condition is sufficient.

Following the steps leading to Proposition 5, we can obtain a characterization of the solution to the planner's problem. For any interior v, the optimal contract $\left(\theta_v, \vec{u}_v, \vec{w}_v\right)$ satisfies the following martingale property (with respect to the probability measure associated with the optimum effort strategy $\mathbb{P}^{\boldsymbol{\theta}}$):

$$
K'(v) = \mathbb{E}^{\theta_v}[-C'(u_v)] = \mathbb{E}^{\theta_v}[K'(w_v)]. \tag{76}
$$

The first-order conditions of the problem imply moreover that $K'\left(w_v\left(y_{(j)}\right)\right) = -C'\left(u_v\left(y_{(j)}\right)\right)$, so that this property can be rewritten as:

$$
\frac{1}{u'(c_t(y^t))} = \sum_{y_{t+1} \in Y} \pi(y_{t+1}|\theta_{t+1}(y^t)) \frac{1}{u'(c_{t+1}(y^t, y_{t+1}))}. \tag{77}
$$

This equation is known in the literature as the *Inverse Euler Equation* (see Diamond and Mirrlees, 1978; Rogerson, 1985; Spear and Srivastava, 1987; Golosov et al., 2003). We derive implications of this equation in Section 4.1 and show by comparing it to the individual's Euler equation in a decentralized economy that agents' savings must be constrained in the optimal insurance arrangement.

We can further analyze problem (75) along the lines of the proof of Proposition 5. A utility-effort pair (v, θ_v) is absorbing if and only if $\theta_v = 0$ and $(u_v(y), w_v(y)) = ((1-\beta)v, v)$. The recommended effort θ_v is strictly positive as long as the promised utility is small enough, $v < \bar{v}$. If $h'(0) = 0$, we find that $\bar{v} = \infty$, so that the recommended effort is always positive, and the Martingale Convergence Theorem implies that immiseration occurs: $v_t(\theta^t) \to \underline{v}$ as $t \to \infty$ with probability 1. If instead $h'(0) > 0$, the principal will eventually "retire" the agent (ie, recommend effort $\theta_t(y^t) = 0$ and provide constant consumption $c_t(y^t) = c$) when $v_t(\theta^t) \geq \bar{v}$, as for a large enough promised utility the benefit of inducing him to work outweighs the cost of providing the necessary incentives and compensating him for the higher effort. We leave the formal proof and derivation of the value of $\bar{v}$ to the reader.

3. ADVANCED TOPICS

In this section we discuss three additional topics that significantly expand the applicability of the recursive contract theory. In Section 3.1 we overview the theory of Lagrange multipliers and show how it can help solve many dynamic incentive problems recursively even if they do not fit into the canonical setup described in Section 2. Section 3.2 shows how to extend the analysis to settings in which the ability of the principal to commit is imperfect. Finally, in Section 3.3, we describe the analysis of dynamic contracting problems in continuous time using martingale methods. Throughout this section we do not aim at the same level of rigor as in Section 2; we omit several technical details and refer to the relevant papers for the complete proofs.

3.1 Lagrange Multipliers

The key feature that allowed us to analyze the dynamic contracting problem (17) is that we could write the incentive constraints in a simple recursive form. In many applications, however, the optimal contracting problem often has additional constraints that cannot easily be written recursively. For example, if we replaced the present value budget constraint (2) with a requirement that the total consumption of all agents should be equal to the total endowment in *each* period, the previous method could not be applied directly. In this section we describe a simple approach that allows us to extend our analysis to such problems. The main idea behind this approach is to assign Lagrange multipliers to all the constraints that do not have a straightforward recursive representation, and to apply the techniques developed in the previous sections to the resulting Lagrangian.

We start in Section 3.1.1 by giving a general theoretical background about the properties of Lagrange multipliers in infinite dimensional spaces. Infinite dimensional spaces are common in macroeconomic applications but the Lagrangian techniques are more subtle in such spaces than in finite dimensions. The main results of this section are, first, Theorems 3 and 4, which provide conditions under which the Lagrangian exists and characterize the solution to the constrained optimization problem, and second, Theorem 5, which provides sufficient conditions that ensure that the Lagrangian can be written as an infinite sum, allowing us to apply the standard techniques familiar from finite-dimensional optimization theory. Sections 3.1.2–3.1.4 give several examples of applications of these techniques. The reader only interested in practical applications can skip Section 3.1.1 in the first reading.

3.1.1 Main Theoretical Results

The classical reference about using Lagrange multipliers to solve optimization problems is Luenberger (1969). Here we state two main results from this book, adapting them to our setting. To use this approach, we need to set our problem in abstract linear spaces.[q] Before starting our analysis we introduce the notions of convex cones and mappings, dual spaces, and l_p spaces.

First, let P be a convex cone in a vector space $\mathcal{V}$, that is, P satisfies $\alpha x + \beta y \in P$ for all $x, y \in P$ and $\alpha, \beta > 0$. This convex cone defines a partial order $\leq$ on $\mathcal{V}$, such that $x \geq y$ if $x - y \in P$. By definition, P is the positive cone with respect to this partial order, ie, the subset $\mathcal{V}^+ = \{x \in \mathcal{V} : x \geq 0\}$. We write $x > 0$ if x is an interior point of the positive cone P. By introducing a cone defining the positive vectors in the vector space $\mathcal{V}$, we thus define an ordering relation $\leq$ and make it possible to consider inequality problems in the abstract vector space $\mathcal{V}$. (Often the positive cones of the vector spaces we consider are constructed naturally, eg, the positive orthant of $\mathbb{R}^n$ or the nonnegative continuous functions of $\mathcal{C}([a,b])$.) A mapping $G : \mathcal{V}_1 \to \mathcal{V}_2$ from a vector space $\mathcal{V}_1$ to a vector space $\mathcal{V}_2$ having a cone P defined as the positive cone is said to be *convex* if the domain Ω of G is a convex set and if $G(\alpha x_1 + (1-\alpha)x_2) \leq \alpha G(x_1) + (1-\alpha)G(x_2)$ for all $x_1, x_2 \in \Omega$ and all $\alpha \in (0,1)$.

Second, the dual $\mathcal{V}^*$ of a normed vector space $\mathcal{V}$ is the space of all bounded linear functionals on $\mathcal{V}$, ie, $f : \mathcal{V} \to \mathbb{R}$. The norm of an element $f \in \mathcal{V}^*$ is $\|f\| = \sup_{\|x\| \leq 1} |f(x)|$. The value of the linear functional $x^* \in \mathcal{V}^*$ at the point $x \in \mathcal{V}$, that is $x^*(x)$, is denoted by $\langle x, x^* \rangle$. For $1 \leq p < \infty$, the space l_p consists of all sequences of scalars $\{u_1, u_2, \ldots\}$ for which $\sum_{n=1}^{\infty} |u_n|^p < \infty$, and the space l_∞ consists of the bounded sequences. The norm of an element $u = \{u_n\}_{n \geq 1} \in l_p$ is defined as $\|u\|_p = \left(\sum_{i=1}^{\infty} |u_n|^p\right)^{1/p}$ for $p < \infty$, and as $\|u\|_p = \sup_n |u_n|$ for $p = \infty$. Then for every $p \in [1, \infty)$, the dual space of l_p is l_q, where $q = (1 - p^{-1})^{-1}$. This is because every bounded linear functional f on l_p, $1 \leq p < \infty$, can be represented uniquely in the form $f(u) = \sum_{n=1}^{\infty} v_n u_n$, where $v = \{v_n\}_{n \in \mathbb{N}^*}$ is an element of l_q; specifically, for all $n \geq 1$, $v_n \equiv f(e_n)$, where $e_n \in l_p$ is the sequence that is identically zero except for a 1 in the n^{th} component. The dual of l_∞, however, *strictly contains* l_1. Finally, given a normed space $\mathcal{V}$ together with a positive convex cone $P \subset \mathcal{V}$, it is natural to define a corresponding positive convex cone P^* in the dual space $\mathcal{V}^*$ by $P^* = \{x^* \in \mathcal{V}^* : \forall x \in P,\ \langle x, x^* \rangle \geq 0\}$.

[q] For a review of basic functional analysis, see Luenberger (1969), or Chapters 3 and 15 in Stokey et al. (1989).

We can now introduce the theory of Lagrange multipliers. Consider a problem

$$\begin{aligned} \min_{\mathbf{x}} \quad & \varphi(\mathbf{x}) \\ \text{subject to} \quad & \Phi(\mathbf{x}) \leq \mathbf{0}, \mathbf{x} \in \Gamma, \end{aligned} \tag{78}$$

where Γ is a convex subset of a vector space X, $\varphi : \Gamma \rightarrow \mathbb{R}$ is a convex functional, and $\Phi : \Gamma \rightarrow Z$ is a convex mapping to a normed vector space Z that has positive cone P. Let Z^* be the dual space of Z and Z_+^* be its positive orthant (ie, all $\mathbf{z}^* \in Z^*$ such that $\mathbf{z}^* \geq \mathbf{0}$). We assume throughout this section that the minimum of problem (78) is attained. This assumption is not necessary but it simplifies the statement of the theorems, and we will see in our context (Proposition 11) that it can often be verified directly. Theorem 1, p. 217, and Corollary 1, p. 219 in Luenberger (1969), give the main results for solving the minimization problem (78) using Lagrange multipliers.

Theorem 3 *Assume that the minimum in (78) is achieved at $\hat{\mathbf{x}}$. Suppose that P contains an interior point, and that there exists $\mathbf{x}' \in \Gamma$ such that $\Phi(\mathbf{x}') < 0$. Then there is $\hat{\mathbf{z}}^* \in Z_+^*$ such that the Lagrangian*

$$\mathcal{L}(\mathbf{x}, \mathbf{z}^*) = \varphi(\mathbf{x}) + \langle \Phi(\mathbf{x}), \mathbf{z}^* \rangle$$

has a saddle point at $(\hat{\mathbf{x}}, \hat{\mathbf{z}}^*)$, ie,

$$\mathcal{L}(\hat{\mathbf{x}}, \mathbf{z}^*) \leq \mathcal{L}(\hat{\mathbf{x}}, \hat{\mathbf{z}}^*) \leq \mathcal{L}(\mathbf{x}, \hat{\mathbf{z}}^*), \forall \mathbf{x} \in \Gamma, \mathbf{z}^* \in Z_+^*. \tag{79}$$

Moreover,

$$\langle \Phi(\hat{\mathbf{x}}), \hat{\mathbf{z}}^* \rangle = 0.$$

Theorem 3 establishes that for convex problems there generally exists a Lagrangian such that the solution to the original constrained minimization problem is also a solution to the minimization of the unconstrained Lagrangian. The next result (Theorem 2, p. 221 in Luenberger, 1969) ensures the sufficiency:

Theorem 4 *Let $X, Z, \Gamma, P, \varphi, \Phi$ be as above and assume that the positive cone $P \subset Z$ is closed. Suppose that there exist $\hat{\mathbf{z}}^* \in Z_+^*$ and an $\hat{\mathbf{x}} \in \Gamma$ such that the Lagrangian $\mathcal{L}(\mathbf{x}, \mathbf{z}^*)$ has a saddle point at $(\hat{\mathbf{x}}, \hat{\mathbf{z}}^*)$. Then $\hat{\mathbf{x}}$ is a solution to (78).*

Thus, if φ and Φ are convex, the positive cone $P \subset Z$ is closed and has nonempty interior, and the regularity condition $\Phi(\mathbf{x}') < 0$ is satisfied, then the saddle point condition is necessary and sufficient for the optimality of $\hat{\mathbf{x}}$.

One way to find a saddle point of $\mathcal{L}$ is to use the following result (see Bertsekas et al., 2003).

Corollary 1 $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$ is a saddle point of $\mathcal{L}$ if and only if the equality

$$\inf_{\mathbf{x}\in\Gamma}\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x},\mathbf{z}^*)=\sup_{\mathbf{z}^*\in Z_+^*}\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*) \tag{80}$$

is satisfied, and

$$\begin{aligned}\hat{\mathbf{x}}= &\quad \arg\min_{\mathbf{x}\in\Gamma}\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x},\mathbf{z}^*),\\ \hat{\mathbf{z}}^*= &\quad \arg\max_{\mathbf{z}^*\in Z_+^*}\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*).\end{aligned} \tag{81}$$

In particular, suppose that the conditions of Theorem 3 hold, so that $\mathcal{L}(\mathbf{x},\mathbf{z}^*)$ has a saddle point at $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$. Suppose moreover that $\arg\min_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)$ exists for each $\mathbf{z}^*\in Z_+^*$ and is unique for $\mathbf{z}^*=\hat{\mathbf{z}}^*$. Then $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$ is the solution to $\max_{\mathbf{z}^*\in Z_+^*}\min_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)$.

Proof Suppose $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$ is a saddle point. Then

$$\inf_{\mathbf{x}\in\Gamma}\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x},\mathbf{z}^*)\leq\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\hat{\mathbf{x}},\mathbf{z}^*)=\mathcal{L}(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)=\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\hat{\mathbf{z}}^*)\leq\sup_{\mathbf{z}^*\in Z_+^*}\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*).$$

By the max–min inequality, $\inf_{\mathbf{x}\in\Gamma}\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x},\mathbf{z}^*)\geq\sup_{\mathbf{z}^*\in Z_+^*}\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)$, establishing that all these inequalities hold with equality, and hence (80) and (81) are satisfied.

Conversely, suppose that (80) and (81) hold. Then

$$\sup_{\mathbf{z}^*\in Z_+^*}\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)=\inf_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\hat{\mathbf{z}}^*)\leq\mathcal{L}(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)\leq\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\hat{\mathbf{x}},\mathbf{z}^*)=\inf_{\mathbf{x}\in\Gamma}\sup_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x},\mathbf{z}^*).$$

Eq. (80) implies that $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$ is a saddle point.

Finally suppose that the conditions of Theorem 3 are satisfied, so that $\mathcal{L}(\mathbf{x},\mathbf{z}^*)$ has a saddle point at $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$, and that $\mathbf{x}(\mathbf{z}^*)\equiv\arg\min_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)$ exists for each $\mathbf{z}^*\in Z_+^*$ and is unique for $\mathbf{z}^*=\hat{\mathbf{z}}^*$. Then, by (81) we have $\hat{\mathbf{z}}^*=\arg\max_{\mathbf{z}^*\in Z_+^*}\mathcal{L}(\mathbf{x}(\mathbf{z}^*),\mathbf{z}^*)$. By the uniqueness assumption we have $\mathcal{L}(\mathbf{x}(\hat{\mathbf{z}}^*),\hat{\mathbf{z}}^*)<\mathcal{L}(\mathbf{x},\hat{\mathbf{z}}^*)$ for all $\mathbf{x}\neq\mathbf{x}(\hat{\mathbf{z}}^*)$, so that the saddle point (79) can only be achieved at $(\mathbf{x}(\hat{\mathbf{z}}^*),\hat{\mathbf{z}}^*)$, establishing that $\hat{\mathbf{x}}=\mathbf{x}(\hat{\mathbf{z}}^*)$. We obtain that the solution to $\max_{\mathbf{z}^*\in Z_+^*}\min_{\mathbf{x}\in\Gamma}\mathcal{L}(\mathbf{x},\mathbf{z}^*)$ is $(\hat{\mathbf{x}},\hat{\mathbf{z}}^*)$. □

The max-min problem in Corollary 1 provides a simple way to find the solution to the minimization problem together with the corresponding Lagrangian. The uniqueness qualifier is important for that result; without it there may exist solutions to the $\max\min$ problem that are not saddle points, ie, that are not a solution to the original optimization problem (see, eg, Messner and Pavoni, 2016).

In economic applications, $\mathbf{\Phi}$ often represents per-period constraints and it can be written as $\mathbf{\Phi}=\{\Phi_1,\Phi_2,\ldots\}$. The most natural vector space to choose in such situations is the space of bounded sequences, l_∞. In this case we define the positive cone P of l_∞ as the positive orthant, ie, the subset of nonnegative sequences of l_∞. Exercise 15.7 in

Stokey et al. (1989) shows that l_∞ is the only l_p space that has a positive orthant with a nonempty interior, which is a requirement needed to apply the theorems above.

A limitation of the space l_∞ is that its dual is complicated. It contains the space of summable sequences l_1, but it also includes other sequences which are not summable. This makes the analysis difficult because the linear operator $\langle \mathbf{\Phi}(\mathbf{x}), \hat{\mathbf{z}}^* \rangle$ may take a complicated form. The analysis simplifies if it can be ensured that the mappings φ and $\mathbf{\Phi}$ are not affected by how $\mathbf{x}$ behaves "at infinity," in which case we can provide an l_1 representation of the Lagrange multipliers and each constraint $\mathbf{\Phi}_n(\mathbf{x})$ will have a scalar multiplier λ_n associated with it. For any $\mathbf{x}, \mathbf{y} \in l_\infty$, define an operator $x^T(\mathbf{x}, \mathbf{y})$ as $x^T(\mathbf{x}, \mathbf{y}) = x_t$ if $t \leq T$ and $x^T(\mathbf{x}, \mathbf{y}) = y_t$ if $t > T$. We use the notation $x_t^T(\mathbf{x}, \mathbf{y})$ to denote the t-th element of this operator.

Assumption 5 Let $X, Z = l_\infty$, $\mathbf{\Psi} = \{\mathbf{x} \in \Gamma : \varphi(\mathbf{x}) < \infty\}$. Suppose that:

(i) If $(\mathbf{x}, \mathbf{y}) \in \mathbf{\Psi} \times l_\infty$ satisfy $x^T(\mathbf{x}, \mathbf{y}) \in \mathbf{\Psi}$ for all T large enough, then $\varphi\left(x^T(\mathbf{x}, \mathbf{y})\right) \to \varphi(\mathbf{x})$ as $T \to \infty$.

(ii) If $\mathbf{x}$,$\mathbf{y} \in \Gamma$ and $x^T(\mathbf{x}, \mathbf{y}) \in \Gamma$ for all T large enough, then:

$$\begin{aligned} &(a) \quad \forall t, \ \lim_{T \to \infty} \mathbf{\Phi}_t\left(x^T(\mathbf{x}, \mathbf{y})\right) = \mathbf{\Phi}_t(\mathbf{x}), \\ &(b) \quad \exists M \text{ s.t. } \forall T \text{ large enough}, \left\| \mathbf{\Phi}\left(x^T(\mathbf{x}, \mathbf{y})\right) \right\| \leq M, \\ &(c) \quad \forall T \text{ large enough}, \ \lim_{t \to \infty} \left[\mathbf{\Phi}_t\left(x^T(\mathbf{x}, \mathbf{y})\right) - \mathbf{\Phi}_t(\mathbf{y})\right] = 0. \end{aligned}$$

Le Van and Saglam (2004) prove that under these assumptions the Lagrangian can be written as an infinite sum:[r]

Theorem 5 *Let $\hat{\mathbf{x}}$ be a solution to (78). Suppose that for all $\mathbf{x} \in \Gamma$, we have $\mathbf{\Phi}(\mathbf{x}) \in l_\infty$. Assume that there exists $\mathbf{x}' \in \Gamma$ such that $\mathbf{\Phi}(\mathbf{x}') < 0$, that is, $\sup_t \mathbf{\Phi}_t(\mathbf{x}') < 0$ (Slater condition). Assume finally that Assumption 5 is satisfied and that $x^T(\hat{\mathbf{x}}, \mathbf{x}') \in \Gamma \cap \mathbf{\Psi}$ for all T large enough. Then there exists $\hat{\mathbf{z}}^* \in l_1$ with $\hat{\mathbf{z}}^* \geq \mathbf{0}$ such that*

$$\sum_{t=1}^{\infty} \hat{z}_t^* \mathbf{\Phi}_t(\hat{\mathbf{x}}) = 0,$$

and

$$\varphi(\mathbf{x}) + \sum_{t=1}^{\infty} \hat{z}_t^* \mathbf{\Phi}_t(\mathbf{x}) \geq \varphi(\hat{\mathbf{x}}) + \sum_{t=1}^{\infty} \hat{z}_t^* \mathbf{\Phi}_t(\hat{\mathbf{x}}), \forall \mathbf{x} \in \Gamma.$$

In the next sections, we apply this theory to dynamic contracting problems.

[r] See also Rustichini (1998) who provides an alternative set of sufficient conditions ensuring the summability of the Lagrange multipliers.

3.1.2 Application: Recursive Contracts in General Equilibrium

Consider a simple modification of the setup in Section 2.3, in which the planner can no longer freely borrow and lend at an exogenous interest rate. Instead we require the economy-wide feasibility constraint to hold period by period, ie,

$$\sum_{\theta^t \in \Theta^t} \pi_t(\theta^t) C(u_t(\theta^t)) \leq e, \forall t \geq 1. \tag{82}$$

This problem is analyzed by Atkeson and Lucas (1992). For simplicity we assume that $|\Theta| = 2$ and that shocks are i.i.d. to parallel our discussion in Sections 2.3 and 2.4. Thus we study the problem

$$\max_{\mathbf{u}} \mathbb{E}_0 \left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t u_t(\theta^t) \right] \tag{83}$$

subject to

$$\mathbb{E}_0[C(u_t(\theta^t))] \leq e, \forall t \geq 1, \tag{84}$$

and

$$\mathbb{E}_0 \left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t \{ u_t(\theta^t) - u_t(\sigma^t(\theta^t)) \} \right] \geq 0, \forall \boldsymbol{\sigma}. \tag{85}$$

Assume for now that the maximum in the problem (83) is attained for all $e > 0$; we will show this formally below.

Let Γ be the set of sequences $\mathbf{u} = \{u_t(\theta^t)\}_{t \geq 1, \theta^t \in \Theta^t}$, indexed by (t, θ^t), such that $\mathbf{u}$ satisfies the period-0 incentive constraint (85) and the sequence $\{\mathbb{E}_0[C(u_t)] - e\}_{t=1}^{\infty}$ is bounded in sup-norm. The set Γ is convex and has an interior point, eg, $u_t(\theta^t) = \varepsilon$ for all t, θ^t and $\varepsilon > 0$ sufficiently small.

We start with the sufficient conditions first. Let X be the space of all infinite sequences, $Z = l_\infty$, and $\mathbf{\Phi} = \{\Phi_1, \Phi_2, \ldots\}$, where $\mathbf{\Phi}_t : \Gamma \to \mathbb{R}$ is defined by $\mathbf{\Phi}_t(\mathbf{u}) = \mathbb{E}_0[C(u_t)] - e$. Suppose that we can find a nonnegative sequence $\boldsymbol{\lambda} = \{\lambda_t\}_{t=1}^{\infty}$ such that the problem[s]

$$\max_{\mathbf{u} \in \Gamma} \mathbb{E}_0 \left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t u_t \right] - \sum_{t=1}^{\infty} \lambda_t \{ \mathbb{E}_0[C(u_t)] - e \} \tag{86}$$

has a maximum $\hat{\mathbf{u}}$ and $\mathbb{E}_0[C(\hat{u}_t)] = e$ for all t. To verify that $(\hat{\mathbf{u}}, \boldsymbol{\lambda})$ is a saddle point, observe that for any $\mathbf{z}^* \in Z_+^*$, we have $\langle \mathbf{\Phi}(\hat{\mathbf{u}}), \mathbf{z}^* \rangle \leq 0 = \langle \mathbf{\Phi}(\hat{\mathbf{u}}), \boldsymbol{\lambda} \rangle$. Moreover, the regularity condition $\mathbf{\Phi}(\mathbf{u}') < 0$ holds for some $\mathbf{u}' \in \Gamma$, ie, $\mathbf{u}'$ satisfies incentive compatibility

[s] To be consistent with discussion in Section 3.1.1, we use the fact that minimizing φ is equivalent to maximizing $-\varphi$.

(take $u_t'(\theta^t) = \varepsilon$). Therefore $\hat{\mathbf{u}}$ is a solution to the original problem (83) by Theorem 4. Note that we impose no boundedness assumption on the utility function.

To illustrate an application of this result, consider an example with logarithmic preferences. We argue that the Lagrange multiplier $\boldsymbol{\lambda}$ has the form $\lambda_t = \lambda_1 \beta^t$ for some λ_1. Following the same steps as in Section 2.3, replace the period-0 incentive constraints with a sequence of one-shot constraints. Moreover, we consider an auxiliary planner's problem that has a recursive structure, by augmenting the set of constraints with the promise-keeping condition

$$\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}\theta_t u_t(\theta^t)\right] = v_0. \tag{87}$$

The constraint set is then the set $\Gamma(v_0)$ defined in (16). We can rewrite the problem (86)–(87) as

$$\max_{(\mathbf{u},\mathbf{v})\in\Gamma(v_0)} v_0 - \sum_{t=1}^{\infty}\lambda_t\{\mathbb{E}_0[C(u_t)] - e\}.$$

The solution to this problem coincides, given our guess $\lambda_t = \lambda_1\beta^t$, with the solution to the problem

$$\max_{(\mathbf{u},\mathbf{v})\in\Gamma(v_0)} -\sum_{t=1}^{\infty}\beta^{t-1}\mathbb{E}_0[C(u_t)],$$

which is, of course, the same problem as the one we analyzed in Section 2.3. Therefore, if we can show that the solution to that problem satisfies the feasibility constraint (82) for each period t, we found the solution to our new problem. We recover the solution to the original problem by maximizing the auxiliary problem over v_0.

We now check that this is the case. Let $(\mathbf{u}, \mathbf{v})$ be the allocation generated by the policy functions to the Bellman equation (23) for some v_0. The optimality conditions (29) imply

$$K'(v_0) = \mathbb{E}_0[-C'(u_1)] = \mathbb{E}_0[K'(v_1)] = \mathbb{E}_0[\mathbb{E}_1[-C'(u_2)]] = \mathbb{E}_0[-C'(u_2)].$$

When preferences are logarithmic, $C = C' = \exp$, thus forward induction implies $\mathbb{E}_0[C(u_1)] = \mathbb{E}_0[C(u_t)]$ for all t. Since v_0 must satisfy $K(v_0) = -\frac{1}{1-\beta}e$, this implies that $\mathbb{E}_0[C(u_t)] = e$ for all t, establishing our result (and justifying our guess for λ_t).

When we set up the maximization problem (86) we assumed the existence of a summable sequence $\boldsymbol{\lambda}$ such that the feasibility constraints are satisfied with equality in all periods at the optimum. We subsequently showed how to explicitly construct such a sequence of multipliers in an example with logarithmic preferences. We now conclude this section by discussing sufficient conditions ensuring the existence of a summable sequence of Lagrange multipliers. Note that without any further assumptions, the maximization problem

$$\max_{\mathbf{u}\in\Gamma,\,\Phi(\mathbf{u})\leq\mathbf{0}} \mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}\theta_t u_t\right]$$

satisfies all the conditions of Theorem 3, so that a Lagrangian exists. To show that it is a summable sequence we verify conditions of Theorem 5. It is the easiest to do in the case of bounded utility.[t] In this case any sequence $\mathbf{u}$ lies in l_∞. Assumption 5.i holds following the arguments we use below in the proof of Proposition 11. Since the constraint (82) holds for each t, we immediately have $\mathbb{E}_0[C(u_t)] = \mathbb{E}_0\left[C\left(x_t^T(\mathbf{u},\mathbf{v})\right)\right]$ for T sufficiently large holding t fixed, and $\mathbb{E}_0\left[C\left(x_t^T(\mathbf{u},\mathbf{v})\right)\right] = \mathbb{E}_0[C(v_t)]$ for t sufficiently large holding T fixed, which verifies Assumptions 5.ii.a and 5.ii.c. Assumption 5.ii.b holds by definition of Γ. Therefore Theorem 5 establishes that the Lagrange multipliers form a summable sequence.

Existence of a Maximum

We finally show the existence of the maximum in problem (83). Note that we already showed the existence in Section 2.3.2 using the (finite-dimensional) Bellman formulation of the problem. Here we do so directly, using techniques that can be applied to other contexts where the previous approach is not readily available.

It is not obvious a priori that the maximum in this problem exists. In finite dimensional spaces, the continuity of the objective function and the compactness of the constraint sets are easily obtained, implying directly the existence of a maximum. These properties are more difficult to obtain in infinite period economies. The next proposition guarantees that the infinite-horizon planner's problem is a well-defined maximization problem, ie, there exist feasible $(\mathbf{u}^*, \mathbf{v}^*)$ for which the supremum is achieved. The reader interested mostly in the applications can skip this section.

Proposition 11 *The maximum in the problem (83) is attained for all $e > 0$.*

Proof One of the easiest ways to show the existence of the maximum in the planner's problem is to truncate the economy at any finite period T, show the existence of the solution for this truncated economy, and finally show that the limit of this solution achieves the supremum of the original problem as $T \rightarrow \infty$. To show these we adapt the arguments of Ekeland and Scheinkman (1986).

We first restrict allocations in each period to compact sets as follows. Fix $e > 0$. For any $t \geq 1$ and $\theta^t \in \Theta^t$, define $\bar{\bar{u}}_t(\theta^t) \in (\underline{u}, \bar{u})$ by

$$\bar{\bar{u}}_t(\theta^t) = C^{-1}\left(\frac{e}{\pi_t(\theta^t)}\right).$$

[t] See Rustichini (1998) for existence arguments when the utility is not bounded.

If $u_t(\theta^t) > \bar{\bar{u}}_t(\theta^t)$ for any history $\theta^t \in \Theta^t$, then $\mathbb{E}_0[C(u_t)] > e$, and the allocation is not feasible. This gives us an upper bound $u_t(\theta^t) \le \bar{\bar{u}}_t(\theta^t)$ for all t, θ^t. Let

$$\bar{\bar{v}}_t = \mathbb{E}_t\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}\bar{\bar{u}}_{t+s}(\theta^{t+s})\right].$$

If $\bar{u} < \infty$, we have $\bar{\bar{v}}_t < \dfrac{\bar{u}}{1-\beta} = \bar{v}$. If $\bar{u} = \bar{v} = \infty$, then we can write

$$\bar{\bar{v}}_t \le \max_{\Theta}\theta \times \sum_{s=1}^{\infty}\beta^{s-1}\left\{\sum_{\theta^{t+s}}\pi_{t+s}(\theta^{t+s})U\left(\frac{e}{\pi_{t+s}(\theta^{t+s})}\right)\right\} \le \theta_{(|\Theta|)}\sum_{s=1}^{\infty}\beta^{s-1}U(|\Theta|e) < \infty,$$

where the second inequality follows from the concavity of U. Therefore we have $v_t(\theta^t) \le \bar{\bar{v}}_t < \bar{v}$, for all t, θ^t. Next, if $\underline{u} > -\infty$, let $\underline{\underline{u}}_t(\theta^t) = \underline{u}$ for all t, θ^t. Now suppose instead that $\underline{u} = -\infty$. We have $\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}\theta_t u_t(\theta^t)\right]$ diverges toward $-\infty$ when $\beta^{s-1}\theta_s u_s(\theta^s) \to -\infty$ for some (s, θ^s), because

$$\begin{aligned}\sum_{t=1}^{\infty}\beta^{t-1}\sum_{\theta^t \in \Theta^t \setminus \{\theta^s\}}\pi_t(\theta^t)\theta_t u_t(\theta^t) &\le \sum_{t=1}^{\infty}\beta^{t-1}\sum_{\theta^t \in \Theta^t \setminus \{\theta^s\}}\pi_t(\theta^t)\theta_t \bar{\bar{u}}_t(\theta^t)\\ &= \bar{\bar{v}}_0 - \beta^{s-1}\pi_s(\theta^s)\theta_s\bar{\bar{u}}_s(\theta^s) < \infty.\end{aligned}$$

Thus, if $u_s(\theta^s)$ is small enough, the allocation is dominated by $\tilde{u}_t(\theta^t) = C^{-1}(e)$ for all (t, θ^t). Hence for each (t, θ^t) we have a lower bound $u_t(\theta^t) \ge \underline{\underline{u}}_t(\theta^t) > -\infty$. Similarly we have $v_t(\theta^t) \ge \underline{\underline{v}}_t > -\infty$, where

$$\underline{\underline{v}}_t = \mathbb{E}_t\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}C^{-1}(e)\right] = \frac{C^{-1}(e)}{1-\beta}.$$

Therefore, defining $\underline{\underline{u}}_t \equiv \min_{\Theta^t}\underline{\underline{u}}_t(\theta^t)$, $\underline{\underline{v}}_t \equiv \min_{\Theta^t}\underline{\underline{v}}_t(\theta^t)$, $\bar{\bar{u}}_t \equiv \max_{\Theta^t}\bar{\bar{u}}_t(\theta^t)$ and $\bar{\bar{v}}_t \equiv \max_{\Theta^t}\bar{\bar{v}}_t(\theta^t)$, we have shown that we can impose the additional constraints

$$\begin{aligned}\underline{\underline{u}}_t &\le u_t(\theta^t) \le \bar{\bar{u}}_t,\\ \underline{\underline{v}}_t &\le v_t(\theta^t) \le \bar{\bar{v}}_t,\end{aligned}$$

for all t, θ^t.

Next, we truncate the economy to $T < \infty$ periods and allow the planner to provide incentives in the last period "for free." That is, we define

$$V^T(e) = \sup_{\substack{u_t(\theta^t) \in \left[\underline{\underline{u}}_t, \bar{\bar{u}}_t\right] \\ v_t(\theta^t) \in \left[\underline{\underline{v}}_t, \bar{\bar{v}}_t\right]}} \mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}\theta_t u_t(\theta^t)\right]$$

subject to the promise-keeping constraints

$$v_t(\theta^t) = \sum_{\theta \in \Theta} \pi(\theta)[\theta u_{t+1}(\theta^t, \theta) + \beta v_{t+1}(\theta^t, \theta)], \forall t \leq T-1,$$

the incentive-compatibility constraints

$$\theta u_t\left(\theta^{t-1}, \theta\right) + \beta v_t\left(\theta^{t-1}, \theta\right) \geq \theta u_t\left(\theta^{t-1}, \hat{\theta}\right) + \beta v_t\left(\theta^{t-1}, \hat{\theta}\right), \forall t \leq T,$$

and the feasibility constraints

$$\mathbb{E}_0[C(u_t)] \leq e, \quad \forall t \leq T.$$

Note that the last incentive constraint is:

$$\theta u_T\left(\theta^{T-1}, \theta\right) + \beta v_T\left(\theta^{T-1}, \theta\right) \geq \theta u_T\left(\theta^{T-1}, \hat{\theta}\right) + \beta v_T\left(\theta^{T-1}, \hat{\theta}\right) \text{ for all } \theta^{T-1}, \hat{\theta},$$

and the last two promise-keeping constraints are:

$$v_{T-1}\left(\theta^{T-1}\right) = \sum_{\theta \in \Theta} \pi(\theta)\left[\theta u_T\left(\theta^{T-1}, \theta\right) + \beta v_T\left(\theta^{T-1}, \theta\right)\right] \quad \text{and} \quad \underline{\underline{v}}_T \leq v_T\left(\theta^T\right) \leq \bar{\bar{v}}_T,$$

that is, the promise in period T has no resource cost. In the truncated problem we maximize a continuous function over a compact set, namely $\prod_{\substack{1 \leq t \leq T \\ \theta^t \in \Theta^t}} \left[\underline{\underline{u}}_t, \bar{\bar{u}}_t\right] \times \left[\underline{\underline{v}}_t, \bar{\bar{v}}_t\right]$, so a maximum exists (which is, in fact, unique, since the objective is strictly convex). Call this maximum $\left(\mathbf{u}^T, \mathbf{v}^T\right) = \left\{u_t^T(\theta^t); v_t^T(\theta^t)\right\}_{t, \theta^t}$.

We now show that $\lim_{T \to \infty}\left(\mathbf{u}^T, \mathbf{v}^T\right)$ achieves the maximum of the original problem. By definition of a supremum, for any $\varepsilon > 0$ we can find an incentive-compatible and feasible allocation $\left(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}\right)$ for the original problem such that

$$\mathbb{E}_0\left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t \tilde{u}_t(\theta^t)\right] > V(e) - \varepsilon.$$

(Note that the r.h.s. is finite.) The truncation at T periods satisfies all the constraints of the truncated economy, so

$$V^T(e) \geq \mathbb{E}_0\left[\sum_{t=1}^{T} \beta^{t-1} \theta_t \tilde{u}_t(\theta^t)\right], \forall T \geq 1.$$

Hence

$$\lim \inf_{T \to \infty} V^T(e) \geq \mathbb{E}_0\left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t \tilde{u}_t(\theta^t)\right].$$

Since ε is arbitrary,

$$\lim_{T\to\infty} \inf V^T(e) \geq V(e).$$

To show the reverse inequality, fix $t \geq 1$. For all $T \geq t$, $\left(u_t^T(\theta^t), v_t^T(\theta^t)\right) \in \left[\underline{\underline{u}}_t, \bar{\bar{u}}_t\right] \times \left[\underline{\underline{v}}_t, \bar{\bar{v}}_t\right]$. Thus, the sequences $\left\{u_t^T(\theta^t)\right\}_{T\geq t}$ and $\left\{v_t^T(\theta^t)\right\}_{T\geq t}$ must have convergent subsequences as $T \to \infty$. We can then use a diagonal procedure to obtain an incentive-compatible and feasible allocation $\left\{\left(u_t^\infty(\theta^t), v_t^\infty(\theta^t)\right)\right\}_{t\geq 1, \theta^t \in \Theta^t}$, as follows. Arrange states as

$$\mathcal{R} = \left\{\theta_{(1)}, \ldots, \theta_{(|\Theta|)}, \left(\theta_{(1)}, \theta_{(1)}\right), \ldots, \left(\theta_{(1)}, \theta_{(|\Theta|)}\right), \ldots\right\}.$$

Choose a subsequence of u^T, v^T so that the first element converges, ie,

$$\lim_{T\to\infty} \left(u_1^T\left(\theta_{(1)}\right), v_1^T\left(\theta_{(1)}\right)\right) = \left(u_1^\infty\left(\theta_{(1)}\right), v_1^\infty\left(\theta_{(1)}\right)\right).$$

From that subsequence choose another subsequence so that the second element converges, ie,

$$\lim_{T\to\infty} \left(u_1^T\left(\theta_{(2)}\right), v_1^T\left(\theta_{(2)}\right)\right) = \left(u_1^\infty\left(\theta_{(2)}\right), v_1^\infty\left(\theta_{(2)}\right)\right).$$

Repeat the procedure to get (u^∞, v^∞), and call the final subsequence $\{T_n\}_{n\geq 0}$. Since for each $t \leq T, \theta^t \in \Theta^t$, $\left(u_t^T(\theta^t), v_t^T(\theta^t)\right)$ lie in a closed set defined by the incentive constraints, $\left(u_t^\infty(\theta^t), v_t^\infty(\theta^t)\right)$ also lie in the same set, ie, they are incentive compatible. Since $C(u)$ is continuous on $\left[\underline{\underline{u}}_t, \bar{\bar{u}}_t\right]$, $C^T(\theta^t) \equiv C(u_t^T(\theta^t))$ (and $C^T(\theta^t) = 0$ for $t \geq T$) converges pointwise,

$$\lim_{T_n\to\infty} C^{T_n}(\theta^t) = C^\infty(\theta^t) \in \left[C\left(\underline{\underline{u}}_t\right), C(\bar{\bar{u}}_t)\right].$$

Now we can think of $\left\{\pi_1\left(\theta_{(1)}\right), \ldots, \pi_1\left(\theta_{(|\Theta|)}\right), \beta\pi_2\left(\theta_{(1)}, \theta_{(1)}\right), ..\right\}$ as a measure on $\mathcal{R}$. For all $t \geq 1$, $\left\{\theta_t u_t^{T_n}(\theta^t)\right\}_{n\geq 1}$ is a sequence of positive measurable functions on that space that converges pointwise to $\theta_t u_t^\infty(\theta^t)$ as $n \to \infty$. By Fatou's lemma (Lemma 7.9 in Stokey et al., 1989) $\theta_t u_t^\infty(\theta^t)$ is also measurable, and

$$\lim_{n\to\infty} \sup \sum_{t=1}^{T_n} \sum_{\theta^t \in \Theta^t} \beta^{t-1} \pi_t(\theta_t) \theta_t u_t^{T_n}(\theta^t) \leq \sum_{t=1}^{\infty} \sum_{\theta^t \in \Theta^t} \beta^{t-1} \pi_t(\theta_t) \theta_t u_t^\infty(\theta^t) \leq V(e),$$

where the last inequality follows from the fact that $\left\{u_t^\infty(\theta^t)\right\}$ satisfies the constraints of problem (9), but may not maximize the objective. Therefore, we obtain

$$\lim_{n\to\infty} \sup V^{T_n}(e) \leq V(e).$$

We therefore showed that $\lim_{n\to\infty} V^{T_n}(e)$ exists and

$$V(e) = \lim_{n\to\infty} V^{T_n}(e).$$

Moreover, we showed that a maximum of $V(e)$ is achieved by the limit of the sequence $\left(\mathbf{u}^{T_n}, \mathbf{v}^{T_n}\right)$. This concludes the proof. □

3.1.3 Application: Sustainability Constraints

Suppose that in addition to constraint (82) we further impose a constraint that social welfare in any period cannot drop below a threshold $\underline{U}$,

$$\mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}u_{t+s}\right] \geq \underline{U}, \forall t \geq 1. \tag{88}$$

Such constraints naturally arise in various settings with imperfect commitment, participation constraints, etc. We discuss an example of those in Section 4.4 in the context of an international finance model, where they capture the need to provide incentives for the agents to stick to the contract rather than defaulting and reverting to their outside option (in that case, the value of autarky).[u] We add this constraint (88) to problem (83) and assume that the utility function is bounded.

As before, we have for all t,

$$\lim_{T\to\infty}\mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}x_t^T(\mathbf{u},\mathbf{u}')\right] = \mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}u_{t+s}\right],$$

since the utility is bounded; and for t sufficiently large holding T fixed, we have

$$\mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}x_t^T(\mathbf{u},\mathbf{u}')\right] = \mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}u'_{t+s}\right],$$

which verifies Assumptions 5.ii.a and 5.ii.c for the constraints (88). The other parts of Assumption 5 are verified as before. As long as $\underline{U}$ is not too high, we can find an interior point $\mathbf{x}'$ that satisfies $\mathbf{\Phi}(\mathbf{x}') < 0$. Theorem 5 thus establishes that there exists a nonnegative summable sequence of Lagrange multipliers $\{\mu_t\}_{t=1}^{\infty}$, such that the solution to our problem is also a solution to

$$\max_{\mathbf{u}\in\Gamma}\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}\theta_t u_t\right] + \sum_{t=1}^{\infty}\mu_t\mathbb{E}_0\left[\sum_{s=1}^{\infty}\beta^{s-1}\theta_{t+s}u_{t+s}\right] - \sum_{t=1}^{\infty}\tilde{\lambda}_t\mathbb{E}_0[C(u_t)].$$

Since $\{\mu_t\}_{t=1}^{\infty}$ is summable, we can rewrite the equation above as

$$\mathbb{E}_0\left[\sum_{t=1}^{\infty}\beta^{t-1}\theta_t u_t + \sum_{t=1}^{\infty}\sum_{s=1}^{\infty}\beta^{s-1}\mu_t\theta_{t+s}u_{t+s} - \sum_{t=1}^{\infty}\tilde{\lambda}_t C(u_t)\right] = \mathbb{E}_0\left[\sum_{t=1}^{\infty}\overline{\beta}_t\{\theta_t u_t - \lambda_t C(u_t)\}\right], \tag{89}$$

[u] Such constraints would also appear in models of political economy in which a government is tempted to reoptimize (see, eg, Acemoglu et al., 2008; Sleet and Yeltekin, 2008; Farhi et al., 2012).

where $\overline{\beta}_t = \beta^{t-1} + \mu_1\beta^{t-2} + \cdots + \mu_{t-2}\beta + \mu_{t-1}$, letting $\mu_0 = 0$, with $\sum_{t=1}^{\infty}\overline{\beta}_t < \infty$ and $\lambda_t = \widetilde{\lambda}_t/\overline{\beta}_t$. This problem can be solved using our usual techniques. Augmenting the problem with a promise-keeping constraint, we can replace $\mathbf{u} \in \Gamma$ with $(\mathbf{u},\mathbf{v}) \in \Gamma(v_0)$ and observe that the problem can be written recursively, letting $\hat{\beta}_{t+1} = \overline{\beta}_{t+1}/\overline{\beta}_t$, as

$$\begin{aligned} k_t(v) = & \max_{\{u(\theta),w(\theta)\}_{\theta\in\Theta}} & \mathbb{E}\left[\theta u - \lambda_t C(u) + \hat{\beta}_{t+1}k_{t+1}(w)\right] \\ & \text{subject to} & (19),(20). \end{aligned}$$

We can extend Lemma 1 directly to k_t, with the only exception that k_t is not strictly decreasing but rather inversely U-shaped. (We can easily show that $v \mapsto k_t(v)$ is concave, continuous, and satisfies $\lim_{v\to\bar{v}} k_t(v) = -\infty$ and $\lim_{v\to\underline{v}} k_t(v) = \underline{v}$.) Much of the analysis in Section 2.4 continues to hold but the condition (29) now becomes

$$k_t'(v) = \frac{\hat{\beta}_{t+1}}{\beta}\mathbb{E}\left[k_{t+1}'(w_v)\right]. \tag{90}$$

Observe that $\hat{\beta}_{t+1} \geq \beta$ with strict inequality if $\mu_t > 0$. Therefore the marginal cost k_t' is no longer a martingale if constraint (88) binds, which implies a form of mean reversion. To see this, observe that since k is inversely U-shaped, k_t' is positive for low v and negative for high v. Therefore Eq. (90) shows that the marginal cost decreases in expectation if v is low (because then $\mathbb{E}\left[k_{t+1}'(w_v)\right] = \frac{\beta}{\hat{\beta}_{t+1}}k_t'(v) \leq k_t'(v)$) and increases if v is high (because then $\mathbb{E}\left[k_{t+1}'(w_v)\right] = \frac{\beta}{\hat{\beta}_{t+1}}k_t'(v) \geq k_t'(v)$).

3.1.4 Using Lagrange Multipliers Instead of Promised Utilities

In our discussion so far we have used the following technique to solve dynamic incentive problems: we formed a Lagrangian using all the constraints except the incentive constraints, and then introduced the promised utilities in order to write the incentive constraints recursively. In principle, there is nothing special about the incentive constraints per se: we could extend the Lagrangian to those constraints also, eliminating the need to use promised utilities at all. Here we describe how this can be done, using a version of our benchmark partial equilibrium model of Section 2.3.2 as an example.

Consider the maximization problem

$$\begin{aligned} K(v_0) \equiv \max_{\mathbf{u}} \mathbb{E}\left[-\sum_{t=1}^{\infty}\beta^{t-1}C(u_t)\right] \\ \text{subject to } (10)\ \forall t \geq 1, \text{ and } (14), \end{aligned} \tag{91}$$

that we analyzed in Section 2.3.2. Since the objective function is strictly concave and the constraint set is convex, its solution $\hat{\mathbf{u}}$ is unique. Define $W : \mathbb{R} \to \mathbb{R}$ as

$$W(\alpha) \equiv \max_{\mathbf{u}} \mathbb{E}\left[\sum_{t=1}^{\infty} \beta^{t-1}(\alpha\theta_t u_t - C(u_t))\right] \tag{92}$$
$$\text{subject to } (10)\ \forall t \geq 1.$$

If $\hat{\alpha}$ is the Lagrange multiplier on constraint (14), then $W(\hat{\alpha})$ is simply the Lagrangian associated with problem (91), whose unique maximum (the objective is strictly concave and the constraints are linear) is attained at $\hat{\mathbf{u}}$ by Theorem 4.[v]

We now show how applying Corollary 1 leads to a recursive characterization of this problem, using different techniques than those described in Section 2.3.2. We then discuss the strengths and weaknesses of these two alternative approaches. For simplicity we assume that $|\Theta| = 2$; the analysis extends straightforwardly to any number of shocks.

When $|\Theta| = 2$ there are two incentive constraints (10) in period 1 corresponding to shocks $\theta_{(1)}$ and $\theta_{(2)}$. Adapting the arguments of Proposition 5 shows that the constraint of type $\theta_{(2)}$ is slack. Let $\hat{\xi}(\theta_{(1)})$ be the Lagrange multiplier on the first-period incentive constraint of type $\theta_{(1)}$ in problem (92). By Corollary 1 (written for a maximization rather than minimization problem),[w] $\hat{\xi}(\theta_{(1)})$ and the solution to (92) are also the solution to

$$\begin{aligned}
W(\alpha) \equiv \min_{\xi \geq 0} \ \max_{\mathbf{u}} \ & \mathbb{E}\left[\sum_{t=1}^{\infty} \beta^{t-1}(\alpha\theta_t u_t - C(u_t))\right] \\
& + \xi\left[\ \left\{\theta_{(1)} u_1(\theta_{(1)}) + \mathbb{E}\left[\sum_{t=2}^{\infty} \beta^{t-1}\theta_t u_t \middle| \theta_1 = \theta_{(1)}\right]\right\}\right. \\
& \left. - \left\{\theta_{(1)} u_1(\theta_{(2)}) + \mathbb{E}\left[\sum_{t=2}^{\infty} \beta^{t-1}\theta_t u_t \middle| \theta_1 = \theta_{(2)}\right]\right\}\right] \\
& \text{subject to } (10)\ \forall t \geq 2.
\end{aligned}$$

Rearrange these terms and use the definition of W to obtain

$$\begin{aligned}
W(\alpha) \equiv \min_{\xi \geq 0} \ \max_{u(\theta_{(1)}),\, u(\theta_{(2)})} \\
\pi(\theta_{(1)}) & \left[\left(\alpha\theta_{(1)} + \frac{\xi\theta_{(1)}}{\pi(\theta_{(1)})}\right) u_1(\theta_{(1)}) - C(u_1(\theta_{(1)})) + \beta W\left(\alpha + \frac{\xi}{\pi(\theta_{(1)})}\right)\right] \\
+ \pi(\theta_{(2)}) & \left[\left(\alpha\theta_{(2)} - \frac{\xi\theta_{(1)}}{\pi(\theta_{(2)})}\right) u_1(\theta_{(2)}) - C(u_1(\theta_{(2)})) + \beta W\left(\alpha - \frac{\xi}{\pi(\theta_{(2)})}\right)\right].
\end{aligned} \tag{93}$$

[v] $\hat{\alpha}$ can be found from a max min problem as in Corollary 1 by observing that by monotonicity we can replace the equality constraint (14) in problem (91) with the inequality constraint $\mathbb{E}\left[\sum_{t=1}^{\infty} \beta^{t-1}\theta_t u_t(\theta^t)\right] \geq v_0$.

[w] We can verify the sufficient conditions allowing us to apply Corollary 1 using the same steps as in Section 3.1.2.

Problem (93) is an alternative way to characterize the solution to the maximization problem (91). The function W can be found using standard contraction mapping techniques (see Marcet and Marimon, 2015 for proofs). The policy functions to this Bellman equation can then be used to generate the solution $\hat{\mathbf{u}}$ the same way we did in Section 2.3.2.

We conclude this section by comparing the two alternative recursive formulations (23) and (93). On the one hand, the max operator in (23) is simpler to handle than the min max operator in (93).[x] This makes (23) easier to use in many simple applications. On the other hand, the function W is defined over an a priori known domain, $\mathbb{R}$, while the domain of K is endogenous. We could easily characterize the latter in the setup of Section 2.3.2 (see Footnote g). In more general settings, however (with Markov shocks, additional constraints, etc.), characterizing the state space is more difficult and requires using the techniques of Abreu et al. (1990) (see Proposition 8), so that using the tools described in this section can be simpler. An in-depth discussion of this approach is outside the scope of this chapter and we refer the interested reader to the papers that describe it in more detail. The pioneering work that first developed this approach is Marcet and Marimon (2015). The more recent applications are Messner et al. (2012, 2014), Cole and Kubler (2012), and Espino et al. (2013).

3.2 Mechanism Design Without Commitment

In our discussion so far we assumed that the principal, which provides insurance to agents, has perfect commitment: it implicitly promises a menu of allocations for infinitely many periods and never entertains the possibility of reneging on those promises as time goes by. This assumption was critical in proving the Revelation Principle in Theorem 1. However, this assumption is not innocuous. For example, we saw in Proposition 6 that long-run immiseration is a common feature of the optimal insurance contracts. While such a contract is optimal ex ante in period 0, it provides the worst possible allocation in the long run. Any benevolent principal would like to reoptimize at that point. Thus the assumption that the principal has perfect commitment is very strong in many applications.

In this section we discuss several approaches to analyze dynamic contracting problems in environments where the principal cannot commit. We start with the set up of Section 2.2 with two modifications. First, we assume that insurance in that economy

[x] Many insights can be obtained from problem (93) without considering the min part. Since $\hat{\xi}\left(\theta_{(1)}\right) \geq 0$ (in fact, with a strict inequality from the discussion in Proposition 5), problem (93) immediately shows that the weight $\alpha\left(\theta_{(1)}\right) \equiv \hat{\alpha} + \dfrac{\hat{\xi}\left(\theta_{(1)}\right)}{\pi\left(\theta_{(1)}\right)}$ increases for the agent who reports $\theta_{(1)}$, ie, $\alpha\left(\theta_{(1)}\right) \geq \hat{\alpha}$, while the weight $\alpha\left(\theta_{(2)}\right) \equiv \hat{\alpha} - \dfrac{\hat{\xi}\left(\theta_{(1)}\right)}{\pi\left(\theta_{(2)}\right)}$ decreases, ie, $\alpha\left(\theta_{(2)}\right) \leq \hat{\alpha}$. To see the implication of this fact, observe that the solution to (92), $\hat{\mathbf{u}}^{\alpha}$, has the property that $\mathbb{E}\left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t u_t^{\alpha}\right]$ is increasing in α, so that higher weights correspond to higher lifetime utilities. Therefore we showed, without explicitly considering the min operator, that the expected lifetime utility starting from next period increases for the agent who reports $\theta_{(1)}$, and decreases for the agent who reports $\theta_{(2)}$. See Acemoglu et al. (2011) for another application of this technique.

is provided by a benevolent principal, which we call "the government," that cannot commit ex ante, in period 0, to its future actions. Second, in order to focus on information revelation and various generalizations of Theorem 1 we abstract from borrowing and lending and assume that the total consumption of all agents should be equal to the total endowment e in each period, as in Section 3.1.2.

Since the government cannot commit, we formally describe the environment as an infinitely repeated game between one large player (the government) and a continuum of atomistic agents.[y] Each period of the game is divided into two stages. In the first stage agents report information about the realization of their idiosyncratic shock to the government, and in the second stage the government chooses allocations.[z] As in Section 2.2, it is helpful to start by describing communication between the agent and the principal using a general message space M.

Agents' reporting strategies in period t are maps $\tilde{\sigma}_t : M^{t-1} \times \Theta^t \times H^t \rightarrow \Delta(M)$, and the government's strategy is a map $\tilde{c}_t : M^t \times \breve{H}^t \rightarrow \Delta(\mathbb{R}_+)$, where M^{t-1} and Θ^t are the histories of reports and the realizations of shocks for each agent, and H^t and $\breve{H}^t$ (described below) are the aggregate histories of the game. To avoid complicating our discussion with measure-theoretic apparatus, we assume that $\Delta(M)$ and $\Delta(\mathbb{R}_+)$ only randomize between finitely many elements. The assumption of a continuum of agents simplifies the analysis. By the law of large numbers, $\tilde{\boldsymbol{\sigma}}$ generates the aggregate distribution of reports that the government receives from the agents, and $\tilde{\boldsymbol{c}}$ generates the distribution of consumption allocations provided by the government. Moreover, these distributions are not affected if an individual agent (who is of measure zero) deviates from his equilibrium strategy. Assuming that these aggregate distributions are observable history H^t consists of the aggregate distributions generated by $\tilde{\boldsymbol{\sigma}}$ and $\tilde{\boldsymbol{c}}$ up to period $t-1$, while $\breve{H}^t$ consists of H^t and the distribution of aggregate reports generated by $\tilde{\sigma}_t$.

We describe how to characterize the perfect Bayesian equilibrium (PBE) of this game that delivers the highest ex ante utility to agents. Well-known arguments (see Chari and Kehoe, 1990 or a textbook treatment in Chapter 23 of Ljungqvist and Sargent, 2012 for details) imply that to characterize such an equilibrium it is sufficient to focus only on a subset of the histories of the game. Namely, it is sufficient to characterize the reporting done by the agents and allocations provided by the government "on the equilibrium path." If the government ever deviates from the equilibrium path distribution of allocations (up to a measure zero) then in subsequent histories agents and the government switch to the worst PBE. With a slight abuse of notation, we use $\left(\tilde{\boldsymbol{\sigma}}, \tilde{\boldsymbol{c}}\right)$ to describe

[y] See Chari and Kehoe (1990, 1993) for classic references.

[z] Although this set up appears a bit stylized, many of its features emerge naturally in more sophisticated models of political economy. For example, models in which policies are chosen via probabilistic voting à la Lindbeck and Weibull (1987) in each period often reduce to our set up with a benevolent government that cannot commit to its future actions. See Farhi et al. (2012), Scheuer and Wolitzky (2014), or Dovis et al. (2015) for applications.

the behavior of agents and the government "on the equilibrium path," ie, the mappings $\tilde{\sigma}_t : M^{t-1} \times \Theta^t \rightarrow \Delta(M)$ and $\tilde{c}_t : M^t \rightarrow \Delta(\mathbb{R}_+)$ which no longer have the aggregate histories $H^t, \breve{H}^t$ as arguments. We use $\tilde{\sigma}_t\left(m \middle| m^{t-1}, \theta^t\right)$ to denote the probability that an agent with history $\left(m^{t-1}, \theta^t\right)$ reports the message m in period t.

The pair $\left(\tilde{\boldsymbol{\sigma}}, \tilde{\boldsymbol{c}}\right)$ must satisfy three constraints. First, in equilibrium each individual agent finds it optimal to stick to his reporting strategy $\tilde{\boldsymbol{\sigma}}$ rather than to deviate to any other reporting strategy $\tilde{\boldsymbol{\sigma}}'$, so that the constraint (4) is satisfied. Note that to write this constraint we implicitly used the assumption of a continuum of agents. If an individual agent chooses $\tilde{\boldsymbol{\sigma}}'$ rather than $\tilde{\boldsymbol{\sigma}}$, the aggregate distribution of reports to the government remains unchanged and therefore the equilibrium allocations remain the same. Thus the same $\tilde{\boldsymbol{c}}$ appears on both sides of the incentive constraint. Second, any allocation that the government chooses must also be feasible, ie, satisfy

$$\mathbb{E}^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}[c_t] \leq e, \quad \forall t. \tag{94}$$

Third, the government should not find it optimal to deviate from its equilibrium play at any point of time. This constraint can be written as

$$\mathbb{E}_t^{\tilde{\boldsymbol{c}} \circ \tilde{\boldsymbol{\sigma}}}\left[\sum_{s=t}^{\infty} \beta^{s-t} \theta_s U(c_s)\right] \geq \tilde{W}_t\left(\left\{\tilde{\sigma}_s\right\}_{s=1}^t\right) + \frac{\beta}{1-\beta} U(e), \quad \forall t. \tag{95}$$

The left hand side of this constraint is the government's payoff from continuing to play its equilibrium strategy in period t. The right hand side consists of two parts: the value of the best one-time deviation $\tilde{W}_t$ (to be defined below) followed by the value of the worst PBE starting from the next period. Since we assumed that shocks are i.i.d., it is easy to show that the worst PBE is such that agents reveal no information to the government and receive forever the same per capita allocation e independently of the shock. The expected value of this allocation is $\frac{1}{1-\beta} U(e)$.

We now derive the value of deviation $\tilde{W}_t$. Let $\mu_t(m^t)$ denote the measure of agents who report history m^t. It is defined recursively as $\mu_{-1} = 1$ and

$$\mu_t(m^t) = \mu_{t-1}\left(m^{t-1}\right) \sum_{\theta^t \in \Theta^t} \pi(\theta^t) \tilde{\sigma}_t\left(m_t \middle| m^{t-1}, \theta^t\right).$$

The measure μ_t depends on the entire history of reports up to period $t, \left\{\tilde{\sigma}_s\right\}_{s=1}^t$. We use $\mathbb{E}^{\tilde{\boldsymbol{\sigma}}}[\theta | m^t]$ to denote the government's posterior expectation of an agent's type being θ, conditional on the history of reports m^t. The best deviation solves

$$\tilde{W}_t\left(\left\{\tilde{\sigma}_s\right\}_{s=1}^t\right) = \max_{\left\{c^w(m^t)\right\}_{m^t \in M^t}} \sum_{m^t \in M^t} \mu_t(m^t)\left[\mathbb{E}^{\tilde{\boldsymbol{\sigma}}}[\theta | m^t] U(c^w(m^t))\right] \tag{96}$$

subject to the feasibility constraint

$$\sum_{m^t \in M^t} \mu_t(m^t) c^w(m^t) \leq e. \tag{97}$$

At this stage of our discussion it is useful to compare our set up to that with commitment in Section 2.2. Relative to the environment in that section, we have one additional constraint, (95). The important feature of this constraint is that posterior beliefs appear on both sides of this constraint. This changes the analysis. In particular, note that the proof of Theorem 1 does not need to go through when constraint (95) is imposed. If we replace $\widetilde{\Gamma} = \left(M, \widetilde{\boldsymbol{c}} \circ \widetilde{\boldsymbol{\sigma}}\right)$ with a direct truthful mechanism $\left(\Theta, \boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}\right)$, we still obtain feasible and incentive-compatible allocations for all agents as in the proof of Theorem 1. However we have $\widetilde{W}_t\left(\left\{\sigma_s^{truth}\right\}_{s=1}^t\right) \geq \widetilde{W}_t\left(\left\{\widetilde{\sigma}_s\right\}_{s=1}^t\right)$, generally with a strict inequality, since a direct mechanism reveals more precise information to the government and increases its incentives to deviate. Since by construction we have $\mathbb{E}^{\widetilde{\boldsymbol{c}} \circ \widetilde{\boldsymbol{\sigma}}}\left[\sum_{s=t}^{\infty} \beta^{s-t} \theta_s U(c_s)\right] = \mathbb{E}^{\boldsymbol{c} \circ \boldsymbol{\sigma}^{truth}}\left[\sum_{s=t}^{\infty} \beta^{s-t} \theta_s U(c_s)\right]$, the direct truthtelling mechanism tightens the sustainability constraint of the government. Intuitively, this mechanism always reveals more information to the government than any other communication mode, increasing the gains for the government from ex post reoptimization and lowering ex ante welfare.

The discussion in the previous paragraph implies that it is generally *not* without loss of generality to restrict attention to mechanisms in which agents report their type directly to the government, as we did in Section 2.2, and that one needs to work with more general message spaces to characterize the optimal insurance in this setting. Here we outline how it can be done. Our discussion is based on Golosov and Iovino (2014); for more detailed discussion and proofs we refer the reader to that paper.[aa]

To find the optimal insurance without commitment, the best PBE solves

$$\max_{\widetilde{\boldsymbol{c}}, \widetilde{\boldsymbol{\sigma}}} \mathbb{E}^{\widetilde{\boldsymbol{c}} \circ \widetilde{\boldsymbol{\sigma}}}\left[\sum_{t=1}^{\infty} \beta^{t-1} \theta_t U(c_t)\right] \tag{98}$$

subject to (4), (94), and (95). Under some technical conditions this problem can be significantly simplified. In particular with i.i.d. shocks the history of past realizations of shocks is irrelevant and we can simply restrict attention to reporting strategies of the form $\widetilde{\sigma}_t : M^{t-1} \times \Theta_t \rightarrow \Delta(M)$. Similarly, one can also show the analogue of Proposition 1 that

[aa] Formally, Golosov and Iovino (2014) study a slightly more general game that allows agents' and government's strategies to depend on the realization of payoff-irrelevant variables. This convexifies the set of equilibrium payoffs and ensures that some technical conditions simplifying the analysis hold. To streamline the exposition we simply assume that those conditions are satisfied.

stochastic allocations of consumption are suboptimal, so that we can assume without loss of generality that $\tilde{c}_t : M^t \to \mathbb{R}_+$. Finally without loss of generality we can restrict M to a finite set.[ab]

We now show how to write this problem recursively. As in Section 2, it is more convenient to change variables and optimize with respect to $u_t = U(\tilde{c}_t)$, and constraint (4) simplifies if we use a one-shot deviation principle. Using the same arguments as those leading to Eq. (13), we can rewrite (4) as: for all $m^t \in M^t$,

$$v_t(m^t) = \sum_{(\theta,m)\in\Theta\times M} \pi(\theta)\tilde{\sigma}_{t+1}(m|m^t,\theta)[\theta u_{t+1}(m^t,m) + \beta v_{t+1}(m^t,m)], \tag{99}$$

and for all $(m^t,\theta) \in M^t \times \Theta$, for all $m \in M$, and some $m_\theta \in M$,

$$\theta u_{t+1}(m^t,m_\theta) + \beta v_{t+1}(m^t,m_\theta) \geq \theta u_{t+1}(m^t,m) + \beta v_{t+1}(m^t,m) \tag{100}$$

with for all $m \in M$,

$$\tilde{\sigma}_{t+1}(m|m^t,\theta)[\{\theta u_{t+1}(m^t,m_\theta) + \beta v_{t+1}(m^t,m_\theta)\} - \{\theta u_{t+1}(m^t,m) + \beta v_{t+1}(m^t,m)\}] = 0. \tag{101}$$

Eq. (99) is simply a generalization of (12) to the setting in which agents reveal noisy information to the government. The next two equations form the incentive-compatibility conditions. Eq. (100) says that there must be some message m_θ that agent θ prefers to all others, given the past history of messages m^t and shock realization θ. Eq. (101) says that if an agent with current shock realization θ reports any message m other than m_θ with positive probability $\tilde{\sigma}_{t+1}(m|m^t,\theta)$, then he must be indifferent between reporting m and m_θ, since any report he sends must give him the highest utility. Eqs. (100) and (101) are a generalization of (13) and have a recursive structure, with $v_t(m^t)$ playing the role of the state variable.

We now show how to write the problem of maximizing (98) subject to (94), (95), and (99)–(101) recursively using the Lagrangian techniques introduced in Section 3.1.2. Let $\tilde{\boldsymbol{\lambda}} = \left\{\tilde{\lambda}_t\right\}_{t=1}^{\infty}$ and $\tilde{\boldsymbol{\chi}} = \{\tilde{\chi}_t\}_{t=1}^{\infty}$ be sequences of multipliers on the constraints (94) and (95), respectively. Assuming that these sequences are summable (see Section 3.1.1), we can write the Lagrangian, using Abel's formula, as[ac]

$$\max_{\mathbf{u},\tilde{\sigma}} \mathbb{E}^{\tilde{\sigma}} \sum_{t=1}^{\infty} \overline{\beta}_t \left[\theta_t u_t - \lambda_t C(u_t) - \chi_t \tilde{W}_t\right] \tag{102}$$

subject to (99)–(101), where $\overline{\beta}_t = \beta^{t-1} + \sum_{s=1}^{t} \beta^{t-s}\tilde{\chi}_s$, $\lambda_t = \tilde{\lambda}_t / \overline{\beta}_t$, and $\chi_t = \tilde{\chi}_t / \overline{\beta}_t$. Note that this problem is very similar to the problem considered in Section 3.1.3, except that

[ab] Specifically, the cardinality of M can be taken to be $2|\Theta| - 1$.

[ac] Since consumption allocations are deterministic, we write $\mathbb{E}^{\tilde{\sigma}*}$ rather than $\mathbb{E}^{\mathbf{u}\circ\tilde{\sigma}*}$.

now we choose the optimal amount of information that is revealed to the government, $\tilde{\boldsymbol{\sigma}}$, and the costs of information revelation are captured by the terms $\chi_t \widetilde{W}_t$.

This problem still does *not* have a natural recursive form. Our recursive characterization in Section 3.1.2 relied on the fact that the linearity of the objective function allowed us to separately solve for the optimal allocations after any history θ^t (ie, in the setting without commitment, after any history of reports m^t) without paying attention to the other histories. The key difficulty now is that $\widetilde{W}_t$ depends on the distribution of reports that are sent by all agents. We show here how to write a recursive formulation under the assumption that preferences are logarithmic. Golosov and Iovino (2014) use the techniques of Section 3.1.1 to obtain the same characterization for arbitrary concave utility functions.

When preferences are logarithmic, $\widetilde{W}_t$ is easy to simplify. The first-order conditions of problem (102) give

$$\lambda_t^w C'\left(u_t^w(m^t)\right) = \mathbb{E}^{\tilde{\boldsymbol{\sigma}}}[\theta|m^t] = \frac{\tilde{\sigma}_t\,(m_t|m^{t-1},\theta)}{\sum\limits_{\theta'\in\Theta}\pi(\theta')\tilde{\sigma}_t\,\left(m_t|m^{t-1},\theta'\right)},$$

where $u_t^w \equiv U\left(u_t^w\right)$ and λ_t^w is the Lagrange multiplier on constraint (97). With logarithmic preferences, $C' = C = \exp$. Using this fact together with (97) we can easily find that $\lambda_t^w = 1/e$. The key property is that this multiplier does not depend on particular values of $\left\{\tilde{\sigma}_t\right\}_{m^t,\theta^t}$, and therefore $\widetilde{W}_t$ can be written as

$$\widetilde{W}_t\left(\left\{\tilde{\sigma}_s\right\}_{s=1}^t\right) = \sum_{m^{t-1}}\mu_{t-1}\left(m^{t-1}\right)W_t\left(\left\{\tilde{\sigma}_t\left(m|m^{t-1},\theta\right)\right\}_{(m,\theta)\in M\times\Theta}\right),$$

where

$$W_t\left(\left\{\tilde{\sigma}(m|\cdot,\theta)\right\}_{(m,\theta)\in M\times\Theta}\right) = \max_{\{u^w(m)\}_{m\in M}}\ \sum_{(m,\theta)\in M\times\Theta}\pi(\theta)\,\tilde{\sigma}(m|\cdot,\theta)\left[\theta u^w(m) - \lambda_t^w C(u^w(m))\right].$$

If we substitute this equation into (102), we can easily write the problem recursively, letting $\hat{\beta}_{t+1} \equiv \overline{\beta}_{t+1}/\overline{\beta}_t$, as

$$k_t(v) = \max_{\substack{\{u(m),w(m),\sigma(m|\theta)\}_{(m,\theta)\in M\times\Theta} \\ \sigma(\cdot|\theta)\in\Delta(M)}} \mathbb{E}^{\sigma}\left[\theta u - \lambda_t C(u) + \hat{\beta}_{t+1}k_{t+1}(w)\right] - \chi_t W_t\left(\left\{\sigma(m|\theta)\right\}_{m,\theta}\right) \tag{103}$$

subject to: for all θ,

$$v = \sum_{(\theta,m)\in\Theta\times M}\pi(\theta)\sigma(m|\theta)\left[\theta u(m) + \beta w(m)\right],$$

for all m and some m_θ,

$$\theta u(m_\theta)+\beta w(m_\theta)\geq \theta u(m)+\beta w(m),$$

and for all m,

$$\sigma(m|\theta)[\{\theta u(m_\theta)+\beta w(m_\theta)\}-\{\theta u(m)+\beta w(m)\}]=0.$$

Note that problem (103) is very similar to problem (18) in Section 2, with two modifications. First, the objective function has an additional term $-\chi_t W_t$ which captures the additional cost of information revelation off the equilibrium path. Second, agents generally play mixed strategies over the message space M rather than a pure reporting strategy over the set Θ.

Golosov and Iovino (2014) analyze this problem and show that the optimal amount of information that each agent reveals depends on the promised utility v. The key insight of their paper is that the agents who should reveal more information to the government are those for whom such revelation saves the most resources to the government *on the equilibrium path*. In particular, in the set up discussed above, the government loses relatively little resources if it delivers a low value of v without knowing the realization of θ, while information revelation by agents with higher v leads the government to save more resources. Golosov and Iovino (2014) show that for all v sufficiently small agents reveal no information to the government and play the same reporting strategy independently of the realization of their shock; on the other extreme, agents with sufficiently high promise v reveal full information to the government (at least as long as U exhibits decreasing absolute risk aversion) just as in Section 2.2. They show that the government's participation constraints imply the existence of an endogenous lower bound in the invariant distribution below which agents' promised utility never falls, preventing the emergence of long-run immiseration which was obtained in Section 2.4. Golosov and Iovino (2014) further generalize their analysis by considering Markov shocks and obtaining a recursive characterization along the lines of Section 2.5.[ad]

3.2.1 Optimal Insurance with a Mediator

In the game described in the previous section we assumed a particular communication protocol between the agents and the government: agents first report some information to the government, then the government takes some action. In settings where the government could commit, as in Section 2.5, restricting attention to such communication protocols was without loss of generality due to Theorem 1. As we saw, Theorem 1 fails when the government cannot commit. One may wonder if better outcomes can be attained if richer ways to communicate between agents and the government are available.

[ad] The problem of information revelation with persistent shocks is related to the literature on the ratchet effect (see Freixas et al., 1985; Laffont and Tirole, 1988).

The answer to this question turns out to be yes. Here we describe what the optimal communication devices are and how to characterize the optimal contracts in such settings.

Suppose agents and the government can communicate indirectly, using a third party called a "mediator." The mediator can be a trusted third person with no stake in the outcome of the game, or simply a machine that takes reports from the agents and recommends the action to the government as a function of those reports using a predetermined rule. Thus, the game is essentially the same as in the previous section, with the following modification. In each period, the agents first send reports $\tilde{\sigma}_t : M^{t-1} \times \Theta^t \to \Delta(M)$ to the mediator, then the mediator makes recommendations $\tilde{\sigma}_t^{med} : M^t \to \Delta(\mathbb{R}_+)$ to the government about which consumption allocation the government should pick. The government is then free to make any choice it wants.

Studying equilibria in this communication game using a mediator is interesting for the following reason. First, without loss of generality we can restrict attention to direct truth-telling strategies $\boldsymbol{\sigma}^{truth}$ for the agents, as defined in Section 2.2 (and hence we can assume that $\tilde{\sigma}_t^{med}$ is a mapping from Θ^t to $\Delta(\mathbb{R}_+)$). Moreover, with a mediator we can replicate the outcome of any PBE with any other communication device. Thus, we get a version of Theorem 1 for Bayesian Nash equilibria (see Myerson, 1982, 1986 and Mas-Colell et al., 1995 (Sec. 23.D)). Therefore, the equilibrium with a mediator provides an upper bound on what can be achieved using any other communicating device.

We want to make two observations about games with a mediator. First, while without loss of generality we can assume that agents report their types truthfully to the mediator, the mediator generally randomizes to garble the information that the government receives—otherwise the government would be able to learn information perfectly about the agent's type and this mechanism would be equivalent to the direct truthtelling mechanism discussed in the previous section. Second, while any PBE (using arbitrary communicating devices) can be implemented as a PBE in a game with a mediator, the converse is not true. Thus, whether the equilibrium with a mediator provides a reasonable description of the optimal insurance arrangement often depends on the context. For example, many negotiations of the resolutions of conflicts between countries already use mediators, so that this approach may be natural. On the other hand, in many political settings it seems often difficult to introduce an uninterested third party outside of the politician's control, and the approach we described in the previous section may be preferable.

To see how this approach alters the incentive constraints, we consider the analogue of the recursive problem (103). The mediator generally needs to randomize between different allocations that it recommends to the government. For simplicity we assume that the mediator offers finitely many recommendations $m_1,\ldots,m_I$ to the government for each agent's report. The reporting strategies of the mediator are now simply $\tilde{\sigma}_t^{med}\left(m \middle| m^{t-1}, \theta^t\right)$ for $m \in M \equiv \{m_1, \ldots, m_I\}$. Assuming that the one-shot deviation principle holds and that the dependence of period-t strategies on θ^{t-1} is redundant, we can write the agents' incentive constraint as (99) and

$$\begin{aligned}&\sum_m \tilde{\sigma}_{t+1}^{med}(m|m^t,\theta)\left[\theta u\left(m^{t+1}\right)+\beta v_{t+1}\left(m^{t+1}\right)\right]\\ \geq &\sum_m \tilde{\sigma}_{t+1}^{med}(m|m^t,\theta')\left[\theta u\left(m^{t+1}\right)+\beta v_{t+1}\left(m^{t+1}\right)\right],\quad \forall\theta'.\end{aligned} \tag{104}$$

Constraint (104) is weaker than constraints (100) and (101), so that more allocations are incentive compatible when a mediator is used. One way to understand the intuition is as follows. When an agent communicates using a mediator, he has no control over which recommendation the mediator makes to the government. Thus his incentive constraint (104) should hold in expectation, over all the recommendations that the mediator may make. When an agent communicates with the government directly, he would never send any message to the government which is dominated by another message. Therefore his incentive constraint (100), (101) should be satisfied for all the messages sent to the government.

It remains to describe how the government forms posterior beliefs based on the mediator's recommendations. The government's behavior is formally identical to that in (96) except that the value of the best deviation is now simply $\tilde{W}_t\left(\left\{\tilde{\sigma}_s^{med}\right\}_{s=1}^{t}\right)$ rather than $\tilde{W}_t\left(\left\{\tilde{\sigma}_s\right\}_{s=1}^{t}\right)$, so that the government uses the mediator's recommendations described by $\tilde{\boldsymbol{\sigma}}^{med}$ rather than agents' reports $\tilde{\boldsymbol{\sigma}}$ to form its posterior beliefs. Nevertheless the mathematical structure of the two problems is identical and we obtain a similar recursive representation as in (103), except that the incentive constraints are replaced by: for all θ',

$$\sum_m \sigma^{med}(m|\theta)[\theta u(m)+\beta w(m)]\geq \sum_m \sigma^{med}(m|\theta')[\theta u(m)+\beta w(m)].$$

A Word of Caution

We conclude this section with a word of caution about the usage of the term "Revelation Principle" in the literature. Some authors reserve this term only for principal–agent models and Theorem 1. Since Theorem 1 does not hold if the principal cannot commit, those authors often say that "the Revelation Principle fails without commitment" (see, eg, Laffont and Tirole, 1988 or Bester and Strausz, 2001). Other authors use this term more broadly as in Section 3.2.1, when the mechanism designer is thought not as a principal per se but rather as a mechanical randomizing device. In such settings truthful direct revelation holds both when the agents and the principal can and cannot commit (see, eg, Myerson, 1982, 1986 and Mas-Colell et al., 1995), and one often hears that "the Revelation Principle always holds." While it may be confusing, there is no disagreement about the mathematical facts, and one just needs to be careful about which version of the Revelation Principle one refers to.

3.3 Martingale Methods in Continuous Time

We now show how dynamic contracting problems can be conveniently analyzed in continuous time frameworks. We only briefly touch on this literature here. Sannikov (2008, 2014) analyzed a continuous-time dynamic moral hazard problem where observable output follows a Brownian motion whose drift is given by the agent's unobservable effort. Williams (2009, 2011) uses the stochastic Pontryagin principle based on the work of Bismut (1973, 1978) to analyze a continuous-time version of the Thomas and Worrall (1990) endowment shock model, and Cvitanić and Zhang (2013) apply the same techniques to moral hazard and adverse selection problems. Zhang (2009) considers a dynamic contracting problem with a finite Markov chain for the types. Miao and Zhang (2015) extend the Lagrangian techniques introduced in Section 3.1 to a model of limited commitment (see Section 4) in continuous time.

Here we follow Sannikov (2008) who uses the dynamic programming principle in continuous time to analyze the moral hazard model described in the discrete time setting in Section 2.7. We start with a short section on the mathematical techniques that allow us to solve this problem. A fully rigorous exposition of these techniques is beyond the scope of this paper, but we present the main tools that allow us to describe Sannikov (2008)'s model in a self-contained way.

3.3.1 *Mathematical Background*

For the basics of Brownian motion and stochastic processes, see, eg, Revuz and Yor (1999), Øksendal (2003), or Karatzas and Shreve (2012). For an exposition of the theory of stochastic optimal control, see, eg, Yong and Zhou (1999). In this section, after briefly introducing the basics of stochastic processes, we simply state the three fundamental theorems that will be important in the analysis of the continuous-time dynamic contracting model below, namely Itô's lemma, the Martingale Representation Theorem, and Girsanov's theorem. We also describe heuristically the dynamic programming principle in continuous time.

A stochastic process X is a family of random variables $\{X_t\}_{t\geq 0}$ on a probability space $(\Omega, \mathscr{F}, \mathbb{P})$. Define the filtration $\{\mathscr{F}_t\}_{t\geq 0}$ such that for all t, $\mathscr{F}_t = \sigma\left(\{X_s\}_{s\leq t}\right)$ is the σ-algebra generated by X from time 0 to time t. We say that the process X is Markovian if $\mathbb{P}(X_t \in A | \mathscr{F}_s) = \mathbb{P}(X_t \in A | X_s)$ for all $t > s$ and all Borel sets A. The process X is a martingale (resp., submartingale) if $\mathbb{E}[|X_t|] < \infty$ for all $t \geq 0$ and $\mathbb{E}[X_t | \mathscr{F}_s] = X_s$ (resp., $\mathbb{E}[X_t | \mathscr{F}_s] \geq X_s$) for all $t > s$. An important example of martingale is the Brownian motion. A stochastic process $\mathcal{Z} = \{\mathcal{Z}_t\}_{t\geq 0}$ on $(\Omega, \mathscr{F}, \mathbb{P})$ is a *Brownian motion* if it satisfies (see Section 37 in Billingsley, 2008):

(i) The process starts at 0: $\mathbb{P}(\mathcal{Z}_0 = 0) = 1$;

(ii) The increments are independent: if $0 \leq t_0 \leq \cdots \leq t_n$, then

$$\mathbb{P}(\mathcal{Z}_{t_k} - \mathcal{Z}_{t_{k-1}} \in A_k, \quad \forall k \leq n) = \prod_{k=1}^{n} \mathbb{P}(\mathcal{Z}_{t_k} - \mathcal{Z}_{t_{k-1}} \in A_k);$$

(iii) For $0 \leq s < t$ the increment $\mathcal{Z}_t - \mathcal{Z}_s$ is normally distributed with mean 0 and variance $t - s$:

$$\mathbb{P}(\mathcal{Z}_t - \mathcal{Z}_s \in A) = \frac{1}{\sqrt{2\pi(t-s)}} \int_A e^{-x^2/2(t-s)} dx;$$

(iv) The sample paths are continuous: for each $\omega \in \Omega$, the function $t \mapsto \mathcal{Z}_t(\omega)$ is continuous.

We now define the concept of quadratic variation of a martingale. Consider a martingale M that has continuous sample paths. Consider a partition $\pi_t = \{t_0, \ldots, t_n\}$ of the interval $[0, t]$ with $0 = t_0 < t_1 < \cdots < t_n = t$, and denote its mesh by $\|\pi_t\| \equiv \max_{1 \leq k \leq n}(t_k - t_{k-1})$. Denoting by $\mathbb{P}\lim$ the limit of a process in the sense of the convergence in probability, we can show that

$$\mathbb{P}\lim_{\|\pi_t\| \to 0} \sum_{k=1}^{n} (M_{t_k} - M_{t_{k-1}})^2 = \langle M \rangle_t,$$

where $\langle M \rangle$ is an adapted process with continuous and nondecreasing sample paths, called the *quadratic variation* of the martingale M. In particular, in the case where M is a Brownian motion, $\langle M \rangle$ is the deterministic process $\langle M \rangle_t = t$, and the convergence holds almost surely. Since $\langle M \rangle$ has nondecreasing sample paths ω, we can define the (path-by-path) Lebesgue–Stieltjes integral $\int_0^t X_s(\omega) d\langle M \rangle_s(\omega)$ for each ω of a stochastic process X on an interval $[0, T]$ with $T < \infty$ (in the case where M is a Brownian motion, $d\langle M \rangle_s = ds$ is simply the Lebesgue measure).

We refer to Revuz and Yor (1999) for the rigorous construction of the stochastic integral $\int_0^t X_s dM_s$ of a process X with respect to a martingale M that has continuous sample paths (eg, a Brownian motion). For such a martingale M, let $L^2(M)$ denote the (Hilbert) space of processes X such that for all $t \geq 0$ the map $(\omega, s) \mapsto X_s(\omega)$ defined on $\Omega \times [0, t]$ is measurable with respect to $\mathscr{F}_t \otimes \mathcal{B}([0, t])$, and $\mathbb{E}[\int_0^T X_s^2 d\langle M \rangle_s] < \infty$. The construction of the stochastic integral involves several steps. Suppose first that X is a "simple" process, in the sense that there exists a partition $0 = t_0 < t_1 < \cdots < t_n = T$ of $[0, T]$ such that $X_s = \xi_j$ for all $s \in (t_j, t_{j+1}]$, where ξ_j is a bounded $\mathscr{F}_{t_j}$-measurable random variable. That is, X can be written as

$$X_s(\omega) = \sum_{j=0}^{n-1} \xi_j(\omega) \mathbb{I}_{(t_j, t_{j+1}]}(s).$$

We can then define, for $t_k < t \leq t_{k+1}$,

$$I_t(X) = \int_0^t X_s dM_s \equiv \sum_{j=0}^{k-1} \xi_j \left(M_{t_j+1} - M_{t_j} \right) + \xi_k (M_t - M_{t_k}).$$

The integral $I(X)$ is then a square integrable continuous martingale with quadratic variation given by $\langle I(X) \rangle_t = \int_0^t X_s^2 d\langle M \rangle_s$. Next, any process $X \in L^2(M)$ can be approximated by a sequence of simple processes $\{X^n\}_{n \geq 0}$ in the sense that $\mathbb{E}[\int_0^T \left(X_s^n - X_s \right)^2 d\langle M \rangle_s] \to 0$. We can then show that the sequence of integrals $I(X^n)$ is a Cauchy sequence in the complete space $L^2(M)$. Its limit defines the stochastic integral. It satisfies $\mathbb{E}[I_t(X)] = 0$ and is a martingale.

We now state the three main theorems which we use in our analysis. The first, *Itô's lemma*, is an extension of the chain rule from standard calculus:

Theorem 6 (Itô's lemma) *Let f be a deterministic $\mathcal{C}^2$ function and M a squared integrable martingale. We have:*

$$f(M_t) = f(M_0) + \int_0^t f'(M_s) dM_s + \frac{1}{2} \int_0^t f''(M_s) d\langle M \rangle_s.$$

The second important result is the *Martingale Representation Theorem*. If M is a martingale, define the *exponential martingale*

$$\mathcal{E}(M)_t = \exp\left(M_t - \frac{1}{2} \langle M \rangle_t \right). \tag{105}$$

We can then show that $\mathcal{E}(M)_t$ is a supermartingale, and it is a martingale if in addition $\mathbb{E}\left[\exp\left(\frac{1}{2} \langle M \rangle_T \right) \right] < \infty$. In particular, if M_t is defined as a stochastic integral with respect to a Brownian motion $\mathcal{Z}$, ie, $M_t = \int_0^t \mu_s d\mathcal{Z}_s$ with $\int_0^t \mu_s^2 ds < \infty$ a.s., then

$$\mathcal{E}(M)_t = \exp\left(\int_0^t \mu_s d\mathcal{Z}_s - \frac{1}{2} \int_0^t \mu_s^2 ds \right) \tag{106}$$

is a martingale if $\mathbb{E}\left[\exp\left(\frac{1}{2} \int_0^T \mu_s^2 ds \right) \right] < \infty$.

Theorem 7 (Martingale Representation Theorem) *Let $\mathcal{Z}$ be a given Brownian motion. Every square integrable continuous martingale M adapted to the filtration $\mathscr{F}^{\mathcal{Z}}$ generated by $\mathcal{Z}$ admits a unique representation*

$$M_t = M_0 + \int_0^t \beta_s d\mathcal{Z}_s$$

for some process β *adapted to* $\mathscr{F}^{\mathcal{Z}}$ *that satisfies* $\mathbb{E}\left[\exp\left(\int_0^T \beta_s^2 ds\right)\right] < \infty$.

Finally, the third important result that we will use is *Girsanov's theorem*, which concerns the changes of measures.

Theorem 8 (Girsanov theorem) *Let* $\mathcal{Z}$ *be a Brownian motion and* μ *be an adapted process with* $\int_0^t \mu_s^2 ds < \infty$ *a.s. Let* $\mathcal{E}(M)_t$ *be defined by (106). If* $\mathbb{E}\left[\mathcal{E}(M)_T\right] = 1$ *(which implies that* $\mathcal{E}(M)$ *is a martingale) then, under*

$$\widetilde{\mathbb{P}}\,(d\omega) = \mathcal{E}(M)_T(\omega) \times \mathbb{P}(d\omega),$$

the process

$$\widetilde{\mathcal{Z}} = \mathcal{Z} - \int_0^t \mu_s ds$$

is a Brownian motion.

Finally we describe heuristically the dynamic programming principle in continuous time. We skip many of the technicalities and refer to Yong and Zhou (1999) for a rigorous exposition. Consider a filtered probability space $\left(\Omega, \mathscr{F}, \{\mathscr{F}_t\}_{t\geq 0}, \mathbb{P}\right)$, on which a Brownian motion $\mathcal{Z}$ is defined, and let $T \in (0, \infty)$ and $A \subset \mathbb{R}$ be a given Borel set. The state of a system at time t is described by a stochastic process $X_t \in \mathbb{R}$ that evolves according to

$$X_{t'} = x + \int_t^{t'} b(s, X_s, u_s) ds + \int_t^{t'} \sigma(s, X_s, u_s) d\mathcal{Z}_s, \quad 0 \leq t \leq t' \leq T, \tag{107}$$

where $\boldsymbol{u} : [0, T] \times \Omega \to A$ is the *control process*, and $b, \sigma : [0, T] \times \mathbb{R} \times A \to \mathbb{R}$. The goal is to choose $\boldsymbol{u}$ to maximize the functional

$$J(\boldsymbol{u}) \equiv \mathbb{E}\left[\int_t^T f(s, X_s, u_s) ds + g(X_T)\right], \tag{108}$$

where $f : [0, T] \times \mathbb{R} \times A \to \mathbb{R}$ and $g : \mathbb{R} \to \mathbb{R}$.[ae] We assume that the functions b,σ,f,g, satisfy suitable conditions ensuring that there exists a unique solution X to (107) for any $t,x,\boldsymbol{u}$ and that the functional $J(\boldsymbol{u})$ in (108) is well defined (see Definition 6.15. and Conditions (S1)$'$ and (S2)$'$ p. 177 in Yong and Zhou, 1999). The control process $\boldsymbol{u}$ is *admissible* if: (i) u_t

[ae] Here the control problem ends at a fixed duration T. In our analysis of the moral hazard problem we will deal instead with random horizons T optimally chosen by the principal (retirement), that is, where T is the stopping time $T \equiv \inf\{t \geq 0 : x_t \notin \mathcal{O}\}$ for some open set $\mathcal{O} \subset \mathbb{R}$. The dynamic programming principle can be extended to this case, see, eg, Section 2.7. in Yong and Zhou (1999) and Chapter 4 in Øksendal and Sulem (2007).

is $\{\mathscr{F}_t\}_{t\geq 0}$-adapted; (ii) X is the unique solution of Eq. (107); and (iii) the functions $f(\cdot, X., u.)$ and $g(X_T)$ are in $L^1_{\mathscr{F}}([0,T],\mathbb{R})$ and $L^1_{\mathscr{F}_T}(\boldsymbol{\Omega},\mathbb{R})$, respectively. The value function of the stochastic control problem that we consider is

$$V(t,x) = \sup_{\boldsymbol{u}} J(\boldsymbol{u}),$$

where the supremum is over all admissible controls $\boldsymbol{u}$.[af]

Theorem 9 (Dynamic Programming Principle) *For any stopping time τ with values in $[0,T]$, the value function $V(t,x)$ is equal to*

$$V(t,x) = \sup_{\boldsymbol{u}} \mathbb{E}\left[\int_t^\tau f(s,X_s,u_s)ds + V(\tau,X_\tau)|X_t = x\right].$$

Moreover, for all admissible controls $\boldsymbol{u}$,

$$M_{t'} \equiv \int_t^{t'} f(s,X_s,u_s)ds + V(t',X_{t'})$$

is a supermartingale (ie, $-M_{t'}$ is a submartingale), and it is a martingale if and only if $\boldsymbol{u}$ is optimal. Suppose that the value function $V \in \mathcal{C}^{1,2}([0,T]\times\mathbb{R})$. Then V is a solution to the following second-order Hamilton–Jacobi–Bellman partial differential equation:

$$\begin{cases} -\dfrac{\partial V}{\partial t} + \sup\limits_{u\in A}\left[f(t,x,u) + b(t,x,u)\dfrac{\partial V}{\partial x} + \dfrac{1}{2}\sigma^2(t,x,u)\dfrac{\partial^2 V}{\partial x^2}\right] = 0, & \forall (t,x)\in[0,T]\times\mathbb{R}, \\ V(T,x) = g(x), & \forall x\in\mathbb{R}. \end{cases}$$

Note that the last statement assumes smoothness conditions about the value function V, which is endogenous.[ag]

3.3.2 Moral Hazard in Continuous Time

We now analyze the moral hazard problem in a continuous time framework (see Section 2.7 for the discrete time version of the model), following Sannikov (2008)'s exposition. Our aim is to derive and explain the main results with the minimum of

[af] Rigorously, it is often natural and necessary to consider a *weak formulation* of the problem, in which the filtered probability space $(\Omega,\mathcal{F},\{\mathcal{F}_t\}_{t\geq 0},\mathbb{P})$ and the Brownian motion $\mathcal{Z}$ are not fixed, but parts of the control (see Sections 2.4.4. and 4.3.1. in Yong and Zhou, 1999). This is because the objective of the stochastic control problem is to minimize the expectation of a random variable that depends only on the distribution of the processes involved. We ignore this distinction in the sequel.

[ag] There exist other notions of solutions to stochastic differential equations, called viscosity solutions, which avoid making such assumptions, see, eg, Section 4.5. in Yong and Zhou (1999).

technicalities. Therefore we omit many technical details and refer to Sannikov's work for the fully rigorous proofs.

We analyze a model where the agent's current effort affects only current output. The agent derives utility $U(c_t) - h(\theta_t)$ from consumption $c_t \geq 0$ and effort $\theta_t \in \left[0, \overline{\theta}\right]$ at time t, where U is twice continuously differentiable, increasing, and concave with $U(0) = 0$ and $\lim_{c\to\infty} U'(c) = 0$, and h is differentiable, increasing, and convex with $h(0) = 0$ and $h'(0) > 0$.

Fix a reference probability space $(\boldsymbol{\Omega}, \mathscr{F}, \mathbb{P})$ with a standard Brownian motion $\mathcal{Z}$ under $\mathbb{P}$. If the agent works according to the effort process $\boldsymbol{\theta} = \{\theta_t\}_{t\in[0,\,\infty)}$ with $0 \leq \theta_t \leq \overline{\theta}$ for all t, he generates an output y_t given by $y_t = \int_0^t \theta_s ds + \sigma \mathcal{Z}_t$, ie,

$$dy_t = \theta_t dt + \sigma d\mathcal{Z}_t,$$

where $\sigma > 0$ is a constant. The principal observes y_t, but not θ_t or $\mathcal{Z}_t$, and compensates the agent with a consumption process $\mathbf{c} = \{c_t\}_{t\geq 0}$ with $c_t \geq 0$ for all t. Denoting by $\mathscr{F}_t^y$ the filtration generated by y_t, we impose that the process c_t is $\mathscr{F}_t^y$-adapted, ie, the agent's compensation c_t is conditional on past output $\{y_s\}_{s\leq t}$.

Rather than solving for the agent's effort choice $\boldsymbol{\theta}$ as a function of the fixed underlying Brownian motion $\mathcal{Z}$, we can instead view the agent as choosing a probability measure $\mathbb{P}^{\boldsymbol{\theta}}$ on the output space.[ah] That is, for each effort process $\boldsymbol{\theta}$ we can define a process $\mathcal{Z}_t^{\boldsymbol{\theta}} = \sigma^{-1}\left(y_t - \displaystyle\int_0^t \theta_s ds\right)$. By Girsanov's theorem, $\mathcal{Z}_t^{\boldsymbol{\theta}}$ is a Brownian motion under the measure $\mathbb{P}^{\boldsymbol{\theta}}$, where

$$\mathbb{P}^{\boldsymbol{\theta}}(d\omega) = \mathcal{E}(\mathcal{Z})_t \mathbb{P}(d\omega) = e^{\int_0^t \theta_s d\mathcal{Z}_s - \frac{1}{2}\int_0^t \theta_s^2 ds} \mathbb{P}(d\omega).$$

A change of measure from $\mathbb{P}^{\boldsymbol{\theta}}$ to $\mathbb{P}^{\hat{\boldsymbol{\theta}}}$ on the space of output paths corresponds to a change in the drift of the output process from $\boldsymbol{\theta}$ to $\hat{\boldsymbol{\theta}}$.

Planner's Problem

If he receives consumption $\mathbf{c} = \{c_t\}_{t\geq 0}$ and provides effort $\boldsymbol{\theta} = \{\theta_t\}_{t\geq 0}$, the agent gets the expected utility

$$U(\mathbf{c}, \boldsymbol{\theta}) = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(U(c_t) - h(\theta_t))dt\right], \tag{109}$$

where $\mathbb{E}^{\boldsymbol{\theta}}$ denotes the expectation under the probability measure $\mathbb{P}^{\boldsymbol{\theta}}$ induced by the strategy $\boldsymbol{\theta}$, as defined above. The superscript $\boldsymbol{\theta}$ over the expectation $\mathbb{E}^{\boldsymbol{\theta}}$ highlights that the agent's strategy affects the probability distribution over the paths of output, and thus over

[ah] Similarly, in the standard static moral hazard problem, we can view the agent as choosing the probability distribution $\mathbb{P}(y|\theta)$ over output values y generated by his effort θ.

the compensation realizations. Thus, the utility depends on the agent's effort directly, as it enters the cost of effort $h(\theta_t)$, and indirectly through its effect on the probability distribution over the paths of y_t.

The principal gets expected profit

$$\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(dy_t - c_t dt)\right] = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(\theta_t - c_t)dt\right]. \tag{110}$$

A contract $(\mathbf{c},\boldsymbol{\theta})$ is *incentive compatible* if the agent finds it optimal to exert the contractual effort θ_t at every t, ie, if $\{\theta_t\}_{t\geq 0}$ maximizes his expected utility $U(\mathbf{c},\boldsymbol{\theta})$ given $\{c_t\}_{t\geq 0}$:

$$\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(U(c_t) - h(\theta_t))dt\right] \geq \mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[\int_0^\infty e^{-rt}\left(U(c_t) - h\left(\hat{\theta}_t\right)\right)dt\right], \forall \hat{\boldsymbol{\theta}}. \tag{111}$$

The contract must deliver initial promised utility $\hat{v}_0$, ie,

$$\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(U(c_t) - h(\theta_t))dt\right] \geq \hat{v}_0. \tag{112}$$

The principal's problem consists of choosing the contract $(\mathbf{c},\boldsymbol{\theta})$ that maximizes his expected profit (110) among all the contracts that satisfy the incentive-compatibility (111) and promise-keeping (112) constraints, that is,

$$\max_{\mathbf{c},\boldsymbol{\theta}} \ \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rt}(\theta_t - c_t)dt\right]$$
$$\text{subject to} \quad (111),\ (112).$$

The principal can commit to the contract he offers.

Reducing the Planner's Problem to an Optimal Stochastic Control Problem

The planner's problem can be solved by reducing it to an optimal stochastic control problem. As in the discrete time framework, we use the agent's continuation utility v_t (defined formally below) as state variable. The key simplification of the planner's problem comes again from the (continuous-time equivalent of the) one-shot deviation principle, which substantially reduces the set of incentive constraints: the agent's incentive constraints hold for all alternative strategies $\hat{\boldsymbol{\theta}} = \left\{\hat{\theta}_t\right\}_{t\geq 0}$ if they hold just for strategies that differ from $\boldsymbol{\theta} = \{\theta_t\}_{t\geq 0}$ for an instant. The Martingale Representation Theorem then allows us to express the instantaneous incentive constraints in terms of v_t.

Fix an arbitrary consumption process $\mathbf{c} = \{c_t\}_{t\geq 0}$ and an effort strategy $\boldsymbol{\theta} = \{\theta_t\}_{t\geq 0}$ (not necessarily optimal for the agent given $\mathbf{c}$). The agent's *continuation value* $v_t(\mathbf{c},\boldsymbol{\theta})$, defined as his expected future payoff from $(\mathbf{c},\boldsymbol{\theta})$ after time t (ie, after a given history of output $\{y_s\}_{s\leq t}$), is given by

$$v_t(\mathbf{c},\boldsymbol{\theta}) = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_t^\infty e^{-r(s-t)}(U(c_s)-h(\theta_s))ds|\mathscr{F}_t\right]. \tag{113}$$

Throughout this section, for a given time t and contract $(\mathbf{c},\boldsymbol{\theta})$, we also define the agent's *total* expected payoff from the contract $(\mathbf{c},\boldsymbol{\theta})$ given the information at time t as:[ai]

$$V_t^{\mathbf{c},\boldsymbol{\theta}} = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rs}(U(c_s)-h(\theta_s))ds|\mathscr{F}_t\right] = \int_0^t e^{-rs}(U(c_s)-h(\theta_s))ds + e^{-rt}v_t(\mathbf{c},\boldsymbol{\theta}). \tag{114}$$

We first derive the law of motion of $v_t(\mathbf{c},\boldsymbol{\theta})$ by applying the Martingale Representation Theorem.

Proposition 12 *Fix a contract $(\mathbf{c},\boldsymbol{\theta})$ with finite expected payoff to the agent. An adapted process v_t is the continuation value process (as defined in (113)) associated with the contract $(\mathbf{c},\boldsymbol{\theta})$ if and only if there exists an $\mathscr{F}_t$-adapted process $\boldsymbol{\beta} = \{\beta_t\}_{t\geq 0}$ with $\mathbb{E}\left[\int_0^t \beta_s^2 ds\right] < \infty$ for all t such that, for all $t \geq 0$,*

$$dv_t = (rv_t - U(c_t) + h(\theta_t))dt + \beta_t(dy_t - \theta_t dt) \tag{115}$$

and the transversality condition $\lim_{t\to\infty}\mathbb{E}^{\boldsymbol{\theta}}[e^{-rt}v_{t_0+t}|\mathscr{F}_{t_0}] = 0$ holds almost everywhere.

Proof Fix a contract $(\mathbf{c},\boldsymbol{\theta})$. The process $V_t^{\mathbf{c},\boldsymbol{\theta}}$ defined in (114) is a martingale under the probability measure $\mathbb{P}^{\boldsymbol{\theta}}$. Hence by the Martingale Representation Theorem there exists an adapted process β_t such that

$$V_t^{\mathbf{c},\boldsymbol{\theta}} = V_0^{\mathbf{c},\boldsymbol{\theta}} + \int_0^t e^{-rs}\beta_s\sigma d\mathcal{Z}_s^{\boldsymbol{\theta}}, \quad 0 \leq t < \infty,$$

where $\mathcal{Z}_t^{\boldsymbol{\theta}} = \sigma^{-1}\left(y_t - \int_0^t \theta_s ds\right)$ is a Brownian motion under $\mathbb{P}^{\boldsymbol{\theta}}$. Differentiating both expressions for $V_t^{\mathbf{c},\boldsymbol{\theta}}$ with respect to t and equating them implies that $v_t(\mathbf{c},\boldsymbol{\theta})$ satisfies (115). The transversality condition (for simplicity with $t_0 = 0$) follows from

$$\lim_{t\to\infty}\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^t e^{-rs}(U(c_s)-h(\theta_s))ds\right] = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\infty e^{-rs}(U(c_s)-h(\theta_s))ds\right],$$

by the Dominated Convergence Theorem using that θ_s, and thus $\int_0^t e^{-rs}(U(c_s)-h(\theta_s))ds$, is bounded. A similar argument shows that $\lim_{t\to\infty}\mathbb{E}^{\boldsymbol{\theta}}[e^{-rt}v_{t_0+t}|\mathscr{F}_{t_0}] = 0$ for all times $t_0 \geq 0$.

[ai] See Theorem 9 above.

Conversely, suppose that v_t is a process that satisfies (115) (for some starting value v_0 and some volatility process β_t) and the transversality condition. Define V_t as

$$V_t = \int_0^t e^{-rs}(U(c_s) - h(\theta_s))ds + e^{-rt}v_t.$$

Differentiating V_t implies that it is a martingale when the agent is following the effort strategy $\boldsymbol{\theta}$, ie, under the probability measure $\mathbb{P}^{\boldsymbol{\theta}}$. Therefore

$$v_0 = \quad V_0 = \mathbb{E}^{\boldsymbol{\theta}}[V_t|\mathscr{F}_0] = \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^t e^{-rs}(U(c_s) - h(\theta_s))ds|\mathscr{F}_0\right] + \mathbb{E}^{\boldsymbol{\theta}}[e^{-rt}v_t|\mathscr{F}_0].$$

Since the transversality condition is satisfied (for $t_0 = 0$), taking limits as $t \to \infty$ in the previous equation implies that $v_0 = v_0(\mathbf{c}, \boldsymbol{\theta})$. A similar argument shows that v_t is the continuation value process $v_t(\mathbf{c}, \boldsymbol{\theta})$ defined by (113) at any time $t \geq 0$. □

The law of motion (115) of the continuation utility has the following interpretation. Since $dy_t - \theta_t dt = \sigma d\mathcal{Z}_t^{\boldsymbol{\theta}}$ is a Brownian motion when the agent takes the recommended effort level $\boldsymbol{\theta}$, $[rv_t(\mathbf{c}, \boldsymbol{\theta}) - (U(c_t) - h(\theta_t))]$ is the drift of the agent's continuation value. The value that the principal owes to the agent (future expected payoff), $v_t(\mathbf{c}, \boldsymbol{\theta})$, grows at the rate of interest r, and falls due to the flow of repayments $(U(c_t) - h(\theta_t))$. The transversality condition has to hold if the debt is eventually repaid. Since the agent's compensation and recommended effort are determined by output y_t, his continuation payoff $v_t(\mathbf{c}, \boldsymbol{\theta})$ is also determined by output, and the process β_t then expresses the sensitivity of the agent's continuation value to output at a given time, which will be the key to affect the agent's incentives.

The previous lemma is useful because it allows us to simplify the set of incentive constraints with a version of the one-shot deviation principle (Proposition 13), which shows that the agent's incentive constraints hold for all alternative strategies $\hat{\boldsymbol{\theta}}$ if they hold for all strategies which differ from $\boldsymbol{\theta}$ for an infinitesimally small amount of time. Heuristically, suppose that the agent has conformed to the contract (c_s, θ_s) for $s \leq t$ and cheats by performing effort $\hat{\theta}$ in the interval $[t, t + dt]$ and reverting to $\{\theta_s\}$ for $s \geq t + dt$. His immediate consumption c_t is unaffected, his cost on $[t, t + dt]$ is $h(\hat{\theta})dt$, and his expected benefit on $[0, \infty)$, ie, the expected impact of effort on his continuation value, is $\mathbb{E}^{\hat{\boldsymbol{\theta}}}[\beta_t dy_t] = \beta_t \hat{\theta} dt$. Hence for the contract to be incentive compatible we must have

$$\beta_t \theta_t - h(\theta_t) = \max_{\hat{\theta} \geq 0} \left\{-h(\hat{\theta}) + \beta_t \hat{\theta}\right\},$$

almost everywhere.[aj] This argument can be made rigorous, and in addition the condition is not only necessary but also sufficient: if this one-shot condition holds at each instant t, then any dynamic deviation strategy $\hat{\boldsymbol{\theta}} = \left\{\hat{\theta}_s\right\}_{s \geq 0}$ is suboptimal.

[aj] Note the fixed point nature of the argument: θ_t generates $v_t(\mathbf{c}, \boldsymbol{\theta})$ which yields β_t; in turn, the incentives have to be satisfied given this process β_t.

Proposition 13 *Let $(\mathbf{c},\boldsymbol{\theta})$ be a contract with agent's continuation value $v_t(\mathbf{c},\boldsymbol{\theta})$ and let β_t be the process from Proposition 12 that represents $v_t(\mathbf{c},\boldsymbol{\theta})$. Then $(\mathbf{c},\boldsymbol{\theta})$ is incentive compatible if and only if $\forall\hat{\theta}\in[0,\overline{\theta}]$, $\forall t\geq 0$,*

$$\theta_t \in \arg\max_{\hat{\theta}\geq 0}\left\{\beta_t\hat{\theta}-h\left(\hat{\theta}\right)\right\}, \text{a.e.} \tag{116}$$

Proof Suppose that (116) is satisfied. Suppose that an agent follows the alternative effort process $\hat{\boldsymbol{\theta}}=\left\{\hat{\theta}_s\right\}_{s\geq 0}$ until time t and reverts back to $\boldsymbol{\theta}$ thereafter; denote by $\hat{\boldsymbol{\theta}}^t$ this strategy. The time-t expectation of his total payoff is given by $V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}$ defined in (114),

$$V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}=\int_0^t e^{-rs}\left(U(c_s)-h\left(\hat{\theta}_s\right)\right)ds+e^{-rt}v_t(\mathbf{c},\boldsymbol{\theta}).$$

Differentiating $V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}$ and using Eq. (115) to compute $d[e^{-rt}v_t(\mathbf{c},\boldsymbol{\theta})]$, we find[ak]

$$dV_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}=e^{-rt}\left\{\left(\beta_t\hat{\theta}_t-h\left(\hat{\theta}_t\right)\right)-\left(\beta_t\theta_t-h(\theta_t)\right)\right\}dt+e^{-rt}\beta_t\left(dy_t-\hat{\theta}_t dt\right).$$

Thus, since $\left(dy_t-\hat{\theta}_t dt\right)$ is a Brownian motion under $\mathbb{P}^{\hat{\boldsymbol{\theta}}}$, if (116) holds the drift of $V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}$ under the probability measure $\mathbb{P}^{\hat{\boldsymbol{\theta}}}$ is nonpositive and thus $V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}$ is a $\mathbb{P}^{\hat{\boldsymbol{\theta}}}$-supermartingale. Hence we have

$$\mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[\int_0^t e^{-rs}\left(U(c_s)-h\left(\hat{\theta}_s\right)\right)ds\right]+\mathbb{E}^{\hat{\boldsymbol{\theta}}}[e^{-rt}v_t(\mathbf{c},\boldsymbol{\theta})]=\mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}|\mathscr{F}_0\right]\leq V_0^{\mathbf{c},\hat{\boldsymbol{\theta}}^0}=v_0(\mathbf{c},\boldsymbol{\theta}).$$

Taking the limit as $t\to\infty$ using the fact that $\mathbb{E}^{\hat{\boldsymbol{\theta}}}[e^{-rt}v_t(\mathbf{c},\boldsymbol{\theta})]\geq -e^{-rt}h\left(\overline{\theta}\right)$, we obtain $v_0\left(\mathbf{c},\hat{\boldsymbol{\theta}}\right)\leq v_0(\mathbf{c},\boldsymbol{\theta})$.

Conversely, if (116) does not hold on a set of times and sample paths with positive measure, then pick a deviation $\hat{\boldsymbol{\theta}}$ defined as $\hat{\theta}_t=\arg\max_{\hat{\theta}}\left(-h\left(\hat{\theta}\right)+\beta_t\hat{\theta}\right)$ everywhere. The drift of $V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}$ under $\mathbb{P}^{\hat{\boldsymbol{\theta}}}$ is nonnegative and positive on a set of positive measure, so that for t large enough the time-0 expected payoff from following $\hat{\boldsymbol{\theta}}$ until time t and switching to $\boldsymbol{\theta}$ thereafter is $v_0\left(\mathbf{c},\hat{\boldsymbol{\theta}}^t\right)=\mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[V_t^{\mathbf{c},\hat{\boldsymbol{\theta}}^t}|\mathscr{F}_0\right]>V_0^{\mathbf{c},\hat{\boldsymbol{\theta}}^0}=v_0(\mathbf{c},\boldsymbol{\theta})$. Thus the strategy $\boldsymbol{\theta}$ is suboptimal. □

For a given sensitivity β, denote by $\theta(\beta)$ the effort that maximizes $(-h(\theta)+\beta\theta)$, namely $\theta(\beta)=h'^{-1}(\beta)$ if $\beta>0$ and $\theta(\beta)=0$ if $\beta=0$. Conversely, for a given effort level θ define the sensitivity $\beta(\theta)$ that ensures incentive compatibility as $\beta(\theta)=h'(\theta)$ if $\theta>0$, and $\beta(\theta)=0$ if $\theta=0$.

[ak] This equation evaluates the incremental change in the agent's utility from pursuing the alternative effort strategy $\hat{\boldsymbol{\theta}}$ for an additional unit of time during $[t,t+dt]$, and shows that in expectation such an incremental deviation hurts the agent. The next equation then uses a supermartingale argument to obtain inductively that the whole deviation strategy $\left\{\hat{\theta}_t\right\}_{t\geq 0}$ is worse than $\{\theta_t\}_{t\geq 0}$.

We are now ready to reformulate the planner's problem as a stochastic control problem, using the continuation value v_t as the single state variable.

Solution to the Optimal Stochastic Control Problem

The planner maximizes his expected profit (110) over incentive-compatible contracts $(\mathbf{c},\boldsymbol{\theta})$ subject to the law of motion of v_t, the transversality condition, and delivering initial promised utility $\hat{v}_0$. We consider a relaxed problem without the transversality condition (to be checked ex post). Before we analyze this problem, note that as in the discrete time setting, the principal has the option of "retiring" the agent at a given time τ by allocating a constant consumption $c_t = c$ and recommending zero effort $\theta_t = 0$ for all $t \geq \tau$. The continuation value at retirement time τ is then $v_\tau = r^{-1}U(c)$, so that $c = U^{-1}(rv_\tau)$. The retirement time τ must be specified in the contract, so it is a stopping time with respect to the filtration $\mathscr{F}_t$ generated by the output process y. We can thus write the principal's value of the optimal contract as

$$K(\hat{v}_0) = \max_{\mathbf{c},\boldsymbol{\theta},\tau} \mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\tau e^{-rt}\left((\theta_t - c_t)dt + \sigma d\mathcal{Z}_t^{\boldsymbol{\theta}}\right) - \frac{e^{-r\tau}}{r}U^{-1}(rv_\tau)\right] \tag{117}$$

$$\text{subject to } \; dv_t = (rv_t - U(c_t) + h(\theta_t))dt + \beta(\theta_t)\sigma d\mathcal{Z}_t^{\boldsymbol{\theta}} \tag{118}$$

$$v_0 = \hat{v}_0. \tag{119}$$

Note in particular that the incentive constraints (111) are automatically satisfied if the constraint (118) holds. The function $K(v)$ can be found using standard optimal control and optimal stopping techniques, where the control variables are θ_t, c_t, τ and the state variable is v_t. The principal's problem can be solved in two steps: first, guess an optimal contract using the appropriate Bellman equation; second, verify ex post that this contract is indeed optimal.

We start by conjecturing the optimal contract. The function K is continuous on $[0, \infty)$ with $K(v) \geq -r^{-1}U^{-1}(rv)$ for all v. It satisfies the following Hamilton–Jacobi–Bellman (HJB) equation:[al]

[al] In fact, this is a Hamilton–Jacobi–Bellman Variational Inequality (HJBVI), where the HJB comes from the optimal stochastic control problem and the VI comes from the optimal stopping problem. See Chapter 4 in Øksendal and Sulem (2005).

$$rK(v) = \max\left\{ -U^{-1}(rv); \max_{\substack{0\le\theta\le\bar{\theta}\\ c\ge 0}} (\theta - c) + (rv - U(c) + h(\theta))K'(v) + \frac{1}{2}\sigma^2(\beta(\theta))^2 K''(v) \right\} \tag{120}$$

with the three boundary conditions

$$K(0) = 0, \quad K(\bar{v}) = -r^{-1}U^{-1}(r\bar{v}), \quad K'(\bar{v}) = -U^{-1\prime}(r\bar{v}), \tag{121}$$

for some $\bar{v} \ge 0$. Intuitively, (120) means that the principal maximizes the expected current flow of profit $(\theta - c)$ plus the expected change of future profit due to the drift and volatility of the agent's continuation value, until the stopping time τ at which the principal either retires the agent (if $v_\tau = \bar{v}$) or fires him (if $v_\tau = 0$). The second and third boundary conditions in (121) mean that the optimal retirement time occurs at the continuation value $\bar{v}$ where the value-matching condition (which equates the value of retiring the agent with that of continuing with positive effort) and the smooth-pasting condition (which equates the marginal values of retiring and continuing) are satisfied. We can show that there exists a unique function K that satisfies the HJB equation (120) with the three boundary conditions (121). The stopping time $\tau = \inf\{t \ge 0 : K(v) \le -r^{-1}U^{-1}(rv)\}$ satisfies $\tau < \infty$ a.s.,[am] and the function K is concave.

Define, for an arbitrary control policy $(\boldsymbol{c}, \boldsymbol{\theta})$, the process

$$G_t^{\boldsymbol{c},\boldsymbol{\theta}} = \int_0^t e^{-rs}(\theta_s - c_s)ds + e^{-rt}K(v_t). \tag{122}$$

The following proposition conjectures the optimal contract from the solution to (120), (121) and then verifies that it is indeed optimal using martingale techniques:

Proposition 14 *Denote by $\theta(v), c(v)$ the maximizers in the right hand side of the HJB equation.*[an] *Consider the unique solution $K(v) \ge -r^{-1}U^{-1}(rv)$ to the HJB equation (120) that satisfies the conditions (121) for some $\bar{v} \ge 0$. For any $\hat{v}_0 \in [0, \bar{v}]$, define the process v_t by $v_0 = \hat{v}_0$ and*

[am] If $h'(0) = 0$, the retirement point $\bar{v}$ may not be finite, so that $K(v)$, $c(v)$, $\theta(v)$ asymptote to $-r^{-1}U^{-1}(rv)$, ∞, 0 as $v \to \infty$.

[an] The optimal effort maximizes the difference between the expected flow of output θ, and the costs of compensating the agent for his effort, $-h(\theta)K'(v)$, and of exposing him to income uncertainty to provide incentives, $-\frac{\sigma^2}{2}\beta(\theta)^2K''(v)$. The optimal consumption is 0 for v small enough (ie, for $K'(v) \ge -1/u'(0)$), and it is increasing in v according to $K'(v) = -1/U'(c)$ otherwise, where $1/U'(c)$ and $-K'(v)$ are the marginal costs of giving the agent value through current consumption and through his continuation payoff, respectively.

$$dv_t = r(v_t - u(c(v_t)) + h(\theta(v_t)))dt + r\beta(\theta(v_t))(dy_t - \theta(v_t)dt) \tag{123}$$

until the stopping time τ when v_τ hits 0 or $\bar{v}$. Define the contract $(\mathbf{c},\boldsymbol{\theta})$ with payments $c_t = c(v_t)$ and recommended effort $\theta_t = \theta(v_t)$ for $t < \tau$, and $c_t = U^{-1}(rv_\tau)$ and $\theta_t = 0$ for $t \geq \tau$. Then $(\mathbf{c},\boldsymbol{\theta})$ is incentive compatible and it has a value $\hat{v}_0 = v_0(\mathbf{c},\boldsymbol{\theta})$ to the agent and profit $K(\hat{v}_0)$ to the principal. Moreover, consider a concave solution K of the HJB equation (120). Any incentive-compatible contract $(\mathbf{c},\boldsymbol{\theta})$ yields to the principal a profit less than or equal to $K(v_0(\mathbf{c},\boldsymbol{\theta}))$.

Proof Let v_t be given by the stochastic differential equation (123) for $t \leq \tau$ and $v_t = v_\tau$ for $t > \tau$ (note in particular that $v_t \in [0,\bar{v}]$ is bounded). We show that $v_t = v_t(\mathbf{c},\boldsymbol{\theta})$ for all $t \geq 0$, where $v_t(\mathbf{c},\boldsymbol{\theta})$ is the agent's true continuation value in the contract $(\mathbf{c},\boldsymbol{\theta})$ constructed above. This will imply in particular that the agent gets value $v_0(\mathbf{c},\boldsymbol{\theta}) = \hat{v}_0$ from the contract. From the representation of $v_t(\mathbf{c},\boldsymbol{\theta})$ in Proposition 12, we have

$$d(v_t(\mathbf{c},\boldsymbol{\theta}) - v_t) = r(v_t(\mathbf{c},\boldsymbol{\theta}) - v_t)dt + (\beta_t - \beta(\theta(v_t)))\sigma d\mathcal{Z}_t^{\boldsymbol{\theta}},$$

hence for all $s \geq 0$, $\mathbb{E}^{\boldsymbol{\theta}}[v_{t+s}(\mathbf{c},\boldsymbol{\theta}) - v_{t+s}] = e^{rs}(v_t(\mathbf{c},\boldsymbol{\theta}) - v_t)$. But $\mathbb{E}^{\boldsymbol{\theta}}[v_{t+s}(\mathbf{c},\boldsymbol{\theta}) - v_{t+s}]$ is bounded, hence $v_t = v_t(\mathbf{c},\boldsymbol{\theta})$. Moreover, the contract $(\mathbf{c},\boldsymbol{\theta})$ is incentive compatible by construction since the process from Proposition 12 that represents $v_t(\mathbf{c},\boldsymbol{\theta})$ is $\beta_t = \beta(\theta_t)$.

Next we show that the principal gets expected profit $K(\hat{v}_0)$ from the contract. Differentiating expression (122) and applying Itô's lemma to $K(v_t)$ yields that the drift of $G_t^{\mathbf{c},\boldsymbol{\theta}}$ under $\mathbb{P}^{\boldsymbol{\theta}}$ is

$$e^{-rt}\left\{(\theta_t - c_t - rK(v_t)) + (rv_t - U(c_t) + h(\theta_t))K'(v_t) + \frac{1}{2}\sigma^2(\beta(\theta_t))^2 K''(v_t)\right\}.$$

Thus, when $c_t = c(v_t)$ and $\theta_t = \theta(v_t)$, the drift of $G_t^{\mathbf{c},\boldsymbol{\theta}}$ under $\mathbb{P}^{\boldsymbol{\theta}}$ is equal to zero before time τ, so that $G_t^{\mathbf{c},\boldsymbol{\theta}}$ is a martingale. By the Optional Stopping Theorem, we thus obtain that the principal's profit from the contract is

$$\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\tau e^{-rs}(\theta_s - c_s)ds\right] + \mathbb{E}^{\boldsymbol{\theta}}[e^{-r\tau}K(v_\tau)] = \mathbb{E}\left[G_\tau^{\mathbf{c},\boldsymbol{\theta}}\right] = G_0^{\mathbf{c},\boldsymbol{\theta}} = K(v_0(\mathbf{c},\boldsymbol{\theta})).$$

Finally, consider an alternative incentive-compatible contract $(\mathbf{c},\boldsymbol{\theta})$. Then (120) implies that the drift of $G_t^{\mathbf{c},\boldsymbol{\theta}}$ under $\mathbb{P}^{\boldsymbol{\theta}}$ is smaller than zero, so that $G_t^{\mathbf{c},\boldsymbol{\theta}}$ is a bounded supermartingale. By the Optional Stopping Theorem, we obtain that the principal's expected profit at time 0 is less than or equal to $G_0^{\mathbf{c},\boldsymbol{\theta}} = K(v_0(\mathbf{c},\boldsymbol{\theta}))$. We refer to Sannikov (2008) for the technical details omitted in this sketch of proof. □

For any $v_0 > \bar{v}$, the function $K(v)$ is negative and is an upper bound on the principal's value function; thus, there is no profitable contract with positive profit to the principal in that range. In the range $(0,\bar{v})$, substituting for the optimal consumption $c(v)$ and effort

$\theta(v)$ into the HJB equation, we obtain a nonlinear second-order differential equation for $K(v)$ which can be solved numerically. Finally, note that the envelope theorem applied to the HJB equation before retirement implies

$$(rv - U(c) + h(\theta))K''(v) + \frac{1}{2}\sigma^2(\beta(\theta))^2 K'''(v) = 0.$$

By Itô's lemma, the left hand side is the drift of $K'(v_t) = -1/U'(c_t)$ on the interval $[\underline{v}, \bar{v}]$. Thus the inverse of the agent's marginal utility is a martingale when the agent's consumption is positive, a result that parallels the Inverse Euler Equation (77) found in the discrete-time model.

Sannikov (2014) extends the analysis of the moral hazard model in continuous time to the case where current actions affect not only current output but also future output. The solution to this problem is more involved than that of Sannikov (2008), but the steps and the martingale techniques (using the Martingale Representation Theorem to simplify the set of incentive constraints and reduce the problem to a stochastic control problem) are similar.

We conclude this section with a brief discussion of the benefits of using a continuous-time rather than discrete-time framework to analyze dynamic contracting problems. First, the Hamilton–Jacobi–Bellman equation is more tractable analytically than the discrete-time Bellman equation (23). In particular DeMarzo and Sannikov (2006) show how differentiating the HJB equation and its boundary conditions that characterize the optimal contract allows us to derive comparative statics results analytically. Here we illustrate their method on a simple example. Suppose, for instance, that we are interested in the effect of the volatility σ^2 on the principal's profit $K(v)$. Differentiating (120) yields, for $v \in (0, \bar{v})$,

$$r\frac{\partial K(v)}{\partial \sigma^2} = \frac{1}{2}(\beta(\theta))^2 K''(v) + (rv - U(c) + h(\theta))\left(\frac{\partial K(v)}{\partial \sigma^2}\right)' + \frac{1}{2}\sigma^2(\beta(\theta))^2\left(\frac{\partial K(v)}{\partial \sigma^2}\right)'',$$

with the following boundary condition, obtained by differentiating the value-matching condition (121) at $\bar{v}$:

$$\frac{\partial K}{\partial \sigma^2}(\bar{v}) = -\left(K'(\bar{v}) + U^{-1\prime}(r\bar{v})\right)\frac{\partial \bar{v}}{\partial \sigma^2} = 0.$$

A generalization of the Feynman–Kac formula (see DeMarzo and Sannikov, 2006 for the technical details) implies that the solution to this differential equation can be written as a conditional expectation:

$$\frac{\partial K(v)}{\partial \sigma^2} = \frac{1}{2}\mathbb{E}^{\boldsymbol{\theta}}\left[\int_0^\tau e^{-rt}\beta^2(\theta_t)K''(v_t)dt + e^{-r\tau}\frac{\partial K}{\partial \sigma^2}(\bar{v})|v_0 = v\right] < 0,$$

where v_t evolves according to (118), and where the inequality follows from the strict concavity of the profit function K. Intuitively, the right hand side of this equation sums the profit gains and losses along the path of v_t due to an increase in σ^2. This shows that a higher volatility σ^2 reduces the principal's profit. We can similarly evaluate the effects of all the parameters of the model on the principal's profit, the agent's time-0 utility (by differentiating the optimality condition $K'(v_0)=0$), or the value at retirement $\bar{v}$ (by differentiating the boundary conditions (121)).

Finally, another advantage of the continuous-time problem is that it is also more tractable computationally. In particular, the continuous-time formulation (120) can be computed more easily as the solution to an ordinary differential equation with a free boundary, while computing the solution to the discrete time Bellman equation (23) is more involved.

4. APPLICATIONS

In this section we discuss several applications of the theory of recursive contracts. The methods developed in the previous sections can be used to analyze questions in public economics, corporate finance, development, international finance, and political economy. Our goal is not to provide a comprehensive overview of those fields. Rather we want to show how several general principles emphasized above can be used to obtain rich insights in very different areas and relate those insights to empirical observations.

4.1 Public Finance

Individuals are subject to a variety of idiosyncratic shocks. Illness, disability, job loss, structural changes in the economy that diminish the value of human capital, unexpected promotions and demotions, success and failure in business ventures, all significantly affect individuals' incomes. It has been recognized at least since the work of Vickrey (1947) that the tax and transfer system can provide insurance against such shocks and help individuals smooth their consumption across different dates and states. A natural question is then how to design the optimal social insurance system that provides the best insurance given the distortions imposed by those programs.

Diamond and Mirrlees (1978, 1986) and Diamond et al. (1980) were some of the first papers to systematically study this question. At the same time, solving these problems either analytically or computationally is very difficult even in relatively simple dynamic settings. The advances in the theory of recursive contracts in the late 1980s and 1990s delivered a set of tools that allowed researchers to overcome many of the difficulties. The New Dynamic Public Finance literature applied those tools to the study of dynamic optimal taxation: see, eg, Golosov et al. (2003, 2006, 2016), Albanesi and Sleet (2006), Golosov and Tsyvinski (2006, 2007), Farhi and Werning (2013, 2012, 2007), Werning (2009), Kocherlakota (2010), Stantcheva (2014). In what follows, we describe a model that illustrates some of the main results of this literature.

We focus on a partial equilibrium model in which individuals are subject to idiosyncratic shocks to labor productivity.[ao] The economy lasts T periods, where T can be finite or infinite. Each agent's preferences are described by a time separable utility function over consumption $c_t \geq 0$ and labor supply $l_t \geq 0$,

$$\mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}U(c_t,l_t)\right], \tag{124}$$

where $\beta \in (0,1)$ is a discount factor, $\mathbb{E}_0$ is a period-0 expectation operator conditional on the shock at date $t = 0$, and $U : \mathbb{R}^2_+ \rightarrow \mathbb{R}$ is differentiable, strictly increasing, and concave in consumption, and decreasing and concave in labor supply. The partial derivatives of the utility function are denoted by U_c and U_l.

Agents draw their initial type (skill) θ_1 from a distribution $\pi_1(\cdot)$ in period 1. From then on skills follow a Markov process $\pi_t(\theta_t|\theta_{t-1})$, where θ_{t-1} is the agent's skill realization in period $t-1$. We denote the probability density function of period-t types conditional on θ_{t-1} by $\pi_t(\cdot|\theta_{t-1})$. Skills are nonnegative: $\theta_t \in \Theta \subset \mathbb{R}_+$ for all t. At this stage we are agnostic about the dimensionality of Θ and allow Θ to be discrete or continuous. The set of possible histories up to period t is denoted by Θ^t. An agent of type θ_t who supplies l_t units of labor produces $y_t = \theta_t l_t$ units of output.

In this partial equilibrium economy, y_t also denotes the labor income of individuals. Individuals can freely borrow and lend at an exogenous interest rate R. We assume that there is no insurance available to individuals except self-insurance through borrowing and lending and through taxes and transfers provided by the government. We are interested in understanding how the government can design the optimal tax system $\mathcal{T}_t(\cdot)$ as a function of the information it has about individuals. We are thinking of the function $\mathcal{T}_t$ in very general terms: it is a combination of all taxes and transfers that individuals pay to or receive from the government. We are seeking a function $\mathcal{T}_t$ that maximizes welfare given by (124) in a competitive equilibrium.[ap]

If individuals' skills are observable, the optimal tax function is very simple: $\mathcal{T}_t$ should depend on the realization of the shocks θ^t and prescribe positive or negative transfers without distorting either labor supply or savings decisions. In reality idiosyncratic shocks are difficult to observe. Even disability insurance programs which extensively employ medical examinations to determine whether an applicant is subject to medical conditions that make a person unable to work are subject to substantial moral hazard problems and asymmetric information (see Golosov and Tsyvinski, 2006 and references therein).

[ao] See Albanesi (2011), Shourideh (2010), and Abraham and Pavoni (2008) for applications of recursive contracting tools to taxation with shocks to savings, Stantcheva (2014) for human capital accumulation, and Hosseini et al. (2013) for fertility choices.

[ap] It is straightforward to extend this analysis and allow other welfare criteria or expenditures on public goods (see, eg, Golosov et al., 2003).

Therefore we make the assumption that the realizations of θ_t are not observed by the government and the only observable choices are labor income, consumption, and capital.

We study the optimal taxes using a two-step procedure. In the first step, we invoke the Revelation Principle (see Section 2.2) and write the problem as a mechanism design program whose solution can be characterized using recursive techniques. In the second step, we back out a tax function $\mathcal{T}_t$ that can implement that solution in a competitive equilibrium.

The mechanism design problem is as follows. Let reports be given by $\sigma_t : \Theta^t \to \Theta$ and allocations by $c_t : \Theta^t \to \mathbb{R}_+$, $y_t : \Theta^t \to \mathbb{R}_+$, for all $t \geq 1$. The incentive constraint (8) writes

$$\begin{aligned} & \mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}U\left(c_t(\theta^t), \frac{y_t(\theta^t)}{\theta_t}\right)\right] \\ \geq\ & \mathbb{E}_0\left[\sum_{t=1}^{T}\beta^{t-1}U\left(c_t(\sigma^t(\theta^t)), \frac{y_t(\sigma^t(\theta^t))}{\theta_t}\right)\right], \forall \sigma^T \in \Sigma^T, \end{aligned} \tag{125}$$

and the feasibility constraint (2) becomes

$$\mathbb{E}_0\left[\sum_{t=1}^{T}R^{1-t}c_t(\theta^t)\right] \leq \mathbb{E}_0\left[\sum_{t=1}^{T}R^{1-t}y_t(\theta^t)\right]. \tag{126}$$

The planner maximizes the ex ante expected utility (124) of the agents, ie, provides optimal ex ante insurance. This problem is thus similar to that analyzed in Section 2 (see Eqs. (9) or (74)). Solving this problem directly is difficult. There are prohibitively many incentive constraints (125) either for analytical or numerical analysis in most applications. In the next sections we overcome this problem using recursive techniques. For concreteness, we assume separable isoelastic preferences

$$U(c,l) = \frac{c^{1-\sigma}-1}{1-\sigma} - \frac{l^{1+\varepsilon}}{1+\varepsilon}. \tag{127}$$

While these preferences are not needed for most of the insights, they simplify the exposition of the main results.

4.1.1 Analysis with i.i.d. Shocks

We start the analysis by assuming that shocks are independent and identically distributed over time, so that the probability of realization of any $\theta \in \Theta$ in any period can be written as $\pi(\theta)$. This assumption, although unrealistic, allows us to illustrate many insights very transparently.

We follow the steps familiar from the analysis in Sections 2.3 and 2.4. To ensure convexity, we rewrite our maximization problem in terms of utils of consumption and leisure rather than c and l. To this end we define the functions $C(u) = [1 + (1-\sigma)u]^{1/(1-\sigma)}$ and

$Y(h)=[(1+\varepsilon)h]^{1/(1+\varepsilon)}$. We apply the one-shot deviation result from Propositions 2 and 3 to write the incentive-compatibility and promise-keeping constraints as:

$$u_t(\theta^t)-\theta_t^{-(1+\varepsilon)}h(\theta^t)+\beta v_t(\theta^t)\geq u_t\left(\theta^{t-1},\hat{\theta}\right)-\theta_t^{-(1+\varepsilon)}h\left(\theta^{t-1},\hat{\theta}\right)+\beta v_t\left(\theta^{t-1},\hat{\theta}\right)$$

for all $\theta^{t-1}\in\Theta^{t-1}$, $\theta_t\in\Theta$, $\hat{\theta}\in\Theta$, with

$$v_{t-1}\left(\theta^{t-1}\right)=\int_{\Theta}\left[u_t\left(\theta^{t-1},\theta\right)-\theta^{-(1+\varepsilon)}h\left(\theta^{t-1},\theta\right)+\beta v_t\left(\theta^{t-1},\theta\right)\right]d\pi(\theta).$$

Following the same steps as in Section 2.3 we write the Bellman equation as

$$K_t(v)=\min_{\{u(\theta),h(\theta),w(\theta)\}_{\theta\in\Theta}}\int_{\Theta}\left[C(u(\theta))-Y(h(\theta))+R^{-1}K_{t+1}(w(\theta))\right]d\pi(\theta) \tag{128}$$

subject to the incentive constraints: for all $\theta,\hat{\theta}\in\Theta$,

$$u(\theta)-\theta^{-(1+\varepsilon)}h(\theta)+\beta w(\theta)\geq u\left(\hat{\theta}\right)-\theta^{-(1+\varepsilon)}h\left(\hat{\theta}\right)+\beta w\left(\hat{\theta}\right),$$

the promise-keeping constraint:

$$v=\int_{\Theta}\left[u(\theta)-\theta^{-(1+\varepsilon)}h(\theta)+\beta w(\theta)\right]d\pi(\theta),$$

and $K_{T+1}(w)=0$ for all w if T is finite. When T is infinite, the subscript t drops out of the Bellman equation above.

Many of the qualitative properties of this model can be obtained along the lines of Proposition 5. For example, using steps analogous to those of Section 2.4, it is easy to show the analogue of Eqs. (29) and (76):[aq]

$$K_t'(v)=\mathbb{E}[C'(u_{v,t})]=(\beta R)^{-1}\mathbb{E}\left[K_{t+1}'(w_{v,t})|v\right]. \tag{129}$$

Moreover, optimality also requires: for all θ,t,v,

$$C'(u_{v,t}(\theta))=(\beta R)^{-1}K_{t+1}'(w_{v,t}(\theta)). \tag{130}$$

The intuition for this result is simple. The planner can provide incentives to reveal information either intratemporally, by giving an agent higher contemporaneous utility, or intertemporally, by giving higher future promises. Condition (130) implies that it is optimal to equalize the marginal costs of the two ways of providing incentives.

These conditions have some immediate but unexpected implications for taxation. Note that $C'=\frac{1}{U_c}$, where U_c is the marginal utility of consumption, and hence (129) can be rewritten as

[aq] This condition is particularly easy to derive if Θ is finite, in which case it can be obtained by simple manipulation of the Lagrangians on the incentive constraints.

$$\frac{\beta R}{U_c(c_{v,t}(\theta))} = \mathbb{E}\left[\frac{1}{U_c(c_{v,t+1})}\middle| v\right], \quad \forall v, t, \theta.$$

The policy functions generate the constrained-optimal stochastic processes $\{c_t^*, y_t^*\}_{t=1}^T$ which satisfy the Inverse Euler Equation (see our discussion in Section 2.7 as well as Golosov et al., 2003):

$$\frac{\beta R}{U_c(c_t^*)} = \mathbb{E}_t\left[\frac{1}{U_c(c_{t+1}^*)}\right]. \tag{131}$$

By Jensen's inequality, we have $\mathbb{E}\left[\frac{1}{X}\right] \geq \frac{1}{\mathbb{E}[X]}$ for any random variable X, with strict inequality if X is nondeterministic. Therefore this equation implies that at the optimum,

$$U_c(c_t^*) \leq \beta R \mathbb{E}_t\left[U_c(c_{t+1}^*)\right],$$

with strict inequality if future consumption is uncertain. Therefore, it follows that the optimal tax system must introduce positive savings distortions in this economy. One useful way to summarize the distortions introduced by the tax system is to define the *savings wedge* as

$$1 - \tau_t^s(\theta^t) \equiv \frac{1}{\beta R} \frac{U_c(c_t^*(\theta^t), y_t^*(\theta^t)/\theta_t)}{\mathbb{E}_t\left[U_c(c_{t+1}^*(\theta^{t+1}), y_{t+1}^*(\theta^{t+1})/\theta_{t+1})\right]}. \tag{132}$$

Optimality implies that $\tau_t^s(\theta^t) \geq 0$ for all θ^t, with strict equality if consumption in $t+1$ is uncertain.

Decentralization

We now describe how the government can design a tax system $\mathcal{T}_t$ such that agents optimally choose consumption and income $\{c_t^*, y_t^*\}_{t=1}^T$ given a budget constraint

$$c_t + k_{t+1} \leq y_t + Rk_t - \mathcal{T}_t.$$

That is, this tax function $\mathcal{T}_t$ is an *implementation* or *decentralization* of the constrained optimum. We want to understand on what arguments $\mathcal{T}_t(\cdot)$ should depend, and how to construct this function.

In general, there are many tax systems that implement the same allocation.[ar] Here we consider a particularly simple implementation that arises naturally from the recursive problem. Observe that to find the optimal allocations in period t in the Bellman equation

[ar] For example, an extreme tax system $\mathcal{T}_t(\{y_s\}_{s=1}^t)$ defined as $\mathcal{T}_t(\{y_s\}_{s=1}^t) = y_t^*(\theta^t) - c_t^*(\theta^t)$ if $y_s = y_s^*(\theta^s)$ for all $\theta^s \leq \theta^t$ and $\mathcal{T}_t(\{y_s\}_{s=1}^t) = \infty$ otherwise ensures that the only feasible choices for a consumer are $\{c_t^*, y_t^*\}_{t=1}^T$. Then the incentive-compatibility constraint ensures that $\mathcal{T}_t(\{y_s\}_{s=1}^t)$ implements $\{c_t^*, y_t^*\}_{t=1}^T$.

(128), we did not need to know the whole past history θ^t. It was sufficient to know the summary statistics $v_{t-1}\left(\theta^{t-1}\right)$ together with the current period shock θ_t. A natural analogue of the promised utility in competitive equilibrium is the agent's savings. Albanesi and Sleet (2006) use this insight to show that when types are i.i.d. and the utility function is separable between consumption and labor supply we can construct an optimal tax system in which taxes in period t depend only on labor income y_t and on savings k_t at the beginning of that period.

Proposition 15 *Assume that shocks are i.i.d. and preferences are separable in consumption and labor. The optimal allocations can be implemented by a tax system $\mathcal{T}_t(k_t, y_t)$.*

Proof We show this result in a two-period economy. Let $K_2(w_2)$ denote the planner's minimized cost function (128) in period 2, and $u^*_{w_2}(\theta), h^*_{w_2}(\theta)$ denote the policy functions that solve the second-period planner's problem.

In period 2, consider an individual who enters the period with savings k_2 and chooses labor income y_2. Suppose that $k_2 = K_2(w_2)$ for some promised utility w_2, and $y_2 = Y\left(h^*_{w_2}(\theta)\right)$ for some $\theta \in \Theta = \left[\underline{\theta}, \overline{\theta}\right]$. We then define the tax function $T_2(k_2, y_2)$ as[as]

$$T_2\left(K_2(w_2), Y\left(h^*_{w_2}(\theta)\right)\right) = K_2(w_2) + Y\left(h^*_{w_2}(\theta)\right) - C\left(u^*_{w_2}(\theta)\right).$$

By incentive compatibility, an agent with savings $k_2 = K_2(w_2)$ and type θ in period 2 chooses labor supply and consumption $(y_2, c_2) = \left(Y\left(h^*_{w_2}(\theta)\right), C\left(u^*_{w_2}(\theta)\right)\right)$, that is, the levels optimally assigned to his promised utility-type pair (w_2, θ).

In period 1, consider an individual who enters the period with savings k_1 and chooses labor income $y'{}_1$ (which may or may not be optimal given his first-period type θ). Denote by $\left(c_1', R^{-1}k_2'\right)$ his optimal consumption-savings choice given $\left(k_1, y_1'\right)$, and by $\tilde{u}' = U\left(c_1'\right) + \beta\mathbb{E}\left[V_2\left(k_2', \theta_2\right)\right]$ (where V_2 is the maximized objective of the agent in period 2) the utility that he achieves with this combination, gross of the first-period disutility of labor. We can show that the cost-minimizing way for the planner to deliver utility $\tilde{u}'$ to the agent is to offer the pair $\left(u_1', w_2'\right) = \left(U\left(c_1'\right), K_2^{-1}\left(k_2'\right)\right)$, and the corresponding cost is $C_{\tilde{u}'} = c_1' + R^{-1}k_2'$.

Now suppose that $y_1' = y_1^*(k_1, \theta')$ for some $\theta' \in \Theta = \left[\underline{\theta}, \overline{\theta}\right]$, where $y_1^*(k_1, \theta')$ denotes the first-period income optimally allocated to type θ' in the solution to the planner's problem. Define the tax function $T_1\left(k_1, y_1'\right)$ as

$$T_1\left(k_1, y_1^*(k_1, \theta')\right) = k_1 + y_1^*(k_1, \theta') - C_{\tilde{u}'}.$$

[as] The tax function can be easily extended to deter any move $y_2 < Y\left(h^*_{w_2}(\underline{\theta})\right)$ and $y_2 > Y\left(h^*_{w_2}(\overline{\theta})\right)$.

If the individual's true type is $\theta \neq \theta'$, by lying he reaches utility $\tilde{u}' - \theta^{-(1+\varepsilon)} h\left(y_1^*(k_1, \theta')\right)$. But by incentive compatibility this is smaller than the utility he gets by reporting his true type, namely $\tilde{u} - \theta^{-(1+\varepsilon)} h\left(y_1^*(k_1, \theta)\right)$. Thus under this tax function the agent finds it optimal to choose the income that corresponds to his true type in period 1, and his choice of savings will be exactly equal to $k_2 = K_2(w_2(\theta))$, since his net income is $C_{\tilde{u}}$. □

This proposition shows simultaneously that optimal allocations can be implemented by a joint tax on current period savings and labor income, and provides a method of constructing this tax.

When thinking about the relationship between this tax $\mathcal{T}_t$ and taxes in the data, it is important to keep in mind that $\mathcal{T}_t$ in the model corresponds to the sum of all taxes and transfers in the data. The marginal distortions with respect to capital and labor income, $\frac{\partial \mathcal{T}_t}{\partial k_t}$ and $\frac{\partial \mathcal{T}_t}{\partial y_t}$, correspond to the effective marginal tax rates in the data, which are a sum of statutory tax rates and the rates of phasing out of transfers in capital and labor income, respectively. Because of the phasing out of transfers, there is no reason to expect a priori that marginal taxes in the model and effective marginal taxes in the data are progressive.[at] For example, if individuals with more wealth receive less insurance against labor income shocks (eg, if they are not eligible to some welfare programs because of means-testing), we should expect the marginal labor taxes to be decreasing in capital.

4.1.2 Persistent Shocks

An important limitation of the previous discussion is the assumption that shocks are i.i.d. The empirical labor literature has emphasized that idiosyncratic shocks are highly persistent (for example, Storesletten et al., 2004 or Guvenen et al., 2015). In this section we discuss how to extend our analysis to persistent (Markov) shocks.

It is useful to assume, both for analytical tractability and for connecting the analysis to the empirical literature, that shocks are drawn from a continuous distribution. We focus on a family of stochastic processes frequently used in the applied labor and public finance literatures.[au]

[at] In the United States there is significant heterogeneity in the shapes of the effective tax rates as a function of income as they vary by state, family status, age, type of residence a person lives in, etc. Some typical patterns of the effective marginal rates in the US data are increasing, U-shaped, and inverted S-shaped (see CBO, 2007 and Maag et al., 2012).

[au] For example, Storesletten et al. (2004) and Farhi and Werning (2013) use lognormal distributions, Badel and Huggett (2014) and Lockwood et al. (2014) use Pareto-lognormal distributions, Geweke and Keane (2000) and Guvenen et al. (2015) use mixtures of lognormals.

Assumption 6 Suppose that shocks θ_t evolve according to

$$\ln\theta_t = b_t + \rho\ \ln\theta_{t-1} + \eta_t,$$

where e^{η_t} is drawn from one of the following three distributions:

(a) lognormal: $\eta_t \sim \mathcal{N}(0,\nu)$;

(b) Pareto-lognormal: $\eta_t \sim \mathcal{NE}(\mu,\nu,a)$, where $\mathcal{NE}$ is a normal-exponential distribution;

(c) mixture of lognormals: $\eta_t \sim \mathcal{N}(\mu_i,\nu_i)$ with probability p_i for $i=1,\ldots,I$; let $\nu = \max_i \nu_i$.

We can write the planner's problem recursively by applying the first-order approach discussed in Section 2.5.2. Under these assumptions the Bellman equation writes:

$$K_t(v,\hat{v},\theta_-) = \max_{\{u(\theta),h(\theta),w(\theta),\hat{w}(\theta)\}_{\theta\in\Theta}} \cdots \\ \int_0^\infty \big(Y(h(\theta)) - C(u(\theta)) + R^{-1}K_{t+1}(w(\theta),\hat{w}(\theta),\theta)\big)\pi(\theta|\theta_-)d\theta \tag{133}$$

subject to the promise-keeping and marginal promise-keeping constraints

$$v \ = \textstyle\int_0^\infty \varpi(\theta)\pi(\theta|\theta_-)d\theta, \tag{134}$$

$$\hat{v} \ = \textstyle\int_0^\infty \varpi(\theta)\hat{\pi}(\theta|\theta_-)d\theta, \tag{135}$$

$$\varpi(\theta) \ = u(\theta) - \theta^{-(1+\varepsilon)}h(\theta) + \beta w(\theta), \tag{136}$$

and the envelope condition

$$\dot{\varpi}(\theta) = (1+\varepsilon)\theta^{-(2+\varepsilon)}h(\theta) + \beta\hat{w}(\theta). \tag{137}$$

This problem can then be analyzed using optimal control techniques (see Golosov et al., 2016).

The analysis of savings distortions remains unchanged. In particular, the Inverse Euler Equation (131) continues to hold in this economy. The same arguments as in the previous section immediately imply the optimality of savings distortions.

We now turn to the analysis of labor distortions. We define the *labor wedge* as

$$1 - \tau_t^y(\theta^t) \equiv \frac{-U_l\big(c_t^*(\theta^t), y_t^*(\theta^t)/\theta_t\big)}{\theta_t U_c\big(c_t^*(\theta^t), y_t^*(\theta^t)/\theta_t\big)}. \tag{138}$$

To simplify the notations, for any history $\theta^t = \big(\theta^{t-1},\theta\big)$ and random variable x_t, we use the short-hand notations $x_t(\theta)$ to denote $x_t\big(\theta^{t-1},\theta\big)$ and x_{t-1} to denote $x_{t-1}\big(\theta^{t-1}\big)$. Manipulating the first-order conditions we obtain

$$\frac{\tau_t^y(\theta)}{1-\tau_t^y(\theta)}=(1+\varepsilon)\frac{\int_\theta^\infty \pi_t(x')dx'}{\theta\pi_t(\theta)}\int_\theta^\infty \frac{U_{c,t}(\theta)}{U_{c,t}(x)}\left(1-\int_0^\infty \frac{U_{c,t}(x)}{U_{c,t}(x')}\pi_t(x')dx'\right)\frac{\pi_t(x)dx}{\int_\theta^\infty \pi_t(x')dx'}$$
$$+\rho\beta R\frac{\tau_{t-1}^y}{1-\tau_{t-1}^y}\frac{U_{c,t}(\theta)}{U_{c,t-1}}. \tag{139}$$

Eq. (139) shows that the optimal labor distortion is the sum of two terms. The first (intratemporal) term on the right hand side captures the costs and benefits of labor distortions in providing insurance against period-t shocks. A labor distortion for type θ discourages that type's labor supply, as captured by the Frisch elasticity of labor supply $1/\varepsilon$. This lowers total output in proportion to $\theta\pi_t(\theta)$ but allows the planner to relax the incentive constraints for all types above θ, a trade-off summarized by the hazard ratio (of period-t shocks conditional on a given history θ^{t-1}), $\frac{\int_\theta^\infty \pi_t(x')dx'}{\theta\pi_t(\theta)}$. Finally, the relaxed incentive constraints allow the planner to extract more resources from individuals with skills above θ and transfer them to all agents. The social value of this transfer is captured by the integral term on the r.h.s., which depends on the marginal utilities of consumption of agents with skills above θ, weighted by the average marginal utility. The second term (intertemporal) on the right hand side captures how the planner uses distortions in the current period t to provide incentives for information revelation in earlier periods. It depends on the information that the period-t shock carries about θ^{t-1}, summarized by the coefficient ρ, and on the ratio $\frac{U_{c,t}(\theta)}{U_{c,t-1}}$ which captures the fact that it is cheaper to provide incentives in those states in which the marginal utility of consumption is high.

We can also use the decomposition (139) to obtain insights about the time series properties of the optimal labor distortions, as studied by Farhi and Werning (2013). Multiplying the expression above by $\frac{1}{U_{c,t}}\pi_t(\theta)$ and integrating by parts yields

$$\mathbb{E}_{t-1}\left[\frac{\tau_t^y}{1-\tau_t^y}\frac{1}{U_{c,t}}\right]=\rho\beta R\frac{\tau_{t-1}^y}{1-\tau_{t-1}^y}\frac{1}{U_{c,t-1}}+(1+\varepsilon)\mathrm{Cov}_{t-1}\left(\ln\theta,\frac{1}{U_{c,t}}\right). \tag{140}$$

Eq. (140) shows that the marginal utility-adjusted labor distortions follow an AR(1) process with a drift. The persistence of that process is determined by the persistence of the shock process ρ, and its drift is strictly positive since we should generally expect that $\mathrm{Cov}_{t-1}\left(\ln\theta,\frac{1}{U_{c,t}}\right)>0$. Farhi and Werning (2013) conclude that the optimal labor distortions should increase with age.

Golosov et al. (2016) use condition (139) to characterize the dependence of labor wedges on the realization of the shock θ. In particular they show the asymptotic laws of motion[av]

$$\frac{\tau_t^y(\theta)}{1-\tau_t^y(\theta)} \underset{\theta\to\infty}{\sim} \begin{cases} \left(\frac{a}{1+\varepsilon}-\frac{\sigma}{\sigma+\varepsilon}\right)^{-1}, & \text{if } \eta_t \text{ is Pareto} - \text{lognormal}, \dfrac{a}{1+\varepsilon}-\dfrac{\sigma}{\sigma+\varepsilon}>0 \\ \left(\frac{\ln\theta}{\nu^2}\frac{1}{1+\varepsilon}\right)^{-1}, & \text{if } \eta_t \text{ is lognormal or a mixture}, \end{cases} \tag{141}$$

and

$$\frac{\tau_t^y(\theta)}{1-\tau_t^y(\theta)} \underset{\theta\to 0}{\sim} \rho\beta R \frac{\tau_{t-1}^y}{1-\tau_{t-1}^y}\left(\frac{c_t(0)}{c_{t-1}}\right)^{-\sigma}. \tag{142}$$

Given the fact that $(\ln\theta)^{-1}$ is very slowly moving, Eq. (141) implies that the labor distortions are approximately flat for high realizations of θ_t for all three classes of distributions (although in the cases of lognormal and mixture of lognormal distributions they eventually converge to zero), they do not depend on the past history of shocks, and they are given by relatively simple closed-form expressions. Eq. (142) shows that the labor distortions for low shocks depend on the persistence, the past history, and the growth rate of consumption, and are generally increasing in age.

Another implication of these equations is that the higher moments, such as the kurtosis, play an important qualitative and quantitative role for the size of the labor distortions. Some of the best estimates of those moments are obtained by Guvenen et al. (2014, 2015) who use US administrative data on a random sample of 10% of the US male taxpayers to estimate the stochastic process for labor earnings. Golosov et al. (2016) use that finding to calibrate their model using newly available estimates of idiosyncratic shocks. The optimal labor distortions are U-shape, while savings distortions are increasing in current earnings. Welfare in the constrained optimum is 2–4% higher than in the equilibrium with affine taxes. These findings (both the U-shaped and the relatively high welfare gains from nonlinear, history-dependent taxation) are largely driven by the high kurtosis found in the labor earnings process in the data. This suggests that a system of progressive taxes and history-dependent transfers that are being phased out relatively quickly with income can capture most of the welfare gains in this economy.

4.2 Corporate Finance

In this section we describe some applications of the recursive contract theory to corporate finance. We show how financing frictions arise endogenously from agency problems, leading to implications for the capital structure and dynamics of firms. To cite only a few papers in this literature, such models have been analyzed by Albuquerque and Hopenhayn (2004), Clementi and Hopenhayn (2006), and DeMarzo and Fishman

[av] For any functions h,g and $c\in\bar{\mathbb{R}}$, $h(x)\underset{x\to c}{\sim}g(x)$ if $\lim_{x\to c}h(x)/g(x)=1$.

(2007a,b) in discrete-time environments, and by DeMarzo and Sannikov (2006), Biais et al. (2007), DeMarzo et al. (2012), Biais et al. (2010), and He (2009) in continuous-time environments.

Endogenous Financing Frictions and Firm Dynamics

A large empirical literature (see, eg, Caves, 1998 for a survey) describes the properties of firm dynamics, eg, the characteristics and evolution of their size, growth rate, and survival probability. In particular, as firms get older, their size and survival probability increase, the mean and variance of their growth rates decrease, and the hazard rates for exit first increase and then decrease. Moreover, starting with the work of Fazzari et al. (1988), many authors have found that firms' investment responds positively to innovations in the cash-flow process (after controlling for Tobin's q), suggesting the importance of borrowing constraints, and that the investment-cash flow sensitivity decreases with the firm's age and size.

Clementi and Hopenhayn (2006) analyze a dynamic moral hazard model where such features arise *endogenously* in the optimal contract between a borrower (a firm, or agent) and a lender (bank, or principal) who cannot observe the outcome of the project. They describe the optimal contract and show that the model yields rich testable predictions about firm dynamics that are in line with the evidence presented above.

In their model, the agent's project requires a fixed initial investment $I_0 > 0$, and subsequently a per-period investment of capital which we denote by k_t. At the beginning of each period the bank can liquidate the project, with scrap value $S \geq 0$. If the bank decides to finance the project, the firm's revenues are stochastic (i.i.d.) and increase with the amount of capital k_t advanced by the lender. Specifically, in each period t, with probability π the project is successful and yields revenue $R(k_t)$, where R is continuous, bounded, and concave, whereas with probability $(1-\pi)$ it yields zero revenues. Denote the outcome of the project in period t by $\theta_t \in \Theta = \{\theta_{(1)}, \theta_{(2)}\} = \{0, 1\}$, where $\theta_{(1)} = 0$ is failure and $\theta_{(2)} = 1$ is success, and histories up to period t by θ^t. The borrower and the lender are both risk-neutral, have the same discount factor β, and have the ability to commit to contracts.

Suppose first that revenues are observable. The efficient amount of capital is advanced in every period, $k^* = \arg\max(\pi R(k_t) - k_t)$, and running the project is efficient if $W^* \equiv \dfrac{1}{1-\beta}(\pi R(k^*) - k^*) > I_0$. Thus, in the benchmark complete-information version of the model, the firm neither grows, nor shrinks, nor exits: its size k^* is constant. This feature allows us to cleanly analyze the implications of informational frictions on the firm's dynamics.

Now suppose that revenues are private information to the agent, so that the lender must rely on the borrower's reports of the outcome of the project in each period. Denote by $\boldsymbol{\sigma} = \{\sigma_t(\theta^t)\}_{t \geq 1}$ the borrower's reporting strategy.

The timing of events is as follows. At the beginning of each period t, the bank decides whether (and if so, with which probability) to liquidate the firm, in which case it gets the scrap value S and compensates the agent with a transfer $Q_t \geq 0$. Denote by $\boldsymbol{\alpha} = \left\{\alpha_t\left(\sigma^{t-1}\left(\theta^{t-1}\right)\right)\right\}_{t\geq 1}$ the liquidation probabilities and by $\mathbf{Q} = \left\{Q_t\left(\sigma^{t-1}\left(\theta^{t-1}\right)\right)\right\}_{t\geq 1}$ the transfers from the lender to the borrower in case of liquidation. Then, if the firm is not liquidated, the bank chooses the amount of capital k_t it lends to the firm, and the borrower's repayment τ_t if the project is successful. Denote by $\boldsymbol{k} = \left\{k_t\left(\sigma^{t-1}\left(\theta^{t-1}\right)\right)\right\}_{t\geq 1}$ the capital advancements and by $\boldsymbol{\tau} = \left\{\tau_t\left(\sigma^{t-1}\left(\theta^{t-1}\right), \sigma_t(\theta_t)\right)\right\}_{t\geq 1}$ the contingent payments from the borrower to the lender in case of success (there is no transfer in case of failure). The firm is restricted at all times to have a nonnegative cash flow, ie, the following limited-liability constraint must be satisfied: $\tau_t\left(\sigma^{t-1}\left(\theta^{t-1}\right), \theta_{(2)}\right) \leq R\left(k_t\left(\sigma^{t-1}\left(\theta^{t-1}\right)\right)\right)$ for all t, θ^{t-1}. The outcome θ_t of the project is then realized and privately observed by the borrower, who sends a report $\sigma_t(\theta^t)$ and transfers $\tau_t(\sigma^t(\theta^t))$ to the bank in case of a (truthfully reported) success.

We define "equity" as the entrepreneur's share of the total firm's value, and "debt" as the lender's share. That is, equity $V_t\left(\{\boldsymbol{k}, \boldsymbol{\tau}, \boldsymbol{\alpha}, \mathbf{Q}, \boldsymbol{\sigma}\}, \sigma^{t-1}\left(\theta^{t-1}\right)\right)$ and debt $B_t\left(\{\boldsymbol{k}, \boldsymbol{\tau}, \boldsymbol{\alpha}, \mathbf{Q}, \boldsymbol{\sigma}\}, \sigma^{t-1}\left(\theta^{t-1}\right)\right)$ are the expected discounted cash flows (or continuation values) accruing to the borrower and the lender, respectively, under the contract $\{\boldsymbol{k}, \boldsymbol{\tau}, \boldsymbol{\alpha}, \mathbf{Q}\}$ and reporting strategy $\boldsymbol{\sigma}$, given the time-t history of reports $\sigma^{t-1}\left(\theta^{t-1}\right)$. Note that the value of equity corresponds to the promised utility variable (11) in the taste shock model of Section 2.

This setup is formally similar to that in Section 2.3 and can be analyzed using the same recursive techniques. Specifically, we write the problem in recursive form using the value of equity v as the state variable. We can show that the set of continuation values v that can be supported by a feasible contract is $[0, \infty)$. A constrained-efficient contract maximizes the value obtained by the lender, $B(v_0)$, in the space of incentive-compatible and feasible contracts, subject to delivering some utility $v_0 \geq 0$ to the entrepreneur. The pair $(v_0, B(v_0))$ defines the capital structure of the firm (equity and debt) and implies a total value for the firm $W(v_0) = v_0 + B(v_0)$.

Denote by $W(\cdot)$ the total value of the firm prior to the liquidation decision, and by $\hat{W}(\cdot)$ the total value of the firm conditional on not being liquidated. Following the steps of Proposition 3, we obtain that the latter value function is given by the following Bellman equation:

$$\hat{W}(\hat{v}) = \max_{k, \tau, \{w(\theta)\}} (\pi R(k) - k) + \beta\left[(1-\pi) W\left(w\left(\theta_{(1)}\right)\right) + \pi W\left(w\left(\theta_{(2)}\right)\right)\right]$$

subject to the promise-keeping constraint:

$$\hat{v} = \pi(R(k) - \tau) + \beta\left[(1-\pi) w\left(\theta_{(1)}\right) + \pi w\left(\theta_{(2)}\right)\right], \tag{143}$$

the incentive-compatibility constraint in the high state:

$$R(k)-\tau+\beta w\left(\theta_{(2)}\right)\geq R(k)+\beta w\left(\theta_{(1)}\right), \tag{144}$$

and the limited liability constraint:

$$\tau\leq R(k). \tag{145}$$

The liquidation decision of the firm can be formalized as follows. At the beginning of the period, the firm is liquidated with probability α, in which case the borrower receives Q, and it is kept in operation with probability $1-\alpha$, in which case the borrower receives the continuation value $\hat{v}$. The value function $W(\cdot)$ then solves the following Bellman equation:

$$W(v)=\max_{\alpha,\,Q,\,\hat{v}}\alpha S+(1-\alpha)\hat{W}(\hat{v})$$

subject to

$$v=\alpha Q+(1-\alpha)\hat{v}.$$

Clementi and Hopenhayn (2006) characterize the solution to this problem as follows.

First, if the equity (or promised value) v is large enough, then the policy of providing the unconstrained efficient level of capital k^* in every period is both feasible and incentive compatible. The minimum value v^* for which this is the case is given by the solution to the following problem:

$$\begin{aligned} v^*\equiv \min_{\tau,\{w(\theta)\}_{\theta\in\Theta}} \quad & \pi(R(k^*)-\tau)+\beta\left[(1-\pi)w\left(\theta_{(1)}\right)+\pi w\left(\theta_{(2)}\right)\right] \\ \text{subject to} \quad & R(k^*)-\tau+\beta w\left(\theta_{(2)}\right)\geq R(k^*)+\beta w\left(\theta_{(1)}\right), \\ & \tau\leq R(k^*),\quad w\left(\theta_{(1)}\right)\geq v^*,\quad w\left(\theta_{(2)}\right)\geq v^*. \end{aligned}$$

Solving this problem yields $v^*\equiv\dfrac{1}{1-\beta}\pi R(k^*)=W^*+\dfrac{1}{1-\beta}k^*$.

Second, we can show that there exists a value $v_*\in(0,v^*)$ such that:

(i) when $v\geq v^*$, the firm's value $W(v)$ is equal to W^*. Letting $k_v=k^*$ at any future date, with $\tau_v=0$ and $w_v\left(\theta_{(j)}\right)=v^*$ for all $j\in\{1,2\}$, is optimal.

(ii) when $v\in[v_*,v^*)$, the value function $W(v)$ is strictly increasing and concave and the policy functions are $\alpha(v)=0$, $k_v<k^*$, $\tau_v=R(k_v)$, and $w_v\left(\theta_{(1)}\right)<v<w_v\left(\theta_{(2)}\right)$. The values $w_v\left(\theta_{(1)}\right),w_v\left(\theta_{(2)}\right)$ are given as a function of k_v by the promise-keeping and incentive-compatibility constraints (143), (144), which both hold with equality.[aw]

[aw] If these values are such that $w_v\left(\theta_{(2)}\right)>v^*$, then other values for the transfer τ_v (along with $w_v\left(\theta_{(2)}\right)$) are also optimal.

Moreover, k_v is increasing in v for v close enough to v^*, $w_v(\theta_{(1)}), w_v(\theta_{(2)})$ are increasing in v, and equity is a submartingale, ie, $v < \mathbb{E}[w_v]$.

(iii) when $v < v_*$, the firm is liquidated with positive probability $\alpha(v) = 1 - v/v_*$ and transfer $Q = 0$, and continues at value $\hat{v} = v_*$ with probability $(1 - \alpha(v))$. The firm's value is equal to $W(v) = \alpha(v)S + (1 - \alpha(v))\hat{W}(v_*)$.

This characterization of the optimal contract has the following interpretation and implications. The contract determines stochastic processes for the firm size k_t, equity v_t, and debt $B(v_t) = W(v_t) - v_t$. Specifically, consider an entrepreneur who starts with equity $v_0 \in (v_*, v^*)$. Starting from this region, a good shock raises the value of equity to $w_v(\theta_{(2)}) > v$, and a bad shock reduces it. The submartingale property (which follows from Eq. (143)) implies that the equity v_t of surviving firms on average increases over time, and the monotonicity of the functions $w_v(\theta)$ implies that this process v_t displays persistence. Eventually, equity reaches either the lower threshold v_* (after a series of negative shocks), leading to the region where it is optimal to liquidate the firm with positive probability, or the upper threshold v^* (after a series of positive shocks), at which point the incentive constraints no longer bind and the unconstrained efficient level of capital k^* is advanced from then on. There are therefore two absorbing states: either the firm is liquidated or it attains its efficient size. In the transition, the transfer τ_v in the event of a good shock is set equal to the maximum possible amount $R(k_v)$. This is because the bank and the firm are both risk-neutral, so that it is optimal to backload the distribution of dividends to the borrower (by choosing the highest possible value of transfers τ and raising $w_v(\theta_{(j)})$ accordingly) in order to allow the equity to reach v^* as fast as possible. Finally, when v^* is attained, the firm's future cash flows are equal to $v^* = W(v^*) + \frac{k^*}{1-\beta} = W^* + \frac{k^*}{1-\beta}$, and the lender's continuation value is $B(v^*) = -\frac{k^*}{1-\beta}$. This means that the entrepreneur has accumulated assets at the bank (at the interest rate r such that $\beta = \frac{1}{1+r}$) up to the positive balance $k^*/(1-\beta)$, while his payments were being postponed and all the cash flows were received by the lender; this balance is exactly enough to self-finance the project at the efficient scale from then on.

Next, the optimal contract shows that when equity v is below the threshold v^*, the amount of capital advanced by the bank is strictly smaller than the unconstrained efficient level: $k_v < k^*$. We can interpret this result as an (endogenous) borrowing constraint to which the entrepreneur is subject. Moreover, if v is close enough to v^*, higher equity relaxes the borrowing constraint and allows the entrepreneur to finance the project on a more efficient scale, as k_v is increasing in v. Such financing frictions arise endogenously in the optimal contract due to moral hazard. To provide incentives for the successful entrepreneur to truthfully report the (good) outcome of his project, the optimal contract requires the borrower's compensation to be sensitive to reported output, which necessitates a spread $w_v(\theta_{(2)}) - w_v(\theta_{(1)})$ between the future equity values in the successful versus unsuccessful states. Moreover, advancing more capital today tightens the incentive constraint (as the borrower will have to repay more in case of success, since $\tau = R(k)$) and thus requires a larger spread between future continuation values. But this spread is costly, because the marginal revenue is decreasing in capital and hence the firm's total value $W(\cdot)$ is concave. Therefore, the trade-off between higher capital and profits today against a lower firm's value in future periods implies an inefficient level of financing $k_v < k^*$ in the optimal contract.

These results imply that revenue shocks affect the financial structure $(v, B(v))$ of the firm, and yield rich implications for firm dynamics (size, growth, and survival probability). Defining the firm's size as the level of capital k_t invested in the project, investment as $k_t - k_{t-1}$, and simulating a calibrated version of the model, the authors obtain the following testable predictions. First, firm age and size are positively correlated. Second, the mean and variance of growth decrease with size and age. Third, the survival probability $\mathbb{P}(T > t|v)$, where T is the stopping time for exit, increases with the value of equity v and thus with age. The hazard rates for exit follow an inverted U-shaped function of age, as it takes a few periods for young firms to reach the liquidation region from their initial value v_0, and a selection effect implies that older (surviving) firms have on average higher values and hence lower hazard rates. All these properties are consistent with the empirical evidence on firm dynamics (see the references in Clementi and Hopenhayn, 2006 for a survey of the empirical literature). Finally, the authors argue that simulated data generated using the policy functions of the model would reproduce the empirical prediction that investment responds positively to innovations in the cash-flow process, and that the sensitivity of investment to cash flows decreases with the age and size of the firm. Importantly, in the model, the financing frictions (borrowing constraints) arise *endogenously* as a feature of the optimal contract.

Optimal Capital Structure

We now describe another application of recursive contracts to corporate finance in a continuous-time framework using the techniques described in Section 3.3.2, following a simple version of DeMarzo and Sannikov (2006).[ax] In their model the agent (firm) can unobservably divert cash flows for its private benefit; investors control its wage and choose when to liquidate the project. While the closely related framework of Clementi and Hopenhayn (2006) focused on the importance of informational frictions for firm investment and growth as a function of the history of profit realizations (so that

[ax] A discrete time version of this problem has been analyzed by DeMarzo and Fishman (2007b).

the scale, ie, the capital, of the firm is an endogenous part of the optimal incentive contract), DeMarzo and Sannikov (2006) assume instead that the firm has a fixed size, and they focus on the optimal choice of the firm's capital structure.[ay] Specifically, they propose an implementation of the optimal contract using simple financial instruments. This implementation is composed of a combination of long-term debt with a constant coupon, a credit line, and equity. In this implementation the firm is compensated by holding a fraction of the equity, and defaults if debt service payments are not made or the credit line is overdrawn; dividends are paid when cash flows exceed debt payments and the credit line is paid off. This analysis can therefore help understand the choice between various forms of borrowing for firms, in particular the characteristics of credit line contracts, an empirically important component of firm financing. Finally, as we saw in Section 3.3.2, setting the model in continuous time allows the authors to obtain both a clean characterization of the optimal contract through an ordinary differential equation, and analytical comparative statics of the optimal contract with respect to the parameters of the model.

We now turn to a formal description of the model. An agent manages a project that generates stochastic cash flows given by:

$$d\hat{y}_t = (\mu - \theta_t)dt + \sigma d\mathcal{Z}_t,$$

where $\mathcal{Z}_t$ is a standard Brownian motion, and $\theta_t \geq 0$ is the agent's private action, which can be interpreted as cash flow diversion. This unobserved diversion generates private benefit to the agent at rate $\lambda\theta_t$, with $\lambda \in (0,1]$. The principal observes only the reported cash flows $\{\hat{y}_t\}_{t\geq 0}$.[az] The principal and the agent are risk-neutral and discount the future at rate r and γ, respectively, with $r < \gamma$. The project requires an external capital of $I_0 \geq 0$ to be started. The principal offers a contract $(\mathbf{c}, \tau)$ that specifies the agent's compensation $dc_t \geq 0$ for all t and a termination date τ, as functions of the histories $\{\hat{y}_s\}_{s\leq t}$. In the event of termination, the agent gets his outside option $R \geq 0$ and the principal receives the liquidation payoff $L \geq 0$.

The optimal contract maximizes the principal's expected profit subject to delivering expected utility $\hat{v}_0$ to the agent and the incentive-compatibility constraints. We can show that in the optimal contract we have $\theta_t = 0$ for all $t \geq 0$. The problem is similar to the model analyzed in Section 3.3.2 and can be expressed as:

$$\max_{\mathbf{c},\tau} \mathbb{E}^{\boldsymbol{\theta}=0}\left[\int_0^{\tau} e^{-rt}(d\hat{y}_t - dc_t) + e^{-r\tau}L\right]$$

[ay] DeMarzo et al. (2012) extend this model to include investment and nonconstant firm size.

[az] DeMarzo and Sannikov (2006) consider a more general model in which the agent can secretly save and thus overreport, ie, $\theta_t < 0$, but show that in the optimal contract the agent always chooses to maintain zero savings.

subject to the promise-keeping constraint:

$$\hat{v}_0 = \mathbb{E}^{\boldsymbol{\theta}=0}\left[\int_0^{\tau} e^{-\gamma t} dc_t + e^{-\gamma \tau} R\right]$$

and the incentive-compatibility constraints:

$$\hat{v}_0 \geq \mathbb{E}^{\hat{\boldsymbol{\theta}}}\left[\int_0^{\tau} e^{-\gamma t}\left(dc_t + \lambda \hat{\theta}_t dt\right) + e^{-\gamma \tau} R\right],$$

for any deviation strategy $\hat{\boldsymbol{\theta}}$.

Following identical steps as in Section 3.3.2 (see in particular Proposition 12), we find that there is a one-to-one correspondence between incentive-compatible contracts $(\mathbf{c}, \tau)$ and controlled processes (with controls (c_t, β_t))

$$dv_t = \gamma v_t dt - dc_t + \beta_t (d\hat{y}_t - \mu dt), \tag{146}$$

where the sensitivity of the agent's promised value to his report satisfies $\beta_t \geq \lambda$ for all $t \leq \tau$. The termination time τ is the earliest time that the agent's promised value v_t reaches R. The one-shot incentive constraint (Proposition 13) here says that truthtelling is incentive compatible if and only if $\beta_t \geq \lambda$ for all t, since the agent has incentives not to steal cash flows if he gets at least λ of promised value for each reported dollar.

DeMarzo and Sannikov (2006) characterize the optimal contract as follows. Denote by $K(v)$ the principal's value function. It is easy to see that the optimal contract must satisfy $K'(v) \geq -1$ for all v. This is because the principal can always give to the agent with current promised utility v a lump-sum transfer $dc > 0$ and then revert to the optimal contract with utility $v - dc$, so that $K(v) \geq K(v - dc) - dc$. Defining $\bar{v}$ as the lowest value such that $K'(\bar{v}) = -1$, it is optimal to keep the agent's promised utility in the range $[R, \bar{v}]$ and to set $dc_v = (v - \bar{v})\mathbb{I}_{\{v \geq \bar{v}\}}$. The function $K(v)$ can then be characterized recursively as in Section 3.3.2. The Hamilton–Jacobi–Bellman equation is

$$rK(v) = \max_{\beta \geq \lambda} \mu + \gamma v K'(v) + \frac{1}{2}\beta^2 \sigma^2 K''(v),$$

$$\text{with} \quad K(v) = K(\bar{v}) - (v - \bar{v}) \text{ for } v > \bar{v},$$

with the following value-matching, smooth-pasting, and super-contact conditions

$$K(R) = L, \quad K'(\bar{v}) = -1, \quad K''(\bar{v}) = 0.$$

The function $K(\cdot)$ is concave so that it is optimal to set $\beta_t = \lambda$ for all t. The optimal contract (with $\hat{v}_0 \in [R, \bar{v}]$) is such that v_t evolves according to (146) with $dc_t = 0$ when

$v_t \in [R, \bar{v})$. If $v_t = \bar{v}$, payments dc_t cause v_t to reflect at $\bar{v}$. The contract is terminated at time τ when v_t reaches R.[ba]

DeMarzo and Sannikov (2006) propose an implementation of the optimal contract using equity, long-term debt D, and a credit line C^L. If the agent defaults on a debt coupon payment or his credit balance exceeds C^L, the project is terminated. The idea behind this implementation is to map the interval of continuation values $[R, \bar{v}]$ into a credit line, with point $\bar{v}$ corresponding to balance 0. From (146), we can write the evolution of the credit balance $\lambda^{-1}(\bar{v} - v_t)$ (where λ is simply a normalization) as

$$d\left(\frac{\bar{v} - v_t}{\lambda}\right) = -d\hat{y}_t + \left\{\gamma\left(\frac{\bar{v} - v_t}{\lambda}\right)dt + \left(\mu - \frac{\gamma}{\lambda}\bar{v}\right)dt + \frac{dc_t}{\lambda}\right\}.$$

The first term in the right hand side of this expression, $-d\hat{y}_t$, is the credit balance reduction due to the cash flows, where each dollar of cash flow subtracts exactly one dollar from the credit line balance. The next three terms in the right hand side (inside the brackets) are the three components that compose the implementation of the contract. The first term inside the brackets is the interest charged on the credit balance $\lambda^{-1}(\bar{v} - v_t)$, so that the implementation of the optimal contract has a credit line $C^L = \lambda^{-1}(\bar{v} - R)$, up to which credit is available to the firm at interest rate γ. The second term inside the brackets is the coupon rD on long-term debt, so that the face value of the debt is $D = r^{-1}(\mu - \gamma\bar{v}/\lambda)$. Finally the third term inside the brackets consists of the dividend payments made by the firm, ie, the equity. The agent gets a fraction λ of the dividends dc_t, while outside investors hold the remaining firm's equity, debt, and credit line. Cash flows in excess of the debt coupon payments are issued as dividends once the credit line is fully repaid. Termination occurs when the credit line balance reaches the credit limit C^L. Observe that the balance on the credit line fluctuates with the past performance of the firm, in particular leverage decreases with its profitability since the firm pays off the credit line when it makes profits.

DeMarzo and Sannikov (2006) further analyze this optimal capital structure, ie, how the amount of long-term debt and the size of the credit line depend on the parameters of the model, by deriving analytical comparative statics using the techniques described in Section 3.3.2. We refer the reader to the original paper for an in-depth analysis of these questions.

[ba] In the discrete-time setting described in the previous section (based on the work of Clementi and Hopenhayn (2006)), allowing for randomization over the decision to terminate the project could improve the contract. DeMarzo and Sannikov (2006) show that in the continuous-time framework, such randomization is not necessary: without loss of generality the termination time τ is based only on the firm's (reported) past performance.

4.3 Development Economics

There is a large literature that studies informal insurance arrangements in the context of village economies. An early work of Townsend (1994), for example, showed that in rural India idiosyncratic variation in consumption is systematically related to idiosyncratic variation in income, implying that households can only achieve partial insurance against their idiosyncratic risks. Models of limited commitment developed by Thomas and Worrall (1988), Kehoe and Levine (1993), Kocherlakota (1996), Alvarez and Jermann (2000), and Ligon et al. (2000, 2002) can potentially explain these observations. In these models, all the information is public (there is no information friction); instead there is an *enforcement* friction: agents are free to walk away from the insurance contract at any time. Nevertheless, these models can be analyzed using the same recursive techniques as those described in Section 2. Analogous to the asymmetric information models we analyzed, the state variable is the utility promised to the agent. The only formal difference is that the incentive-compatibility constraints (8) are replaced by participation constraints that we formally define in Eq. (147).

Here we describe the two-sided limited commitment framework analyzed by Ligon et al. (2002). The (observable) period-t state of nature $\theta_t \in \Theta = \left\{\theta_{(1)}, \ldots, \theta_{(|\Theta|)}\right\}$ is stochastic and follows a Markov process with transition probability $\pi\left(\theta_{(i)} \middle| \theta_{(j)}\right) > 0$ for all i, j. There are two agents with period-t utilities $U^1\left(c_t^1\right), U^2\left(c_t^2\right)$ and exogenous nonstorable endowments $\left(y_t^1, y_t^2\right)$ determined by θ_t. At least one of the two households is risk averse, and they both discount the future at rate β. A risk-sharing contract $\boldsymbol{\tau}$ specifies for every date t and history θ^t a (possibly negative) transfer $\tau_t(\theta^t)$ from household 1 to household 2. A first-best, or full risk-pooling, contract $\boldsymbol{\tau}$ is such that the ratio of marginal utilities $\dfrac{U^{2\prime}\left(y_t^2(\theta_t) + \tau_t(\theta^t)\right)}{U^{1\prime}\left(y_t^1(\theta_t) - \tau_t(\theta^t)\right)}$ is constant across all histories and dates, so that each individual's consumption is only a function of the aggregate endowment.

The key friction of the model is that agents can walk away from the insurance contract, after which both households consume at autarky levels forever after, ie, $\tau_t(\theta^t) = 0$ for all t, θ^t. Household $j \in \{1, 2\}$ has no incentive to break the contract if the following *sustainability constraint* holds: for all $\theta^t \in \Theta^t$,

$$U^j\left(c_t^j(\theta^t)\right) + \mathbb{E}_t\left[\sum_{s=1}^{\infty} \beta^s U^j\left(c_{t+s}^j(\theta^{t+s})\right)\right] \geq U^j\left(y_t^j(\theta_t)\right) + \mathbb{E}_t\left[\sum_{s=1}^{\infty} \beta^s U^j\left(y_{t+s}^j(\theta_{t+s})\right)\right], \tag{147}$$

where $c_s^1(\theta^s) = y_s^1(\theta_s) - \tau_s(\theta^s)$ and $c_s^2(\theta^s) = y_s^2(\theta_s) + \tau_s(\theta^s)$ for all s, and where $\mathbb{E}_t$ is the expectation conditional on θ^t.

As in Section 3.2 (where the government was unable to commit), it is useful to describe the present environment with bilateral lack of commitment as a repeated game between the two agents. Since reversion to autarky is the worst subgame-perfect punishment, there is a one-to-one relationship between sustainable contracts and subgame-perfect equilibria (see Abreu, 1988).

We now show how to characterize the set of constrained-efficient sustainable contracts, using recursive arguments formally similar to those we used in Section 2. The constrained efficient allocations maximize the expected lifetime utility of agent 2 subject to both sustainability constraints (147), and to delivering at least a given utility level v^1 to agent 1, given that the current state is θ. Before we formally write this problem, we describe the space of discounted expected utilities v^1,v^2 for each agent (defined as in (11)) for which there exists a sustainable contract that delivers those values, given that the current state is θ. We can show that this set is an interval of the form $\left[\underline{v}^j(\theta), \bar{v}^j(\theta)\right]$ for each agent $j \in \{1,2\}$, where the minimum sustainable utilities when the current state is θ are

$$\underline{v}^j(\theta) = U^j\left(y^j(\theta)\right) + \mathbb{E}\left[\sum_{s=1}^{\infty} \beta^s U^j\left(y_s^j(\theta_s)\right) | \theta\right]$$

for $j \in \{1,2\}$, that is, the value of autarky for agent j from state θ onward.

The ex post efficiency frontier, calculated once the current state θ is known, can then be characterized in recursive form as follows: for $v^1 \in \left[\underline{v}^1(\theta), \bar{v}^1(\theta)\right]$,

$$V\left(v^1,\theta\right) = \max_{\tau(\theta),\{w^1(\theta')\}_{\theta' \in \Theta}} \quad U^2\left(y^2(\theta) + \tau(\theta)\right) + \beta \sum_{\theta' \in \Theta} \pi(\theta'|\theta) V\left(w^1(\theta'),\theta'\right)$$

subject to the promise-keeping constraint

$$U^1\left(y^1(\theta) - \tau(\theta)\right) + \beta \sum_{\theta' \in \Theta} \pi(\theta'|\theta) w^1(\theta') = v^1, \tag{148}$$

the sustainability constraints

$$w^1(\theta') \geq \underline{v}^1(\theta'), \forall \theta', \tag{149}$$

$$V\left(w^1(\theta'),\theta'\right) \geq \underline{v}^2(\theta'), \forall \theta', \tag{150}$$

(the constraint $w^1(\theta') \leq \bar{v}^1(\theta')$ is equivalent to (150)), and the nonnegativity constraints

$$y^1(\theta) - \tau(\theta) \geq 0 \quad \text{and} \quad y^2(\theta) + \tau(\theta) \geq 0. \tag{151}$$

The Lagrange multiplier λ associated with the constraint (148) is the key variable in the analysis of optimal insurance contracts. The first-order conditions and envelope condition of the problem imply that λ is related to the ratio of the marginal utilities of consumption by

$$\lambda = -\frac{\partial}{\partial v} V\left(v^1,\theta\right) = \frac{U^{2\prime}(y^2(\theta) + \tau(\theta))}{U^{1\prime}(y^1(\theta) - \tau(\theta))} + \frac{\psi_2 - \psi_1}{U^{1\prime}(y^1(\theta) - \tau(\theta))}, \tag{152}$$

where ψ_1,ψ_2 are the Lagrange multipliers associated with the nonnegativity constraints (151).

Suppose that the value of λ is known. If λ is in the set of marginal utility ratios $\frac{U^{2\prime}(y^2(\theta)+\tau(\theta))}{U^{1\prime}(y^1(\theta)-\tau(\theta))}$ which can be generated by feasible transfers in state θ (ie, by $\tau(\theta)\in[-y_2(\theta),y_1(\theta)]$), then there is a unique interior solution and the value of the transfer $\tau(\theta)$ is pinned down by Eq. (152) with $\psi_1 = \psi_2 = 0$. Otherwise, there is a corner solution with all income going to one of the households, ie, $\tau(\theta) = -y_2(\theta)$ or $\tau(\theta) = y_1(\theta)$ (with a positive multiplier ψ_2 or ψ_1, respectively).

Therefore the constrained efficient contracts can be fully characterized by the evolution of the multiplier $\lambda(\theta^t)$ (along with an initial value λ_0). This can be easily done using the first-order conditions with respect to $w^1(\theta')$, which writes, for all $\theta'\in\Theta$,

$$-\frac{\partial}{\partial v}V\left(w^1(\theta'),\theta'\right)=\frac{\lambda+\chi_1(\theta')}{1+\chi_2(\theta')}, \tag{153}$$

where $\beta\pi(\theta'|\theta)\chi_1(\theta')$ and $\beta\pi(\theta'|\theta)\chi_2(\theta')$ are the multipliers associated with the constraints (149) and (150). For each $\theta\in\Theta$, we can then define an interval $\left[\underline{\lambda}_\theta,\overline{\lambda}_\theta\right]$ by

$$\underline{\lambda}_\theta \equiv -\frac{\partial}{\partial v}V\left(\underline{v}^1(\theta),\theta\right) \text{ and } \overline{\lambda}_\theta \equiv -\frac{\partial}{\partial v}V\left(\overline{v}^1(\theta),\theta\right),$$

where $\overline{v}^1(\theta)$ is the maximum feasible expected value for agent 1, which satisfies $V\left(\overline{v}^1(\theta),\theta\right)=\underline{v}^2(\theta)$. We thus obtain the following law of motion for $\lambda(\theta^t)$:

$$\lambda(\theta^t,\theta_{t+1})=\begin{cases}\underline{\lambda}_{\theta_{t+1}}, & \text{if } \lambda(\theta^t)<\underline{\lambda}_{\theta_{t+1}},\\ \lambda(\theta^t), & \text{if } \lambda(\theta^t)\in\left[\underline{\lambda}_{\theta_{t+1}},\overline{\lambda}_{\theta_{t+1}}\right],\\ \overline{\lambda}_{\theta_{t+1}}, & \text{if } \lambda(\theta^t)>\overline{\lambda}_{\theta_{t+1}}.\end{cases} \tag{154}$$

Finally, varying the initial value λ_0 in the interval $\left[\min_{\theta\in\Theta}\{\underline{\lambda}_\theta\},\max_{\theta\in\Theta}\{\overline{\lambda}_\theta\}\right]$ traces out the Pareto frontier.

To understand intuitively this characterization, suppose for simplicity that the nonnegativity constraints on consumption (151) never bind, ie, $\psi_1 = \psi_2 = 0$. We already argued that in a full risk-pooling contract, the current transfers in every period are chosen such that the ratio of the two households' marginal utilities (152) is constant. Now consider a constrained-efficient contract, where the evolution of this ratio is given by Eq. (154). Suppose that the marginal utility ratio last period was $\lambda(\theta^t)$, and that the current state is $\theta_{t+1}=\theta'$, which defines an interval of possible marginal utility ratios $\left[\underline{\lambda}_{\theta'},\overline{\lambda}_{\theta'}\right]$. If $\lambda(\theta^t)\in\left[\underline{\lambda}_{\theta'},\overline{\lambda}_{\theta'}\right]$, then we choose $\tau(\theta^t)$ so that $\lambda(\theta^t,\theta')=\lambda(\theta^t)$. If instead $\lambda(\theta^t)<\underline{\lambda}_{\theta'}$

(respectively, if $\lambda(\theta^t) > \overline{\lambda}_{\theta'}$), household 1 (resp., household 2) would want to break the contract if the ratio of marginal utilities remained constant, as the short-term costs of making the corresponding transfer in the current period would exceed the long-term insurance benefits coming from promises of future reciprocation. That is, the constraint (149) (resp., (150)) is binding and the multiplier $\chi_1(\theta')$ (resp., $\chi_2(\theta')$) is strictly positive, implying (from (153)) that $\lambda\left(\theta^{t+1}\right) > \lambda(\theta^t)$ (resp., $\lambda\left(\theta^{t+1}\right) < \lambda(\theta^t)$). Therefore full risk-pooling, which would occur with complete markets, is not feasible in this case. We then choose $\lambda(\theta^t, \theta') = \underline{\lambda}_{\theta'}$ (resp., $\lambda(\theta^t, \theta') = \overline{\lambda}_{\theta'}$). The value $\lambda = \underline{\lambda}_{\theta'}$ (respectively, $\lambda = \overline{\lambda}_{\theta'}$) corresponds to household 1 receiving its minimum possible sustainable surplus $\underline{v}^1(\theta')$ in state θ' (resp., its maximum surplus $\bar{v}^1(\theta')$), or equivalently household 2 getting $\bar{v}^2(\theta')$ (resp., $\underline{v}^2(\theta')$). In other words, if full risk sharing is not possible, the ratio of marginal utilities must change to an endpoint (ie, by the minimum possible amount) so that one of the households is just indifferent between staying in the contract and reneging.[bb]

Ligon et al. (2002) then test the model on the data for three Indian villages, using the model to predict consumption allocations (by estimating empirically the initial ratio of marginal utilities and values for the model's parameters that provide the best fit to the data), and measuring the difference between these predictions and the actual data. They find that the dynamic limited commitment model does a substantially better job at explaining the dynamic response of consumption to income than do models of full insurance, static limited commitment, or autarky.

In models of limited commitment, the key to the amount of informal insurance that can be provided in the optimal contract depends on how costly reneging is for the households. That is, the value of autarky is the most important determinant of the extent of insurance. Recent work by Morten (2013) studies a model of risk sharing with endogenous commitment in which temporary migration is possible. The possibility of migration has the unintended consequence of improving self insurance of individuals and the value of autarky, and worsening the risk sharing in the economy. She studies the joint determination of risk sharing and migration decisions and decomposes the welfare effects of migration between changes in income and changes in the endogenous structure of insurance. Morten (2013) further structurally estimates the model on a panel from rural India and argues that the possibility of migration may significantly reduce risk sharing.

[bb] We can show that for a sufficiently high discount factor $\beta \geq \beta^* \in [0,1)$ the λ-intervals overlap and thus there is some first-best contract which is sustainable, whereas if the households are sufficiently impatient, ie, $\beta \leq \beta_* \in (0,1)$, then no nonautarkic contract exists. In the former case, irrespective of the initial value of λ_0, and hence of the initial division of the surplus, the contract converges with probability 1 to a first-best contract. Thus, if people are sufficiently patient, absence of commitment cannot justify the observed lack of diversification in individual consumption as being efficient.

There is by now a large literature studying the predictions of models with contracting frictions in the development economics context. For example, Karaivanov and Townsend (2014) is a comprehensive study comparing exogenously incomplete markets to markets which are endogenously incomplete due to contractual frictions. Their focus is on consumption, income, investment, and asset behavior of small businesses in Thailand. They conclude that the exogenously incomplete market model has the best fit for their rural sample, while the dynamic moral hazard model is more appropriate for urban households. A recent paper by Kinnan (2011) develops a test to distinguish barriers to informal insurance in Thai villages for three types of models: limited commitment, moral hazard, and hidden income, based on the theoretical prediction (see, eg, Eq. (77)) that a single lag of inverse marginal utility is sufficient to forecast current inverse marginal utility, which is satisfied by the first two models but not the latter. She concludes that hidden income is more likely to be the cause of barriers to insurance.

4.4 International Finance

In this section, we describe an application of the recursive contract models to the international finance context, based on Kehoe and Perri (2002). The benchmark model is one of limited commitment similar to that studied in the previous section, but we now analyze it using the duality theory described in Section 3.1.4. Models of limited commitment are useful to analyze questions related to sovereign debt default as they provide a framework that can explain the mechanisms by which countries are induced to participate in contracts involving transfers backed only by promises of future repayment, ie, without a legal authority enforcing them. In such models, countries are free to renege on their debts; the only threat is exclusion from future participation in the financial market.

Standard international business cycle models with either complete or exogenously incomplete markets typically deliver predictions that are at odds with the data (see Backus et al., 1992), for instance, that cross-country correlations of consumption are much higher than those for output, and that both employment and investment in different countries comove negatively. Moreover, net exports and investment are much more volatile in these models than in the data. Kehoe and Perri (2002) show that introducing endogenously incomplete markets due to limited loan enforcement frictions in an otherwise standard international business cycle model can resolve these puzzles. This feature allows the model to reproduce the data's positive cross-country comovements of factors of production, consumption, and output.

Formally, the model consists of two countries $i = 1,2$ that produce their output using domestic labor and capital inputs and face exogenous idiosyncratic Markov technology shocks $A_i(\theta^t)$. (For simplicity, in this section we ignore the subscripts "t" when there is no ambiguity.) Output in country i after a history of shocks θ^t is given by

$F\left(k_i\left(\theta^{t-1}\right), A_i(\theta^t) l_i(\theta^t)\right)$. The social planner's problem consists of choosing allocations $\left\{c_i(\theta^t), l_i(\theta^t), k_i\left(\theta^{t-1}\right)\right\}_{i,t,\theta^t}$ to maximize a weighted (with weights λ_i) sum of utilities of the representative consumers in each country:

$$\max_{\mathbf{c},\boldsymbol{l},\boldsymbol{k}} \sum_{i=1,2} \lambda_i \left\{ \sum_{t=0}^{\infty} \sum_{\theta^t \in \Theta^t} \beta^t \pi_t(\theta^t) U(c_i(\theta^t), l_i(\theta^t)) \right\} \tag{155}$$

subject to the feasibility constraint

$$\sum_{i=1,2} (c_i(\theta^t) + k_i(\theta^t)) = \sum_{i=1,2} \left[F\left(k_i\left(\theta^{t-1}\right), A_i(\theta^t) l_i(\theta^t)\right) + (1-\delta) k_i\left(\theta^{t-1}\right)\right],$$

and the enforcement constraints (similar to (147)): for all $i = 1,2$ and t,θ^t,

$$\sum_{s=t}^{\infty} \sum_{\theta^s \geq \theta^t} \beta^{s-t} \pi_s(\theta^s|\theta^t) U(c_i(\theta^s), l_i(\theta^s)) \geq \underline{V}_i\left(k_i\left(\theta^{t-1}\right), \theta^t\right), \tag{156}$$

where $\underline{V}_i\left(k_i\left(\theta^{t-1}\right), \theta^t\right)$ denotes country i's value of autarky from θ^t onward, given by

$$\begin{aligned} \underline{V}_i\left(k_i\left(\theta^{t-1}\right), \theta^t\right) = \max_{\mathbf{c},\boldsymbol{l},\boldsymbol{k}} & \sum_{s=t}^{\infty} \sum_{\theta^s \geq \theta^t} \beta^{s-t} \pi_s(\theta^s|\theta^t) U(c_i(\theta^s), l_i(\theta^s)) \\ \text{subject to} \quad & c_i(\theta^s) + k_i(\theta^s) \leq F\left(k_i\left(\theta^{s-1}\right), A_i(\theta^s) l_i(\theta^s)\right) + (1-\delta) k_i\left(\theta^{s-1}\right). \end{aligned} \tag{157}$$

The enforcement constraints are formally derived from arguments similar to those we used to obtain (95) in Section 3.2. They ensure that it is the best response for each country to stick to their equilibrium strategies.

We can rewrite this problem recursively using the Marcet and Marimon (2015) approach (see Section 3.1.4). Letting $\beta^t \pi_t(\theta^t) \mu_i(\theta^t)$ denote the multipliers on the enforcement constraints (156), a similar derivation as Eq. (89) implies that we can write the Lagrangian of the social planner's problem as

$$\begin{aligned} \sum_{t=0}^{\infty} \sum_{\theta^t \in \Theta^t} \sum_{i=1,2} \beta^t \pi_t(\theta^t) \quad & \left\{ M_i\left(\theta^{t-1}\right) U(c_i(\theta^t), l_i(\theta^t)) \right. \\ & \left. + \mu_i(\theta^t) \left[U(c_i(\theta^t), l_i(\theta^t)) - \underline{V}_i\left(k_i\left(\theta^{t-1}\right), \theta^t\right) \right] \right\} \end{aligned} \tag{158}$$

subject to the feasibility constraint, where $M_i(\theta^t)$ is a cumulative Lagrange multiplier defined recursively as

$$M_i(\theta^t) = M_i\left(\theta^{t-1}\right) + \mu_i(\theta^t), \tag{159}$$

for $t \geq 0$, with $M_i\left(\theta^{-1}\right) = \lambda_i$. Thus the cumulative multiplier $M_i(\theta^t)$ is equal to the original planning weight λ_i at time 0, plus the sum of the past multipliers on the enforcement constraints at time t and history θ^t. Using the techniques described in

Section 3.1.4 and denoting by $z(\theta^t) = \frac{M_2(\theta^t)}{M_1(\theta^t)}$ the relative weight on country 2, this problem can be written recursively and its solution is stationary in the state space that consists of the current shock, the current capital stocks, and the relative weight, ie, $x_t = \left(\theta_t, k_1\left(\theta^{t-1}\right), k_2\left(\theta^{t-1}\right), z\left(\theta^{t-1}\right)\right)$.

It is instructive to compare this objective (158) with the unconstrained objective (155). The enforcement constraints introduce three key differences. First, starting at the beginning of the period, the cumulative Lagrange multiplier $M_i\left(\theta^{t-1}\right)$ shifts the (relative) weights of each agent. Second, the current Lagrange multiplier $\mu_i(\theta^t)$ on the sustainability constraint further changes the weight on current consumption (as well as on future consumption by affecting the future cumulative multiplier $M_i(\theta^t)$). These two forces translate in the first-order conditions into a distortion of the relative marginal utilities of consumption (letting $U_{ic}(\theta^t)$ denote the marginal utility of consumption in country i in history θ^t):

$$\frac{U_{1c}(\theta^t)}{U_{2c}(\theta^t)} = \frac{M_2\left(\theta^{t-1}\right) + \mu_2\left(\theta^t\right)}{M_1\left(\theta^{t-1}\right) + \mu_1\left(\theta^t\right)}. \tag{160}$$

Third, accumulating more capital $k_i\left(\theta^{t-1}\right)$ tightens the enforcement constraint by increasing the value of autarky. As a result, the Euler equation (and capital accumulation) is distorted as follows (letting $F_{ik}(\theta^t)$ denote the marginal product of capital in country i in history θ^t):

$$\begin{aligned} U_{ic}(\theta^t) = \beta \sum_{\theta_{t+1}} \pi(\theta_{t+1}|\theta_t) \\ \times \left[\frac{M_i\left(\theta^{t+1}\right)}{M_i(\theta^t)} U_{ic}\left(\theta^{t+1}\right)\left(F_{ik}\left(\theta^{t+1}\right) + 1 - \delta\right) - \frac{\mu_i\left(\theta^{t+1}\right)}{M_i(\theta^t)} \underline{V}_{ik}\left(\theta^{t+1}\right)\right]. \end{aligned} \tag{161}$$

The last first-order condition writes $\frac{U_{il}(\theta^t)}{U_{ic}(\theta^t)} = F_{il}(\theta^t)$ (letting $U_{il}(\theta^t)$ and $F_{il}(\theta^t)$ denote the marginal disutility and marginal product of labor in country i in history θ^t): there is no distortion in the consumption–labor decision, since this margin does not affect the enforcement constraint.[bc] These first-order conditions along with the transition law for $z_2(\theta^t)$ can be straightforwardly rewritten as functions of $z_2\left(\theta^{t-1}\right)$ and the normalized multipliers $\tilde{\mu}_i(\theta^t) \equiv \frac{\mu_i(\theta^t)}{M_i\left(\theta^{t-1}\right)}$. The solution to this problem can then be characterized

[bc] Kehoe and Perri (2004) show how to decentralize the constrained efficient allocation as a competitive equilibrium using a tax on capital income to replicate the wedge in the Euler equation (161) generated by the enforcement constraint.

by allocations of the form $(c_i(x_t), l_i(x_t), k_i(x_t))$, where the state vector is $x_t = \left(\theta_t, k_1\left(\theta^{t-1}\right), k_2\left(\theta^{t-1}\right), z\left(\theta^{t-1}\right)\right)$. These policy functions satisfy the first-order conditions above, the feasibility and enforcement constraints, and the complementary slackness conditions on the multipliers.

The model has the following implications. Suppose that the home country (say, country $i = 1$) is hit in history (t, θ^t) with a positive and persistent productivity shock $A_1(\theta^t) > 0$. Eq. (157) shows that such a shock increases the home country's value of autarky, and thus tightens its enforcement constraint (156). This may lead the enforcement constraint to bind, which translates into a positive multiplier $\mu_1(\theta^t)$ in the first-order condition (160). This in turn implies that the planner increases the relative weight to the home country in its objective and allocates it higher consumption $c_1(\theta^t)$ (ie, lower marginal utility $U_{1c}(\theta^t)$) to prevent it from defaulting. Moreover, this increase in consumption is persistent, because the productivity shock is persistent and the positive multiplier $\mu_1(\theta^t)$ raises the cumulative multiplier $M_1(\theta^s)$ of the home country (defined in (159)) in all future periods $s \geq t$. In contrast, consumption in the foreign country does not vary much, as risk sharing in this economy is limited. Finally, the planner optimally restricts the investment flow into country 1 in order to reduce the home country's future value of autarky in Eq. (161) and relax the enforcement constraint. It also increases labor effort and investment in the foreign country to raise country 1's value of participating into the contract, leading to positive cross-country correlations of investment and employment and to a trade surplus (positive net exports) in the home country.

Now compare these effects with those that would occur in an economy without enforcement frictions, ie, with complete markets. In response to a positive productivity shock in the home country, and hence a higher productivity of capital and labor, the planner optimally increases the domestic labor effort and the capital stock, both by saving more and increasing investment flowing from abroad. In contrast, foreign labor effort and investment decrease. Moreover, because of risk sharing, the domestic economy shares its consumption gains, leading to an increase in the consumption of the foreign country. The responses are qualitatively similar but muted in a model where markets are exogenously incomplete (only bonds are allowed). In such models, therefore, output is less correlated across countries than is consumption, the cross-country correlations of investment and employment are negative, and a positive productivity shock leads to a trade deficit in the home country (due to the net inflow of investment).

Kehoe and Perri (2002) calibrate the economy and analyze numerically these implications of the model with endogenously incomplete markets. They find that it matches the data's positive cross-country comovements of factors of production (employment, investment) and the cross-country comovements of consumption and output. This resolves several of the puzzles arising in standard (complete or exogenously incomplete market-)models of international finance described in the first paragraph of this section.

There is a large literature that analyzes questions of international debt and sovereign default using models of (one- or two-sided) limited commitment. The seminal paper is Eaton and Gersovitz (1981), and this literature has been comprehensively reviewed by Aguiar and Amador (2013). In particular, Aguiar et al. (2009) analyze the behavior of sovereign debt and foreign direct investment in a small open economy (rather than in a two-country general equilibrium environment as analyzed in the previous paragraphs) where the government lacks commitment (leading to potential default and expropriation of capital) and is more impatient than the market. While the standard one-sided limited commitment model (see Thomas and Worrall, 1988) predicts that the government will eventually accumulate enough assets to overcome its commitment problem,[bd] the additional assumption of a higher degree of impatience (and hence, the combination of front loading due to impatience and back loading due to limited commitment) leads to cycles in both sovereign debt and foreign direct investment, as well as a "debt overhang" effect whereby investment is distorted by more in recessions than in booms.

5. CONCLUSION

The theory of recursive contracts underpins a variety of applications in a range of fields, from public finance to development economics to corporate finance, international finance, and political economy. A unifying feature of these applications is that they feature frictions such as unobservability of shocks or actions or nonenforceability of contracts that endogenously limit the amount of risk sharing and insurance that can be achieved. This chapter provides a self-contained treatment of the fundamental techniques and the more advanced topics of recursive contracts. We also survey a number of applications through the lens of this unified theoretical treatment that illustrate the versatility of the theoretical apparatus.

[bd] One-sided limited commitment models generally imply that the optimal contract features a form *back loading*: the profile of consumption is shifted toward the future. The intuition is as follows. Additional consumption in a particular period helps ensure the agent's participation in the contract. Moreover, it also helps satisfy the enforcement constraints in all previous periods as well, since the left-hand side of the enforcement constraint (eg, (156)) is forward-looking. At the margin, therefore, consumption in the future is preferable as it relaxes all the preceding participation constraints. As a result the relevant Euler equation includes the cumulative sums of Lagrange multipliers that take into account all of the binding constraints in the previous periods. When the government and the market have the same degree of impatience, the economy will eventually achieve perfect risk sharing with constant consumption, so that a country has an incentive to save to grow out of the enforcement constraints if it is patient enough. Ray (2002) shows that the backloading result and eventual reaching of the unconstrained allocations apply in very general settings.

Abstract

The goal of this chapter is to study how, and by how much, household income, wealth, and preference heterogeneity amplify and propagate a macroeconomic shock. We focus on the US Great Recession of 2007–09 and proceed in two steps. First, using data from the Panel Study of Income Dynamics, we document the patterns of household income, consumption, and wealth inequality before and during the Great Recession. We then investigate how households in different segments of the wealth distribution were affected by income declines, and how they changed their expenditures differentially during the aggregate downturn. Motivated by this evidence, we study several variants of a standard heterogeneous household model with aggregate shocks and an endogenous cross-sectional wealth distribution. Our key finding is that wealth inequality can significantly amplify the impact of an aggregate shock, and it does so if the distribution features a sufficiently large fraction of households with very little net worth that sharply *increase* their saving (ie, they are not hand-to mouth) as the recession hits. We document that both these features are observed in the PSID. We also investigate the role that social insurance policies, such as unemployment insurance, play in shaping the cross-sectional income and wealth distribution, and through it, the dynamics of business cycles.

1. INTRODUCTION

How important is household heterogeneity for the amplification and propagation of macroeconomic shocks? The objective of this chapter is to give a quantitative answer to a narrower version of this broad question.[a] Specifically, we narrow the focus of this question along two dimensions. First, we mainly focus on a specific macroeconomic event, namely the US Great Recession of 2007–09.[b] Second, we focus on specific dimensions of household heterogeneity, namely that in earnings, wealth, and household preferences, and their associated correlations with, and consequences for, the cross-sectional inequality in disposable income and consumption expenditures.[c]

The Great Recession was the largest negative macroeconomic downturn the United States has experienced since World War II. The initial decline in economic activity was deep and had an impact on all macroeconomic aggregates—notably private aggregate consumption and employment—and the recovery has been slow. Is the cross-sectional distribution of wealth an important determinant of the dynamics of the initial downturn and the ensuing recovery? That is, does household heterogeneity matter in terms of aggregate economic activity (as measured by output and labor input), its composition

[a] In this chapter we focus on household heterogeneity. A sizeable literature has investigated similar questions in models with firm heterogeneity. Representative contributions from this literature include Khan and Thomas (2008) and Bachmallnn et al. (2013). We abstract from firm heterogeneity in this chapter, but note that the methodological challenges in computing these classes of models are very similar to the ones encountered here.

[b] By focusing on a business cycle event, and macroeconomic fluctuations more generally, we also abstract from the interaction between income or wealth inequality and aggregate income growth rates in the long run. See Kuznets (1955), Benabou (2002), or Piketty (2014) for important contributions to this large literature.

[c] Excellent earlier surveys of different aspects of the literature on macroeconomics with microeconomic heterogeneity are contained in Deaton (1992), Attanasio (1999), Krusell and Smith (2006), Heathcote et al. (2009), Attanasio and Weber (2010), Guvenen (2011) as well as Quadrini and Rios-Rull (2015).

between consumption and investment, and, eventually, the cross-sectional distribution of consumption and welfare?

To address these questions *empirically*, we make use of recent waves of the Panel Study of Income Dynamics (PSID), which provides household-level panel data on earnings, income, consumption expenditures, and wealth for the United States. To answer these questions *theoretically and quantitatively*, we then study various versions of the canonical real business cycle model with aggregate technology shocks and ex-ante household heterogeneity in preferences and ex-post household income heterogeneity induced by the realization of uninsurable idiosyncratic labor earnings shocks, as in Krusell and Smith (1998). In the model, a recession is associated with lower aggregate wages and higher unemployment (ie, a larger share of households with low labor income). The main empirical and model-based focus of the chapter is on the dynamics of macroeconomic variables—specifically, aggregate consumption, investment, and output—in response to such a business cycle shock. Specifically, we investigate the conditions under which the degree of wealth inequality plays a quantitatively important role for shaping this response. We also study how a stylized unemployment insurance program shapes the cross-sectional distribution of wealth and welfare, and how it affects the recovery of the aggregate economy after a Great Recession-like event.

We proceed in four steps: First, we make use of the PSID earnings, income, consumption and wealth data to document three sets of facts related to cross-sectional inequality. We summarize the key features of the joint distribution of income, wealth, and consumption prior to the Great Recession (ie, for the year 2006). Next, we show how this joint distribution changed during the recession—over the 2006–10 period—exploiting the panel dimension of the data to investigate how individual households fared and adjusted their consumption-savings behavior. The purpose of this empirical analysis is two fold. First, we believe the facts are interesting in their own right, as they characterize the distributional consequences of the Great Recession. Second, the facts serve as important moments for the evaluation of the different versions of the quantitative heterogeneous household model we study next.

In the second step, then, we construct, calibrate, and compute various versions of the canonical Krusell–Smith (1998) model and study its cross-sectional and dynamic properties. We first revisit the well-known finding that idiosyncratic unemployment risk and incomplete financial markets alone are insufficient to generate a sufficiently dispersed model-based cross-sectional wealth distribution. The problem is two fold: in the model, the very wealthy are not nearly wealthy enough, and the poor hold far too much wealth relative to the data. We argue that it is the discrepancy at bottom of the distribution that implies that the model generates an aggregate consumption response to a negative technology shock that is essentially identical to the response in a representative agent model.

We then study extensions of the model in which preference heterogeneity, idiosyncratic labor productivity risk conditional on employment, and a stylized life-cycle structure interact with the presence of unemployment insurance and social security to deliver a wealth distribution that is consistent with the data. In these economies, the decline in aggregate consumption is substantially larger than in the representative agent economy, by approximately 0.5 percentage points. This finding is primarily due to these economies now being populated by more wealth-poor households whose consumption responds strongly to the aggregate shock, both for those households that experience a transition from employment to unemployment, but also for households that have not lost their job, but understand they are facing a potentially long-lasting recession with elevated unemployment *risk*. We also stress that data and theory show that these wealth poor households do not behave as hand-to-mouth consumers, but are the group that reduces their expenditure rates strongly as their recession hits. This behavior implies that our benchmark model has quantitatively very different implications relative to a model where a large fraction of households is exogenously assumed to be hand-to-mouth consumers.

The more severe consumption declines in economies with larger wealth inequality imply a smaller collapse in investment, and thus a faster recovery from the recession, although this last effect is quantitatively small.

In light of the previous finding that larger wealth inequality—specifically, the importance of a large fraction of wealth-poor households—is an important contributor to an aggregate consumption collapse in the Great Recession, in the third step we determine whether public unemployment insurance is important for the dynamics of the economy in response to an aggregate shock. The answer to this question depends crucially on whether the distribution of household wealth has had a chance to respond to changes in the policy. In the short run, an unexpected cut or expiration of unemployment insurance benefits induces a significantly larger negative consumption response. These dynamics are explained by forward-looking households responding to lower public insurance by increasing their precautionary savings. The increased investment generates a medium-run boost to output, at the cost of a slow recovery of consumption.

In the long run, the new ergodic distribution of wealth features fewer people with zero or few assets. The consumption dynamics in response to a negative technology shock under this rightward shift in the wealth distribution are less severe than in they are in response to an unexpected shock, but still larger than in the economy with high unemployment insurance. Thus, for a *given wealth distribution* a cut in social insurance will result in a larger aggregate consumption drop. However, since social insurance policies themselves shape the ergodic distribution of wealth, and especially influence the share of households with zero or close to zero net worth, the aggregate consumption response across different economies is partially offset by these distributional shifts.

In the models considered thus far, the wealth distribution has had a potentially large effect on the *division* of aggregate output between consumption and investment, but not on output itself. In the final step, we therefore study an economy with a New Keynesian flavor—we introduce an aggregate demand externality that makes output partially demand-determined and generates an endogenous feedback effect from private consumption to total factor productivity, and thus output. In this model, social insurance policies might not only be beneficial in providing public insurance, but can also serve a potentially positive role for stabilizing aggregate output. We find that the output decline with an unemployment insurance benefit replacement rate of 50% to a Great Recession-like shock is 1 percentage point smaller on impact than in an economy with a replacement rate of 10%.

This work is part of a broader research agenda (and aims to partially synthesize it) that seeks to explore the importance of micro heterogeneity in general, and household income and wealth heterogeneity in particular, for classic macroeconomic questions (such as the impact of a particular aggregate shock) that have traditionally been answered within the representative agent paradigm (ie, goes from micro to macro). It also builds upon, and contributes to, the related but distinct literature that studies the distributional consequences of macroeconomic shocks (ie, goes from macro to micro).

The chapter is organized as follows. Section 2 documents key dimensions of heterogeneity among US households, prior to and during the Great Recession. Sections 3 and 4 present our benchmark real business cycle model with household heterogeneity and discuss how we calibrate it. Section 5 studies to what extent the benchmark model is consistent with the cross-sectional facts presented in Section 2, and Section 6 studies how the aggregate consumption response to a large shock depends on the cross-sectional wealth distribution. In Section 7 we augment the model with demand externalities in order to investigate the importance of cross-sectional wealth heterogeneity for the dynamics of aggregate output. Section 8 concludes, and the appendix contains details about the construction of the empirical facts, about the theory, and the computational algorithm used.

2. THE GREAT RECESSION: A HETEROGENEOUS HOUSEHOLD PERSPECTIVE

In this section, we present the basic facts about the cross-sectional distribution of earnings, income, consumption, and wealth before and during the Great Recession. The main data set we employ is the Panel Survey of Income Dynamics (PSID) for the years 2004, 2006, 2008, and 2010. This data set has two key advantages for the purpose of this study. First, it contains information about household earnings, income, a broad and comprehensive measure of consumption expenditures, and net worth for a sample of households representative of the US population. Second, it has a panel dimension so we can, in the same data set, both measure the key dimensions of cross-sectional household heterogeneity as well as investigate how different groups in the income and wealth distribution changed their consumption expenditure patterns during the Great Recession.[d]

The purpose of this empirical section is to provide simple and direct evidence for the importance of household heterogeneity for macroeconomic questions. It complements the large empirical literature documenting inequality trends in income, consumption and wealth in the United Sates and around the world.[e] If, as we will document, there are significant differences in behavior (for example, along the consumption and savings margin) across different groups of the earnings and wealth distribution during the Great Recession, then keeping track of the cross-sectional earnings and wealth distribution and understanding their dynamics is likely important for analyzing the unfolding of the Great Recession from a macroeconomic and distributional perspective.

2.1 Aggregates

We start our analysis by comparing the evolution of basic US macroeconomic aggregates from the National Income and Product Accounts (NIPA) with the aggregates for the same variables obtained from the PSID. In Fig. 1, we compare trends in aggregate per capita disposable income (panel A) and per capita consumption expenditures (panel B) from the Bureau of Economic Analysis (BEA) with the corresponding series obtained by aggregating household level in the PSID, for the years 2004 through 2010, the last available data point for the PSID.[f]

The main conclusion we draw from Fig. 1 is that both the NIPA and the PSID paint the same qualitative picture of the US macroeconomy over the period 2004–10. Both disposable income and consumption expenditures experience a slowdown, which is somewhat more pronounced in the PSID. Furthermore, PSID consumption expenditure data also display a much weaker aggregate recovery than what is observed in the NIPA data.[g]

2.2 Inequality Before the Great Recession

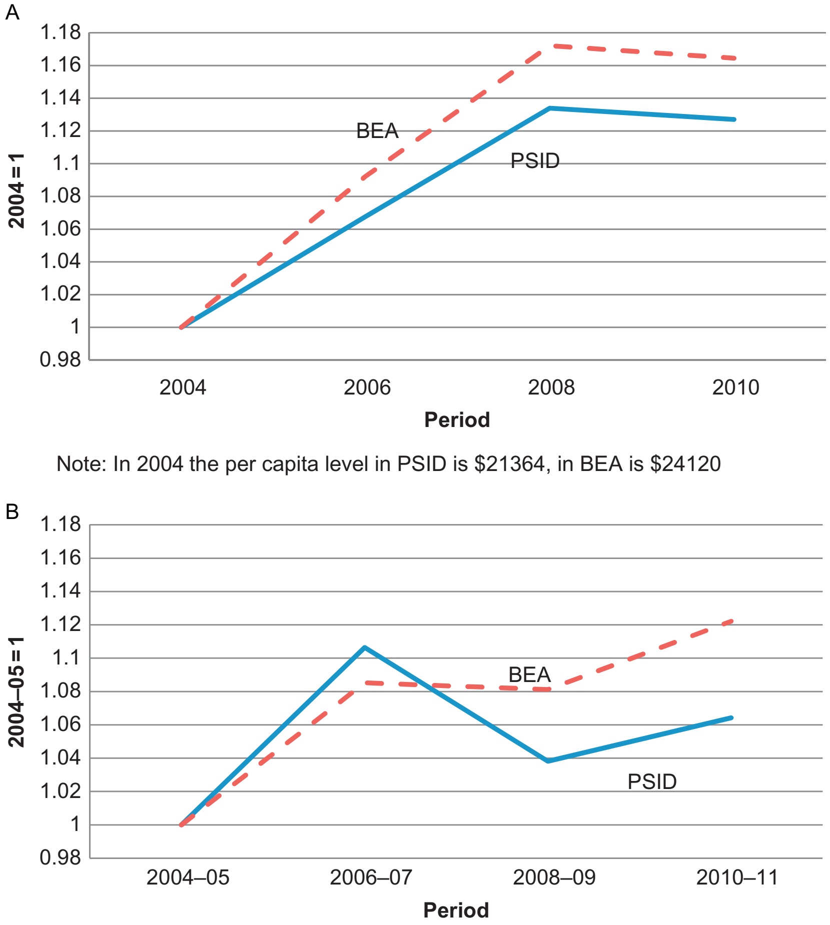
In this section, we document basic inequality facts in the United States for the year 2006, just before the Great Recession hit the economy. Since the Great Recession greatly affected households in the labor market, and our models below focus on labor earnings

[d] Empirical analyses of the joint wealth, income, and consumption distribution using the same panel data set are also contained in Fisher et al. (2015) for the United States, and in Krueger and Perri (2011) for Italy. See Skinner (1987), Blundell et al. (2008), and Smith and Tonetti (2014) for an alternative method for constructing an income-consumption panel using both the PSID and the Consumer Expenditure Survey (CE).

[e] For representative contributions, see eg, Piketty and Saez (2003), Krueger and Perri (2006), Krueger et al. (2010), Piketty (2014), Aguiar and Bils (2015), Atkinson and Bourguignon (2015), and Kuhn and Rios-Rull, 2015.

[f] In Section A.1, we describe in detail how these series are constructed.

[g] As Heathcote et al. (2010) document, this discrepancy between macro data and aggregated micro data is also observed in previous recoveries from US recessions.



Note: In 2004 the per capita level in PSID is $21364, in BEA is $24120

Note: In 2004–05 the per capita level in PSID is $15084, in BEA is $18705

Fig. 1 The Great Recession in the NIPA and in the PSID data. (A) Per capita disposable income. (B) Per capita consumption expenditures.

risk, we restrict attention to households with heads between ages 25 and 60, which in 2006 represents slightly less than 80% of total households in the PSID. Table 1 reports statistics that characterize, for this group of households, the distributions of four key variables: earnings, disposable income, consumption expenditures, and net worth. Our definition of earnings captures income sources that we will model as exogenous to household choices; they include all sources of labor income plus transfers (but not including unemployment benefits) minus tax liabilities.[h] Disposable income includes earnings

[h] During the Great Recession, transfers and taxes have played an important role in affecting household income dynamics. See, for example, Perri and Steinberg (2012).

plus unemployment benefits, plus income from capital, including rental equivalent income of the main residence of the household. Consumption expenditures include all expenditure categories reported by the PSID, ie, cars and other vehicles purchases, food at home and away, clothing and apparel, housing including rent and imputed rental services for owners, household equipment, utilities and transportation expenses. Finally, net worth includes the value of the sums of households' assets minus liabilities.[i]

Table 1 reports, for each variable (earnings, disposable income, consumption expenditures, and net worth), the cross-sectional average (in 2006 dollars), as well as the share of the total value held by each of the five quintiles of the corresponding distribution. At the bottom of the table, we also report the share held by the households between the 90th and 95th percentile, between the 95th and 99th percentile, by those in the top 1% of the respective distribution, and the Gini index of concentration. All statistics are computed from PSID data, but for disposable income, consumption expenditures, and net worth we also compare the statistics from the PSID with the same statistics computed from alternative micro data sets. In particular, for disposable income we use households from the 2006 Current Population Survey (CPS), which is a much larger sample often used to compute income inequality statistics. For consumption expenditures, we use household

[i] Assets include the value of farms and of any businesses owned by the household, the value of checking/saving accounts, the value of stocks or bonds owned, the value of primary residence and of other real estate assets, the value of vehicles, and the value of individual retirement accounts. Liabilities include any form of debt including mortgages on the primary residence or on other real estate, vehicle debt, student loans, medical debt, and credit card debt.

data from the 2006 Consumer Expenditure Survey (CE). Finally, for net worth we use the 2007 Survey of Consumer Finances (SCF), which is the most commonly used dataset for studying the US wealth distribution.

The table reveals features that are typical of distributions of resources across households in developed economies. Earnings and disposable income are both quite concentrated, with the bottom quintiles of the respective distributions holding shares smaller than 5% (3.6% and 4.5% to be exact) and the top quantiles holding almost 50% (48.5% and 47.5% to be precise). The distributions of earnings and disposable income look quite similar, since for the households in our sample (ages 25 to 60), capital income is a fairly small share of total disposable income (constituting only roughly 1/6 of disposable income).[j] Note also that the distributions of disposable income in PSID and CPS look quite similar.[k]

The table also shows that consumption expenditures are less unequally distributed than earnings or income, with the bottom quintile accounting for a bigger fraction (5.6%) of total expenditures. The distributions of consumption expenditures in the PSID and the CE are also fairly comparable.

Finally, net worth is by far the most concentrated variable, especially at the top of the distribution. The bottom 40% of households hold essentially no net worth at all, whereas the top quintile owns 83% of all wealth, and the top 10% holds around 70% of total wealth. Comparing the last two columns demonstrates that, although the average level of wealth in the PSID is substantially lower than in the SCF, the distribution of wealth across the five quintiles lines up quite closely between the two data sets, suggesting that the potential underreporting or mismeasurement of wealth in the PSID might affect the overall amount of wealth measured in this data set, but not the cross-sectional distribution too significantly, which is remarkably comparable to that in the SCF.

Although the marginal distributions of earnings, income, and wealth are interesting in their own right, the more relevant object for our purposes is the joint distribution of wealth, earnings, disposable income, and consumption expenditures.[l] To document

[j] Recall that our definition of earnings is net of taxes and it already includes government transfers.

[k] The CPS income has a lower mean because it does not include the rental equivalent from the main residence. Notice also that both distributions are much less concentrated at the top than are income distributions computed by using tax returns, as in Piketty and Saez (2003). Two reasons account for this difference. The first is that Piketty–Saez focus on income measures before taxes and transfers, whereas here we restrict attention to after-tax and after-transfers income, which is less concentrated; the second is that they focus on tax units, which is a unit of a analysis different than households. See Burkhauser et al. (2012) for more on this distinction.

[l] The class of models we will construct below will have wealth—in addition to current earnings—as the crucial state variable, and thus we stress the correlation of net worth with earnings, income, and especially consumption here.

Table 2 PSID Households across the net worth distribution: 2006

the salient features of this joint distribution, we divide the households in our 2006 PSID sample into net worth quintiles, and then for each *net worth quintile* we report, in Table 2, key differences across these wealth groups.

The table shows two important features of the data. The first is that, perhaps not surprisingly, households with higher net worth tend to have higher earnings and higher disposable incomes. The last row of the table shows more precisely the extent to which earnings and disposable income are positively correlated with net worth. One simple explanation for this is that wealthier households tend to be older and more educated, as confirmed by the last two columns of the table. The second observation is that consumption expenditures are also positively correlated with net worth, but less so than the two income variables. The reason is that, as can be seen in the last two columns of the table, the lower is net worth, the higher the consumption rate. We measure the consumption rate by computing total consumption expenditures for a specific wealth quintile and then dividing it by total earnings (or disposable income) in that wealth quintile. The differences in the consumption rates across wealth quintiles are economically significant: for example, between the bottom and the top wealth quintile, the differences in the consumption rates range between 20% and 30%.

Another way to look at the same issue is to notice that the households in the bottom two net worth quintiles, basically hold no wealth (see Table 1), but are responsible for 11.3% + 12.4% = 23.7% of total consumption expenditures (see Table 2), making this group quantitatively consequential for aggregate consumption dynamics. The differences across groups delineated by wealth constitute *prima facie* evidence that the shape of the wealth distribution *could* matter for the aggregate consumption response to macroeconomic shocks such as the ones responsible for the Great Recession.

In the next section, we will go beyond household heterogeneity at a given point in time and empirically evaluate how, during the Great Recession, expenditures and saving behavior changed differentially for households across the wealth distribution.

2.3 The Great Recession Across the Income and Wealth Distributions

In Table 3, we report for all households, and for households in each of the five quintiles of the net worth distribution, the changes (both percentages and absolute) in net worth, percentage changes in disposable income, and consumption expenditures and change in consumption expenditure rates (in percentage points).[m] For each variable we first establish a benchmark (the growth rate in a nonrecession period) by reporting the change or growth rate for the 2004–06 period, and then report the same variable for the 2006–10 period, which covers the whole recession. To make the two measures comparable, all changes are annualized.[n]

Table 3 reveals a number of interesting facts that we want to highlight. From the first four columns of the table, notice that all groups of households experienced increases in net worth between 2004 and 2006, likely mainly because of the rapid growth in asset prices (stock prices and especially real estate prices) during this period, with low-wealth households experiencing the strongest percentage growth in wealth (but of course starting from very low levels: see again Table 1). Turning to disposable income (second variable of Table 3), we observe that households originally at the bottom of the wealth

Table 3 Annualized changes in selected variables across PSID net worth

	Net worth[a]				Disp. *Y* (%)		Cons. Exp.(%)		Exp. Rate (pp)	
	(1) 04–06		(2) 06–10		(3) 04–06	(4) 06–10	(5) 04–06	(6) 06–10	(7) 04–06	(8) 06–10
All	**15.7**	**44.6**	**−3.0**	**−10**	**4.1**	**1.2**	**5.6**	**−1.3**	**0.9**	**−1.6**
NW Q										
Q1	NA	12.9	NA	6.6	7.4	6.7	7.1	0.6	−0.2	−4.2
Q2	121.9	19.5	24.4	3.7	6.7	4.1	7.2	2	0.3	−1.3
Q3	32.9	23.6	4.3	3.3	5.1	1.8	9	0	2.3	−1.1
Q4	17.0	34.7	1.7	3.8	5.0	1.7	5.9	−1.5	0.5	−2
Q5	11.6	132.2	−4.9	−68.4	1.8	−1.2	2.7	−3.5	0.5	−1.4

[a] The first figure is the percentage change (growth rate), the second is the change in 000's of dollars.

[m] To construct these changes, we keep the identity of the households fixed; for example, to compute the 2004–06 change in net worth for Q1 of the net worth distribution, we select all households in the bottom quintile of the wealth distribution in 2004, compute their average net worth (or income or consumption) in 2004 and 2006, and then calculate the percent difference between the two averages. For the consumption expenditure rates, we report percentage point differences.

[n] Table A.2 reports bootstrap standard errors for all figures in Table 3. In Tables A.3 and A.4, we separately report the changes for the 2006–08 and 2008–10 time periods.

distribution experience faster disposable income growth than those in the highest wealth quintile (7.4% vs 1.8%). This is most likely due to mean reversion in income: low-wealth households are also low-income households, and on average low income households experience faster income growth. Finally, expenditure growth roughly tracked the growth of income variables between 2004 and 2006, and as a result the consumption rates of each group remained roughly constant, perhaps with the exception of households initially in the middle quintile who experienced strong consumption expenditure growth, and thus their consumption rate displays a marked rise.

Now we turn to the dynamics in income, consumption, and wealth during the Great Recession. The columns labeled 06-10 display very significant changes in the dynamics of household income, consumption, and net worth throughout the wealth distribution, relative to the previous time period. Growth in net worth slowed down substantially for all households (it actually turned negative, from +15.6% to −3%) and most significantly so at the top of the wealth distribution. In fact, for households initially (that is, in 2006) in the top wealth quintile net worth fell 4.9% per year over the period 2006–10. Income growth also slowed down, although not uniformly across the wealth distribution. Table 3 shows that the slowdown in income growth is modest at the bottom of the wealth distribution (from 7.4% to 6.7%), whereas the middle and top quintiles experience a more substantial slowdown. For example, the fourth wealth quintile went from annual disposable income growth of 5% between 2004 and 2006 to a growth rate of 1.7% between 2006 and 2010.

Most important for our purposes is the change in consumption expenditures at different points in the wealth distribution, especially in relation to the magnitude of the associated earnings and disposable income changes (as evident in the movement of the consumption rates over time). The first fact we want to highlight is that, overall, PSID households cut the growth in expenditures from +5.6% to −1.3%. Although the decline in the growth rate of consumption expenditures is sizeable across all quintiles, the fall is most pronounced at the bottom of the wealth distribution. To highlight the starkest differences across the wealth distribution, focus on the difference between the top and the bottom wealth quintile. Between 2004 and 2006 the households in both the bottom and the top wealth quintiles display small (less than 0.5 percentage point) changes in the consumption rate (out of disposable income). By contrast, between 2006 and 2010, households at the bottom end of the 2006 wealth distribution reduced the change in their consumption rate by 4 percentage points (from −0.2% to −4.2%), whereas the top quintile's change in the consumption rate declined by only 1.9 percentage points (from 0.5% to −1.4%). In other words, during the Great Recession saving rates increased across the wealth distribution, but more strongly so at the bottom of the wealth distribution.[o]

[o] Heathcote and Perri (2015) also document a similar pattern using data from the Consumer Expenditure Survey.

Table 4 Decomposing changes in expenditure growth

	Change *C* growth	**Change *Y* growth**	**Change *C/Y* growth**
	$g_{c,t} - g_{c,t-1}$	$g_{y,t} - g_{y,t-1}$	$\frac{\rho_{it}-\rho_{it-1}}{\rho_{it-1}} - \frac{\rho_{it-1}-\rho_{it-2}}{\rho_{it-2}}$
All	−6.9	−2.9 (42%)	−3.8 (55%)
NW Q			
Q1	−6.5	−0.7 (11%)	−4.5 (69%)
Q2	−5.2	−2.6 (50%)	−2.3 (44%)
Q3	−9.0	−3.3 (37%)	−5.2 (58%)
Q4	−7.4	−3.3 (48%)	−3.8 (55%)
Q5	−6.2	−3.0 (42%)	−3.4 (55%)

To investigate the sources of the decline in expenditures growth across the wealth distribution in greater detail, we now decompose the difference in consumption growth across the two periods as follows:

$$g_{c,it} - g_{c,it-1} \simeq g_{y,it} - g_{y,it-1} + \frac{\rho_{it}-\rho_{it-1}}{\rho_{it-1}} - \frac{\rho_{it-1}-\rho_{it-2}}{\rho_{it-2}}, \tag{1}$$

where $g_{c,it} = \frac{C_{it}-C_{it-1}}{C_{it-1}}$ is the growth rate of consumption expenditure for group i (for example households in the first wealth quintile in period $t-1$) across periods t and $t-1$, $g_{y,it}$ is the same measure for disposable income, and $\rho_{it} = \frac{C_{it}}{Y_{it}}$ is the consumption rate out of disposable income for group i in period t.

The first column of Table 4 reports the changes in consumption growth rates for all households and for each group, ie, the term $g_{c,it} - g_{c,it-1}$, which is the difference between column (6) and column (5) in Table 3. The second and third columns of the table report the two right-hand-side terms from Eq. (1): the first term, labeled as change in disposable income growth Y, and the second term, labeled as change in the growth of the expenditure rate C/Y. Intuitively, if we see group i's consumption growth slowing down, it could be because its income growth is slowing down, ie, $g_{y,it} - g_{y,it-1}$ falls, or because, keeping income growth fixed, the growth in its expenditure rates, ie, $\frac{\rho_{it}-\rho_{it-1}}{\rho_{it-1}}$, falls. The numbers in parentheses in the table represent the relative contribution of each term.[p]

Overall Table 4 portrays a clear message. Households in the PSID reduce their expenditure growth significantly more than the slowdown in their disposable income alone would suggest (−6.9% vs 2.9%). This implies that, overall, households increase their

[p] The relative contributions do not sum to 1 as the decomposition in 1 is not exact, and it excludes terms that involve the product of growth rates.

saving rate. However, the increase in saving rates, although present among all wealth quintiles, is quantitatively most potent for the first quintile, ie, for those households entering the recession with the lowest net worth. Indeed, for these households the increase in the saving rate accounts for over two-thirds (69%) of the consumption growth decline, whereas for the other wealth groups consumption expenditure growth fell because both income growth slowed down and saving increased. We believe this fact is especially interesting, since it suggests that the decline in consumption at the bottom of the wealth distribution is not simply explained by standard hand-to-mouth behavior (ie, the decline in income of these households), but primarily by changes in consumption behavior though a decline in expenditure rates.

Having documented the salient features of the joint wealth, income, and consumption distribution in the United States prior to the Great Recession and their dynamics over the course of the downturn, we now proceed with a quantitative evaluation of how well standard economic theory, in the form of the canonical heterogeneous household business cycle model with uninsurable idiosyncratic earnings risk, can explain these patterns. We then use this model as a quantitative laboratory to assess the importance of cross-sectional household heterogeneity for aggregate business cycles.

3. A CANONICAL BUSINESS CYCLE MODEL WITH HOUSEHOLD HETEROGENEITY

In this section, we lay out the benchmark model on which this chapter is built. The model is a slightly modified version of the original Krusell and Smith (1998) real business cycle model with household wealth and preference heterogeneity[q] and shares many features of the model recently studied by Carroll et al. (2015).

3.1 Technology

In the spirit of real business cycle theory, aggregate shocks take the form of productivity shocks to the aggregate production function

$$Y = Z^{*}F(K,N). \tag{2}$$

Total factor productivity Z^{*} in turn is given by

$$Z^{*} = ZC^{\omega}, \tag{3}$$

where the exogenous part of technology Z follows a first-order Markov process with transition matrix $\pi(Z'|Z)$. Here C is aggregate consumption and the parameter $\omega \geq 0$

[q] Krusell and Smith (1998) in turn build on stationary versions of the model with household wealth heterogeneity, and thus on Bewley (1986), Imrohoroglu (1989), Huggett (1993), Huggett (1997), and Aiyagari (1994). See Deaton (1991) and Carroll (1992, 1997) for important early partial equilibrium treatments.

measures the importance of an aggregate demand externality. In the benchmark model, we consider the case of $\omega = 0$ in which case total factor productivity is exogenous and determined by the stochastic process for Z (and in which case we do not distinguish between Z and Z^*). In Section 7, we consider a situation with $\omega > 0$. In that case current TFP and thus output is partially determined by demand (aggregate consumption).

In either case, in order to aid the interpretation of the results, we will mainly focus on a situation in which the exogenous technology Z can take two values, $Z \in Z_l, Z_h$. We then interpret Z_l as a severe recession and Z_h as normal economic times.

Finally, we assume that capital depreciates at a constant rate $\delta \in [0, 1]$.

3.2 Household Demographics, Endowments, and Preferences

3.2.1 Demographics and the Life Cycle

In each period a measure 1 of potentially infinitely lived households populates the economy. Households are either young, working households (denoted by W) and participate in the labor market or are old and retired (and denoted by R). We denote a household's age by $j \in \{W, R\}$. Young households have a constant probability of retiring $1 - \theta \in [0, 1]$, and old households have a constant probability of dying $1 - \nu \in [0, 1]$. Deceased households are replaced by new young households. Given these assumptions, the distribution of the population across the two ages is given by

$$\Pi_W = \frac{1-\theta}{(1-\theta)+(1-\nu)}$$

$$\Pi_R = \frac{1-\nu}{(1-\theta)+(1-\nu)}.$$

This simple structure captures the life cycle of households and thus their life-cycle savings behavior in a parsimonious way.

3.2.2 Preferences

Households do not value leisure, but have preferences defined over stochastic consumption streams, determined by a period utility function $u(c)$ with the standard concavity and differentiability properties, as well as a time discount factor β that may be heterogeneous across households (but is fixed over time for a given household). Denote by B the finite set of possible time discount factors.

3.2.3 Endowments

Since households do not value leisure in the utility function, young households supply their entire time endowment (which is normalized to 1) to the market. However, they face idiosyncratic labor productivity and thus earnings risk. This earnings risk comes from two sources. First, households are subject to unemployment risk. We denote by $s \in S = \{u, e\}$ the current employment status of a household, with $s = u$ indicating unemployment. Employment follows a first-order Markov chain with transitions $\pi(s'|s, Z', Z)$ that depend on the aggregate state of the world. This permits the dependence of unemployment-employment transitions on the state of the aggregate business cycle.

In addition, conditional on being employed, a household's labor productivity $y \in Y$ is stochastic and follows a first order Markov chain; denote by $\pi(y'|y) > 0$ the conditional probability of transiting from state y today to y' tomorrow, and by $\Pi(y)$ the associated (unique) invariant distribution. In the benchmark model we assume that, conditional on being employed, transitions of labor productivity are independent of the aggregate state of the world.[r]

For both idiosyncratic shocks (s, y) we assume a law of large numbers, so that idiosyncratic risk averages out, and only aggregate risk determines the number of agents in a specific idiosyncratic state $(s, y) \in S \times Y$. Furthermore, we assume that the share of households in a given idiosyncratic employment state s only depends on the current aggregate state[s] Z, and thus denote by $\Pi_Z(s)$ the deterministic fraction of households with idiosyncratic unemployment state s if the aggregate state of the economy is given by Z. We denote the cross-sectional distribution over labor productivity by $\Pi(y)$; by assumption this distribution does not depend on the aggregate state Z.

Households can save (but not borrow)[t] by accumulating (moderately risky) physical capital[u] and have access to perfect annuity markets.[v] We denote by $a \in A$ the asset holdings of an individual household and by A the set of all possible asset holdings. Households are born with zero initial wealth, draw their unemployment status according to $\Pi_Z(s)$ and their initial labor productivity from $\Pi(y)$. The cross-sectional population distribution of employment status s, labor productivity y, asset holdings a, and discount factors β is denoted as Φ and summarizes, together with the aggregate shock Z, the aggregate state of the economy at any given point in time.

[r] Even for the unemployed, the potential labor productivity y evolves in the background and determines the productivity upon finding a job, as well as unemployment benefits while being unemployed, as described below.

[s] This assumption imposes consistency restrictions on the transition matrix $\pi(s'|s, Z', Z)$. By assumption, the cross-sectional distribution over y is independent of Z to start with.

[t] We therefore abstract from uncollateralized household debt, as modeled in Chatterjee et al. (2007) and Livshits et al. (2007). Herkenhoff (2015) provides an investigation of the impact of increased access to consumer credit on the US business cycle.

[u] We therefore abstract from household portfolio choice. See Cocco et al. (2005) for the analysis of portfolio choice in a canonical partial equilibrium model with idiosyncratic risk, and Krusell and Smith (1997) and Storesletten et al. (2007) for general equilibrium treatments.

[v] Thus the capital of the deceased is used to pay an extra return on capital $\frac{1}{\nu}$ of the retired survivors.

3.3 Government Policy

3.3.1 Unemployment Insurance

The government implements a balanced budget unemployment insurance system whose size is parameterized by a replacement rate $\rho = \frac{b(y, Z, \Phi)}{w(Z, \Phi)y}$ that gives benefits b as a fraction of potential earnings wy of a household, with $\rho = 0$ signifying the absence of public social insurance against unemployment risk.[w] These benefits are paid to households in the unemployment state $s = u$ and financed by proportional taxes on labor earnings with tax rate $\tau(Z, \Phi)$. Taxes are levied on both labor earnings and unemployment benefits.

Recall that by assumption the number of unemployed $\Pi_Z(u)$ only depends on the current aggregate state. The budget constraint of the unemployment insurance system then reads as

$$\Pi_Z(u)\sum_y \Pi(y)b(y, Z, \Phi) = \tau(Z, \Phi)\left[\sum_y \Pi(y)[\Pi_Z(u)b(y, Z, \Phi) + (1-\Pi_Z(u))w(Z, \Phi)y]\right].$$

Exploiting the fact that $b(y, Z, \Phi) = \rho w(Z, \Phi)y$ and that the cross-sectional distribution over y is identical among the employed and unemployed we can simply write

$$\Pi_Z(u)\rho = \tau(Z, \Phi)[\Pi_Z(u)\rho + (1-\Pi_Z(u))]$$

and conclude that the tax rate needed to balance the budget satisfies

$$\tau(Z, \Phi; \rho) = \left(\frac{\Pi_Z(u)\rho}{1-\Pi_Z(u)+\Pi_Z(u)\rho}\right) = \left(\frac{1}{1+\frac{1-\Pi_Z(u)}{\Pi_Z(u)\rho}}\right) = \tau(Z; \rho) \in (0, 1). \quad (4)$$

That is, the tax rate $\tau(Z; \rho)$ only depends (positively) on the exogenous policy parameter ρ measuring the size of the unemployment system as well as (negatively) on the exogenous ratio of employed to unemployed $\frac{1-\Pi_Z(u)}{\Pi_Z(u)}$, which in turn varies over the business cycle.

3.3.2 Social Security

The government runs a balanced budget PAYGO system whose size is determined by a constant payroll tax rate τ_{SS} (that applies only to labor earnings). Social security benefits $b_{SS}(Z, \Phi)$ of retirees are assumed to be independent of past contributions, but because of

[w] Recall that even unemployed households carry with them the idiosyncratic state y even though it does not affect their current labor earnings since they are unemployed.

fluctuations in the aggregate tax base will vary with the aggregate state of the economy Z. The budget constraint then determines the relationship between benefits and the tax rate according to

$$b_{SS}(Z,\Phi)\Pi_R = \tau_{SS}\Pi_W\left[\sum_{\gamma}\Pi(\gamma)(1-\Pi_Z(u))w(Z,\Phi)\gamma\right],$$

Note that in the absence of unemployment (and with average labor productivity of working people equal to 1), we have

$$\tau_{SS} = \frac{b_{SS}(Z,\Phi)}{w(Z,\Phi)}\frac{\Pi_R}{\Pi_W}$$

In this case, the social security tax rate is simply equal to the average replacement rate $\frac{b_{SS}(Z,\Phi)}{w(Z,\Phi)}$ times the old age dependency ratio $\frac{\Pi_R}{\Pi_W}$.

3.4 Recursive Competitive Equilibrium

As is well known, the state space in this economy includes the entire cross-sectional distribution Φ of individual characteristics,[x] (j, s, γ, a, β). Since the dynamic programming problems of young, working age households and retired households differ significantly from each other (in terms of both individual state variables as well the budget constraint) it makes notation easier to separate age $j \in \{W, R\}$ from the other state variables. The dynamic programming problem of retired households then reads as

$$v_R(a,\beta;Z,\Phi) = \max_{c,a'\geq 0}\left\{u(c) + \nu\beta\sum_{Z'\in Z}\pi(Z'|Z)v_R(a',\beta;Z',\Phi')\right\}$$

subject to

$$c + a' = b_{SS}(Z,\Phi) + (1 + r(Z,\Phi) - \delta)a/\nu$$
$$\Phi' = H(Z,\Phi',Z')$$

[x] In order to make the computation of a recursive competitive equilibrium feasible, we follow Krusell and Smith (1998), and many others since, and define and characterize a recursive competitive equilibrium with boundedly rational households who use only a small number of moments (and concretely here, just the mean) of the wealth distribution to forecast future prices. For a discussion of the various alternatives in computing equilibria in this class of models, see the January 2010 special issue of the *Journal of Economic Dynamics and Control*.

For working household households, the decision problem is given by

$$v_W(s,y,a,\beta;Z,\Phi)=\left\{\max_{c,a'\geq 0} u(c)+\beta\sum_{(Z',s',y')\in(Z,S,Y)}\pi(Z'|Z)\pi(s'|s,Z',Z)\pi(y'|y)\right.$$
$$\left.\times\left[\theta v_W(s',y',a',\beta;Z',\Phi')+(1-\theta)v_R(a',\beta;Z',\Phi')\right]\right\}$$

subject to

$$c+a'=(1-\tau(Z;\rho)-\tau_{SS})w(Z,\Phi)y[1-(1-\rho)1_{s=u}]+(1+r(Z,\Phi)-\delta)a$$
$$\Phi'=H(Z,\Phi',Z'),$$

where $1_{s=u}$ is the indicator function that takes the value 1 if the household is unemployed, and thus labor earnings equal unemployment benefits $b(y, Z, \Phi) = \rho w(Z, \Phi)y$.

Definition 1 A recursive competitive equilibrium is given by value and policy functions of working and retired households, v_j, c_j, a_j', pricing functions r, w, and an aggregate law of motion H such that

1. Given the pricing functions r, w, the tax rate given in Eq. (4), and the aggregate law of motion H, the value function v solves the household Bellman equation above and c, a' are the associated policy functions.
2. Factor prices are given by

$$w(Z,\Phi)=ZF_N(K(Z,\Phi),N(Z,\Phi))$$
$$r(Z,\Phi)=ZF_K(K(Z,\Phi),N(Z,\Phi)).$$

3. Budget balance in the unemployment system: Eq. (4) is satisfied
4. Market clearing

$$N(Z,\Phi)=(1-\Pi_Z(u))\sum_{y\in Y}y\Pi(y)$$
$$K(Z,\Phi)=\int a d\Phi.$$

5. The aggregate law of motion H is induced by the exogenous stochastic processes for idiosyncratic and aggregate risk as well as the optimal policy function a' for assets.[y]

3.5 A Taxonomy of Different Versions of the Model

Table 5 summarizes the different versions of the model we will study in this chapter, including the section of the chapter in which it will appear. We start with a version of the model in which total factor productivity is exogenous. The only source of propagation of the aggregate shocks is the capital stock, which is predetermined in the short run (and thus output is exogenous), but responds in the medium run to technology

[y] We give the explicit statement of the law of motion H in Appendix B.

Table 5 Taxonomy of different versions of the model used in the chapter

Name	Discounting	Techn.	Soc. Ins.	Section
KS	$\beta = \overline{\beta}$	$\omega = 0$	$\rho = 1\%$	Section 6.1
Het. β	$\beta \in [\overline{\beta} - \epsilon \overline{\beta} + \epsilon]$	$\omega = 0$	$\rho = 50\%$	Section 6.1
Het. β	$\beta \in [\overline{\beta} - \epsilon \overline{\beta} + \epsilon]$	$\omega = 0$	$\rho = 10\%$	Section 6.3
Dem. Ext.	$\beta \in [\overline{\beta} - \epsilon \overline{\beta} + \epsilon]$	$\omega > 0$	$\rho = 50\%$	Section 7

shocks and/or reforms of the social insurance system. We study two versions of the model, the original Krusell–Smith (1998) economy without preference heterogeneity (which we will alternatively refer to as the KS economy, the low–wealth inequality economy, or the homogeneous discount factor economy), and a model with permanent discount factor heterogeneity (which we refer to as the high–wealth inequality economy, the heterogeneous discount factor economy, or simply the benchmark economy). The latter economy also features an unemployment insurance system whose size is consistent with US data. In Section 5.1, we discuss the extent to which both versions of this model match the empirically observed US cross-sectional wealth distribution, and in Section 6.1 we trace out the model-implied aggregate consumption, investment, and output dynamics in response to a Great Recession type shock.

In order to assess the interaction of wealth inequality and social insurance policies for aggregate macro dynamics, in Section 6.3, we study a version of the heterogeneous discount factor economy with smaller unemployment insurance. In Section 7, the assumption of exogenous TFP is relaxed, and we present a version of the model in which TFP and thus output is partially demand-determined. In this version of the model, household heterogeneity has a potential impact not only on the size of the consumption recession, but also on the magnitude of the output decline, and by stabilizing individual consumption demand, unemployment insurance may act as a quantitatively important source of macroeconomic stabilization.

4. CALIBRATION OF THE BENCHMARK ECONOMY

In this section, we describe how we map our economy to the data. Since we want to address business cycles and transitions into and out of unemployment, we calibrate the model to *quarterly* data.

4.1 Technology and Aggregate Productivity Risk

Following Krusell and Smith (1998), we assume that output is produced according to a Cobb-Douglas production function

$$Y = ZK^{\alpha}N^{1-\alpha}. \tag{5}$$

We set the capital share to $\alpha = 36\%$ and assume a depreciation rate of $\delta = 2.5\%$ per quarter. For the aggregate technology process, we assume that aggregate productivity Z can take two values $Z \in \{Z_l, Z_h\}$, where we interpret Z_l as a potentially severe recession. The aggregate technology process is assumed to follow a first-order Markov chain with transitions

$$\pi = \begin{pmatrix} \rho_l & 1-\rho_l \\ 1-\rho_h & \rho_h \end{pmatrix}.$$

The stationary distribution associated with this Markov chain satisfies

$$\Pi_l = \frac{1-\rho_h}{2-\rho_l-\rho_h}$$
$$\Pi_h = \frac{1-\rho_l}{2-\rho_l-\rho_h}$$

With the normalization that $E(Z) = 1$, the aggregate productivity process is fully determined by the two persistence parameters ρ_l, ρ_h and the dispersion of aggregate productivity, as measured by Z_l/Z_h.

For the calibration of the aggregate productivity process, we think of a $Z = Z_l$ realization as a severe recession such as the Great Recession or the double-dip recession of the early 1980s (and a realization of $Z = Z_h$ as normal times). In this interpretation of the model, by choice of the parameters ρ_l, ρ_h, Z_l/Z_h we want the model to be consistent with the fraction of time periods spent in severe recessions, their expected length conditional on slipping into one, and the decline in GDP per capita associated with severe recessions.[z]

For this we note that with the productivity process set out above, the fraction of time spent in severe recessions is Π_l, whereas, conditional on falling into one, the expected length is given by

$$EL_l = 1 \times 1 - \rho_l + 2 \times \rho_l(1-\rho_l) + \ldots = \frac{1}{1-\rho_l}. \tag{6}$$

This suggests the following calibration strategy:

1. Choose ρ_l to match the average length of a severe recession EL_l. This is a measure of the persistence of recessions.
2. Given ρ_l, choose ρ_h to match the fraction of time the economy is in a severe recession, Π_l.
3. Choose $\frac{Z_l}{Z_h}$ to match the decline in GDP per capita in severe recessions relative to normal times.

In order to measure the empirical counterparts of these entities in the data, we need an operational definition of a severe recession. This definition could be based on GDP per

[z] This chapter shares the focus on rare but large economic crises with the body of work on rare disasters, see eg, Rietz (1988), Barro (2006), and Gourio (2013).

capita, total factor productivity, or unemployment rates, given the model assumption that the aggregate unemployment rate $\Pi_Z(y_u)$ is only a function of the aggregate state of the economy Z.

We chose the latter and define a severe recession to be one where the unemployment rate rises above 9% at least for one quarter and determine the length of the recession to be the period for which the unemployment rate remains above 7%. Using this definition over period from 1948.I to 2014.III we identify two severe recession periods: from 1980.II to 1986.II and from 2009.I to 2013.III. This delivers a frequency of severe recessions of $\Pi_l = 16.48\%$ with expected length of 22 quarters. The average unemployment rate in these severe recession periods is $u(Z_l) = 8.39\%$ and the average unemployment rate in normal times is $u(Z_h) = 5.33\%$. The implied Markov transition matrix that delivers this frequency and length of severe recessions has $\rho_l = 0.9545$ and $\rho_h = 0.9910$ and thus is given by

$$\pi = \begin{pmatrix} 0.9545 & 0.0455 \\ 0.0090 & 0.9910 \end{pmatrix}.$$

For the ratio $\frac{Z_l}{Z_h}$, we target a value of $\frac{Y_l}{Y_h} = 0.9298$, that is, a drop in GDP per capita of 7% relative to normal times.[aa] With average labor productivity if employed equal to 1 and if unemployed equal to zero, unemployment rates in normal and recession states equal to $u(Z_l) = 8.39\%$ and $u(Z_h) = 5.33\%$, and a capital share $\alpha = 0.36$, this requires $\frac{Z_l}{Z_h} = 0.9614$, which, together with the normalization

$$Z_l \Pi_l + Z_h \Pi_h = 1.$$

determines the levels of Z as $Z_l = 0.9676$, $Z_h = 1.0064$. Note that because of endogenous dynamics of the capital stock which falls significantly during the recession, the dispersion in total factor productivity is smaller than what would be needed to engineer a drop in output by 7% only through TFP and increased unemployment (which is the drop in output on impact, given that the capital stock is predetermined).[ab]

[aa] This is the decline in real GDP per capita during the two recession periods we identified, after GDP per capita is linearly detrended. The exact magnitude of the real GDP per capita decline is not crucial for our results, but it is important that severe recessions are deeper and (especially) more persistent than regular business cycle fluctuations.

[ab] In the short run,

$$\frac{Y_l}{Y_h} = \frac{Z_l}{Z_h}\left(\frac{1-u(Z_l)}{1-u(Z_h)}\right)^{0.64}$$

so that in order to generate a drop in output of 7% in the short run would require

$$\frac{Z_l}{Z_h} = \frac{0.9298}{\left(\frac{0.9161}{0.9467}\right)^{0.64}} = 0.9496.$$

.

4.2 Idiosyncratic Earnings Risk

Recall that households face two types of idiosyncratic risks: countercyclical unemployment risk described by the transition matrices $\pi(s'|s,Z',Z)$ and, conditional on being employed, acyclical earnings risk determined by $\pi(y'|y)$. We describe both components in turn.

4.2.1 Unemployment Risk

Idiosyncratic unemployment risk is completely determined by the four 2 by 2 transition matrices $\pi(s'|s,Z',Z)$ summarizing the probabilities of transiting in and out of unemployment for each (Z,Z') combination. Thus $\pi(s'|s,Z',Z)$ has the form

$$\begin{bmatrix} \pi_{u,u}^{Z,Z'} & \pi_{u,e}^{Z,Z'} \\ \pi_{e,u}^{Z,Z'} & \pi_{e,e}^{Z,Z'} \end{bmatrix}, \tag{7}$$

where, for example, $\pi_{e,u}^{Z,Z'}$ is the probability that an unemployed individual finds a job between one period and the next, when aggregate productivity transits from Z to Z'. Evidently each row of this matrix has to sum to 1. Note that, in addition, the restriction that the aggregate unemployment rate only depends on the aggregate state of the economy imposes one additional restriction on each of these 2 by 2 matrices, of the form

$$\Pi_{Z'}(u) = \pi_{u,u}^{Z,Z'} \times \Pi_Z(u) + \pi_{e,u}^{Z,Z'} \times (1 - \Pi_Z(u)). \tag{8}$$

Thus, conditional on targeted unemployment rates in recessions and expansions, (Π_l, Π_h) this equation imposes a joint restriction on $(\pi_{u,u}^{Z,Z'}, \pi_{e,u}^{Z,Z'})$ for each (Z,Z') pair. With these restrictions, the idiosyncratic transition matrices are uniquely pinned down by $\pi_{u,e}^{Z,Z'}$, ie, the job-finding rates.[ac]

We compute the job finding rate for a quarter as follows. We consider an individual that starts the quarter as unemployed and compute the probability that at the end of the quarter that individual is still unemployed. The possible ways that this can happen are (denoting as f_1, f_2, f_3 and as s_1, s_2, s_3 the job-finding and job-separation rates in months 1,2, and 3 of the quarter):

1. Does not find a job in month 1, 2, or 3, with probability $(1 - f_1) \times (1 - f_2) \times (1 - f_3)$.
2. Finds a job in month 1, loses it in month 2, does not find in month 3, with probability $f_1 \times s_2 \times (1 - f_3)$.
3. Finds a job in month 1, keeps it in month 2, loses it in month 3, with probability $f_1 \times (1 - s_2) \times s_3$.
4. Finds a job in month 2, loses it in month 3, with probability $(1 - f_1) \times f_2 \times s_3$.

[ac] One could alternatively use job-separation rates $\pi_{e,u}^{Z,Z'}$.

Thus the probability that someone that was unemployed at the beginning of the quarter is not unemployed at the end of the quarter is:

$$f = 1 - ((1 - f_1)(1 - f_2)(1 - f_3) + f_1 s_2 (1 - f_3) + f_1 (1 - s_2) s_3 + (1 - f_1) f_2 s_3) \tag{9}$$

We follow Shimer (2005) to measure the job-finding and separation rates from CPS data as averages for periods corresponding to specific Z, Z' transitions.[ad] Equating these with $\pi_{u,e}^{Z,Z'}$ delivers the following employment-unemployment transition matrices:

- Aggregate economy is and remains in a recession: $Z = Z_l . Z' = Z_l$

$$\begin{pmatrix} 0.3378 & 0.6622 \\ 0.0606 & 0.9394 \end{pmatrix} \tag{10}$$

- Aggregate economy is and remains in normal times: $Z = Z_h . Z' = Z_h$

$$\begin{pmatrix} 0.1890 & 0.8110 \\ 0.0457 & 0.9543 \end{pmatrix} \tag{11}$$

- Aggregate economy slips into recession: $Z = Z_h . Z' = Z_l$

$$\begin{pmatrix} 0.3382 & 0.6618 \\ 0.0696 & 0.9304 \end{pmatrix} \tag{12}$$

- Aggregate economy emerges from recession: $Z = Z_l . Z' = Z_h$

$$\begin{pmatrix} 0.2220 & 0.7780 \\ 0.0378 & 0.9622 \end{pmatrix} \tag{13}$$

We observe that the resulting matrices make intuitive sense. One possible (but quantitatively minor) exception is that the job-finding rate is higher if the economy remains in normal times than if it emerges from a recession. On the other hand, the lower job-finding rate is consistent with the experience during the Great Recession per our definition, as job-finding rates did not recover until well into 2014, whereas by our calibration the recession ended in 2013.

4.2.2 Earnings Risk Conditional on Employment

In addition to unemployment risk, we add to the model earnings risk, conditional on being employed. This allows us to obtain a more empirically plausible earnings distribution and makes earnings risk a more potent determinant of wealth dispersion (and thus reduces the importance of preference heterogeneity for this purpose). We assume that,

[ad] Let u_t = unemployment rate and u_t^S = short-term unemployment rate (people who are unemployed this month, but were not unemployed last month). Then we can define the monthly job-finding rate as $1 - (u_{t+1} - u_{t+1}^S)/u_t$ and the separation rate as $u_{t+1}^S/(1 - u_t)$. The series we use from the CPS are the unemployment level (UNEMPLOY), the short-term unemployment level (UNEMPLT5) and civilian employment (CE16OV). There was a change in CPS coding starting in February 1994 (inclusive), so UNEMPLT5 in every month starting with February 1994 is replaced by $UEMPL5 \times 1.1549$.

conditional on being employed, log-labor earnings of households follow a process with both transitory and persistent shocks.[ae] The process is specified as

$$\log(y') = p + \epsilon \tag{14}$$

$$p' = \phi p + \eta \tag{15}$$

with persistence ϕ and innovations of the persistent and transitory shocks (η, ϵ), respectively.[af] The associated variances of the shocks are denoted by $(\sigma_\eta^2, \sigma_\epsilon^2)$, and therefore the entire process is characterized by the parameters $(\phi, \sigma_\eta^2, \sigma_\epsilon^2)$. We estimate this process for household labor earnings after taxes (after first removing age, education and time effects) from *annual* PSID data and find estimates of $\phi, \sigma_\eta^2, \sigma_\epsilon^2$ equal to 0.9695, 0.0384 and 0.0522 respectively.[ag] Next we translate these estimates into a quarterly persistence and variance.[ah] We then use the Rouwenhorst procedure to discretize the persistent part of the process into a seven-state Markov chain.[ai] The *iid* shock only enters the computation of the expectation on the right-hand side of the Euler equation.[aj] We approximate the integral calculating the expectation using a Gauss–Hermite quadrature scheme with three nodes. Thus, we effectively approximate the continuous state space process by a discrete Markov chain with 7 × 3 = 21 states.[ak]

[ae] The formulation of log-earnings or log-income as a stochastic process with transitory and persistent (or fully permanent) shocks follows a large empirical literature in labor economics. See Meghir and Pistaferri (2004), Storesletten et al. (2004b), Guvenen (2009) and the many references discussed therein.

[af] Note that we assume that the variance and persistence of this process are independent of the state of the business cycle. Earnings risk in the data *is* countercyclical, as stressed by Storesletten et al. (2004a, 2007), and Guvenen et al. (2014); in our benchmark model earning risk is also countercyclical but only because of countercyclical unemployment risk.

[ag] For the exact definition of the labor earnings after taxes, sample selection criteria and estimation method, see Appendix A.

[ah] In order to ensure that quarterly log-earnings has the same persistence as annual log-earnings, we choose the persistence of the quarterly AR(1) to be $\phi = \hat{\phi}^{\frac{1}{4}}$. For the variances, we note that the main purpose of the earnings shocks is to help deliver a plausible cross-sectional distribution of labor income. Therefore we aim to maintain the same cross-sectional distribution of earnings at the quarterly frequency as we estimate at the annual frequency. Choosing a quarterly transitory variance equal to its annual counterpart and

$$\frac{\sigma_\eta^2}{1-\phi^2} = \frac{\hat{\sigma}_\eta^2}{1-\hat{\phi}^2}$$

achieves this goal.

[ai] See Kopecky and Suen (2010) for a detailed description and evaluation of the Rouwenhorst method.

[aj] This is because we use cash at hand and the persistent income state as state variables in the individual household dynamic programming problem.

[ak] For the computation of the distributional statistics we simulate a panel of households. In this simulation, realizations of the persistent shock remain on the grid, but the transitory shock is drawn from a normal distribution and thus is not restricted to fall on one of the quadrature points.

4.3 Preferences and the Life Cycle

In the benchmark economy, we assume that the period utility function over current consumption is given by a constant relative risk aversion utility function with parameter $\sigma = 1$. As described above, we study two versions of the model: the original Krusell–Smith (1998) economy in which households have identical time discount factors, and a model in which households, as in Carroll et al. (2015) have permanently different time discount factors (and die with positive probability, in order to ensure a bounded wealth distribution).

For the model with preference heterogeneity, we assume that households at the beginning of their life draw their permanent discount factor β from a uniform distribution[al] with support $[\overline{\beta} - \epsilon, \overline{\beta} + \epsilon]$ and choose $(\overline{\beta}, \epsilon)$ so that the model wealth distribution (with an unemployment insurance replacement rate of 50%) has a Gini coefficient for the working age population of 77% as in the data and a quarterly wealth-to-output ratio of 10.26 (as in Carroll et al., 2015) This requires $(\overline{\beta} = 0.9864, \epsilon = 0.0053)$ and implies that annual time discount factors in this economy range from $\beta = 0.9265$ to $\beta = 0.9672$. Finally, households in the working stage of their life cycle face a constant probability $1 - \theta$ of retiring, and retired households face a constant probability $1 - \nu$ of dying. For our quarterly model we choose $1 - \theta = 1/160$, implying an expected work life of 40 years, and $1 - \nu = 1/60$, with a resulting retirement phase of 15 years in expectation.

For the original Krusell–Smith economy, we choose the common quarterly discount factor $\beta = 0.9899$ to ensure that the capital-output ratio in this economy (again at quarterly frequency) equals that in the heterogeneous β economy. In this economy households neither retire nor die.

4.4 Government Unemployment Insurance Policy

The size of the social insurance (or unemployment insurance, more concretely) system is determined by the replacement rate ρ. For the benchmark economy that we assume $\rho = 50\%$ (see, eg, Gruber, 1994). We will also consider a lower value of $\rho = 10\%$, motivated by the observation that many households qualifying for unemployment insurance benefits fail to claim them (see, eg, Blank and Card, 1991 or Chodorow-Reich and Karabarbounis, 2016).

[al] In practice, we discretize this distribution and assume that each household draws one of five possible β's with equal probability; thus $B = \{\beta_1, \ldots \beta_5\}$ and $\Pi(\beta) = 1/5$. We also experimented with stochastic β's as in Krusell and Smith (1998) but found that the formulation we adopt enhances the model's ability to generate sufficiently many wealth-poor households. The results for the stochastic β economy generally lie in between those obtained in the original Krusell and Smith (1998) economy documented in detail in this chapter, and the results obtained in the model with permanent β heterogeneity, also documented in great detail below.

Finally, the payroll tax rate for social security is set to $\tau_{SS} = 15.3\%$. This choice implies an average (over the business cycle) and empirically plausible replacement rate of the social security system of approximately 40%. In the KS economy, in order to avoid numerical problems with zero consumption, we include a minimal unemployment insurance system with a replacement rate of $\rho = 1\%$.

5. EVALUATING THE BENCHMARK ECONOMY

5.1 The Joint Distribution of Earnings, Income, Wealth, and Consumption in the Benchmark Economy

In this section, we evaluate the extent to which our benchmark model is consistent with the main empirical facts characterizing the joint distribution of wealth, income, and consumption expenditures, as well as the changes in this distribution when the economy is subjected to a large negative aggregate shock.

5.1.1 Wealth Inequality in the Benchmark Economy

We have argued in the introduction that a model-implied cross-sectional wealth distribution that is consistent with the empirically observed concentration, and especially with a share of wealth of the bottom 40% of close to zero, is crucial when using the model as a laboratory for studying aggregate fluctuations. We now document that our benchmark economy has this property, whereas an economy akin to the one studied in Krusell and Smith's (1998) original work in which wealth inequality is entirely driven by idiosyncratic unemployment shocks and incomplete financial markets does not.[am]

Table 6 reports selected statics for the wealth distribution, those computed from the data (PSID and SCF) as well as those from two model economies, the original Krusell–Smith (1998) economy and our benchmark model with idiosyncratic income risk, incomplete markets, a rudimentary life cycle structure, unemployment insurance, and heterogeneous discount factors.[an] As indicated in the calibration section, through appropriate choice of the time discount factor(s), both economies have the same average (over the business cycle) capital-output ratio, and the benchmark economy displays a wealth Gini coefficient in line with the micro data from the PSID. All other moments of the empirical cross-sectional wealth distribution were not targeted in the calibration of the models.

[am] We retain *our* calibration of idiosyncratic unemployment risk, and thus the cross-sectional wealth distribution in our version of the Krusell–Smith economy differs from their original numbers, but not in a magnitude substantial enough to change any of the conclusions below.

[an] Recall that in the data, we restrict attention to working-age households. Consequently, when we report cross-sectional statistics from the benchmark model (which includes a retirement phase), we restrict attention to households in the working stages of their life.

Table 6 Net worth distributions: Data vs models

	Data		Models	
% Share held by:	**PSID, 06**	**SCF, 07**	**Bench**	**KS**
$Q1$	−0.9	−0.2	0.3	6.9
$Q2$	0.8	1.2	1.2	11.7
$Q3$	4.4	4.6	4.7	16.0
$Q4$	13.0	11.9	16.0	22.3
$Q5$	82.7	82.5	77.8	43.0
90–95	13.7	11.1	17.9	10.5
95–99	22.8	25.3	26.0	11.8
$T1\%$	30.9	33.5	14.2	5.0
Gini	0.77	0.78	0.77	0.35

From the table we note that, overall, the benchmark model fits the empirical wealth distribution in the data quite well (albeit not perfectly), especially at the bottom of the distribution. Specifically, it captures the fact that households constituting the bottom two quintiles of the wealth distribution hardly have any wealth, but also that the top wealth quintile holds approximately 80% of all net worth in the US economy. We also acknowledge that the benchmark model makes the wealth upper middle class (quintile 4 and also the bottom part of quintile 5) somewhat too wealthy. For example, households between the 90th and 99th percentiles of the net worth distribution account for about 36% of wealth in the data, but 44% in the model. Most problematically, the benchmark model still misses the wealth concentration at the *very top* of the distribution significantly. In the data the top 1% wealth holders account for over 30% of overall net worth in the economy, whereas the corresponding figure in the model is only 14.0%. A histogram of the model-implied wealth distribution can be found in Fig. 10.[ao]

Finally, Table 6 reproduces the well-known—since Krusell and Smith (1998)—result that transitory unemployment risk and incomplete financial markets alone are incapable of generating sufficient wealth dispersion. The problem relative to the data is two-fold: households at the top of the wealth distribution are not nearly wealthy enough, and, as we will argue, more importantly for the results to follow, households at the bottom of the distribution hold significantly too much wealth in the model. Relative to SCF or PSID micro data, in the model the bottom 40% own about 19% of net worth in the economy, whereas in the data that share is approximately 0. As a summary measure of wealth

[ao] Although this is clearly a shortcoming, note that in this range of wealth levels, the consumption function is essentially linear (as we will display below) and thus mechanically reshuffling wealth between the top 1% and the top 20% through top 1% would not alter aggregate consumption responses to shocks significantly. We will return to this point in Section 6.2.

inequality, whereas the wealth Gini in the data is well above 0.7, the original Krusell–Smith model delivers a number of only 0.35.

In the next section, we now decompose which model elements in the benchmark economy are responsible for generating a more realistic wealth distribution than in the original Krusell–Smith economy. We then turn to an evaluation of the benchmark model's success in reproducing the empirical *joint* distribution of earnings, income, consumption, and wealth in the data.

5.2 Inspecting the Mechanism I: What Accounts for Wealth Inequality in the Benchmark Economy?

A substantial literature, recently surveyed in De Nardi (2015), De Nardi et al. (2015), and Benhabib and Bisin (2016), explores alternative mechanisms for generating the empirically observed high wealth concentration in the data.[ap] These mechanisms include the use of very large but transient income realizations that the PSID misses out on (as in Castaneda et al., 2003; Kindermann and Krueger, 2015; or Brüggemann and Yoo, 2015), large uninsured or only partially insured medical expenditure shocks in old age (see eg, De Nardi et al., 2010 or Ameriks et al., 2015), the intergenerational transmission of wealth through accidental and intended bequests (as eg, in De Nardi, 2004), the interaction between wealth accumulation and entrepreneurship (see Quadrini, 2000; Cagetti and De Nardi, 2006; and Buera, 2009) or idiosyncratic shocks to investment opportunities or its returns, as in Benhabib et al. (2011).

In our benchmark model, we instead follow the sizeable literature that has explored the potential importance of empirically realistic, highly persistent earnings risk (conditional on employment) as well as preference heterogeneity in general, and cross-sectional dispersion in patience specifically, for generating an empirically plausible cross-sectional wealth distribution. Household heterogeneity in time discount factors had already been explored by the original Krusell and Smith (1998) paper, and has been further analyzed by Hendricks (2007) and Carroll et al. (2015); the latter also incorporates a stochastic earnings process in the analysis.

In the previous section, we argued that preference heterogeneity, when combined with idiosyncratic unemployment and earnings shocks as well as rudimentary life cycle elements[aq] and social insurance policies, generates a wealth distribution that resembles the

[ap] Gabaix et al. (2014) evaluate whether the existing theories discussed there are consistent with the secular rise in the share of income and wealth accruing to the top 1% of households, and argue that only theories embedding "superstar" phenomena are capable of reproducing the facts at the very top of these distributions.

[aq] The literature on quantitative studies of the cross-sectional wealth distributions in general equilibrium life-cycle economies with uninsurable idiosyncratic income risk starts with Huggett (1996).

Table 7 Net worth distributions and consumption decline: Different versions of the model

	Models[a]				
% Share:	**KS**	**+$\sigma(y)$**	**+Ret.**	**+$\sigma(\beta)$**	**+UI**
$Q1$	6.9	0.7	0.7	0.7	0.3
$Q2$	11.7	2.2	2.4	2.0	1.2
$Q3$	16.0	6.1	6.7	5.3	4.7
$Q4$	22.3	17.8	19.0	15.9	16.0
$Q5$	43.0	73.3	71.1	76.1	77.8
90–95	10.5	17.5	17.1	17.5	17.9
95–99	11.8	23.7	22.6	25.4	26.0
$T1\%$	5.0	11.2	10.7	13.9	14.2
Wealth Gini	0.350	0.699	0.703	0.745	0.767

[a]The KS model only has unemployment risk and incomplete markets, and thus the first column repeats information from Table 6. The column +$\sigma(y)$ adds idiosyncratic earnings shocks (transitory and permanent) while employed. The column +Ret. adds the basic life cycle structure (positive probability of retirement and positive probability of death, plus social security in retirement). The column +$\sigma(\beta)$ incorporates preference heterogeneity into the model, and finally the column +UI raises the replacement of the unemployment insurance system from 1% to 50%; the resulting model is therefore the benchmark model, with results already documented in Table 6. In all models, the (mean) discount factor is calibrated so that all versions have the same capital-output ratio.

data in 2006 well, both at the bottom and at the top of the distribution. In Table 7, we now show precisely which model elements are responsible for this finding.[ar]

The table (which partially repeats information from Table 6 to facilitate comparisons across different model economies) displays the share of net worth held by the five wealth quintiles, the wealth Gini, and more detailed information about the top of the net worth distribution, in the data and in a sequence of models, ranging from the original Krusell–Smith (1998) economy to our benchmark economy in the last column.

The table contains several important quantitative lessons. First, comparing the first and the second model columns, we see that the inclusion of highly persistent earnings risk, in addition to unemployment risk, increases wealth dispersion very significantly, relative to the economy with *only* unemployment risk. Consistent with a sizeable literature estimating stochastic labor earnings or income processes (see eg, Storesletten et al., 2004b) we find that the persistent component is indeed very persistent, with an annual autocorrelation (conditional on remaining employed) of 0.97. Thus, the economy contains a share of households with close to permanently low earnings, even in the absence of unemployment. These households, located predominantly in the lowest wealth quintile, have had no opportunity to accumulate significant wealth.[as] Consequently the share of

[ar] Castaneda et al. (1998) provide a decomposition similar in spirit, but focus on the evolution of the cross-sectional income distribution over the cycle.

[as] And if an unemployment insurance system with replacement rate of $\rho = 50\%$ is in place, as in the benchmark economy, they have no strong motive, either.

wealth held by the poorest households shrinks to fairly close to zero with idiosyncratic income risk, as observed in the data. At the same time, the top wealth quintile is populated with households with high earnings realizations for whom the risk of a persistent fall in earnings provides motivation to accumulate substantial wealth. As a result, the wealth Gini doubles in the economy with earnings risk, relative to the original Krusell–Smith unemployment-only model.

Second, adding a more explicit life-cycle structure does not change the wealth distribution (of the working-age population) much, but as we will see in the next section, will imply a more plausible *joint* wealth-consumption distribution, by adding a life-cycle savings for retirement motive to the precautionary saving motive. It also somewhat reduces wealth concentration at the top of the distribution, since earnings risk ceases with retirement and thus trims the precautionary motive of the wealth-rich.[at]

Third, as the examination of the very top of the wealth distribution in the first three columns of Table 7 reveals, income risk and life-cycle elements alone are insufficient to generate the very high wealth concentration observed in the data. This is where the discount factor heterogeneity in the benchmark model plays a crucial role. It creates a class of households that are patient and have a high propensity to save, and the fact that in addition to a precautionary saving motive, they also save for retirement (a phase they value highly because of their patience) ensures that they do not start to decumulate wealth even at high wealth levels. As Table 7 displays (comparing the last two columns), the model with both features (the life cycle and preference heterogeneity) is able to generate the wealth concentration at the top quintile of the distribution close to what is observed in US data (albeit not at the very top of the distribution).

Finally, inserting an unemployment insurance system into the model further reduces the wealth held by the bottom two quintiles of the distribution, since now losing a job with little net worth is not nearly as harmful. In Krueger et al. (2016), we argue that the size of the unemployment insurance system not only crucially shapes the bottom of the wealth distribution, but also has a strong impact on the welfare losses from severe recessions in the class of heterogeneous household macro models we study in this chapter.

5.2.1 Income and Consumption at Different Points of the Wealth Distribution

In this section, we evaluate the ability of the benchmark model to reproduce key features of the joint distribution of income, consumption, and wealth in the PSID data. To do so, Table 8 reports the share of earnings, disposable income, consumption expenditures, and the expenditure rates for the five quintiles of the wealth distribution, both for the data (as already contained in Table 2) and for the benchmark model.

[at] Our model imposes substantial structure on the link between idiosyncratic income shocks and consumption over the life cycle. In methodologically complementary work, Arellano et al. (2015) estimate a more flexible nonlinear empirical model of household earnings and consumption over the life cycle.

Table 8 Selected variables by net worth: Data vs models

	% Share of:						**% Expend. rate**			
	Earnings		**Disp. *Y***		**Expend.**		**Earnings**		**Disp. *Y***	
NW Q	**Data**	**Mod**	**Data**	**Mod**	**Data**	**Mod**	**Data**	**Mod**	**Data**	**Mod**
Q1	9.8	6.5	8.7	6.0	11.3	6.6	95.1	96.5	90.0	90.4
Q2	12.9	11.8	11.2	10.5	12.4	11.3	79.3	90.3	76.4	86.9
Q3	18.0	18.2	16.7	16.6	16.8	16.6	77.5	86.0	69.8	81.1
Q4	22.3	25.5	22.1	24.3	22.4	23.6	82.3	87.3	69.6	78.5
Q5	37.0	38.0	41.2	42.7	37.2	42.0	83.0	104.5	62.5	79.6
	Correlation with net worth									
	0.26	0.46	0.42	0.67	0.20	0.76				

On the positive side, first, the model is consistent with the significantly positive correlation between net worth on the one hand, and earnings, disposable income and consumption expenditures on the other. The shares of the latter three variables are all increasing with the net worth quintiles. Second, as in the data, disposable income (which includes capital income) displays a higher correlation with net worth than with labor earnings. Third, the model reproduces the crucial fact that the bottom two wealth quintiles, while accounting for essentially zero net worth, contribute a very significant share to aggregate consumption expenditures. In the data, that share is 23.7%, and in the model it is still highly significant at 17.9%. Since, as we will show below, this low-wealth group has the largest declines in their consumption, the fact that it accounts for a substantial part of aggregate consumption to start with is in turn crucial for the macro responses to an aggregate shock in the model. Fourth, turning to the consumption expenditure rates, the model is broadly consistent with the levels found in the data, and is broadly consistent with the empirical finding in the data that these rates decline with net worth. However, the wealth gradient is not quite as steep in the model as it is in the data, and in the model the top wealth quintile has expenditure rates that are higher than the forth quintile (very slightly so in relation to disposable income, much more strongly so in relation to labor earnings).

For this last finding, the inclusion of a retirement phase and thus a life cycle savings motive into the model is absolutely crucial. A pure infinite horizon version of the model, even with idiosyncratic income shocks and preference heterogeneity, displays expenditure rates that are significantly too high—averaging 100% across wealth quintiles—and implies expenditure rates that are U-shaped with respect to net worth. Absent the life-cycle savings motive, households accumulate wealth exclusively for the purpose of smoothing out negative income fluctuations, and thus individuals in the fourth and fifth wealth quintiles, having accumulated enough net worth for this purpose, display very high expenditure rates (in fact, significantly larger than 100%)—especially with respect to labor earnings. Preference heterogeneity mitigates this effect somewhat, but the resulting model still displays grossly counterfactual expenditure rates, whereas the version of the model with stochastic retirement brings the implications of the model much closer to their empirical counterpart, and is our primary justification for the presence of this model element.

We would also like to flag another dimension along which the model is not fully successful in capturing the empirical facts. First, although the model does generate consumption expenditure shares that are strongly increasing with wealth, not only are the wealth-poor too consumption-poor in the model (as already discussed above), but also the wealth rich (quintile 5) consume too much in the model (42% relative to 37.2% in the data). This is true even though the model captures the earnings and income share of this group of households quite well. This problem of the model is summarized by the fact that the correlation between net worth and consumption expenditures is positive in the model, as it is in the data, but is much larger than it is in the PSID.

We conclude this section with the overall assessment that the benchmark model captures well many qualitative features of the cross-sectional joint distribution of net worth, earnings, income and consumption expenditures, but fails to quantitatively match the joint distribution of net worth and expenditures, with the wealth poor consuming too little, and the wealth rich consuming too much, relative to the data.

5.3 The Dynamics of Income, Consumption, and Wealth in Normal Times and in a Recession

The previous section studied the joint distribution of the key economic variables at a given point in time (2006 in the data, a period after a long sequence of normal macroeconomic performance in the model). We now put the model to a more ambitious (and to our knowledge novel) test and assess whether the *dynamics* of wealth, income and consumption implied by the model can match those observed in the data. We ask this question both for a period of macroeconomic stability (in Section 5.3.1), and then, in Section 5.3.2, for a period characterized by a severe macroeconomic crisis. Note that none of the empirical moments along this dimension were targeted in the calibration of the model.

5.3.1 Normal Times: 2004–06

In the data we are somewhat limited in our choices by the sparse time series dimension of the PSID (for which comprehensive consumption data are available). We take *normal times* in the data to be the period from 2004 to 2006; we map this period into the model by studying an episode of eight quarters of good productivity, $Z = Z_h$, which in turn followed a long sequence of good aggregate shocks so that aggregates and distributions have settled down prior to this episode.

Table 9 Annualized changes in selected variables by net worth in normal times (2004-06): Data vs model

	Net worth (%)		Disp. *Y* (%)		Expend (%)		Exp. Rate (pp)	
NW Q	Data	Model	Data	Model	Data	Model	Data	Model
Q1	NaN	44	7.4	7.2	7.1	6.7	−0.2	−0.4
Q2	122	33	6.7	3.1	7.2	3.6	0.3	0.5
Q3	33	20	5.1	1.6	9	2.5	2.3	0.8
Q4	17	9	5	0.5	5.9	1.7	0.5	1.2
Q5	12	3	1.8	−1.0	2.7	0.5	0.5	1.4
All	16	5	4.1	0.7	5.6	1.8	0.9	0.7

Table 9 reports the statistics for the data (and thus repeats the information from Table 3) together with the model.[au] Recall from the description of Table 9 that for a given variable x (wealth, income, and consumption) and each wealth quintile we compute the quintile average for x in 2004 and the average x for the *same* households[av] in 2006 and then report the annualized percentage difference between the two figures. For the expenditure rates, which are already in percentage units, we compute the annualized percentage point differences between 2004 and 2006.

For net worth, the model captures the fact that in good economic times, wealth-poor households accumulate wealth at a faster rate than wealth-poor households. The percentage increase in wealth for all groups is lower in the model than in the data. We should note that in the data, the 2004–06 period was one of rapid appreciation of house prices and financial asset valuations, whereas in our model the relative price of wealth (capital) is constant at one, and thus an increase in net worth during normal times in the model has to come from net capital accumulation of households.[aw]

In terms of earnings (not reported) and disposable income, the model displays the substantial mean reversion built into the estimates of the idiosyncratic unemployment and earnings process, with income of the lowest wealth quintile rising fast (7.2%) and income of the highest wealth group actually falling (by 1%) even though aggregate incomes do not. This is because low wealth households tend to be low labor earnings and thus low income households with income. As we saw earlier, this is qualitatively consistent with the data, but quantitatively the model implies differences in income growth between the top and the bottom of the wealth distribution that are too large. In other words, the

[au] Since in Tables 9 and 10 the statistics for earnings and disposable income are quite similar, we only report those for disposable income.

[av] These households would typically not be in the same wealth quintile in 2006 as they were in 2004.

[aw] In a model without retirement and thus without life-cycle saving, generating positive changes in net worth for *all* wealth quintiles is of course very difficult; justifying again the inclusion of a basic life cycle element into the economy.

Table 10 Annualized changes in selected variables by net worth in a severe recession: Data vs model

	Net worth (%)		**Disp. *Y* (%)**		**Expend. (%)**		**Exp. rate (pp)**	
NW Q	**Data**	**Model**	**Data**	**Model**	**Data**	**Model**	**Data**	**Model**
Q1	NaN	24	6.7	4.9	0.6	4.5	−4.2	−0.4
Q2	24	15	4.1	0.3	2.0	1.2	−1.3	0.8
Q3	4	8	1.8	−2.4	0.8	0.0	−1.1	2.2
Q4	2	4	1.7	−4.0	−1.7	−1.5	−2.0	3.2
Q5	−5	−1	−1.2	−6.4	−3.7	−3.5	−1.4	4.6
All	−3	1	1.2	−3.7	−1.3	−0.8	−1.6	2.0

model implies slightly too much downward and upward mobility in incomes when households are ranked by wealth.[ax]

Finally, for changes in consumption expenditures, Table 10 reveals that during normal times, as in the data (and as for disposable income), consumption growth is strongest at the low end of the wealth distribution. The wealth gradient of the consumption growth rates (again, as for disposable income), is somewhat steeper in the model. As in the data, the expansion of consumption for households in the lowest (in 2004) wealth quintile falls short of their income growth and thus the expenditure rate of this group falls during normal times. The opposite is true for the wealthiest group of households in the population: as in the data, the expenditure rate of this group expands as the macro economy remains in normal times. The reason for this differential behavior in expenditure rates between the wealth-poor and the wealth-rich is intuitive from the perspective of the model: low wealth households have had, on average, unfortunate earnings realizations and their wealth is below their target wealth. Therefore, these households cut their expenditure to re-build their wealth buffers. The opposite logic applies to households at the top of the wealth distribution. This implication of the model matches the data, although quantitatively, the difference in changes in expenditure rates between the top and the bottom wealth quintiles is a bit larger in the model than in the data.

5.3.2 A Great Recession

After documenting the dynamics of wealth, income, and consumption (ordered by wealth) in normal times, Table 10 displays the same *model* statistics during a period in which the macro economy undergoes a large recession, induced by a transition of aggregate TFP from $Z = Z_h$ to $Z = Z_l$.[ay] To facilitate comparisons between the two tables, we

[ax] Ranking households by earnings or income would make this statement even stronger.

[ay] In the model the Great Recession hits in Q.I, 2009, consistent with our calibration. In that quarter, Z switches from $Z = Z_h$ to $Z = Z_l$ and remains there until Q.III, 2013. The statistics are based on comparing the average of the four 2010 quarters to the average of the four 2008 quarters. In the data, as discussed in Section 2, we consider the period from 2006 to 2010 because of the timing of the income and consumption data. Note that in the data, changes are all annualized.

Table 11 Difference in annualized growth rates between recession period and normal times: Data and Model

	Net worth (%)		Disp. *Y* (%)		Expend. (%)		Exp. rate (pp)	
NW Q	Data	Model	Data	Model	Data	Model	Data	Model
Q1	NaN	−20	−0.7	−2.3	−6.5	−2.2	−4.0	0.0
Q2	−98	−18	−2.6	−2.8	−5.2	−2.4	−1.6	0.3
Q3	−29	−12	−3.3	−4.0	−9.0	−2.7	−3.4	1.4
Q4	−15	−5	−3.3	−4.5	−7.4	−2.8	−2.5	2.0
Q5	−17	−4	−3.0	−5.4	−6.2	−2.9	−1.9	3.2
All	−19	−4	−2.9	−4.4	−6.9	−2.6	−2.5	1.3

display the difference in the growth rates between the recession period and normal times in Table 11.

Again, first focusing on net worth, the key endogenous state variable in our model that underlies the dynamics of all other economic variables, we observe that as in normal times (as in the data), the growth rate of net worth is declining in the level of net worth. And as in the data, the Great Recession significantly slows down the pace of wealth accumulation across all quintiles, and turns it negative for the wealthiest households, although the reduction predicted by the model is smaller than in the data. In the model, the wealth of the top net worth quintile declines by 1%, relative to the 3% growth in normal times. For the same quintile, annual wealth growth in the data slows down from 12% to −5% over a two-year period. As discussed above, in the data a large part of this reduction in wealth at the top of the distribution is likely the consequence of asset *price* movements which are, by construction, absent in the one-asset model studied here.[az]

The two other empirical facts we have documented in Section 2.3 were that income declines in the recession hit the top wealth quintiles more than the bottom quintiles, and that households in the bottom quintiles cut expenditure rates more than households in the top quintiles. Comparing disposable income growth rates in Tables 9 and 10, we observe that the first fact is captured well by the model, at least qualitatively. In the model, the decline in the income growth rate is 2.3 percentage points for the lowest wealth quintile, but 5.4 percentage points for the highest wealth quintile (and the decline is monotonically increasing in wealth in between these two extreme wealth quintiles). In the data, the wealth-poorest 20% of the working-age population see their income growth rate slow down by 0.7 percentage point, whereas for the wealthiest households, income growth slows down by 3.0 percentage points.

In contrast, the performance of the model with respect to the changes in consumption rates is more mixed. In the model, in the recession households all increase consumption

[az] Huo and Rios-Rull (2016) and Kaplan et al. (2016a) investigate the role of price movements in housing in explaining aggregate consumption dynamics in the Great Recession.

by more, or cut consumption by less, than disposable income, resulting in a rise in consumption rates, with the increase in consumption rates being smallest at the low end of the wealth distribution. In the data, all groups instead cut their consumption rates, the more so the less wealthy they are. Thus, although the model is consistent with the relative movement (in the recession vis-á-vis normal times) in consumption rates across wealth levels, with the wealth-poor decreasing consumption rates the most—in the data—or increasing them the least—in the model, the latter overstates consumption growth in the recession and thus underpredicts the decline in expenditure rates evident in the data.

In the model, when the recession hits and thus incomes decline (or grow less) relative to normal times, households have strong incentives to use their wealth to smooth consumption. This is especially true for those falling into unemployment. On the other hand, since the recession is long-lasting and comes with elevated unemployment risk, the motive to engage in precautionary saving against future unemployment spells increases, especially among those with little wealth coming into the recession. For high wealth households, the first motive dominates and the consumption rates of these households increase in the recession, whereas for low-wealth households both motives roughly balance out, leaving consumption rates roughly unchanged across the two time periods. We will show below that in an economy with less generous unemployment insurance, the precautionary savings motive becomes more potent, especially at the low end of the wealth distribution, and low-wealth households indeed cut their consumption rates during recessions, as is the case in the data.

We conclude this section by briefly summarizing the strengths and shortcomings of our baseline model when confronted with the PSID earnings, income, consumption, and wealth data. The model succeeds in replicating the observed cross-sectional wealth distribution (except at the very top) and does well in capturing the salient features of the joint distribution of wealth, income, and expenditures. It also replicates the relative movements of expenditure rates by wealth as the economy falls into a recession. However, it fails to predict the *decline* in consumption expenditure rates during recessions and fails to capture the large movements in wealth we see in the data during the years 2006–10, since it abstracts from asset price movements.

In the next section, we use the benchmark model and some of its variants to quantify the extent to which wealth inequality is important in determining the magnitude of aggregate consumption movements in response to a Great Recession type business cycle shock in TFP.

6. CROSS-SECTIONAL HOUSEHOLD HETEROGENEITY AND THE AGGREGATE DYNAMICS OF CONSUMPTION AND INVESTMENT IN A SEVERE CRISIS

In this section, we argue that the cross-sectional distribution of households across individual characteristics (primarily in wealth and impatience) is a crucial determinant of the aggregate consumption and investment response to a negative business cycle shock. In addition, we show that in the presence of such significant household heterogeneity, the generosity of social insurance policies strongly affects the dynamics of macroeconomic aggregates.

Our focus on the impact of household heterogeneity in wealth for the aggregate consumption dynamics during large recession is shared with a number of recent studies, including Guerrieri and Lorenzoni (2012), Glover et al. (2014), Heathcote and Perri (2015) as well as Berger and Vavra (2015).

When exploring the role that social insurance policies can play in shaping the aggregate consumption (and, in the next section, output) response to adverse business cycle shocks in economies with household heterogeneity we build, on the work by Krusell and Smith (2006), which also focuses on income insurance programs, and more concretely, unemployment insurance.[ba] Our work is also related to McKay and Reis (2016), who conduct a comprehensive study of automatic stabilization programs on business cycle dynamics, to Heathcote (2005), Kaplan and Violante (2014), and Jappelli and Pistaferri (2014), who study the role of discretionary changes in income taxation on aggregate consumption, and Brinca et al. (2016), who investigate the magnitude of aggregate fiscal multipliers in this class of heterogeneous agent models.

6.1 Benchmark Results

We consider two thought experiments, both of which take as an initial condition the wealth distribution after a long sequence of good shocks so that the cross-sectional distribution has settled down. Then a severe recession hits. In the first thought experiment, productivity returns to the normal state $Z = Z_h$ after one quarter (and remains there forever after). Although this thought experiment is not a good depiction of the actual Great Recession because of the short duration of the downturn, it displays the mechanics of the model recession most clearly.[bb] In the second thought experiment, we plot the responses of the economy to a Great Recession of typical length (according to our calibration) that lasts for 5.5 years (22 quarters). In both cases we trace out the impulse response functions (henceforth IRF) for the key macroeconomic aggregates. The main focus of interest is on the extent to which the aggregate consumption and investment responses differ across two economies that differ fundamentally in their extent of household heterogeneity.

To make our main point, we perform both experiments for two model economies: the original Krusell–Smith economy without preference heterogeneity, life-cycle structure, and only modest unemployment insurance, and our benchmark model that includes

[ba] As we do, Auclert (2014), Auclert and Rognlie (2016), and Kekre (2015) also stress the importance of the heterogeneity in the marginal propensity to consume across households for the dynamics of aggregate demand and the impact of redistributive policies. Wong (2015) stresses the heterogeneity in age across households for the transmission of monetary policy shocks to aggregate consumption.

[bb] Of course, households form expectations and make decisions based on the persistent Markov chain for Z driving the model even in this thought experiment.

these features and therefore, as documented above, provides a model wealth distribution that matches its empirical counterpart very well. We will also show that the aggregate consumption and investment behavior over the business cycle in the KS economy approximates an economy with representative agents (RA) very well (as already noted in the original Krusell and Smith (1998) paper), and thus as far as macroeconomic aggregates are concerned, the KS and the RA economy can be treated as quantitatively equivalent.

In Fig. 2, we plot the model impulse response to a onetime negative technology shock in which Z switches to Z_l after a long spell of good realizations Z_h. The upper left panel plots the time series of TFP Z fed into the model, and the remaining sub-plots show the model-implied dynamics of aggregate consumption, investment, and output induced by the Great Recession type TFP shock. By construction the time paths of exogenous TFP Z are identical in both economies in the short run; for output they are identical on impact and virtually identical over time. Since TFP and labor supply are exogenous in both

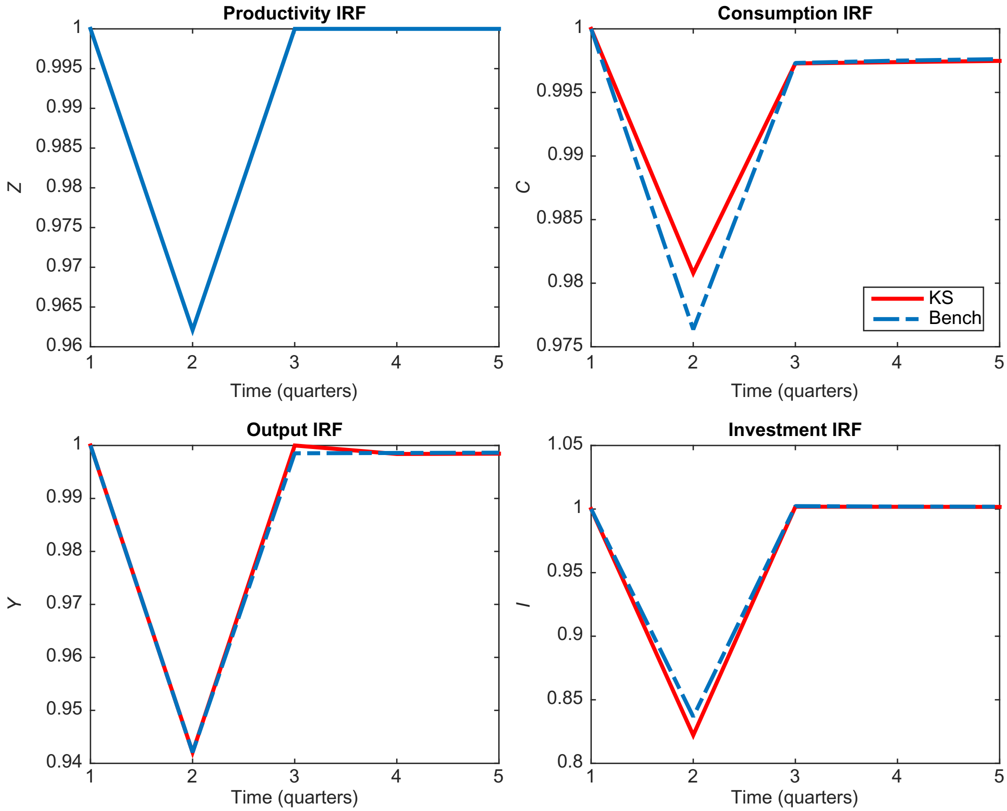

Fig. 2 Impulse response to aggregate technology shock in two economies: One time technology shock.

economies and follow the same time path, capital is predetermined on impact, and the one time shock is not sufficient to trigger a substantially different dynamics of the capital stock, the time path of output is virtually identical in both economies. Thus, the key distinction between both economies is the extent to which a very similar decline and recovery in output is reflected in lower aggregate consumption rather than aggregate investment.

The key observation we want to highlight is that the aggregate consumption (and thus investment) response to the negative productivity shock differs substantially between the two economies. In the benchmark model, consumption falls by 2.4% in response to a technology shock that induces a decline in output by 6% on impact. The same fall in output triggers a decline of only 1.9% in the original Krusell–Smith (labeled as KS) economy. Thus the impact of the recession on aggregate consumption increases by 0.5% percentage points more in the economy with empirically plausible wealth heterogeneity. Given that output is exogenous in the short run, and is used for consumption and investment only in this closed economy, the investment impulse response necessarily shows the reverse pattern: the decline in investment is much weaker in the high wealth inequality economy. This in turn triggers a less significant decline and more rapid recovery of the macro economy once the recession has ended. However, given that new investment is only a small fraction of the capital stock, these differential effects on capital, and thus output, are quantitatively minor, at least in the case in which the recession is short-lived.[bc]

Note that for all practical purposes, in what follows the KS economy displays aggregate consumption-investment dynamics that are very close to those in a representative agent (RA) economy. Fig. 3 shows this fact by displaying impulse responses to a one-period recession shock in the KS and RA economies. Although not identical, the impulse responses are quantitatively very close. For example, the aggregate consumption decline in the RA economy amounts to 1.78%, relative to a fall in aggregate consumption of 1.9% in the KS economy.

In Fig. 4, we display the dynamics of macroeconomic aggregates in a prolonged and severe recession, with a length of 22 quarters, under our operational definition of a severe recession. It demonstrates that in a Great Recession lasting several years, the differences in capital and output dynamics across the low-wealth inequality KS economy and the high inequality benchmark are now more noticeable, especially toward the end of the recession. As a result, the recovery after TFP has turned back up again is substantially stronger in the benchmark economy, by approximately 1 percentage point for capital and 0.3 percentage point for output in the period in which the recession ends.

[bc] In Section C.4, we argue that the fact that the wealth distribution is quantitatively important for the current aggregate consumption response to a TFP shock does not imply that higher moments of the wealth distribution are needed to accurately forecast *future* wages and interest rates.

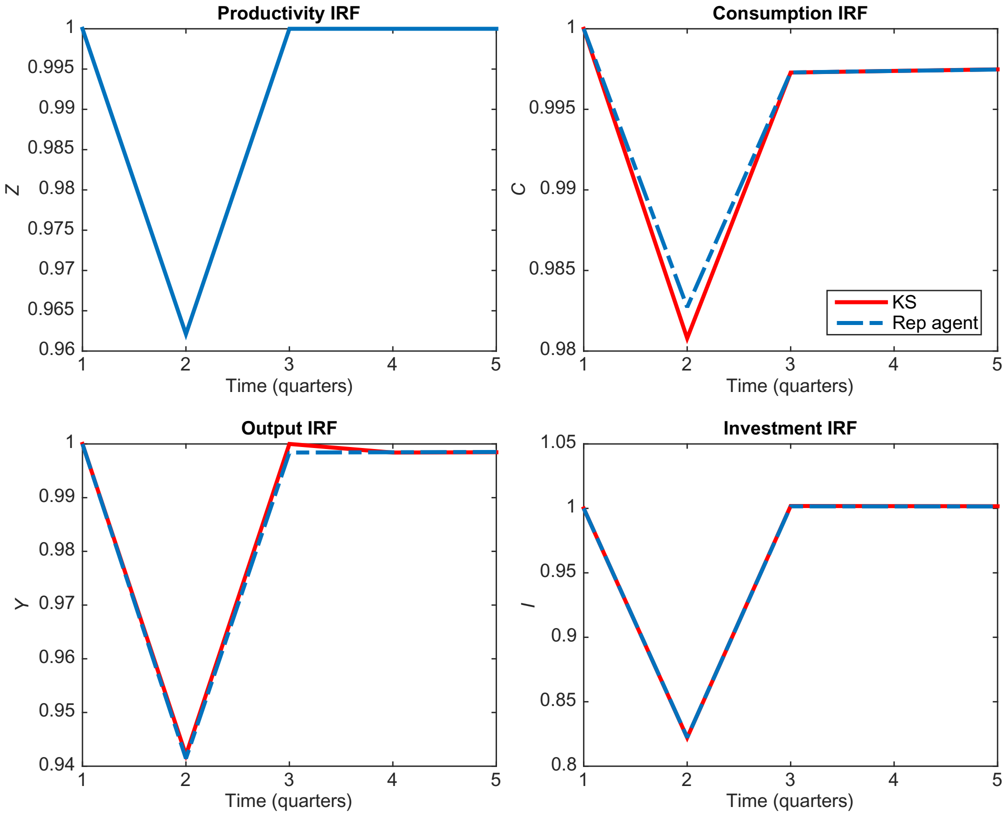

Fig. 3 Impulse response functions (IRF) to aggregate technology shock in KS and RA economies.

Since the KS economy and the benchmark differ along several model dimensions, in the next section we break down the reasons for the differential aggregate consumption response, again focusing on the interaction between the aggregate movement in consumption in a Great Recession and the cross-sectional wealth distribution prior to it.

6.2 Inspecting the Mechanism II: What Accounts for the Size of the Aggregate Consumption Recession

The key finding from the last section is that the aggregate consumption recession in our benchmark economy with preference and realistic wealth heterogeneity is more than twice as deep as it is in the corresponding RA economy (which in turn displays aggregate time series that are very close to those in the original KS economy). In this section, we dissect the reasons behind this finding. To start, in Fig. 5, we display the consumption functions and wealth distributions for both the KS and the benchmark economy. The left panel shows the consumption functions (plotted against individual wealth on the *x*-axis) in the original KS economy for three combinations of idiosyncratic employment

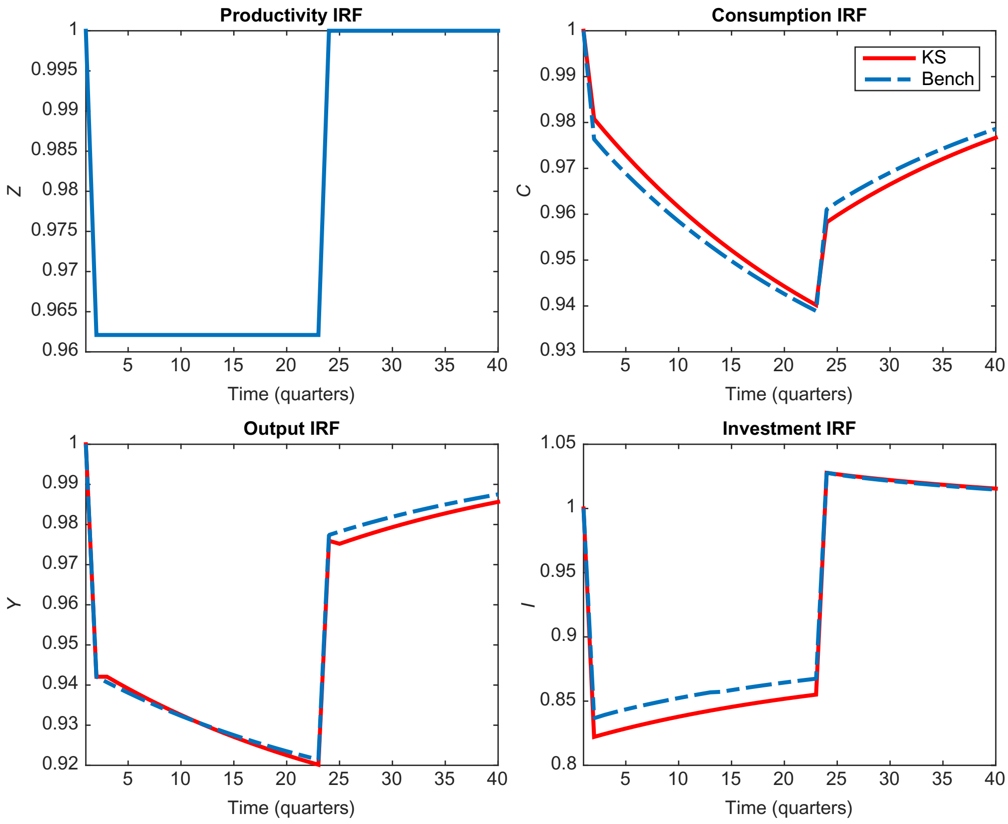

Fig. 4 Impulse response to aggregate technology shock in two economies: "Typical" severe recession technology shock.

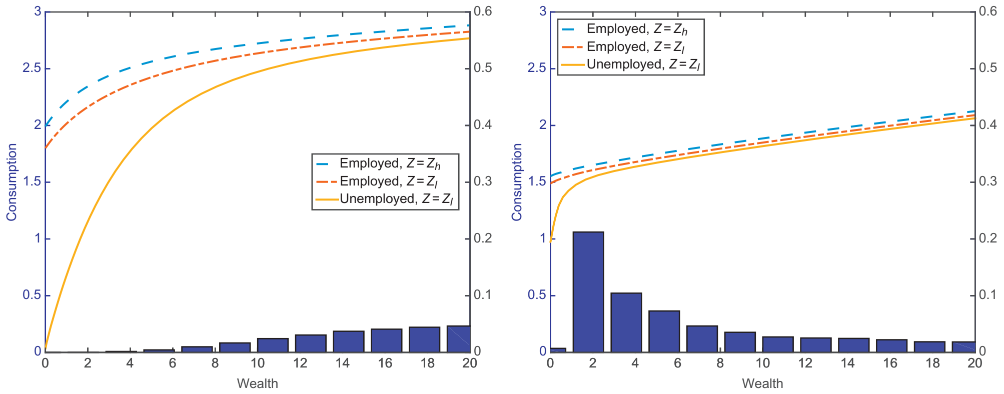

Fig. 5 Consumption function and wealth distribution: Krusell–Smith (left panel) and benchmark (right panel).

and aggregate productivity states. For a given wealth level, the vertical difference between the consumption functions for the employed in aggregate state $Z = Z_h$ (blue dashed line) and the employed in aggregate state $Z = Z_l$ (red dot-dashed line) gives the consumption drop in the Great Recession, conditional on not losing a job. In the same way, the vertical distance between the blue-dashed consumption function and the orange solid consumption function (for the unemployed in the recession) gives the consumption decline for those households that lose their jobs in a recession. The figure also contains the pre-recession wealth distribution, displayed as a histogram, with the mass of a particular wealth bin being measured on the right y-axis.[bd] The right panel displays the same information, but for our benchmark economy, for working-age households with median earnings state y and mean discount factor $\overline{\beta}$.

The first observation we make is that, for a given level of wealth, the drop in individual consumption as the KS economy falls into a Great Recession is substantially *larger* than in our benchmark economy.[be] This is especially true for households with little wealth that lose their jobs at the onset of the recession, because of the virtual absence of unemployment insurance.

The observation of larger individual consumption declines in the KS economy would suggest that the aggregate consumption recession is actually larger than it is in the benchmark economy, in contrast to the result documented in the previous section. However, as Fig. 5 (and Table 6) display clearly, the cross-sectional wealth distribution places almost no mass on households with very little net worth, exactly the households with the largest consumption declines. In contrast, the benchmark model with realistic wealth inequality places substantial probability mass at zero or close to zero wealth where the individual consumption losses are significant, especially (but not only) for newly unemployed households.[bf] Note that average net worth is the same in both economies: we truncate the plots at net worth twenty times average income in order to make the individual consumption declines at the low end more clearly visible, but the benchmark economy has a fat right-tailed wealth distribution that is well approximated by a Pareto distribution (as in the data, see eg, Benhabib and Bisin, 2016), whereas the original KS economy displays a wealth distribution whose right tail more closely resembles that of a log-normal distribution. Thus, both distributions have the same mean even though, as clearly visible from the figure, the benchmark economy has substantially more mass of households at low levels of net worth.

As we will see in Section 6.3, public social insurance programs will affect both the determinants of the aggregate consumption dynamics—the consumption response to

[bd] The aggregate capital stock associated with these plots is the prerecession capital stock; note that both economies, by virtue of the calibration, have the same average (over the cycle) capital stock.

[be] Fig. 5 displays the consumption functions in the benchmark economy for individuals with median (y, β), but the same statement applies, qualitatively, to the consumption functions for households with other (y, β) characteristics. Recall that there is no (y, β) heterogeneity in the original KS economy.

[bf] The wealth distribution in the right panel of Fig. 5 is for the entire working-age population, rather than conditioning on the specific (y, β) types for which the consumption functions are displayed.

aggregate shocks for a given wealth level—and the wealth distribution itself. Both components are crucial when determining the overall impact of unemployment insurance policies on the macro economy over the business cycle. Before turning to this point, we first further explore the precise reasons behind the significant differences in aggregate and distributional characteristics between the original KS economy and our benchmark, thereby pinpointing precisely which model elements (and their interaction) are responsible for the differences in aggregate consumption dynamics across different economies.

Recall that relative to the KS model, our benchmark includes idiosyncratic earnings shocks, a rudimentary life cycle structure with social security system, permanent preference heterogeneity as well as a more generous unemployment insurance system.

In Table 12, we repeat the information from Table 7 on the wealth distribution in different versions of the model, but now we also document the magnitude of the aggregate consumption response on impact in a Great Recession. Fig. 6 displays the associated impulse responses. From the table and figure we observe that the introduction of persistent idiosyncratic income risk on top of unemployment risk significantly amplifies the aggregate consumption response above that of the original KS model. In fact, the magnitude of the aggregate consumption response is larger than that obtained in the benchmark (the second to last column in the table). This is perhaps not surprising given our arguments thus far, as this version of the model generates significantly larger wealth inequality—and importantly—the two lowest wealth quintiles that hold very little net worth.[bg]

Table 12 Net worth distributions and consumption decline: Different versions of the model

	Models*					
% Share:	KS	$+\sigma(y)$	+Ret.	$+\sigma(\beta)$	+UI	KS + Top 1%
$Q1$	6.9	0.7	0.7	0.7	0.3	5.0
$Q2$	11.7	2.2	2.4	2.0	1.2	8.6
$Q3$	16.0	6.1	6.7	5.3	4.7	11.9
$Q4$	22.3	17.8	19.0	15.9	16.0	16.5
$Q5$	43.0	73.3	71.1	76.1	77.8	57.9
90–95	10.5	17.5	17.1	17.5	17.9	7.4
95–99	11.8	23.7	22.6	25.4	26.0	8.8
$T1\%$	5.0	11.2	10.7	13.9	14.2	30.4
Wealth Gini	0.350	0.699	0.703	0.745	0.767	0.525
ΔC	−1.9%	−2.5%	−2.6%	−2.9%	−2.4%	−2.0%

*The KS model only has unemployment risk and incomplete markets, and thus the first column repeats information from table 6. The column $+\sigma(y)$ adds idiosyncratic earnings shocks (transitory and permanent) while employed. The column +Ret. adds the basic life cycle structure (positive probability of retirement and positive probability of death, plus social security in retirement). The column $+\sigma(\beta)$ incorporates preference heterogeneity into the model, and finally the column +UI raises the replacement of the unemployment insurance system from 1% to 50%; the resulting model is therefore the benchmark model, with results already documented in table 6. In all models, the (mean) discount factor is calibrated so that all versions have the same capital-output ratio.

[bg] Note, however, that this mechanism is insufficient to generate the very high wealth concentration, as the examination of the wealth share very top of the wealth distribution reveals.

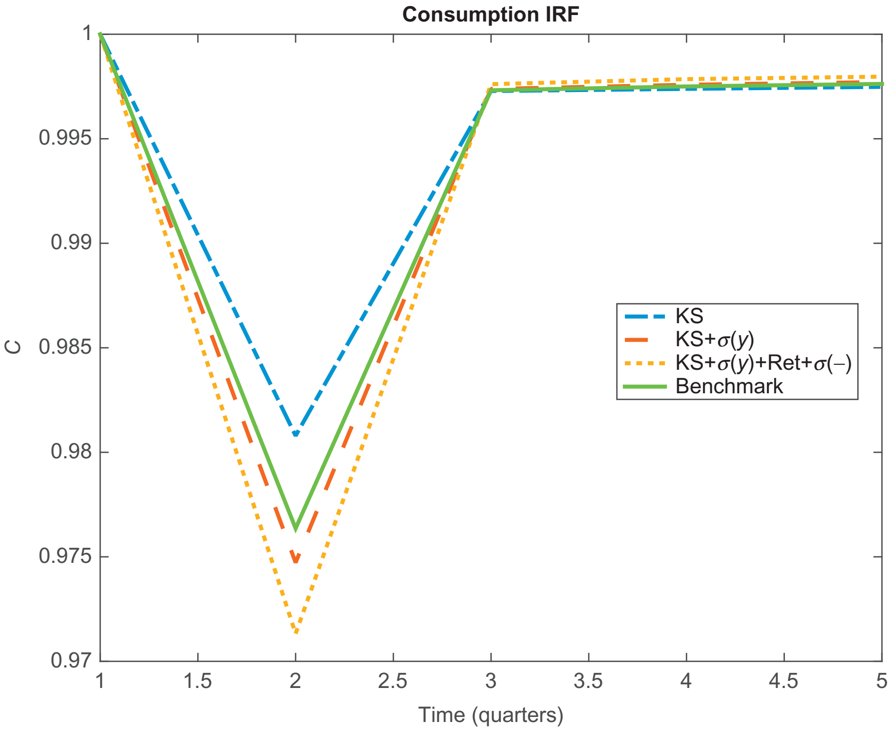

Fig. 6 Consumption recessions in various versions of the model.

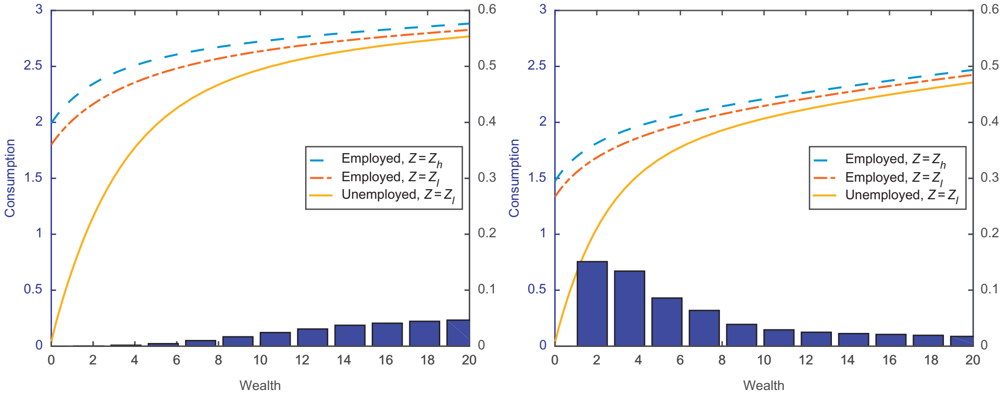

Fig. 7 Consumption function and wealth distribution: KS (left panel) and KS w/income risk (right panel).

Fig. 7 compares the consumption functions and equilibrium wealth distributions in the KS economy and the KS economy with just persistent earnings shocks added. In the latter, the policy functions are displayed for the median y realization. Whereas the consumption policy functions look broadly similar in both economies, the mass of households with low wealth and thus a large consumption response to the recession shock increases very substantially relative to the original KS economy. In this variant, the wealth distribution at the *bottom* looks already quite similar to the benchmark economy, although the absence of significant unemployment insurance implies that the mass of households at exactly zero wealth is negligible. On the other hand, because of the absence of unemployment insurance, the consumption drop of the wealth-poor for a given wealth level is comparable in magnitude to that in the original KS economy.

Fig. 8, which displays the consumption functions and wealth distributions for two different types households in the $KS + \sigma(\gamma)$ economy, clarifies the interaction between earnings inequality and wealth inequality. Households with low current (and very persistent) income realizations are highly concentrated at the low end of the wealth distribution. But even among households with contemporaneous median income, there is significantly more mass in the wealth region where consumption falls substantially upon unemployment.

Moving to the third column of Table 12, we see that although the introduction of life-cycle elements is crucial for delivering joint income-consumption distributions, their impact on the dynamics of aggregate consumption in the recession is limited. In contrast, adding preference heterogeneity to the model helps to amplify the consumption drop. Crucially, now the economy is populated by a share of highly impatient households at the bottom of the wealth distribution. In normal times, unemployment risk is low and these households consume at a high rate because of their impatience, ending up with little or no wealth. When the economy falls into the recession, idiosyncratic unemployment risk goes up significantly for the "foreseeable future" from the point of view of impatient households. Faced with the elevated chance of becoming unemployed,

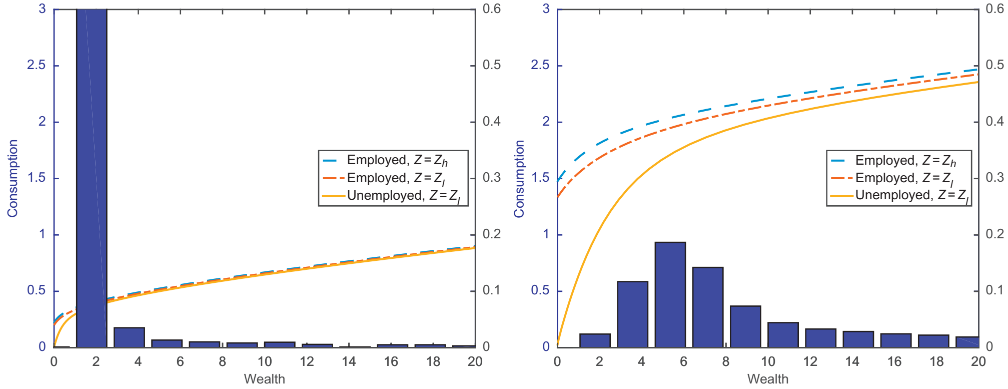

Fig. 8 Consumption function and wealth distribution: KS low income (left panel) and KS median income (right panel).

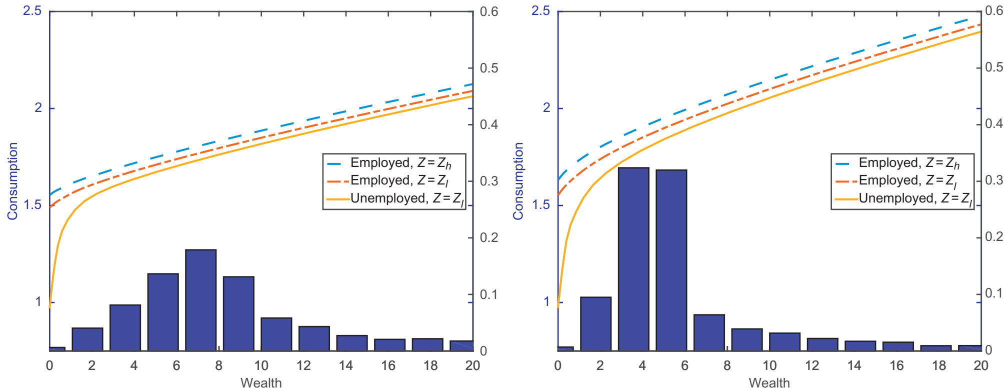

Fig. 9 Consumption function and wealth distribution: Patient households (left panel) and impatient households (right panel).

impatient households who have not yet lost their jobs and have currently medium to high income realizations start to save more for precautionary reasons.[bh]

For more patient employed households, the increase in precautionary saving and resulting drop in consumption at the onset of the recession is not quite as severe. These households were already saving a larger fraction of their income even in good times, since their patience makes them more focused on the long horizon. Because the persistent idiosyncratic income component is more persistent than the recession, patient households with high current income expect to have high income even when exiting the recession, so the short-run possibility of increased unemployment is not as big of a concern to them.

Fig. 9 displays the consumption policy functions for patient and impatient households, as well as the wealth distribution among these households. The key observation is that consumption falls more pronouncedly for impatient households when the aggregate state turns bad, even conditional on *not* losing a job. Also, not unexpectedly, among impatient households wealth levels tend to be lower, as the group-specific wealth distributions underneath the consumption functions in Fig. 9 show. As a broad summary measure of this differential effect, the contribution to the aggregate decline in consumption is more than twice as large for the most impatient group of households than for the most patient group, even though that they constitute equal shares of the population.

In the aggregate, the decline in aggregate consumption in the economy with income and preference heterogeneity amounts to 2.9%, and is thus a full 1 percentage point larger than in the KS economy, and 1.11% larger than in the representative agent economy. Both dimensions of heterogeneity are quantitatively important for the magnitude of the aggregate fluctuations, and so is their interaction, as the previous discussion of the importance of the impatient, employed with high income has indicated.

[bh] The small share of impatient, low-wealth households that do in fact lose their jobs at the onset of the recession behave like hand-to-mouth consumers instead, cutting their consumption one for one with income, and consume whatever little wealth they might have at the beginning of the recession.

Finally, the second to last column of Table 12 raises the unemployment insurance replacement rate to our benchmark value of 50%. As we discuss and quantify in the next part of the chapter, Section 6.3, this change in the generosity of social insurance has a two-fold impact on the economy: for a given wealth level it softens the decline in household consumption in the recession, but it also shifts the wealth distribution toward wealth levels that imply a large decline in consumption and thus make the recession more costly in welfare terms. The first effect reduces the aggregate consumption response to the Great Recession shock, the second magnifies it. As Table 12 shows, the net effect is a reduction of aggregate consumption volatility (with a decline of 2.4%), bringing the implications of the benchmark economy closer to that of the RA and KS economies with absent or limited wealth heterogeneity.

To summarize the main lessons from this section, the key aspects of the benchmark model that make its implied consumption dynamics different from its RA counterpart in a quantitatively meaningful way are (a) an equilibrium wealth distribution that makes the wealth-poor poor enough and has them cut consumption more significantly than the average household when the recession hits; and (b) that these wealth-poor households make up a significant share of aggregate consumption. These requirements are achieved through highly persistent income shocks that generate a set of households that are born wealth-poor and never accumulate much wealth, and are compounded by the presence of impatient households that do not want to accumulate much wealth. If these households do not have access to generous unemployment insurance, their consumption falls a lot more than that of the representative household in a recession, either because they have in fact lost their jobs (and the incidence of job loss is higher in recessions), or because they have not lost their job, but have cut consumption to hedge against a now more likely job loss in the future.

Preference heterogeneity produces not only impatient households with the characteristics discussed thus far, but also patient households that find it optimal to accumulate large amounts of wealth, thereby contributing significantly to wealth inequality. However, it is the lack of wealth at the bottom, as opposed to significant concentration at the very top, that is crucial for explaining aggregate consumption dynamics. To make this point sharply, we consider a version of the model that is identical to the original KS model but adds limited preference heterogeneity. Specifically, it constructs a model in which 99% of the population has a lower time discount factor β_l than the remaining 1% of the population. The two discount factors are chosen to match the capital-output ratio in the benchmark economy (which essentially pins down β_l) and the share of wealth held by the top 1%–30%–as in the PSID data (whereas in the benchmark economy, we match the capital-output ratio and the wealth Gini). This pins down the time discount factor β_h of the remaining 1% of the population.

The purpose of this economy is to evaluate the importance of the wealth concentration at the very top of the distribution for the aggregate consumption decline in a Great Recession (and to demonstrate that it is straightforward, with appropriate preference heterogeneity in time discount factors, to generate a wealth distribution as concentrated at the top as it is in the data). The wealth distribution and aggregate consumption decline from this version of the model are reported in the last column of Table 12. Since consumption functions are approximately linear for households with above-median wealth, and the individual consumption *drop* in a recession is roughly invariant to net worth at that level, it does not matter much *for aggregate consumption dynamics* if the top of the wealth distribution is populated by 1% of astronomically wealthy households, or by 20% of merely super rich households. Consequently, the consumption response is roughly the same in this variant of the model and in the original KS economy (and the RA economy for that matter).

6.2.1 The Importance of Precautionary Saving vs "Hand-to-Mouth" Consumers

Given the importance we assigned to households with *little net worth* in our discussion above, in this section we briefly ask whether a model with a *fixed* fraction of households κ that always have zero wealth and thus simply consume their income in every period has the same implications for the consumption dynamics as our benchmark model.[bi]

We have resolved our model under the assumption that the bottom $\kappa = 40\%$ of the wealth distribution in model period $t-1$ just consumes their earnings and unemployment benefits (if applicable) from period t on, whereas the remainder of the distribution (in period $t-1$) continues to follow the intertemporally optimal decision rules from the benchmark economy.

The drop of consumption in a one-period Great Recession now amounts to 2%, relative to the decline in the benchmark economy of 2.4%. The drop is larger in the benchmark economy since households at the bottom of the wealth distribution on average (and especially those not currently unemployed) find it optimal to *reduce* consumption rates for precautionary reasons: the Great Recession is expected to last a long time, and those not yet affected by a job loss try to build a buffer to hedge against the increased risk of being laid off in the future.[bj] This precautionary saving motive in the face of increased idiosyncratic risk in recessions, also discussed lucidly in a recent paper by McKay (2015), is absent among households that follow a mechanical hand-to-mouth consumption rule and is

[bi] This question is interesting from a modeling perspective since a model in which a fixed fraction of hand-to-mouth households and the remaining fraction employs permanent income consumption and savings functions (which are linear in wealth with identical marginal propensities to consume out of wealth, given our model) would give rise to easy aggregation.

[bj] In the versions of the model studied here, labor supply is exogenous (but its productivity fluctuating over the cycle), and thus saving is the only possible household response to hedge against higher idiosyncratic risk. In models with endogenous labor supply choice, such as the ones studied in Chang and Kim (2007) and Athreya et al. (2015), households have another margin of adjustment and thus the impact of elevated risk on precautionary saving will be smaller. For a model that combines household precautionary saving and *frictional* labor markets, see Krusell et al. (2010).

responsible for the deeper recession in the benchmark economy.[bk] We will return to this point in the next section, where we study the impact of the generosity of unemployment insurance on our results, and will show that with less generous unemployment insurance benefits, the additional precautionary savings motive from elevated unemployment risk is more potent, and the divergence between the class of models studied here and hand-to-mouth consumer models is even more significant.

It is important to note that in our formulation the share of households that behave as hand-to-mouth consumers is exogenous. In recent work Kaplan and Violante (2014) and Bayer et al. (2015) construct models with wealthy hand-to-mouth consumers where a share of households endogenously choose to behave like hand to mouth consumers despite having non-trivial net worth. However, since their net worth is primarily in the form of assets that are costly to liquidate (think of owner-occupied real estate and tax-favored retirement accounts), the consumption behavior of this group of households approximates that of the hand-to-mouth consumers modeled here, especially for income shocks of moderate magnitude.

6.3 The Impact of Social Insurance Policies

In this section, we ask how the presence of public social insurance programs affects the response of the macro economy to aggregate shocks in a world with household heterogeneity.[bl] We focus specifically on the effects of government-provided, and tax-financed unemployment insurance. We will argue that the impact of this policy is two-fold: it changes the consumption-savings response of a household with a *given* wealth level to income shocks, and it changes the cross-sectional wealth distribution in society, at least in the medium to long run. In order to decompose the overall impact of social insurance into these two effects, we consider two thought experiments. In the first, we simply compare the dynamics of macroeconomic aggregates of the benchmark economy with that of an identical economy that has a lower unemployment insurance replacement rate of $\rho = 10\%$. We interpret the latter economy as providing basic social insurance (as embedded in basic welfare programs), or alternatively, as a world where a significant share of households do not claim unemployment benefits despite being entitled to it.[bm] This thought

[bk] Obviously, the magnitude of this effect depends on the share of hand-to-mouth consumers κ. In the limit, as $\kappa = 0$ we are back in the benchmark economy. For $\kappa = 20\%$ the fall in aggregate consumption is 2.1%, about halfway between the RA economy and the benchmark.

[bl] The purpose of this analysis is purely positive in nature, and limited in scope by the assumption that transitions between employment and unemployment are exogenous and thus policy-invariant. See Hagedorn et al. (2013) and Hagedorn et al. (2015) for an analysis of the effects of unemployment benefit extensions on vacancy creation and employment.

[bm] We prefer to model a replacement rate of $\rho = 10\%$ rather than $\rho = 1\%$ as in the original Krusell–Smith economy studied in the previous section, since we think $\rho = 10\%$ is a more empirically relevant case. The resulting macro effects will lie right in between that of the benchmark economy, and the economy with a replacement rate of $\rho = 1\%$ displayed in the forth column (the $\sigma(\beta)$ economy) of Table 12.

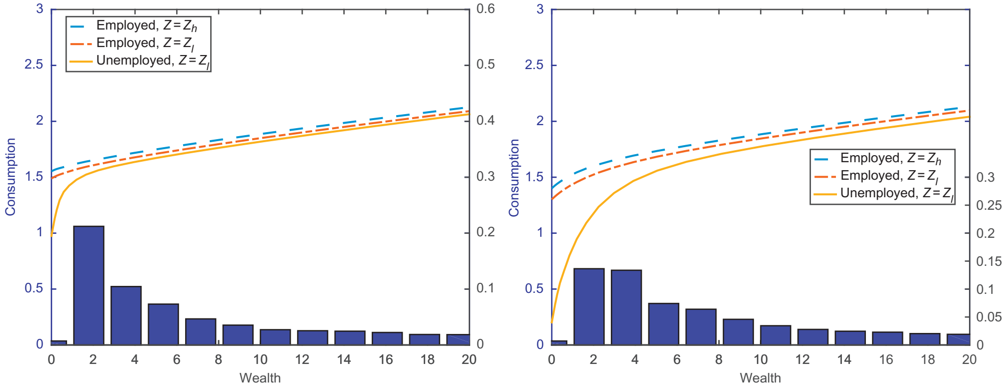

Fig. 10 Consumption function and wealth distribution: Benchmark (left panel) and low UI (right panel).

experiment will encompass the effect of unemployment insurance both on individual consumption behavior as well as on the equilibrium wealth distribution. To isolate the former effect, we will also consider an economy with low unemployment insurance, but entering the recession with the *same pre-recession wealth distribution* as in the benchmark economy.[bn]

In the left panel of Fig. 10, we plot, against wealth, the consumption functions (for the unemployed in the low and the employed in the high aggregate shock, with the mean discount factor) as well as the wealth histogram in the benchmark economy (with a replacement rate of 50%). This was the right panel of Fig. 5. The right panel of Fig. 10 does the same for an economy with an unemployment insurance system of only 10%. We chose to display the consumption function for the employed in an expansion and the unemployed in a recession because this helps us to best to understand what drives the aggregate consumption impulse response below.[bo]

We want to highlight three observations. First, in the high unemployment insurance economy, households with low wealth consume much more than in the economy with small unemployment insurance. Second, and relatedly, the decline in consumption for low-wealth households from experiencing a recession with job loss is much more severe in the low-benefit economy. Third, the size of the social insurance system however, by affecting the extent to which households engage in precautionary saving, is a crucial determinant of the equilibrium wealth distribution. In the benchmark economy (as in the data), a sizeable mass of households has little or no wealth, whereas in the no-benefit economy this share of the population declines notably. Specifically. average

[bn] One can interpret this thought experiment as a surprise permanent removal (or a surprise failure of extension) of unemployment benefits exactly in the period in which the recession hits.

[bo] Setting $\rho = 0$ would create the problem of zero consumption in some of the decomposition analyses we conduct later on.

assets increase by 0.5% relative to the benchmark economy, and only 0.9% of the population holds exactly zero assets, relative to 3.1% in the benchmark economy.

The difference in the consumption decline in a recession across the two economies can then be decomposed into the differential consumption response of households, integrated with respect to the *same* cross-sectional wealth distribution (which is a counterfactual distribution for one of the two economies), and the effect on the consumption response stemming from a policy-induced difference in the wealth distribution coming into the recession. As it turns out, both effects (the change in the consumption functions and the change in the wealth distribution) are quantitatively large, but partially offset each other.

In order to isolate the first effect, we now plot, in Fig. 11, the recession impulse response for the benchmark economy and the economy with low unemployment insurance, but starting at the *same pre-recession wealth distribution* as in the benchmark economy. Under this fixed wealth distribution scenario, the consumption response in both cases is

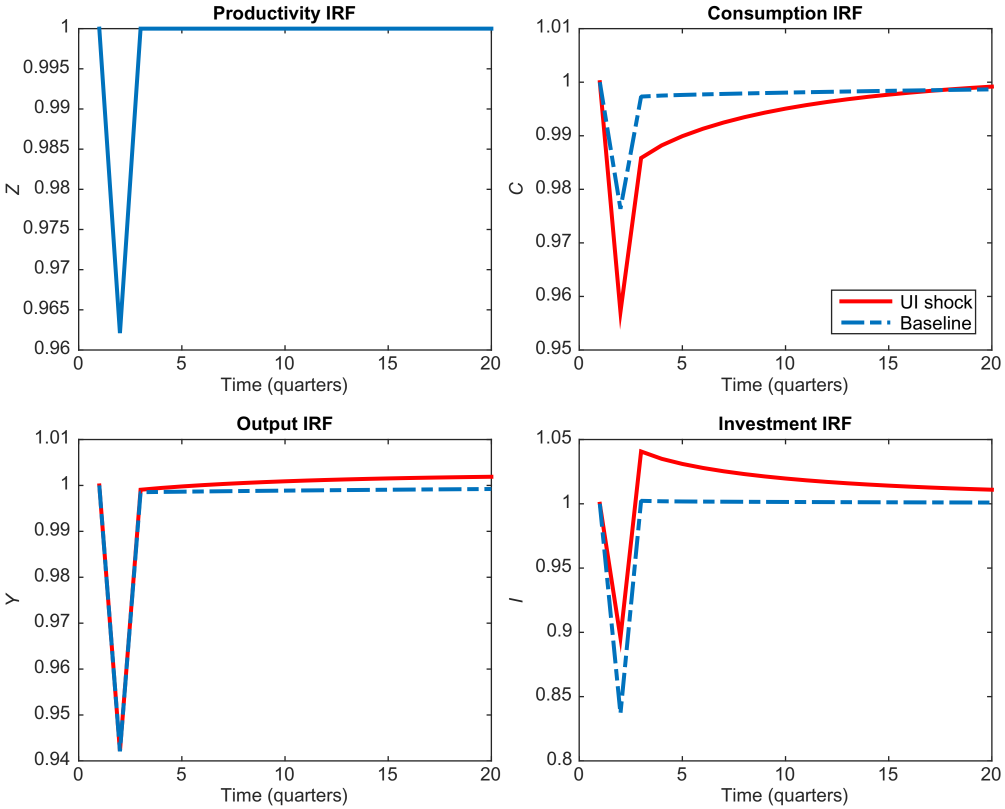

Fig. 11 Impulse response to aggregate technology shock with and without generous unemployment insurance, fixed wealth distribution: Onetime technology shock.

given by the difference in the consumption functions (in both panels) integrated with the wealth distribution of the high UE insurance economy. We find that consumption declines much more substantially in the economy with a low replacement rate, by 4.6%, relative to 2.4% in the benchmark economy. This is, of course, exactly what the consumption functions in Fig. 10 predict.

To further quantify what drives this differential magnitude in the consumption response, in Table 13, we display the fall in consumption for four groups in the population that differ in their transitions between idiosyncratic employment states as the aggregate economy slips into a recession. The share of households undergoing a specific transition is exogenous and the same across both economies, and is given in the second column of the table. Most (88.1%) households retain their jobs even though the aggregate economy turns bad. In contrast, the fraction of households making the transition from employment to unemployment is only 6.6% (and 3.5% of households make the reverse transition), but based on the consumption functions we expect them to display the largest decline in individual consumption.

The aggregate consumption decline documented in the last row of Table 13 corresponds to the impulse responses of Fig. 11. The rows above give the share of the consumption decline accounted for by each of the four groups, so that the sum of the rows adds up to 100%. Similarly, Table 14 summarizes the percentage consumption decline of each of the four groups and gives, in the second column, the prerecession population shares of each of these four groups.

Table 13 Consumption response by group in three economies: Share of total decline

Transitions	Pop. share	ρ = 50%, $\Phi^{\rho=0.5}$	ρ = 10%, $\Phi^{\rho=0.5}$	ρ = 10%, $\Phi^{\rho=0.1}$
$s=e, s'=e$	88.1%	79.8%	72.8%	71.6%
$s=e, s'=u$	6.6%	13.8%	18.5%	21.8%
$s=u, s'=e$	3.5%	2.5%	2.9%	0.3%
$s=u, s'=u$	1.8%	3.8%	5.8%	6.3%
Total decline	100%	−2.4%	−4.6%	−2.7%

Table 14 Consumption response by group in three economies: Consumption growth rates of different groups

Transitions	Pop. share	ρ = 50%, $\Phi^{\rho=0.5}$	ρ = 10%, $\Phi^{\rho=0.5}$	ρ = 10%, $\Phi^{\rho=0.1}$
$s=e, s'=e$	88.1%	−1.5%	−2.3%	−1.5%
$s=e, s'=u$	6.6%	−3.5%	−7.6%	−6.1%
$s=u, s'=e$	3.5%	−1.2%	−2.3%	−0.0%
$s=u, s'=u$	1.8%	−3.5%	−8.8%	−6.8%
Total decline	100%	−2.4%	−4.6%	−2.7%

From both tables we observe that, even though the share of households that become newly unemployed (6.6% of the population, $s=e, s'=u$) and remain unemployed (1.8% of the population, $s=u, s'=u$) is relatively small, these groups account for a disproportionately large fraction of the overall consumption collapse in both the economy with generous, and in the economy with modest unemployment insurance.[bp] See columns 3 and 4 of Table 13 (which are based on the same prerecession wealth distribution).

These two groups of households make up 8.4% of the population, but in the benchmark economy (column 3, Table 13) account for 17.6% of the consumption drop. Carrying out the same decomposition for the economy with a small unemployment insurance system (column 4, Table 13) we observe that the total drop in consumption is about twice as large now, as already displayed in the impulse response plot. Now the (newly and existing) unemployed have significantly larger percentage consumption drops (see the fourth column of Table 14) and the share of the (now larger) consumption drop rises to 24.3%. Of course, the more pronounced consumption drop of the unemployed in a low UI benefit environment (and holding the wealth distribution fixed) is exactly what one would expect, and is already apparent in the policy functions of Fig. 10.

Table 14 contains a second important observation that we wish to stress. Looking at the magnitude of the consumption drops of households that have *not yet* lost their jobs as the economy falls into the recession (households with the idiosyncratic state transitions $s=u, s'=e$ and $s=e, s'=e$), we observe that these households, which constitute the vast majority of the population, also cut their consumption much more significantly in the (surprise) low-benefit economy, again comparing columns 3 and 4 of Table 14. This is true even though these groups in both economies start with the same wealth distribution (by construction of the thought experiment) and experience the same income loss coming from a modest decline in aggregate wages. The lower UI benefits do not have an immediate impact on the earnings of these households, since they are currently employed even though the macro economy is doing poorly. The larger cuts in consumption of these groups instead emerge because future unemployment risk has gone up for these households as the economy falls into the highly persistent recession, and the potential future income losses from unemployment are larger in the economy with low unemployment insurance. Employed households, especially those with little new worth to start with, respond by elevating their saving and cutting their consumption rates, and since employed households make up 91.6% of the population, the extra fall in consumption of about 1 percentage point (in the economy with low UI, relative to the economy with high UI) is an important contributor to the overall larger decline of aggregate consumption in the low UI economy.

[bp] For a recent empirical study on the link between unemployment and consumption expenditures, see Ganong and Noel (2015), who find reductions in consumption expenditures that are quantitatively similar to the ones our model with low unemployment insurance predicts.

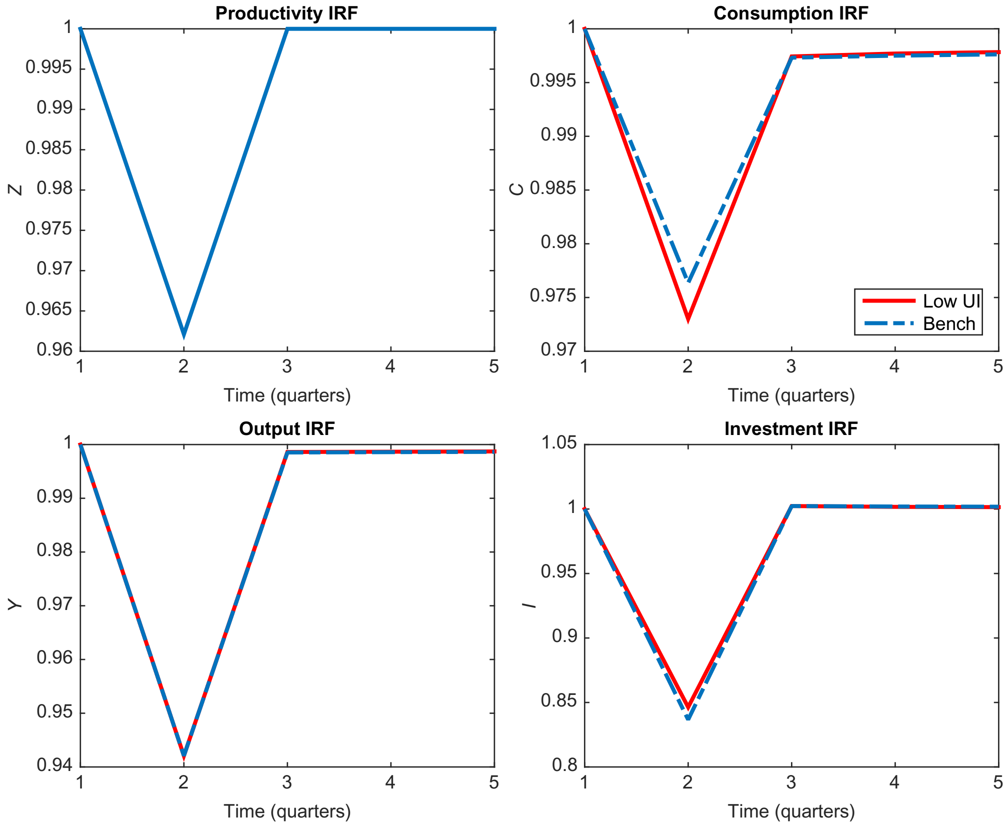

Fig. 12 Impulse response to aggregate technology shock with and without generous unemployment insurance: Onetime technology shock.

Finally, we document what happens if the wealth distribution is determined endogenously and responds to the absence of an unemployment insurance system. Fig. 12 displays the impulse responses for the benchmark economy (again) and the no-benefits economy with a prerecession wealth distribution that emerges in *that economy* after a long period of economic prosperity.[bq] Column 5 of Tables 13 and 14 breaks down the consumption response by subgroups. Overall we observe that the endogenous shift in the wealth distribution to the right that is due to the less generous unemployment insurance partially offsets the larger individual consumption declines in the no-benefits economy for a given wealth level.

To see this more precisely, compare the third and fifth columns of Table 14. The aggregate consumption decline in the economy with little unemployment insurance is somewhat larger than in the benchmark economy (by 0.3 percentage point). But very

[bq] That wealth distribution was displayed in the right panel of Fig. 10.

notably, in this economy the unemployed (both newly and already existing ones) account for a substantially larger share of the reduction in consumption, even though this group understands the possibility of a Great Recession and has access to self-insurance opportunities to prepare for it. This is primarily because the employed, now fully aware of the fact that unemployment benefits will be low if they happen to become unemployed in the recession, enter the recession with larger wealth levels and do not cut their consumption as much as when they were surprised by the expiration of their benefits (compare columns 4 and 5 in Table 14 for the employed, $s' = e$). Thus, all of the larger magnitude of the aggregate consumption decline with low UI benefits is driven by the small group of unemployed (compare columns 3 and 5 of Table 14). The end effect is an aggregate consumption decline of 2.7% that is somewhat larger, but broadly consistent with that in the benchmark economy even though *individual consumption* responses to the crisis differ markedly across the two economies for the unemployed.

6.3.1 Revisiting the Importance of "Hand-to-Mouth" Consumers

In the absence of a generous unemployment insurance system, not only is the decline in aggregate consumption larger, as the previous section has argued, but the wealth-poor, not yet unemployed households have a greater incentive to save for now more likely unemployment spells. As such, our economy with low replacement rate responds to aggregate shocks more strongly, relative to an economy with hand-to-mouth consumers, than the benchmark economy with $\rho = 50\%$. Recall that with $\rho = 50\%$ the aggregate consumption decline was 2.4%, relative to a fall of 2% in an economy with 40% hand-to-mouth consumers. With $\rho = 10\%$, the fall amounts to 2.7% in our economy and 2.1% in the hand-to-mouth consumer economy, and thus the divergence between the two models becomes stronger, on account of the elevated importance of the precautionary savings behavior of the wealth-poor, which is absent in models with exogenously given fixed shares of hand-to-mouth consumers. The recent papers by Ravn and Sterk (2013), McKay (2015), and Den Haan et al. (2016) are important examples that have stressed the importance of precautionary savings in the face of increased idiosyncratic risk for the dynamics of macro aggregates.[br]

7. INEQUALITY AND AGGREGATE ECONOMIC ACTIVITY

In the model studied so far, the wealth distribution did potentially have an important impact on the dynamics of aggregate consumption and investment, but—by construction—only a fairly negligible effect on aggregate economic activity. Output depends on capital, labor input, and aggregate TFP, and in the previous model the latter two are exogenously given.

[br] In related work Harmenberg and Oberg (2016) analyze the dynamics of consumption expenditures on durables in the presence of time-varying income risk.

The capital stock is predetermined in the short run, and even in the medium run only responds to net investment, which is a small fraction of the overall capital stock. So the output response to a negative productivity shock is exogenous on impact and, to a first approximation, exogenous (to the wealth distribution and to social insurance policies) even in the medium run. That is why in the previous section we focused on the distribution of the output decline between aggregate consumption and investment.

In the models discussed so far, aggregate demand played no independent role in shaping business cycle dynamics and, by construction, government demand management is ineffective. We now present a version of the model in which the output response to a negative shock is endogenous even in the short run, and thus potentially depends on the wealth distribution in the economy as well as policies that shape this distribution. The model retains the focus on real, as opposed to nominal, factors.[bs]

The aggregate production function continues to be given by

$$Y = Z^{*} F(K, N)$$

with $Z^{*} = ZC^{\omega}$ and $\omega > 0$,
but now consider a world in which $\omega > 0$ and thus TFP $Z^{*} = ZC^{\omega}$ endogenously responds to the level of aggregate demand. A decline in aggregate consumption triggered by a fall in Z and an ensuing reduction of aggregate wages and household incomes endogenously reduces TFP and thus output further. This model with aggregate demand externalities is in the spirit of Bai et al. (2012), Huo and Rios-Rull (2013), and Kaplan and Menzio (2014), who provide micro foundations for the aggregate productivity process we are assuming here.[bt]

Since in this model a reduction in aggregate consumption C (say, induced by a negative Z shock) feeds back into lower TFP and thus lower output, government "demand management" might be called for, even in the absence of incomplete insurance markets against idiosyncratic risk. A social insurance program that stabilizes consumption demand of those adversely affected by idiosyncratic shocks in a crisis might be desirable not just from a distributional and insurance perspective, but also from an aggregate point of view. In the model with consumption externalities, in addition to providing consumption insurance it increases productivity and accelerates the recovery.[bu]

[bs] In this chapter we abstract completely from nominal frictions that make output partially demand-determined. Representative papers that contain a lucid discussion of the demand- and supply-side determinants of aggregate *output* fluctuations in heterogeneous agent New Keynesian models are Gornemann et al. (2012), Challe et al. (2015), and Kaplan et al. (2016b).

[bt] We are certainly not claiming that our and their formulations are isomorphic on the aggregate level; rather, their work provides the fully micro-founded motivation for the reduced form approach we are taking in this section.

[bu] We think of this model as the simplest structure embedding a channel through which redistribution affects output directly and in the short run.

We now first discuss the calibration of the extended model before documenting how the presence of the demand externality affects our benchmark results.

7.1 Calibration Strategy

We retain all model parameters governing the idiosyncratic shock processes (s, y), but recalibrate the *exogenous* part of aggregate productivity Z. In addition we need to specify the strength of the externality ω. Our basic approach is to use direct observations on TFP to calibrate the exogenous process Z and then choose the magnitude of the externality ω such that the demand externality model displays the same volatility of output as the benchmark model which (as the reader might recall) was calibrated to match the severity of the two severe recession episodes we identified in the data.[bv]

7.1.1 Exogenous TFP Process Z

For comparability with the benchmark results, we retain the transition matrix $\pi(Z'|Z)$ but recalibrate the states (Z_l, Z_h) of the process. To do so, we HP-filter the Fernald (2012) data for total factor productivity, identify as severe recessions the empirical episodes with high unemployment as in the benchmark analysis, and then compute average TFP (average percentage deviations relative to the HP-trend) in the severe recession periods, identified from unemployment data, as well as in normal times. This delivers

$$\frac{Z_l}{Z_h} = \frac{1-1.84\%}{1+0.36\%} = 0.9781.$$

Thus, the newly calibrated exogenous TFP process is significantly less volatile than in the benchmark economy, where the corresponding dispersion of TFP was given by $\frac{Z_l}{Z_h} = 0.9614$.

7.1.2 Size of the Spillover ω

Given the exogenous TFP process, we now choose ω such that the externality economy has exactly the same output volatility as the benchmark economy. This requires $\omega = 0.30$.

7.2 Results

7.2.1 Aggregate Dynamics

In Fig. 13, we display the dynamics of a typical Great Recession (22 quarters of low TFP) in both the baseline economy and the demand externality economy (labeled

[bv] An alternative approach would have been to retain the original calibration of the Z process, choose a variety of ω values, and document how much amplification, relative to the benchmark model, the externality generates. The drawback of this strategy is that output is counterfactually volatile in these thought experiments unless $\omega = 0$.

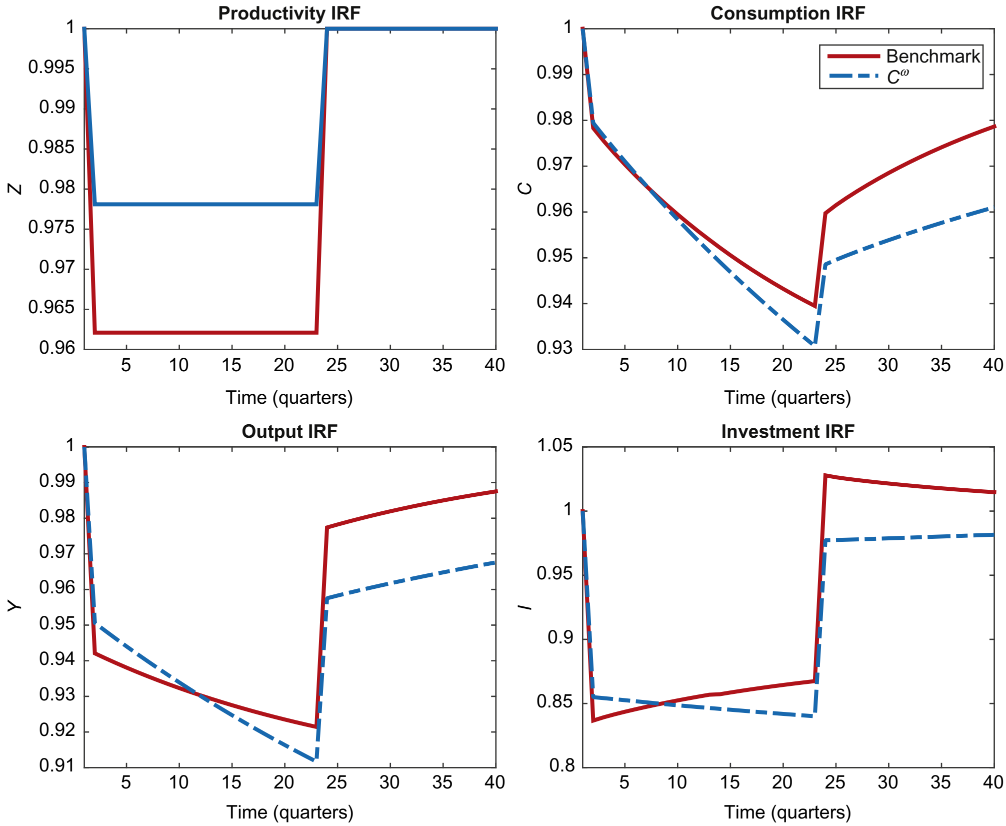

Fig. 13 Impulse response to aggregate technology shock: Comparison between benchmark and demand externality economy.

C^{ω}).[bw] The upper left panel shows that, as determined in the calibration section, a significantly smaller exogenous shock (2.2% as opposed to a 3.9% fall in TFP) is needed in the externality economy to generate a decline in output (and thus consumption and investment) of a given size. The impulse response functions are qualitatively similar in both economies, but with important quantitative differences.

First, the average decline in output in a Great Recession is the same across both economies since this is how $\frac{Z_l}{Z_h}$ was calibrated in the externality economy. However, since aggregate consumption declines during the course of a Great Recession and aggregate consumption demand impacts productivity, the decline in output is more pronounced and the recovery slower in the externality economy. Thus, the consumption externality

[bw] The figure for a one-quarter Great Recession is qualitatively similar, but less useful in highlighting the differences between both economies.

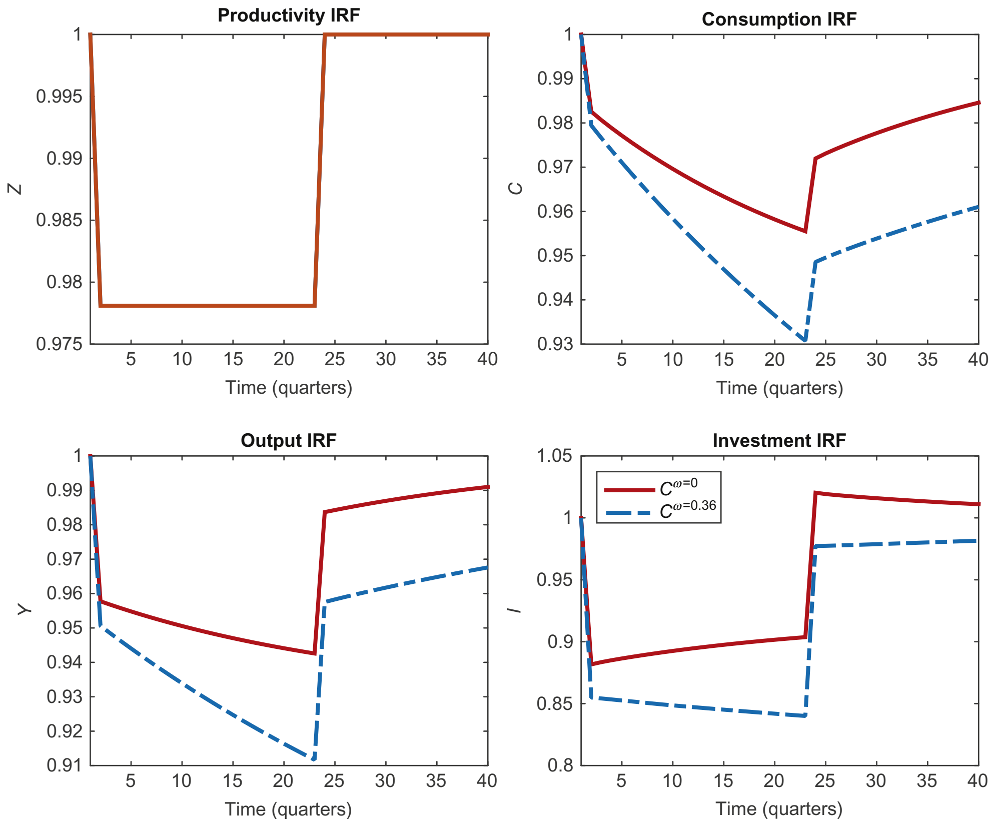

Fig. 14 Impulse response to identical aggregate technology shock: Comparison between economies with and without demand externality.

adds endogenous persistence to the model, over and above the channel already present through endogenous capital accumulation.

Of course, the demand externality mechanism also adds endogenous volatility to the model, but the fact that, via calibration, both models have the same output volatility obscures this fact. In Fig. 14, we display the magnitude of this amplification by comparing the impulse responses in two economies with the *same* exogenous TFP process (the one recalibrated for the demand externality economy), but with varying degrees of the externality ($\omega = 0$ and $\omega = 0.30$).

In contrast to Fig. 13, now the differences in the dynamics of the time series are purely driven by the presence of the demand externality. The amplification of the exogenous shock is economically important: the initial fall in output, consumption and investment is substantially larger (5.0%, 2.1% and 14.5% versus 4.2%, 1.7% and 11.8%, respectively). In addition, and consistent with Fig. 13, these larger output and consumption losses are more persistent in the economy with negative feedback effects from aggregate demand on productivity and thus production.

7.2.2 On the Importance of the Wealth Distribution When Output Is Partially Demand-Determined

In principle, the previous results measuring the importance of aggregate consumption demand for output fluctuations did not require household heterogeneity at all. However, in the previous part of the chapter, we argued that the wealth distribution is a crucial determinant of aggregate consumption fluctuations, so it stands to reason the same is true with *output* fluctuations in economies where GDP is demand-determined. In Fig. 15, we verify this point by displaying the aggregate impulse responses to a Great Recession in both the externality economy with plausible wealth heterogeneity and a version of the original Krusell–Smith economy, but also including the demand externality. The underlying exogenous TFP process is identical in both economies (and the same as in

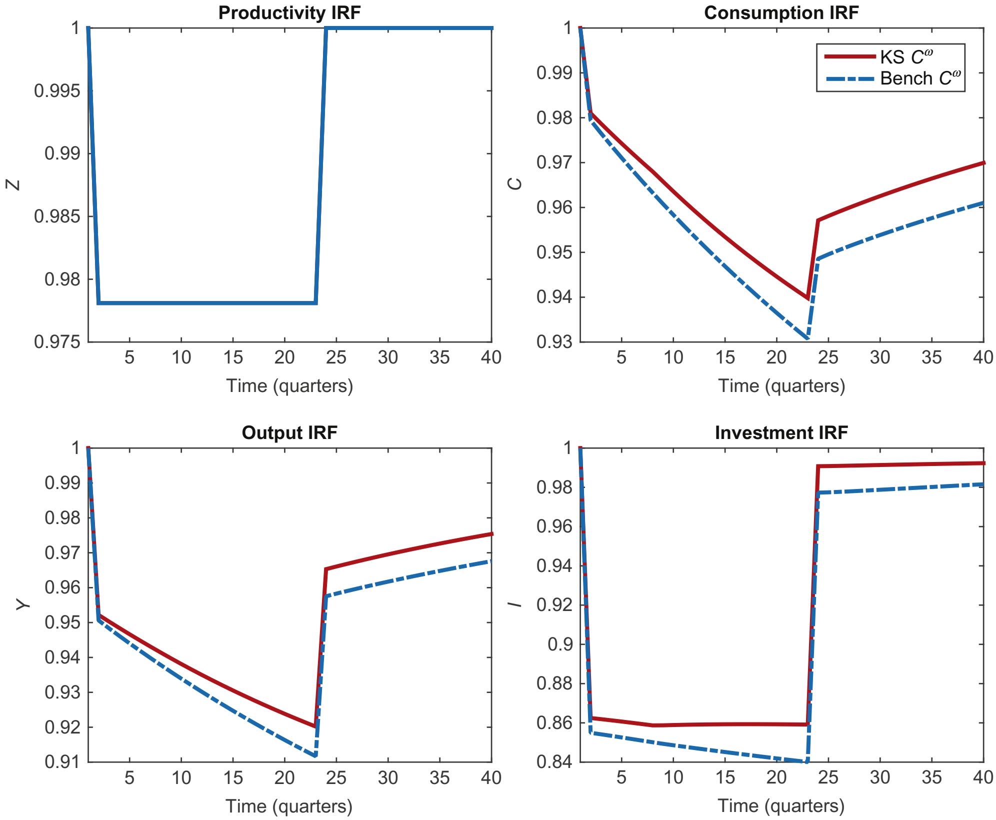

Fig. 15 Impulse response to identical aggregate technology shock: Comparison between economies with high and low wealth inequality.

Table 15 Consumption and output declines in four economies

Economy	$\Delta_1 C$	$\Delta_1 Y$	$\Delta_{22} C$	$\Delta_{22} Y$
KS, $\omega = 0$	−1.9%	−5.8%	−6.0%	−8.0%
Bench., $\omega = 0$	−2.4%	−5.8%	−6.1%	−7.8%
KS, $\omega = 0.3$	−1.9%	−4.8%	−6.0%	−8.0%
Bench., $\omega = 0.3$	−2.1%	−5.0%	−6.9%	−8.8%

Fig. 14), and to display the differences between the models most clearly, we display the dynamics of the macro economy through a 22-quarter Great Recession.

As the figure clearly indicates, in the economy with realistic wealth inequality, the output recession is significantly greater, with output losses of 5.0% on impact and 8.8% at the end of the recession, compared with declines of 4.8% and 8.0% in the original KS economy (but with demand externality).[bx] In Table 15, we summarize the consumption and output declines (on impact, and at the end of a Great Recession) for both the original KS and the benchmark economy, both with and without consumption externality.[by] It reconfirms the main message of Fig. 15: larger wealth dispersion, and especially lower wealth at the bottom of the wealth distribution, amplifies aggregate consumption recessions, as well as aggregate output recessions if the level of production is partially demand-determined. In the latter case, lower output in turn feeds back into an even more severe consumption recession. The magnitude of the differences is quantitatively significant, amounting to an additional drop of aggregate (and thus per capita) consumption of 0.9% at the end of the recession, because of larger wealth inequality induced by more realistic household heterogeneity (again comparing the benchmark model with the original KS economy).

7.2.3 On the Interaction of Social Insurance and Wealth Inequality with Demand Externalities

In Section 6.3, we demonstrated that the presence of social insurance policies has a strong impact on the aggregate consumption response to an adverse aggregate shock *for a given wealth distribution*, but also alters the long-run wealth distribution in the economy. With output partially demand-determined, these policies indirectly impact aggregate productivity and thus output. As the previous figures suggested, the effects are particularly important in the medium run due to the added persistence in the demand externality economy.

[bx] As in the economy without externality, the KS version of the model provides a very good approximation, as far as macroeconomic aggregates are concerned, for the corresponding representative agent economy.

[by] It is important to note that the results with $\omega = 0$ and $\omega = 0.3$ are not directly comparable, since in the economy with demand externality we feed in smaller TFP fluctuations, as described in the calibration section.

In Fig. 11 we documented that, holding the wealth distribution fixed, the size of the social insurance system matters greatly for the aggregate consumption (and thus investment) response to an aggregate productivity shock. Fig. 16 repeats the same thought experiment (an impulse response to a TFP shock in economies with $\rho = 50\%$ and $\rho = 10\%$ with the same prerecession wealth distribution), but now for the consumption externality model.

The key observations from Fig. 16 are that now, in the consumption externality model, the size of the unemployment insurance system affects not only the magnitude of the aggregate consumption decline on impact, but also aggregate output, and the latter effect is quite persistent.

This can perhaps be more clearly seen in Fig. 17, which displays the *difference* in the impulse response functions for output and consumption between economies with $\rho = 50\%$ and $\rho = 10\%$, for both the benchmark model and the demand externality model. The presence of sizeable unemployment insurance stabilizes aggregate

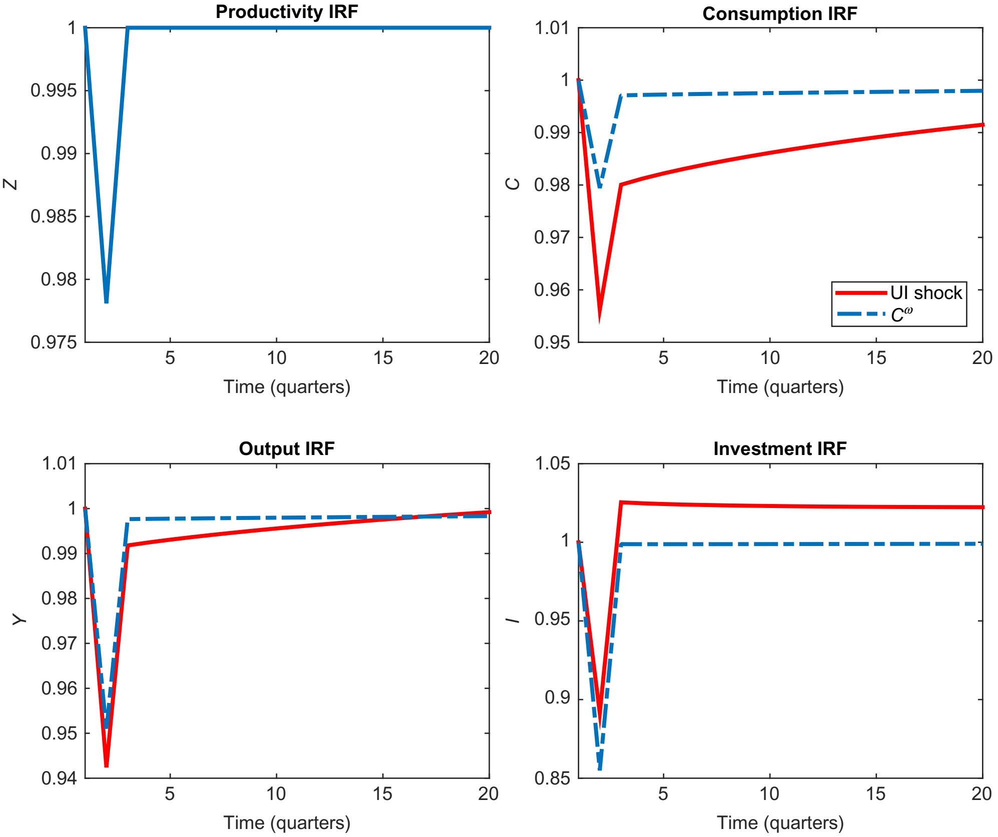

Fig. 16 Impulse response to aggregate technology shock with and without generous unemployment insurance in consumption externality model, fixed wealth distribution.

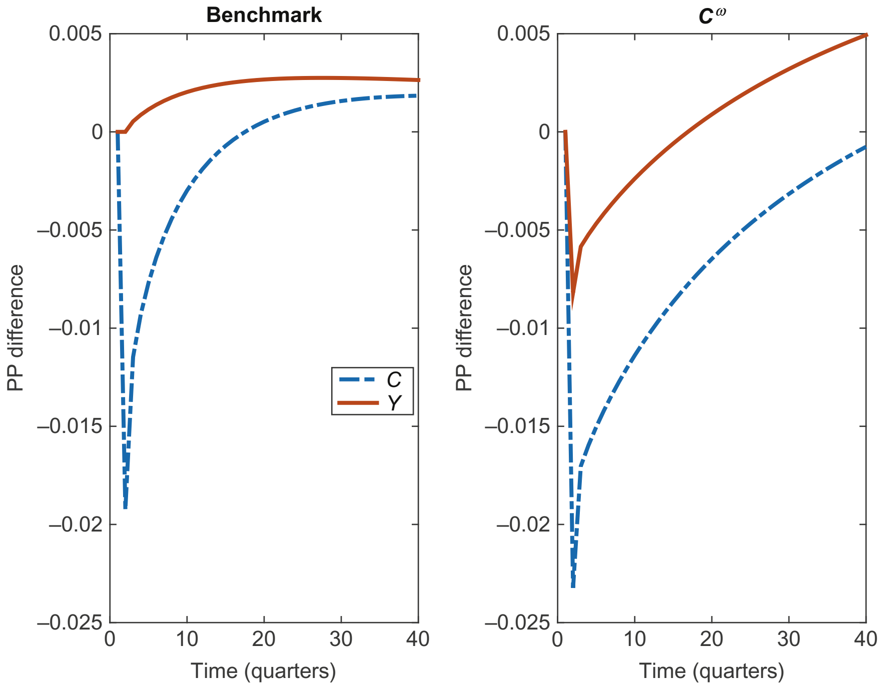

Fig. 17 Difference in IRF between $\rho = 50\%$ and $\rho = 10\%$, with and without consumption externality.

consumption more in the externality economy (the UI-induced reduction in the fall of C is 2.3% on impact and 1.3% after ten quarters of the initial shock in the externality economy, relative to 1.9% and 0.5% in the benchmark economy).

In addition, whereas in the benchmark economy more generous social insurance has no impact on output in the short run (by construction) and a moderately negative impact in the medium run (since investment recovers more slowly in the presence of more generous UI), with partially demand-determined output, UI stabilizes output significantly (close to 1% on impact, with the effect fading away only after 20 quarters—despite the fact that the shock itself only lasts for one quarter in this thought experiment.

Finally, we want to make a perhaps somewhat unexpected observation that turns out to be important for the calculation of the welfare losses of Great Recessions that we pursue in Krueger et al. (2016).[bz] The surprise removal of unemployment benefits leaves

[bz] In that paper, we contribute to the very large literature that studies the normative consequences of social insurance policies (such as unemployment insurance, social security and progressive income taxation) in quantitative heterogeneous household models. See Domeij and Heathcote (2004), Caucutt et al. (2006), Conesa et al. (2009), Peterman (2013), Heathcote et al. (2014), Mitman and Rabinovich (2015), Bakis et al. (2015), Karabarbounis (2015), Krebs et al. (2015), and Krueger and Ludwig (2016) for recent representative contributions to this literature.

households—especially those at the low end of the wealth distribution—with suboptimally small assets. These households start to save massively, especially in light of the elevated unemployment risk. Thus, in the medium run, wealth (the capital stock) and therefore aggregate consumption starts to rise. And since total factor productivity is linked to aggregate consumption demand (and since the capital stock in the economy increases), aggregate wages and output rise strongly in the medium run in the externality economy with low unemployment insurance benefits.[ca] As long as households are sufficiently patient[cb] and have *not* lost their job in the recession, the stronger recovery of the macro economy with low unemployment benefits might make these households prefer less generous unemployment insurance, despite the fact that unemployment insurance benefits act as effective aggregate demand stabilizers in the short run (again as Fig. 17 clarifies).

This last finding, discussed in much greater length in Krueger et al. (2016), leads us back to the main overall theme of this chapter: we have demonstrated that the extent of household heterogeneity with respect to income, wealth and preferences, in a canonical heterogeneous household business cycle model, determines the aggregate consumption and output dynamics over the business cycle in a quantitatively significant way. It gives social insurance policies that shape the income, consumption and wealth distributions a potentially important role in aggregate consumption and output stabilization and has (as we show in our companion work) welfare implications that vary strongly across households with different characteristics. Modeling microeconomic heterogeneity explicitly in the analysis of Great is therefore potentially quantitatively important, even if the object of research interest is purely aggregate in nature.

8. CONCLUSION

In this chapter, we used PSID data on earnings, income, consumption, and wealth as well as different versions of a canonical business cycle model with household earnings and wealth heterogeneity to study the conditions under which the cross-sectional wealth distribution shapes the business cycle dynamics of aggregate output, consumption and investment in a quantitatively meaningful way. We argued that the low end of the wealth distribution is crucial for the answer to this question. We studied mechanisms that helped to generate close to 40% of households without significantly positive net worth, including highly persistent earnings shocks, preference heterogeneity and publicly provided social insurance programs. We showed that the decline in consumption of this group of wealth-poor households at the onset of the recession generates a significantly larger

[ca] Mitman and Rabinovich (2014) argue, reversely, that the *extension* of unemployment benefits goes a long way towards explaining recent slow recoveries in US data.

[cb] Recall that the population is heterogeneous with respect to the time discount factor.

aggregate consumption drop than in a representative-household version of the neoclassical growth model. The same is true for output if it is partially demand-determined. We argued that the key mechanism underlying this result is increased precautionary savings against elevated unemployment risk, and we investigated the extent to which social insurance programs impact the strength of this channel.

Our work suggests that there are at least three important research directions that could yield new insights on the role of heterogeneity for macro outcomes.[cc]

The first is the introduction of additional dimensions of household heterogeneity, so that the model can better capture the *joint* distribution of wealth, income and expenditure we observe in the data. A more accurate mapping between the model and household micro data might change our quantitative conclusions regarding the impact of household heterogeneity on macro dynamics.

The second dimension is the introduction of a richer model of the labor market, with elastic labor supply and other frictions impacting equilibrium hours and unemployment. Doing so would allow us to better understand the link between changes in aggregate consumption expenditures and changes in aggregate output, which in this chapter we have modeled in a very reduced form way.

The final direction for promising work is the explicit introduction of aggregate shocks to the net worth of households (which one may call financial shocks). The micro data on the dynamics of household wealth have shown that during the Great Recession large changes in the net worth of households occurred, and the current model with only one asset does not capture these changes. Introducing a mechanism that can generate these fluctuations in the price of different assets could modify the mechanisms leading from the micro wealth distribution to aggregate consumption and output described in this chapter.

More generally, the emergence of new rich household and firm-level data sets, coupled with continuous theoretical and computational advances in the solutions of macro models with micro heterogeneity, as well as renewed scientific and popular interest in distributional questions, make the research field of quantitative heterogeneous agent macroeconomics an exciting area for future inquiry.

APPENDICES

A Data and Estimation Appendix

A.1 Aggregates in PSID and BEA

The series for disposable income from the BEA is Disposable Personal Income minus Medicare and Medicaid transfers, which are not reported in the PSID. The disposable income series from the PSID is constructed by adding, for each household and from

[cc] We fully acknowledge that exciting work in all these dimensions is already under way.

all members, wage and salary income, income from business and farm, income from assets (including the rental equivalent for the main residence for home owners), and all money transfers minus taxes (computed using the NBER TAXSIM calculator).

The series for consumption expenditures (from both the BEA and the PSID) includes the following expenditures categories: cars and other vehicles purchases, food (at home and away), clothing and apparel, housing (including rent and imputed rental services for owners), household equipment, utilities, transportation expenses (such as public transportation and gasoline), and recreation and accommodation services. In the PSID, imputed rental services from owners are computed using the value of the main residence times an interest rate of 4%. Total consumption expenditures are reported for a two-year period because of the timing of reporting in the PSID. In the PSID, some expenditures categories (food, utilities) are reported for the year of the interview, while others are reported for the year preceding the interview, so total expenditures span a two-year period. The measure of total consumption from the BEA is constructed by aggregating the different categories using PSID timing; so, for example, total expenditures in 2004–05 include car purchases from 2004 and food expenditures from 2005. We have excluded health services because PSID only reports out-of-pocket expenditures and insurance premia. All PSID observations are aggregated using sample weights. Table A.1 reports the 2004 levels of the per capita variables plotted in Fig. 1, alongside, for comparison purposes, the level of food expenditures from both sources and the total household personal consumption expenditures from the BEA.

Table A.1 suggests that the levels from the PSID and the BEA are not too far off, although there are differences. In particular, the aggregated PSID data are different from the aggregates from the BEA for two reasons. Comparing lines 2–3 across columns, we see that for a given category, the average from the PSID is different (typically lower) than that reported by the BEA. This discrepancy between aggregate and aggregate survey data has been widely documented before. The second reason is that some categories are not included in our PSID aggregate, either because they are mismeasured in the PSID (eg, Health expenditures) or because they are not reported by the PSID (eg, expenditures in financial services). One might wonder whether these omitted categories matter for the aggregate pattern of expenditures. Fig. A.1 reports the growth rate of total household personal consumption expenditures from the BEA, along with the growth rate for the BEA consumption expenditures that are included in the PSID

Table A.1 Per capita levels in 2004: BEA vs PSID

	BEA	PSID
1. Disposable income	$24120	$21364
2. Personal consumption (PSID aggregate)	$18705	$15889
3. Food expenditures	$3592	$2707
4. Personal consumption (total)	$27642	–

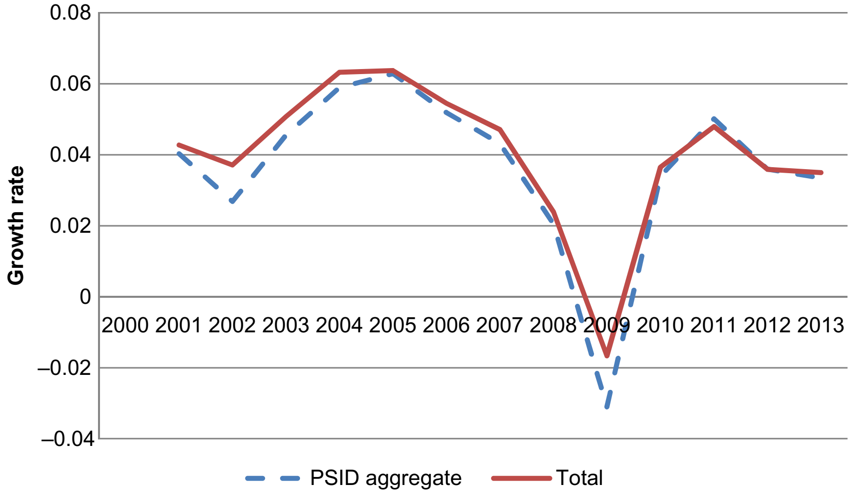

Fig. A.1 BEA consumption growth for two different aggregates.

aggregate defined above. Table A.1 suggests that categories included in the PSID aggregate cover only about 65% of the total consumption expenditures; Fig. A.1, however, shows that the cyclical pattern of total expenditures is similar to the one in the PSID aggregate, suggesting that the missing consumption categories in the PSID aggregate should not make a big difference for our results.

A.2 Standard Errors and Additional Tables

Table A.2 Annualized changes in variables across PSID net worth (2004–06 vs 2006–10) with standard errors[a]

	Net worth[b]				Disp. *Y* (%)		Cons. Exp.(%)		Exp. Rate (pp)

A.3 Estimation of Earnings Process for Employed Households

To estimate the income process for employed households, we use annual household data from the PSID from 1970 to 1997. (These are all the years the PSID survey was conducted annually and for which we can construct comparable data.) We select all households with a head between ages 25 to 60. For each household, we compute total household labor income as the sum of the labor income of the head, the labor income of the spouse, income from farm and business, plus transfers. We then compute tax liabilities for each household using the TAXSIM (ver. 9) tax calculator and subtract it from household labor income to construct household disposable labor income. We then deflate disposable income using the CPI and divide it by the number of members in the household to obtain a measure of per capita real disposable household income. We then exclude the household/years observations where the head of the household is unemployed and where the wage (computed as the head's labor income divided by the head's total hours worked) is below half the minimum wage for that year. On this sample, we regress the log of per capita real disposable income on age dummies, education dummies, interaction of age and education dummies, and year dummies. Before proceeding with estimation we exclude all household income sequences that are shorter than five years. This leaves us with our final sample of 3878 household/years sequences, of an average length of 13.1 years. On these data, we compute the first differences and then the autocovariance matrix of the first differences. We then estimate the stochastic process specified in the text using generalized method of moments, targeting the covariance matrix. The weighting matrix is the identity matrix. Many thanks to Chris Tonetti for providing the Matlab routines that perform the estimation.

B Theoretical Appendix

B.1 Explicit Statement of Aggregate Law of Motion for Distribution

Since the extent of heterogeneity and the choice problem of young and old households differ significantly, it is easiest to separate the cross-sectional probability measure Φ into two components (Φ_W, Φ_R) and note that the measures integrate to Π_W and Π_R, respectively. First define the Markov transition function, conditional on staying in the young age group $j = W$ as

$$Q_{W,(Z,\Phi,Z')}((s,y,a,\beta),(\mathcal{S},\mathcal{Y},\mathcal{A},\mathcal{B})) = \sum_{s'\in\mathcal{S},y'\in\mathcal{Y}} \begin{cases} \pi(s'|s,Z',Z)\pi(y'|y): & d'_W(s,y,a,\beta;Z,\Phi)\in\mathcal{A},\beta\in\mathcal{B} \\ 0 & else \end{cases}$$

and for the old, retired age group, as

$$Q_{R,(Z,\Phi,Z')}((a,\beta),(\mathcal{A},\mathcal{B})) = \begin{cases} 1: & d'_R(a,\beta;Z,\Phi)\in\mathcal{A},\beta\in\mathcal{B} \\ 0 & else \end{cases}$$

For each Borel sets $(\mathcal{S},\mathcal{Y},\mathcal{A},\mathcal{B}) \in P(\mathcal{S}) \times P(\mathcal{Y}) \times B(\mathcal{A}) \times P(\mathcal{B})$, the cross-sectional probability measures of the young and old tomorrow are then given by[cd]

$$\begin{aligned} H_W(Z,\Phi,Z')(\mathcal{S},\mathcal{Y},\mathcal{A},\mathcal{B}) = \theta \int Q_{W,(Z,\Phi,Z')}((s,y,a,\beta),(\mathcal{S},\mathcal{Y},\mathcal{A},\mathcal{B}))d\Phi_W \\ +(1-\nu)\mathbf{1}_{\{0\in\mathcal{A}\}}\sum_{s'\in\mathcal{S}}\Pi_Z(s')\sum_{y'\in\mathcal{Y}}\Pi(y')\sum_{\beta'\in\mathcal{B}}\Pi(\beta') \end{aligned}$$

and

$$\begin{aligned} H_R(Z,\Phi,Z')(\mathcal{A},\mathcal{B}) = \nu \int Q_{R,(Z,\Phi,Z')}((a,\beta),(\mathcal{A},\mathcal{B}))d\Phi_R \\ +(1-\theta)\int Q_{W,(Z,\Phi,Z')}((s,y,a,\beta),(S,Y,\mathcal{A},\mathcal{B}))d\Phi_W. \end{aligned}$$

[cd] These expressions capture the assumption that in each period, a measure $1 - nu$ of newborn households enter the economy as workers, with zero assets and with idiosyncratic productivities and discount factors drawn from the stationary distributions, and that a fraction $1 - \theta$ of working households retire, and that the retirement probability is independent of all other characteristics.

C Computational Appendix

The computational strategy follows the framework developed initially in Krusell and Smith (1998), which was further adapted by Storesletten et al. (2007) and Gomes and Michaelides (2008). In particular, we employ the computational strategy outlined in Maliar et al. (2010), focusing on the nonstochastic simulation algorithm first introduced by Young (2010).

C.1 The Individual Problem

We approximate the true aggregate state (S=(Z, Φ)) by $\hat{S}$, whose specific form depends on which version of the model we solve, which is detailed explicitly later. Thus, the household state is determined by $(s, y, a, \beta; \hat{S})$ in working life and $(a, \beta; \hat{S})$ when retired.

The solution method from Maliar et al. (2010) is an Euler equation algorithm that takes into account occasionally binding borrowing constraints. The problem to be solved is as follows:

$$\begin{aligned}
&\textbf{Retired:}\\
c_R(a,\beta;\hat{S})^{-\sigma} - \lambda &= \nu\beta\mathbb{E}[(1-\delta+r'(\hat{S}'))c_R'(d_R',\beta;\hat{S}')^{-\sigma}]\\
d_R'(a,\beta;\hat{S}) + c_R(a,\beta;\hat{S}) &= b_{SS}(\hat{S}) + (1+r(\hat{S})-\delta)a/\nu\\
d_R'(a,\beta;\hat{S}) &\geq 0\\
\lambda \geq 0, &\quad \lambda d_R'(a,\beta;\hat{S}) = 0
\end{aligned}$$

$$\begin{aligned}
&\textbf{Working:}\\
c_W(s,y,a,\beta;\hat{S})^{-\sigma} - \lambda &= \theta\beta\mathbb{E}[(1-\delta+r'(\hat{S}'))c_W'(s',y',d_W',\beta;\hat{S}')^{-\sigma}]\\
&\quad +(1-\theta)\beta\mathbb{E}[(1-\delta+r'(\hat{S}'))c_R'(d_W',\beta;\hat{S}')^{-\sigma}]\\
d_W'(s,y,a,\beta;\hat{S}) + c(s,y,a,\beta;\hat{S}) &= (1-\tau(Z;\rho))w(\hat{S})y[1-(1-\rho)1_{s=u}] + (1+r(\hat{S})-\delta)a\\
d_W'(s,y,a,\beta;\hat{S}) &\geq 0\\
\lambda \geq 0, &\quad \lambda d_W'(s,y,a,\beta;\hat{S}) = 0,
\end{aligned}$$

where λ is the Lagrange multiplier on the borrowing constraint.

We eliminate consumption via the budget constraint and then guess a policy rule for $d_W'(s,y,a,\beta;\hat{S})$ and $d_R'(a,\beta;\hat{S})$. We then substitute the policy rule to compute $d_W''(s',y',d_W',\beta;\hat{S}')$, $d_R''(d_W',\beta;\hat{S}')$ and $d_R''(d_R',\beta;\hat{S}')$, and use the Euler equation to back out the implied policy rule for d'. If the implied policy rule is the same as the conjectured policy rule, we have computed the optimal policy; if not, we update the guess and repeat.

C.2 The Simulation Algorithm

In order to simulate the model, we pick a grid on $\mathcal{A}$ and fix a distribution of workers $\Phi_0 \in S \times Y \times A \times B$ space. We fix a long time series for the realization of the aggregate shock, Z. Using the realization Z_t and Φ_t, we can compute $\hat{S}_t$ and then apply the policy rules from the individual problem and the Markov transition matrices associated with s and y to compute Φ_{t+1} by interpolating onto the grid points in $\mathcal{A}$.

C.3 Approximating the Aggregate Law of Motion

C.3.1 KS and Benchmark Economies

For the KS and benchmark economies, we approximate the true aggregate state with $\hat{S}_t = (Z_, \bar{K}_t)$ where $\bar{K}_t$ is the average capital in the economy. Agents need to forecast the evolution of the capital stock. We conjecture that the law of motion in capital depends only on the Z and $\bar{K}$:

$$\log(\bar{K}_{t+1}) = a_0(Z_t) + a_1(Z_t)\log(\bar{K}_t)$$

We conjecture coefficients a_0 and a_1, solve the household problem, and simulate the economy. Then, using the realized sequence of $\hat{S}$, we perform the previous regression and check whether the implied coefficients are the same as the conjectured ones. If they are, we have found the law of motion; if not, we update our guess and repeat.

For the KS economy, the computed law of motion is as follows:

$$\begin{aligned} \log(\bar{K}_{t+1}) &= 0.1239 + 0.9652\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_l \\ \log(\bar{K}_{t+1}) &= 0.1334 + 0.9638\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_h. \end{aligned}$$

The R^2 for both regressions are in excess of 0.999999. Note, however, that Den Haan (2010) points out that despite having large R^2 values, the accuracy of the solution can still be poor, and suggests simulation of the capital stock under the policy rule and comparing it with the capital stock that is calculated by aggregating across the distribution. We do this for 3000 time periods. The average error between the implied law of motion from the forecast equations and the computed law of motion is 0.02%, with a maximum error of 0.10%.

For the benchmark economy, the computed law of motion is as follows:

$$\begin{aligned} \log(\bar{K}_{t+1}) &= 0.0924 + 0.9716\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_l \\ \log(\bar{K}_{t+1}) &= 0.0929 + 0.9723\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_h \end{aligned}$$

The R^2 for both regressions are in excess of 0.99999. Similar to the previous computation, we check the accuracy of the law of motion. We find that the average error between the implied law of motion and the actual capital stock computed from the distribution is 0.01%, with a maximum error of 0.07%.

C.3.2 Consumption Externality Economy

In the economy with the aggregate consumption externality, we add contemporaneous consumption as a state variable in our approximation of the true aggregate state, $\hat{S} = (Z, \bar{K}, C)$. We therefore need an additional law of motion for how aggregate consumption evolves. We conjecture the same form of law of motion for the average capital stock; however, we allow the evolution of aggregate consumption to depend on both the average capital stock and aggregate consumption:

$$\log(\bar{K}_{t+1}) = a_0(Z_t) + a_1(Z_t)\log(\bar{K}_t)$$
$$\log(C_{t+1}) = b_0(Z_t, Z_{t+1}) + b_1(Z_t, Z_{t+1})\log(\bar{K}_t) + b_2(Z_t, Z_{t+1})\log(C_t).$$

Note that because capital is predetermined in the current period, the forces rule for capital depends only on contemporaneous variables. Because aggregate consumption is an equilibrium outcome in the next period, we allow for the forecast to depend on the subsequent period's realization of the Z shock. Thus, there are four sets of coefficients to be estimated for the law of motion for consumption. The computed forecast equations are as follows:

$$\begin{aligned} \log(\bar{K}_{t+1}) &= 0.0872 + 0.9736\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_l \\ \log(\bar{K}_{t+1}) &= 0.0626 + 0.9816\log(\bar{K}_t) \quad \text{if} \quad Z_t = Z_h \end{aligned}$$

and

$$\begin{aligned} \log(C_{t+1}) &= -0.0205 + 0.0023\log(\bar{K}_t) + 0.9675\log(C_t) \quad \text{if} \quad (Z, Z') = (Z_l, Z_l) \\ \log(C_{t+1}) &= -0.5061 + 0.2882\log(\bar{K}_t) + 0.5297\log(C_t) \quad \text{if} \quad (Z, Z') = (Z_l, Z_h) \\ \log(C_{t+1}) &= -0.3560 + 0.1893\log(\bar{K}_t) + 0.6626\log(C_t) \quad \text{if} \quad (Z, Z') = (Z_h, Z_l) \\ \log(C_{t+1}) &= -0.0506 + 0.0360\log(\bar{K}_t) + 0.9295\log(C_t) \quad \text{if} \quad (Z, Z') = (Z_h, Z_h) \end{aligned}$$

with R^2 in excess of 0.9999, 0.9999999, 0.9999, 0.9999, 0.99999, 0.99999, respectively. As before, we check the accuracy of the two laws of motion. We find that the average error between the implied law of motion and the actual capital stock computed from the distribution is 0.02%, with a maximum error of 0.30%, and for the path of aggregate consumption the mean error is 0.02% with a maximum error of 0.24%. Although the externality economy has slightly larger forecast errors, the fit of the predicted aggregates is still excellent.

C.4 Digression: Why Quasi-Aggregation?

One of the implications of the results in the main text is that the wealth distribution (and especially the fraction of the population with little or no wealth) is quantitatively important for the macroeconomic consumption and investment response to an aggregate technology shock. This, however, does not imply that Krusell and Smith's (1998) original quasi-aggregation result fails.[ce] Recall that this result states that only the mean of the current wealth distribution (as well as the current aggregate shock Z) is required to accurately predict the future capital stock and therefore future interest rates and wages.

[ce] In fact, our computational method that follows theirs rather closely relies on quasi-aggregation continuing to hold.

The previous experiment compared consumption and investment dynamics in *two economies* that differed substantially in their wealth distributions. For a given economy, if the wealth distribution does not move significantly in response to aggregate shocks, then it would be irrelevant for predicting future aggregates and prices. However, in the high-wealth-inequality economy, the wealth distribution *does* move over the cycle. For example, the share of households at the borrowing constraint displays a coefficient of variation of 7%. However, what is really crucial for quasi-aggregation to occur is whether the movement, over the cycle, in the key features of the wealth distribution is explained well by movements in Z and K, the state variables in the forecast equations of households. We find that it is, even in the high-wealth-inequality economy.

For example, if we regress the fraction of people at the borrowing constraint tomorrow on Z in simulated data, we obtain an R^2 of around 0.8. Therefore, the vast majority of the variation in households at the borrowing limit is very well predicted by the aggregate state variables (Z, K). This finding is robust to alternative definitions of constrained households (households exactly at wealth 0, households who save less than 1%, less than 10%, or less than 25% of the quarterly wage) and alternative moments of the wealth distribution. It is this finding that makes quasi-aggregation hold, despite the strong impact of the wealth distribution on the aggregate consumption and investment response to aggregate technology shocks.

C.5 Recovering the Value Function

As we solve the model by exploiting the Euler equation, if one were to perform welfare calculations (as in Krueger et al. (2016) one needs to recover the value functions as a function of the idiosyncratic and aggregate states. To calculate them, we use policy function iteration. We make an initial guess for the value function, v^0, then calculate v^1 by solving the recursive household decision problem (we need not perform the maximization, since we have already computed the optimal policy function). We approximate the value function with a cubic spline interpolation in assets, as well as in aggregate capital (and for the demand externality model, we also aggregate consumption). If v^1 is sufficiently close to v^0 (in the sup-norm sense), we stop; otherwise, we proceed to compute v^2 taking v^1 as the given value function. We proceed until convergence. For the economies with retirement, we first recover the value function for retired households, v_R, and then proceed to recover the value function for working-age households, v_W.

ACKNOWLEDGMENTS

We wish to thank the editors John Taylor and Harald Uhlig, discussants of the chapter, Carlos Thomas, Claudio Michelacci, Tony Smith, and Chris Tonetti, as well as seminar participants at several conferences and institutions for many useful comments and Simone Civale for outstanding research assistance. D.K. gratefully acknowledges financial support from the NSF under grants SES 1123547 and SES 1326781.

Abstract

A growing literature relies on natural experiments to establish causal effects in macroeconomics. In diverse applications, natural experiments have been used to verify underlying assumptions of conventional models, quantify specific model parameters, and identify mechanisms that have major effects on macroeconomic quantities but are absent from conventional models. We discuss and compare the use of natural experiments across these different applications and summarize what they have taught us about such diverse subjects as the validity of the Permanent Income Hypothesis, the size of the fiscal multiplier, and about the effects of institutions, social structure, and culture on economic growth. We also outline challenges for future work in each of these fields, give guidance for identifying useful natural experiments, and discuss the strengths and weaknesses of the approach.

1. INTRODUCTION

Establishing causality is a major challenge in economics, especially in macroeconomics, where the direction of various important causal relationships is widely discussed, as illustrated, for example, by large-scale debates about the causal effects of monetary and fiscal policies. Most empirical applications of macroeconomic models focus on matching conditional correlations and improving the fit of models to a set of data moments. Despite substantial advances in this area in recent years, these conditional correlations often cannot identify causal chains. For example, New Keynesian models and real business cycle models can match similar sets of conditional correlations but have very different predictions about the causal effects of fiscal or monetary policies. This lack of identification of clear causal channels is especially troubling when it comes to providing policy advice.

In applied microeconomic fields, causality is often established by designing laboratory or field experiments. In these types of experiments, the researcher consciously influences the economic environment in a way that allows the establishment of causality. The most prevalent and clearest method in this spirit is to randomly allocate agents into a treatment group and a control group, and then analyze the effect of the treatment by directly comparing the relevant outcome variables between both groups, or the change in the outcome variables of both groups coinciding with the introduction of the treatment in a difference-in-differences approach. Field experiments randomize treatment in a real-world economic environment, whereas laboratory experiments do so in a controlled environment. Both methods are mostly unavailable to macroeconomists for fairly obvious reasons. Because macroeconomics deals with phenomena that affect the economy at large (eg, economic growth, unemployment, monetary policy, fiscal policy), any field interventions would be very expensive and would have far-reaching consequences because they cannot easily be targeted at a specific small group, making it unlikely that anyone would agree to carry them out. Bringing key features of the economic environment into the laboratory is also complicated in macroeconomics, where the interplay of different agents and markets often plays a key role (see Duffy, 2008 for a survey of laboratory experiments in macroeconomics).

Natural experiments are an alternative to field and laboratory experiments. For the purposes of our discussion, *we define natural experiments as historical episodes that provide observable, quasi-random variation in treatment subject to a plausible identifying assumption.* The "natural" in natural experiments indicates a researcher did not consciously design the episode to be analyzed, but can nevertheless use it to learn about causal relationships. The episode under consideration can be a policy intervention carried out by policy makers (eg, changes in the tax law), historical episodes that go beyond simple policy measures (eg, the fall of Communism), or a so-called "natural natural" experiment that arises from natural circumstances (rainfall, earth quakes, etc.). Maybe the most widely exploited natural experiment in the macroeconomics literature is the German separation in 1949 and subsequent reunification in 1989. This episode split a homogeneous population into two parts that lived under vastly different economic and political systems with minimal contact between them, only to be reunited 40 years later. Importantly, one can argue this split was exogenous to preferences, economic conditions, and other factors that would directly predict different economic outcomes after reunification. Thus, the assignment of an individual to East or West Germany at the date of separation can be considered random, as in a field experiment. At the same time, vast micro and macro data are available to analyze the episode. Fuchs-Schündeln and Schündeln (2005) first used this experiment to study the self-selection into occupations according to risk aversion and its effect on precautionary savings. Later applications have studied diverse subjects ranging from endogenous preferences for economic policies (Alesina and Fuchs-Schündeln, 2007) and the importance of market access (Redding and Sturm, 2008) to the economic impact of social ties (Burchardi and Hassan, 2013).

Whereas the main task of a researcher carrying out a laboratory or field experiment lies in designing it in a way that allows causal inference, the main task of a researcher analyzing a natural experiment lies in arguing that in fact the historical episode under consideration resembles an experiment, and in dealing with weaknesses of the ex-post experimental setup that one would have avoided a priori in a designed experiment.

To show the episode under consideration resembles an experiment, identifying valid treatment and control groups, that is, arguing the treatment is in fact randomly assigned, is crucial. Establishing such quasi-random treatment requires showing that two groups are comparable along all dimensions relevant for the outcome variable except the one involving the treatment. The methods used to do this are often adapted from the microeconometric literature on field and laboratory experiments.

The goal of this chapter is to acquaint the reader with the use of natural experiments in macroeconomics, summarize what we have learned from them so far, and distill what makes a successful application of a natural experiment to answer a macroeconomic question. We provide in the conclusion of this chapter a summary of common features that distinguish successful papers that rely on the use of natural experiments. Although every natural experiment is different and thus leads to different challenges, these features can serve as guidelines for future papers. Moreover, we discuss the embedding of natural experiments into structural models as a promising general avenue for future research, and point out limitations in the use of natural experiments.

Rather than attempt to cover all papers in macroeconomics that feature natural experiments (which would be a formidable task), we instead select three specific lines of enquiry that use natural experiments for three different purposes: to verify underlying model premises (verification), to quantify specific policy parameters (quantification), and to identify causal mechanisms that operate outside conventional models (identification).

The first line is the literature on the Permanent Income Hypothesis. In contrast to the simple Keynesian consumption theory, the Permanent Income Hypothesis assumes agents are rational and forward looking when making their consumption decisions. Therefore, in addition to current income and current assets, the expected value of future income plays a role in the optimal consumption choice today. This forward-looking behavior can be subjected to a simple test using a preannounced income change: the household should adjust consumption as soon as information about the future income change arrives. By contrast, consumption growth should be unaffected at the time of the implementation of the income change, given that the household knew about it in advance. In this literature, natural experiments serve to identify such preannounced income changes. A finding that households adjust their consumption at the time of implementation of the preannounced income change casts doubts on the fundamental assumption of most micro-founded macroeconomic models that agents are forward looking in their decision making.

The second line is the literature striving to quantify the fiscal multiplier. The fiscal multiplier is one of the most important policy parameters in the macroeconomics literature. Can the government stimulate the economy via government spending or tax policies? If yes, how large is the effect of a given fiscal policy on GDP per capita? The main challenge in the estimation of the fiscal multiplier lies in identifying changes in fiscal policies that are not motivated by business-cycle considerations. In this context, researchers specifically use natural experiments to identify such exogenous changes in government spending.

These first two lines of literature rely not only on natural experiments, but also on other approaches, for example, instrumental variables approaches in which the instruments are not historical episodes, or vector autoregression (VAR) models with exclusion restrictions. By contrast, the third line of the literature relies almost exclusively on natural experiments to identify the fundamental causes of growth. The goal of this literature is to identify mechanisms that are absent from standard macroeconomic models. What can explain the vastly different GDP per capita levels across poor and rich countries? Standard growth models point to human or physical capital accumulation or R&D investment as explanations, but these factors are proximate rather than fundamental causes of growth: why have some countries invested much more than others? The literature on the fundamental causes of growth identifies institutions, social structure, and culture as such fundamental causes. All three of these concepts are largely absent from conventional models of economic growth. Moreover, multiple equilibria can lead to different growth paths despite common initial conditions. Empirically analyzing the fundamental causes of growth is intimately linked to using natural experiments: the "historic episodes" are truly historic here in the sense that they typically come from the distant past and are used to establish causal links by providing quasi-random variation in institutions, social structure, or culture across countries, regions, or time.

Within each of the three lines of literature, we again do not attempt to survey the entire literature on the topic but instead focus on showing how different authors use natural experiments to address research questions arising within each of the three specific contexts, by verifying, quantifying, or identifying causal mechanisms. A common theme across almost all of these applications is that the econometric methods used are fairly simple applications of standard methods, such as OLS, instrumental variables, regression discontinuity, or fixed-effects estimators. Instead, the complexity of many of these papers lies in identifying the episode that generates quasi-random variation, and appropriately dealing with any flaws in nature's experimental design. In this sense, the most crucial ingredient of many papers using natural experiments is the appropriate statement and defense of an identifying assumption, which is the focus of our discussion.

This chapter has two target audiences: the first is researchers with a solid background in applied econometrics who are considering studying a natural experiment in any area of macroeconomics. We hope the juxtaposition of natural experiments used in different areas will generate ideas for intellectual arbitrage for this group. In each of the areas that we cover, we also attempt to point out the research frontier in terms of method and substance, and often explicitly point out important avenues for future research. The second target audience is researchers in mainstream macroeconomics. With this group in mind, we attempt to summarize what natural experiments have taught us about the Permanent

Income Hypothesis, the fiscal multiplier, and the fundamental causes of macroeconomic growth, in the hope that this summary will help direct future theoretical research.

A set of slides that develops the material covered in this chapter in two 90-minute lectures is available on the authors' websites.

2. VERIFICATION: THE PERMANENT INCOME HYPOTHESIS

Natural experiments can be used in macroeconomics to test the validity of major underlying model assumptions. This is done in the use of natural experiments to test the validity of the Permanent Income Hypothesis. The Permanent Income Hypothesis, as developed by Friedman (1957), contrasts with the simple Keynesian consumption theory, which postulates that consumption depends on current income only and is equal to a nonincreasing fraction of current income. To the present day, the Permanent Income Hypothesis is the major building block of modern consumption theory, for example, the life cycle theory, the precautionary savings theory, and also behavioral consumption models involving hyperbolic discounting. The most important insight of the Permanent Income Hypothesis is that individuals are rational and forward looking when making their consumption decisions over the life cycle.

According to the Permanent Income Hypothesis, individual i solves a utility maximization problem of the form

$$\max_{\left\{C_{i,t+j}\right\}_{j=0}^{\infty}} E_t \sum_{j=0}^{\infty} \beta^j u\left(C_{i,t+j}\right) \tag{1}$$

subject to the intertemporal budget constraint

$$\sum_{j=0}^{\infty}\left(\frac{1}{1+r}\right)^j C_{i,t+j} = A_{i,t} + \sum_{j=0}^{\infty}\left(\frac{1}{1+r}\right)^j Y_{i,t+j}, \tag{2}$$

where $C_{i,t}$ is consumption of individual i in period t, β is the discount factor, r is the interest rate, $A_{i,t}$ are initial assets in period t, $Y_{i,t}$ is income in period t, and E_t is the expectations operator conditional on information available at time t. For simplicity, let us assume $\beta(1 + r) = 1$. Also for simplicity, let's assume for now that the utility function takes the quadratic form, such that certainty equivalence holds:

$$u\left(C_{i,t+j}\right) = C_{i,t+j} - \frac{\alpha}{2} C_{i,t+j}^2. \tag{3}$$

This simple model has several powerful implications. Most importantly, consumption is not a function only of current income. Instead, it also depends on current assets and expected future income, and is in fact equal to permanent income. Permanent income is defined as the annuity value of total net worth, which is the sum of current assets and the expected discounted net present value of all future income streams:

$$C_{i,t} = \frac{r}{1+r}\left[A_{i,t} + E_t\left(\sum_{j=0}^{\infty}\left(\frac{1}{1+r}\right)^j Y_{i,t+j}\right)\right]. \tag{4}$$

Because the expected discounted net present value of future income enters the optimal consumption decision of an individual, optimal consumption will change whenever new relevant information arrives. Conversely, any *anticipated* change in income will not affect optimal consumption. Consumption growth depends only on changes in the information set between periods t and $t+1$. Thus, we have

$$\Delta C_{i,t+1} = \frac{r}{1+r}\left[E_{t+1}\left(\sum_{j=0}^{\infty}\left(\frac{1}{1+r}\right)^j Y_{i,t+j+1}\right) - E_t\left(\sum_{j=0}^{\infty}\left(\frac{1}{1+r}\right)^j Y_{i,t+j+1}\right)\right] \tag{5}$$

and specifically

$$\Delta C_{i,t+1} = 0 \text{ if } E_{t+1} = E_t. \tag{6}$$

Eq. (6) holds independent of the form of the utility function used in (1), as long as the desired consumption path is flat. The predictions from Eqs. (5) and (6) can be tested by analyzing the reaction of consumption to anticipated and unanticipated income changes in the data. The empirical challenge lies in identifying in the data whether the individual anticipated any observed income change, and natural experiments are used to identify clearly unexpected or clearly anticipated income changes.

We start out describing the few papers analyzing the reaction of consumption to unexpected income shocks. The literature on the reaction of consumption to anticipated income changes is much larger, for reasons described below, and we will use this literature to gain more insights into the specifics of the use of natural experiments.

2.1 Reaction of Consumption to Unexpected Income Shocks

Only a few papers test whether consumption responds to unanticipated income shocks as predicted by Eq. (5). The reason is that the specific optimal reaction of consumption to an income shock depends among other things on the nature of the shock (whether it is temporary or permanent), on the age of the recipient (if we deviate from an infinite horizon assumption and instead employ a life-cycle setup), and on the functional form of the utility function, which in a more realistic setup might involve prudence from part of the household, such that households build a buffer stock of savings to partly self-insure against future income fluctuations in the absence of perfect insurance.

2.1.1 Unexpected Temporary Income Shocks

If we maintain the assumption of a quadratic utility function, and if an unexpected income change, that is, an income shock, is a strict one-time temporary income change, Eq. (5) reduces to

$$\Delta C_{i,t+1} = \frac{r}{1+r}[Y_{i,t+1} - E_t(Y_{i,t+1})]; \tag{7}$$

that is, the optimal consumption change is equal to the annuity value of the unexpected income change. Thus, as a generalization of this prediction, the optimal consumption change after a temporary income shock clearly should be small. One therefore needs large temporary income changes in the data in order to identify the response of consumption.

A very early paper testing this prediction is Kreinin (1961), whose analysis was later supported by further evidence by Landsberger (1966). Kreinin (1961) uses the 1957/58 Israeli Survey of Family Savings to analyze how Israeli households spent one-time restitution payments from Germany, which around 4% of urban Israeli households received during the year of the survey. He finds that Israeli households saved approximately 85% of the restitution payments, which on average amounted to close to one annual disposable income.[a] This behavior seems roughly in line with a small response of consumption to the temporary income change.

Imbens et al. (2001) and Kuhn et al. (2011) analyze the consumption of lottery winners. Lottery wins are historical episodes that clearly identify random large temporary income shocks, and can as such be seen as natural experiments. Kuhn et al. (2011) compare consumption of Dutch lottery winners and nonwinners.[b] The lottery wins in their episode amount to 12,500 Euros, which is equal to eight monthly average household incomes in the Netherlands. In line with the Permanent Income Hypothesis, Kuhn et al. (2011) find that nondurable consumption does not increase significantly after a lottery win, but durable expenditures increase somewhat. Imbens et al. (2001) analyze significantly larger lottery wins, which are reimbursed over 20 years, and find that the increase in savings after a win is in line with the life cycle hypothesis. The authors of both studies collect their own data by sending out questionnaires to lottery winners and a sample of nonwinners. The final sample sizes are then comparatively small, with 220 lottery winners in Kuhn et al. (2011), and 340 in Imbens et al. (2001).

Brueckner and Gradstein (2013) take a macroeconomic approach to analyze the response of consumption to unexpected temporary income shocks. Exploiting the fact that rainfall is a significant driver of annual aggregate output in sub-Saharan African countries, and that annual variations in rainfall are random and unexpected, they use rainfall as an instrument for aggregate output in a regression that analyzes the reaction of aggregate private consumption to aggregate output. They estimate a marginal propensity to consume out of temporary output shocks that is not significantly different from 0, with

[a] By contrast, Bodkin (1959) finds that windfall incomes of National Service Life Insurance dividends paid out to US veterans were largely consumed. However, these windfalls amounted to, on average, only around 5% of annual disposable income.

[b] They also analyze social effects in a partial population design.

a point estimate of 0.2. Thus, similar to the studies relying on micro data, they find evidence of significant consumption smoothing of temporary income shocks.

2.1.2 An Unexpected Permanent Income Shock: the Natural Experiment of German Reunification

Germany's separation and subsequent reunification constitute in many ways a perfect natural experiment. A country with a common history is split into two parts and the two populations live under very different economic and political systems for 40 years before being reunified. Importantly, it can confidently be argued that the separation of Germany was exogenous to the preferences of the underlying populations and the economic conditions in East and West at the time. The exact location of the border was largely determined by the position of the allied forces at the end of the war, which in turn was partly determined by the geographic location of the allies vis-a-vis Germany. To put it bluntly: if the Soviet Union would have been located to the West of Germany, some western part would have been socialist for 40 years. That the location of the East–West border can be considered random is best documented in the paper by Alesina and Fuchs-Schündeln (2007), who provide an overview of the economic and political situation in Germany before World War II, and show that no marked differences existed between East and West prior to separation. Based on this evidence, West Germans can be taken as a control group for East Germans, and economic conditions of East Germans at reunification, resulting from living under the socialist system of the former German Democratic Republic for 40 years, can be considered exogenous with respect to the new economic system after reunification, since German Reunification was an unexpected surprise event. This is a large-scale experiment, affecting close to 20 million people in East Germany in a multitude of dimensions.

German Reunification has thus been used in a number of studies in the last two decades to analyze different questions. The first paper using German Reunification as a natural experiment is Fuchs-Schündeln and Schündeln (2005), who analyze self-selection in occupational choice according to risk preferences and its effects on estimates of precautionary savings. Redding and Sturm (2008) study the role of market access, and Redding et al. (2011) and Ahlfeldt et al. (2015) focus on industrial location choices. Gebhardt (2013) uses German reunification as a natural experiment to analyze the effect of ownership on relationship specific investment in the housing market, and Bursztyn and Cantoni (2016) to investigate the effect of television advertisement on consumption. The studies by Alesina and Fuchs-Schündeln (2007), analyzing endogenous preferences for redistribution, and Burchardi and Hassan (2013), studying the effect of social ties on growth, are described below and also rely on the natural experiment of German reunification.

In the context of the Permanent Income Hypothesis, Fuchs-Schündeln (2008) exploits German Reunification as a large positive permanent income shock for East

Germans. This permanent income shock is embedded into a structural life cycle model of consumption. This is one of the very few papers which combine a structural model in macroeconomics with a natural experiment.[c] As in any structural model, this implies making assumptions about functional forms and calibrating the model carefully. Yet, it has the advantage that one can talk about the match between quantitative model implications and the data, and can distill the relative importance of different model components.

The life cycle model in Fuchs-Schündeln (2008) incorporates a retirement saving motive, a precautionary saving motive due to income risk and an exogenous liquidity constraint, and deterministically changing household size over the life cycle. West German life cycles play out in this model context from start to end, but East German households enter the new economic model environment in 1990 at a certain age. At this point in time, they are endowed with an exogenous wealth level, which is taken as the cohort-specific East–West wealth ratio in 1992 from the data. Importantly for the predictions of the model, the East–West wealth ratio at reunification was very low (lower than the East–West income ratio), which is especially true for older cohorts closer to retirement. From that point on, East Germans also live in this new economic model environment. Life-cycle income growth, income risk, and changing household sizes are calibrated separately for East and West Germans.

The calibrated model is able to qualitatively and quantitatively match three stylized features of East and West German saving rates after reunification: (i) East Germans have higher saving rates than West Germans; (ii) this East–West saving rate difference is increasing in age at reunification; that is, it is larger for older birth cohorts than for younger birth cohorts; and (iii) for every birth cohort, this difference is declining over time, with full convergence of saving rates within roughly 10 years. The higher East German saving rates after reunification are a result of their low initial wealth levels, which leave them unprepared for the new economic environment in terms of both precautionary and retirement savings. The East–West difference in saving rates is especially large for older cohorts, because older cohorts of East Germans are least prepared for the new environment: their wealth position relative to their West German counterparts is especially low, and they have less time left over their working life to accumulate more wealth through higher saving rates. The rapid convergence of East German saving rates toward West German levels is the stylized feature that allows for differentiation between the different components of the life cycle model. A precautionary savings motive is essential to replicate this feature, because precautionary savings imply that saving rates decrease as wealth levels approach the target level of wealth from below.

The demographic developments after reunification alone would actually predict rising East German saving rates for younger cohorts, running counter to the empirical evidence. Disentangling a precautionary saving motive from a demographic saving motive based on

[c] This approach is more common in other fields, see, eg, the paper by Ahlfeldt et al. (2015).

changing household size over the life cycle is difficult in a standard setting, since both saving motives predict a hump-shaped consumption path over the life cycle. In the context of the natural experiment of German reunification, however, both saving motives lead to opposite predictions for the saving behavior of East Germans relative to West Germans. The paper concludes that East Germans react according to the predictions of the life cycle model after the large shock of German Reunification, despite being confronted with entirely new economic conditions, and that a precautionary saving motive is essential for replicating the data. The first conclusion is in line with the conclusions of the other studies analyzing large temporary income shocks. The second conclusion is only possible in a structural model, pointing to the advantages of the approach used in this paper. Relying on a structural model, one can go beyond analyzing main model predictions to analyzing the importance of different specific model components.

2.2 Reaction of Consumption to Expected Income Changes

In this section, we describe the literature using natural experiments to test the prediction of the Permanent Income Hypothesis that consumption growth should be insensitive to preannounced income changes, as specified in Eq. (6). This is a very large literature: Table A.1 lists 25 published studies directly testing this prediction, and six further studies related to it in some way. We first focus on the methodological side by describing the use of natural experiments, then discussing in Section 2.2.1 different ways to support the random treatment assumption in these studies, and next analyzing how the presence of liquidity constraints modifies the predictions of the theory, and how the papers deal with liquidity constraints. Section 2.2.3 then turns away from the methodolgy to focus on the findings of the studies, and Section 2.2.4 tries to reconcile these sometimes contradictory findings by organizing them along two lines: the size of the income change and the repetitiveness of the episode under study.

The second implication of the Permanent Income Hypothesis—that an *anticipated* income change should not lead to a change in consumption—has the advantage of holding independently of the concrete setup of the problem. In particular, it holds also under functional forms of the utility function other than the quadratic one (eg, under constant relative risk aversion), independent of the age of the individual in a life-cycle setup, and independent of the permanency of the income change at hand. This prediction can be tested if the econometrician knows that an observed income change was anticipated; that is, $Y_{t+1} \neq Y_t$, but $E_{t+1} = E_t$. The null hypothesis would then be that $\Delta C_{t+1} = 0$ and can be tested against the alternative $\Delta C_{t+1} \neq 0$ in a simple reduced-form regression of the form

$$\Delta C_{i,t+1} = \alpha + \beta \Delta Y_{i,t+1}^{expected} + \gamma' \Delta X_{i,t+1} + \epsilon_{i,t+1}, \tag{8}$$

where X is a vector containing any characteristics that are relevant for consumption and might have changed over time, for example, age and household size. The identifying assumption is that the error term is uncorrelated with the expected income change, that is, $Cov[\Delta Y_{i,t+1}^{expected}, \epsilon_{i,t+1}] = 0$, meaning no unobserved variables are correlated with the expected income change and the consumption change. The Permanent Income Hypothesis states that $\beta = 0$. If the underlying assumption of rational expectations and forward looking behavior is violated, we would expect that $\beta \neq 0$, and specifically that $\beta > 0$ under the Keynesian consumption theory.

Running this regression is easy if an expected income change can be directly observed in the data, that is, if we know the underlying assumption $E_{t+1} = E_t$ holds. However, in general, whether any observed income change in the data was expected or unexpected by the individual is unclear. A common way to run this regression in the macro literature relying on aggregate consumption data involves the use of instruments. For example, Ludvigson and Michaelides (2001) regress quarterly consumption changes on quarterly income changes, instrumenting income changes with their own lags. Carroll and Summers (1991) run similar regressions on international data, again instrumenting with lags of income growth. However, at the micro level, to which the theory applies, finding a suitable instrument is much harder.

A more elegant and convincing way to run this regression on the micro level is to exploit a natural experiment. Natural experiments in this context are clear historical episodes in which we know that an income change occurred, and that it was preannounced and thus anticipated by the households. Typical income changes of this kind analyzed in the literature are associated with taxation (tax rebates, tax refunds, changes in tax laws, etc.), wages (wage payment schedule, wage changes, social security receipts), and committed consumption (college cost, mortgage payments, etc.). All these changes have in common that they are clearly announced some time in advance, and thus the recipient anticipates them. The Permanent Income Hypothesis predicts that households should adjust their consumption at announcement of the income change. The size of the optimal consumption adjustment at announcement depends among other things on the expectations about the exact nature of the income change and is therefore hard to gauge, as in the papers described in Section 2.1. By contrast, testing the prediction that consumption should not react when the preannounced income change actually happens is easy.

In a more general sense, one can think of the test for whether $\beta = 0$ in Eq. (8) as a general test of the validity of the rational expectation assumption in consumption decisions. We might not care from either a macro or micro point of view whether households adjust their consumption at the announcement or the implementation of an income change, because both typically happen within a short period of time in the natural experiments analyzed in the literature. However, for welfare purposes, whether households build rational expectations and are forward looking when deciding how much to consume and how much to save matters tremendously. For example, to save appropriately for retirement, households have to understand the income process over their life cycle early on and act accordingly.

2.2.1 Random Treatment: Determining an Appropriate Control Group

The estimation of Eq. (8) using a natural experiment to establish that an income change was anticipated still faces some challenges. Importantly, Eq. (8) can only be estimated consistently if the error term is uncorrelated with the preannounced income change; that is, $Cov[\Delta Y_{t+1}^{expected}, \epsilon_{t+1}] = 0$. Otherwise, the preannounced income change and the consumption change would be spuriously correlated due to omitted variables.

One important feature that could lead to correlation between the error term and the preannounced income change could be seasonality effects. For example, workers in many countries receive a 13th salary in the month of December, leading to a preannounced change in monthly income between November and December. At the same time, expenditures increase in December because of holiday shopping. This leads to a spurious correlation between the preannounced income change and the consumption change. The income change is endogenous because the 13th salary in December was established precisely because firms recognized the higher average household expenditure in December.

In the spirit of an experimental setup, a valid control group can overcome this problem. If the above-mentioned preannounced income change exhibits temporal variation, that is, if it does not occur in the same month for all households, then variation is present in the timing of the treatment, and one can include monthly dummies to account for seasonality in expenditures directly. The same applies if the preannounced income change happens in different months in different years, though in that case, one has to argue that expenditure seasonality should be the same year by year, for example by analyzing whether major events usually causing increases in expenditure, like public holidays or vacations, happen in the same months every year. Variation in the individual amount of the preannounced income change relative to permanent income could help, but only if one could reasonably argue that this variation is exogenous to any desired seasonality in expenditure.

In the ideal experiment, one group does not receive any preannounced income change, and another one does, and both should be comparable along all other observable and unobservable characteristics, including preferences that lead to consumption seasonality. In that case, one can think of the first group as the "control" group and of the second group as the "treatment" group. Here, the natural experiment is very close to a designed field or laboratory experiment: two groups exist, one of which is quasi-randomly treated and the other one not, and the behavior of both groups is compared. The analysis of consumption changes then corresponds to a difference-in-differences setup. Whereas laboratory or field experiments would be designed to make the assignment into the treatment group explicitly random, the main challenge of a natural experiment is to convincingly argue the randomness of the assignment and thus the appropriateness of the control group. Arguing this point is generally easiest if both groups receive the same treatment, but at randomly different points in time. This distinguishes natural experiments from field or laboratory experiments, which typically leave a control group untreated.[d]

In this section, we describe different methods to determine randomness in treatment. In passing, we also discuss some findings of the papers, which are, however, the focus of Section 2.2.3.

2.2.1.1 Clearly Established Randomness in Treatment

A set of studies that are particularly successful in establishing randomness in the treatment assignment are the papers by Johnson et al. (2006) and Agarwal et al. (2007), who exploit the 2001 Federal Income Tax Rebates as a natural experiment, and the studies by Parker et al. (2013) and others, who analyze the 2008 Economic Stimulus Payments as a natural experiment.[e] In both cases, households received one-time tax rebates in the form of checks sent to them. The media extensively discussed the rebates in advance, and as such, households should have known about them. In addition, for the 2001 Bush tax rebates, households received an individual letter several months in advance stating the specific amount of the rebate.[f] Although the amount received varied little between households, mostly driven by household size and thus not exogenous, nice and clearly exogenous variation exists in the timing of the payments: because sending out all rebate checks on the same day was logistically impossible, the IRS spread out the payments over 10 weeks in 2001 and 9 weeks in 2008, and determined the exact date on which each household would receive the check by the second to last digit of the Social Security Number of the main tax payer, which is randomly assigned. Thus, in these two cases the randomness in the timing of treatment is as clearly established as in any field or laboratory experiment in which the researcher consciously establishes randomness through a lottery. Exploiting this situation, the "treated" group in the above-mentioned studies is the one that randomly receives the rebate in the period under consideration, whereas the "control" group encompasses all other households, which receive the rebate in a different period.[g]

[d] A valid reason for this approach for field or laboratory experiments is the fact that treatment is typically costly for the researcher.

[e] Johnson et al. (2006) and Parker et al. (2013) analyze consumption responses, whereas Agarwal et al. (2007) analyze the response of credit card spending and debt repayment to the 2001 federal income tax rebates. The 2008 Economic Stimulus Payments have been exploited by a number of studies, including Broda and Parker (2014) and Parker (2014) analyzing consumption responses, Gross et al. (2014) and Bertrand and Morse (2009) analyzing bankruptcy filing and repayment of payday loans, respectively, and Evans and Moore (2011) and Gross and Tobacman (2014) analyzing mortality and morbidity outcomes. Shapiro and Slemrod (2003) and a series of papers by Sahm et al. (2010, 2012) analyze self-reported propensities to consume and to save out of both rebate episodes. Misra and Surico (2014) analyze heterogeneity in consumption responses to both the 2001 and 2008 stimulus programs.

[f] For the 2008 Economic Stimulus Payment, the letter came only 1 week in advance.

[g] In the case of the 2008 Economic Stimulus Payments, part of the households received not a check but a direct deposit, for which the timing was somewhat different. Thus, the studies using the 2008 Economic Stimulus Payments suffer from larger measurement error than the studies using the 2001 federal income tax rebates, if they cannot determine whether a household received a check by mail or a direct deposit, which most cannot.

The week of rebate receipt is clearly exogenously determined. All of these studies find that household consumption adjusts at receipt of the rebates, in violation of the Permanent Income Hypothesis.

2.2.1.2 The "Narrative Approach"

In the absence of such a clear random treatment assignment, different strategies can be used. For example, Browning and Collado (2001) analyze quarterly consumption growth of Spanish workers who are part of one of two different payment schemes: the standard scheme used in the control group encompasses monthly wage payments of twelve equal amounts over the year, whereas the second payment scheme in the treatment group involves higher payments in the months of June (or July) and December. The payment scheme varies on the plant level, and because workers know which payment scheme their plant follows, workers in the treatment group should perfectly anticipate the unusually high monthly income growth between the months of May and June (or June and July, if the extra payment is in July rather than June) as well as November and December, each followed by a month of unusually low income growth. To test the prediction of the Permanent Income Hypothesis that consumption growth should not react to preannounced income changes, the authors then simply compare seasonal consumption patterns of the treatment group (called "bonus group") and the control group (called "nonbonus group").[h] Fig. 1 shows quarterly income growth per calendar week of both groups on the left, and quarterly expenditure growth on the right.[i] Despite strong differences in the income growth patterns between both groups, the expenditure growth patterns are very similar. Thus, the evidence in Browning and Collado (2001) is in line with the predictions from the Permanent Income Hypothesis.

The major challenge here is to argue about the random assignment of the payment scheme. For example, plants might use the second payment scheme because they know their workers have unusually strong preferences for seasonally high expenditures in June/July and December, for example, due to certain holiday traditions in their region. The authors explicitly discuss this assumption and give some historical account of how the two payment schemes arose. They also show that being part of either payment scheme is not significantly correlated with any observable household characteristics. We call this the "narrative approach," because it relies purely on carefully arguing about exogeneity of the treatment, and ruling out potential alternative stories of endogeneity. Placebo exercises, described below, are useful in this regard. Since Browning and Collado (2001) find that expenditure growth patterns of both groups over the year resemble each other, the argument about exogenous treatment becomes somewhat less important; any

[h] Similarly, Hsieh (2003) compares the seasonal consumption patterns of Alaskans to the seasonal consumption patterns in other US states, and Paxson (1993) compares seasonal consumption patterns of farmers and nonfarmers in Thailand.

[i] Income is measured as average income in the three quarters preceding the interview. While the extra payments are called "bonus," there is no performance component involved.

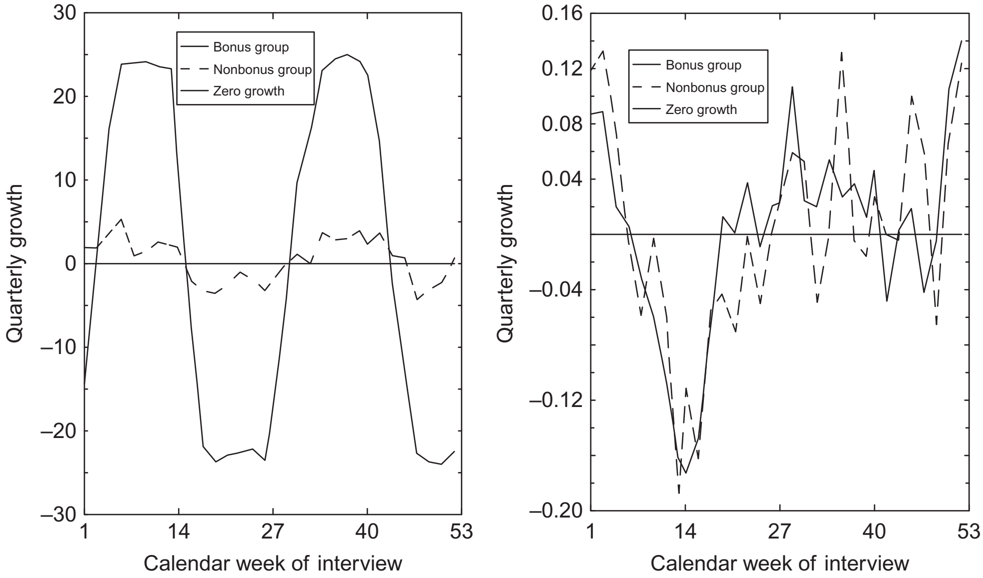

Fig. 1 Quarterly earnings growth (*left*) and quarterly total expenditure growth (*right*) in Browning and Collado (2001).

endogeneity should have led to the observation of stronger seasonal expenditure patterns correlated with the preannounced income changes for the treatment group.

2.2.1.3 Using Different Control Groups and the Matching Approach

Sometimes doubts about exogeneity of the treatment remain after a detailed description and careful analysis of the circumstances leading to treatment vs nontreatment in the "narrative approach." In this case, one can follow different strategies to still establish some confidence into a causal effect. The most basic strategy, followed by many papers, is to establish robustness of the results to the use of different control groups. Consider, for example, the study by Agarwal and Qian (2014b), who analyze the response of consumption and debt repayment to a unique cash pay-out by the government to each adult Singaporean. The pay-out happened at the same time for all eligible individuals, such that no randomness in the timing was present. Although amounts varied across individuals, this variation was not random, because the amount was a function of income and home values. Agarwal and Qian (2014b) use foreigners living in Singapore as a control group: foreigners make up almost 40% of the population living in Singapore and were not eligible to receive the pay-out. They show results of their analysis using this control group, as well as restricting the analysis to Singaporeans and exploiting only the (nonrandom) variation in amounts.

Both approaches clearly have their disadvantages. Specifically, foreigners only constitute a valid control group if their spending patterns are similar to those of Singaporeans in the absence of treatment. In a first step, the authors compare Singaporeans and foreigners along observable characteristics and find some significant differences. To control for these observable differences, they use propensity score matching methods (going back to Rosenbaum and Rubin, 1983) to construct two subsamples of matched treatment and control groups that are comparable across most observable characteristics. Researchers frequently use propensity score matching methods in microeconometric setups in which random treatment cannot be assumed. The basic idea behind a variety of submethods is that one constructs a subsample of the treatment group and a subsample of the control group which are as comparable as possible along a long list of observable characteristics. Importantly, Agarwal and Qian (2014b) also show that both subsamples have comparable seasonal spending patterns prior to the treatment, though this information is not used to construct the subsamples. Agarwal and Qian (2014b) find that Singaporeans increase their consumption already at announcement of the pay-out, and spread the consumption increase over the following 10-month period.

Abdallah and Lastrapes (2012) use a similar approach, analyzing the effect of a preannounced relaxation in the borrowing constraint among Texan home owners in 1997 on Texan retail spending. They start out using two control groups, the first consisting of all other US states except Texas, and the second consisting of all other US states that did not change sales tax rates during the estimation period. They allow for state-specific linear time trends, in order to ensure that a different general time trend in Texan retail spending is not mistakenly attributed to the policy change. In a next step, they also employ a form of matching methodology, specifically, the synthetic control method of Abadie and Gardeazabal (2003) and Abadie et al. (2010), which assigns optimally selected weights to each control group observation in order to minimize the distance between predicted sales in Texas and the control group during the pretreatment period. This study falls into the group of studies analyzing liquidity constraint relaxations (see the discussion in Section 2.2.3), and like all these studies, finds evidence for binding liquidity constraints.

2.2.1.4 The Use of Placebo Exercises

A formal way to gauge the validity of the control group is the use of placebo exercises. The idea of this approach is to define virtual "placebo treatments" and to compare the average effects of these "placebo treatments" to the one of the actual treatment. Consider again the study by Abdallah and Lastrapes (2012). In this study, the "placebo treatment" can be defined as dropping Texas from the analysis and assuming a state other than Texas introduced a similar relaxation of the borrowing constraint at the same point in time when Texas actually did. If one includes all US states in the analysis, one ends up with 49 different "placebo treatments."[j] For each of them, the baseline regression is run, and

[j] In addition, one could specify "placebo treatments" taking place in Texas, but at a different point in time, or even taking place in other states at a different point in time.

the baseline estimate on the true treatment is compared to the distribution of the estimated coefficients β from the placebo treatments. The treatment effect from the baseline regression should be well above the median placebo treatment effect in order to confirm a true effect. This approach can also be applied to control groups built based on a matching method. Gross et al. (2014), Mastrobuoni and Weinberg (2009), and Scholnick (2013) perform similar placebo exercises.

2.2.2 *The Presence of Liquidity Constraints*

As stated above, Eq. (6) holds under different concrete setups, for example, in an infinite or a finite life-time setting, under different assumptions of the functional form of the utility function, and so on. However, one important assumption has to be maintained: the consumer problem laid out in Eqs. (1) and (2) does not contain a liquidity constraint. If liquidity constraints are present and binding, the household will not be able to adjust consumption optimally at the announcement of a future income increase, but only at the implementation of the income increase.

We can deal with this complication in two ways. First, and most convincingly, one can analyze the consumption reaction to a preannounced income *decrease* rather than an increase. The presence of a liquidity constraint does not affect the optimal consumption change triggered by the announcement of a future income decrease: decreasing consumption is always a possibility. Unfortunately, the vast majority of the "natural" situations that researchers can analyze involve income increases rather than decreases. Here, the limitation of natural experiments, which cannot be designed to prevent certain limitations a priori, becomes clear in contrast to self-designed field or laboratory experiments. One paper that does analyze a decrease in income is the study by Souleles (2000). The paper analyzes the change in consumption upon an increase in college expenditure due to a child in the household starting college. Because the college entrance can be foreseen for some time, and college costs are also usually determined in the spring before the start of college, one can think of the increase in college expenditure as a perfectly anticipated increase in committed consumption and therefore as a decrease in net disposable income.[k] Souleles (2000) finds that expenditures on strictly nondurable goods and food do not fall significantly upon the anticipated decrease in net disposable income, or if anything, they fall by a very small amount, depending on the specification. This study thus finds behavior in line with the Permanent Income Hypothesis if households face an anticipated income decrease.

Apart from focusing on income decreases, one can explicitly analyze the importance of liquidity constraints by splitting the sample into potentially constrained and most likely

[k] This decrease in net disposable income is of course endogenous, because parents can choose whether and how much to spend on a child's college education. The paper includes robustness checks instrumenting for college expenditure.

unconstrained households. Because binding liquidity constraints are typically unobservable, this analysis is approximate rather than exact. Consider, for example, the paper by Johnson et al. (2006) cited above. They rely on three different measures that can proxy for liquidity constraints: age, income, and liquid assets, where the assumption is that young households, households with low income and/or a low levels of liquid assets are more likely to be liquidity constrained. Splitting the sample into "high," "medium," and "low" values of the respective variable, they then analyze whether the consumption change of the "low" and thus potentially liquidity constrained group is larger than that of the other groups.[l] Moreover, the coefficient β should be equal to zero for the unconstrained "high" group in the absence of measurement error in measuring liquidity constraints. The evidence points towards liquidity constraints: the "low" group increases consumption more upon receipt of the rebate check than the "high" group, though the difference is not always statistically significant. Moreover, even the "high" group shows a positive consumption response under some measures. These are two common findings in the literature: potentially liquidity constrained groups react stronger upon payment receipt, but groups that are likely not liquidity constrained still react significantly.[m] Misra and Surico (2014) point out that traditional measures of liquidity constraints might miss wealthy hand-to-mouth consumers (Kaplan and Violante, 2014a), who hold most of their assets in illiquid form, and provide evidence that indeed these consumers also react strongly to preannounced income changes. They argue that imposing homogeneous consumption responses not only misses interesting and systematic variation in the data that is potentially linked to liquidity constraints, but can also lead to biased estimates of the average consumption response. Indeed, analyzing measures of liquidity constraints that also incorporate wealthy hand-to-mouth consumers might allow reconciling some of the conflicting evidence on liquidity constraints found so far.

Another set of studies analyzes consumption during the payment cycle. Because income increases from zero to a positive value on the day of wage payment receipt, and then falls to zero again the day after payment receipt, these studies also encompass regular income decreases. These studies typically involve frequencies higher than the monthly one and analyze whether consumption is stable or decreases over the payment cycle (see Gelman et al., 2014; Mastrobuoni and Weinberg, 2009; Shapiro, 2005; Stephens, 2006, and Stephens, 2003). In principle, if one assumes the first payment comes at the end of a "consumption cycle," liquidity constraints could matter. However, if these regular payments have already been received for some time, arguing that households

[l] Part of the literature relying on credit card data can apply more direct measures of liquidity constraints, for example, whether individuals regularly pay interest on their credit card, or how close they are to the credit limits (see Agarwal et al., 2007; Agarwal and Qian, 2014b, and Scholnick, 2013).

[m] Unfortunately, not all studies analyzing liquidity constraints show results testing the latter hypothesis that nonliquidity constrained groups should not react significantly.

could not build up a buffer to smooth variations over the pay cycle is hard. Still, some of these studies employ explicit tests for liquidity constraints as described above and find evidence in favor of liquidity constraints (Gelman et al., 2014; Mastrobuoni and Weinberg, 2009, and Stephens, 2006). Because, in principle, liquidity constraints should not matter in this setup, the evidence in favor of liquidity constraints might indicate that the proxies for liquidity constraints are correlated with other behavioral traits that could drive the excess sensitivity of consumption to preannounced income changes.

2.2.3 Findings

More than two dozen papers test Eq. (8) in various ways. Describing these papers in detail is beyond the scope of this chapter. Nevertheless, Table A.1 at the end of this chapter provides a brief overview listing papers in alphabetical order. The table lists the nature of the specific episode that is analyzed and whether it involves an income increase or decrease, the data source (including country and specific data set used) and sample selection, the main dependent variable and its frequency, whether the paper finds significant evidence against the Permanent Income Hypothesis and what the main result is quantitatively, and finally whether any tests of liquidity constraints are carried out and what their results are. Unfortunately, because the concrete estimations run in each paper are different, one cannot indicate a comparable estimated coefficient β for each study, but we provide the main quantitative result as stated in the respective paper. All but two of the papers involve the use of household or individual data.

Table A.1 distinguishes between three different sets of studies. The first set includes 25 studies that analyze an experiment involving an anticipated change in disposable income, most often because of a direct gross or net income change, sometimes because of a change in payment commitments from mortgages or college expenditures. The dependent variable in these studies is some measure of consumption, which varies from standard measures of nondurable or durable expenditures over caloric intake to credit card spending or retail sales. Most of these studies find evidence against the Permanent Income Hypothesis: consumption growth reacts to the implementation of the preannounced income change. Notable exceptions are the studies by Agarwal and Qian (2014b), Browning and Collado (2001), Coulibaly and Li (2006), Hsieh (2003), Paxson (1993), and Souleles (2000).

The second set includes four studies that analyze the reaction to preannounced relaxations of borrowing constraints. These studies can be seen as direct tests of the presence of binding liquidity constraints: if liquidity constraints are not binding, then any preannounced relaxation of a constraint might lead to consumption reactions at announcement, but not at implementation.[n] If liquidity constraints are, however, currently

[n] Consumption might still react at announcement, because the possibility of liquidity constraints becoming potentially binding in the future affects consumption today.

binding, then any relaxation of the constraint should lead to increased consumption at implementation. The studies either involve an experiment directly relaxing the borrowing constraint and then use a measure of consumption as the dependent variable, or they involve an experiment relying on an expected income change as in the first set of studies but use a measure of loan take-up or bankruptcy filing as the dependent variable. Some of these studies still analyze whether potentially liquidity constrained households react stronger upon implementation than households who are less likely to be liquidity constrained. All of these studies find that liquidity constraints do matter.[o]

The third set includes two studies that deal with experiments that involve temporary price cuts. Under the assumption of forward-looking behavior, expenditures on goods subject to a temporary price cut increase during the period of the price cut, but at the same time, expenditures on these goods decrease before or after the period of the price cut if goods exhibit some degree of durability and the period of the price cut is relatively short.[p] These two studies find different results: Sales tax holidays seem to have long-lasting effects on purchases of some affected goods (Agarwal et al., 2013), whereas the 2009 "Cash for Clunkers" program merely shifted the purchases of new cars in time (Mian and Sufi, 2012).

2.2.4 Violation of Rational Expectations or Need for Model Extension?

A vast majority of the natural experiments investigating the Permanent Income Hypothesis find evidence against it by rejecting the null that $\beta = 0$. This seems to indicate that households are in fact not forward looking when making their consumption decisions, even if they have to take into account only income changes that will occur a few months ahead. How can one then assume that households look many years ahead, as required for retirement planning, saving for childrens' college expenditures, and so on? Thus, one of the major assumptions of the Permanent Income Hypothesis seems to be undermined. The evidence summarized in Section 2.2.2 suggests liquidity constraints can help reconcile theory and evidence, but often a significant consumption response to preannounced income changes can be found even among likely unconstrained households. Apart from analyzing liquidity constraints, the data are rarely rich enough to provide further insights into the sources of the failure of the Permanent Income Hypothesis.[q]

[o] DeFusco (2014) and Agarwal and Qian (2014a) are two recent papers analyzing similar experiments that involve a relaxation of borrowing constraints for home owners in the first case, and an unexpected tightening in the second case.

[p] Expenditures on other goods might also change, depending on the degree of substitutability or complementarity between goods.

[q] The recent study by Parker (2014) is a step in the right direction. It analyzes the spending response to the 2008 Economic Stimulus Payments using data from the Nielsen Consumer Panel, and augments these data with questionnaires that allow the author to draw conclusions about certain personal characteristics such as lack of planning, impatience, and inattention.

Table 1 Studies of the permanent income hypothesis sorted by size and regularity of the income change

	Small	Large
Regular	Aaronson et al. (2012) 0.03% Parker (1999)[a] 0.00038 % Parker (1999)[b] 0.82% Shea (1995) 0.0009%	**Browning and Collado (2001) 2.61%** **Hsieh (2003) 4.79%** **Paxson (1993) –** Souleles (1999) 1.24%

Note: Papers written in bold fail to reject the Permanent Income Hypothesis. The number after each study indicates the equivalent variation associated with the respective experiment. The equivalent variation is calculated as described in the text. Table A.1 provides details on the calculation of the equivalent variation for each paper.

[a] Change in social security tax rate

[b] Cap in social security withholding

[c] Because of the absence of suitable expenditure and income data, the equivalent variation is calculated with price-adjusted average quarterly spending from Johnson et al. (2006).

Table 1 distinguishes the existing natural experiment studies along two lines: how *large* the analyzed income change is, and whether it happens *regularly* over the life cycle. We consider an income change as *regular* if it is a repeated phenomenon that occurs to an individual several times over the life cycle, for example, tax refunds or payment schemes that double the income every year in July and December. On the other hand, unique government interventions such as tax rebates due to a fiscal stimulus program, or the running out of mortgage or college payments are considered irregular events. To classify an episode as large or small, we resort to the equivalent variation as a measure of the welfare loss associated with a certain behavior.[r] Specifically, we compare two hypothetical consumers over the course of 1 year only, considering monthly consumption,[s] and assuming additive separability of monthly utility and no discounting: the first "rational" consumer smoothes a preannounced income change x over the course of 1 year. This behavior is obviously not optimal, because optimality would call for smoothing the income change

[r] The distinction in small and large shocks has already been suggested by, among others, Browning and Collado (2001), Hsieh (2003), and Jappelli and Pistaferri (2010).

[s] The time unit is a month rather than a year because most experiments use monthly data and involve an episode of a predicted income change in a specific month, that is, most papers in the literature follow this timing logic.

over the entire life cycle, but it is a good approximation for those regular income changes that occur once a year, and otherwise provides a lower bound of the welfare losses. We calculate the utility of this consumer over a year as $U^{rational}(c) = 12 * u\left(y + \frac{x}{12}\right)$, where y is regular monthly consumption and x is the extra amount received in the experiment. The second "hand-to-mouth" consumer has the same baseline income as the "rational" consumer, but consumes the extra amount x analyzed in the specific episode entirely in the month of receipt rather than spreading it evenly over 12 months; that is, her utility is $U^{hand-to-mouth}(c) = 11 * u(y) + 1 * u(y + x)$. We then calculate the equivalent variation as the monthly consumption amount z we would have to add to the consumption of the "hand-to-mouth" consumer to make her as well off as the "rational" consumer, expressed as a percentage of regular monthly consumption.[t] In these calculations, we assume a constant relative risk aversion utility function with a risk aversion parameter of 2. We consider an experiment as *large* if the equivalent variation amounts to more than 1%. The spirit of this exercise and the specific threshold of 1% are in line with the study done by Chetty (2012), who analyzes bounds on labor supply elasticities, allowing for adjustment costs or inattention resulting in households not reacting to tax changes, as long as the associated utility loss amounts to less than 1% in a life-cycle setup. Table A.1 explains in detail which values are used to calculate the equivalent variation for each study.

In table 1, papers that fail to reject the Permanent Income Hypothesis are written in bold. As the table shows, four of the six studies that do not reject the Permanent Income Hypothesis analyze large income changes, three of these analyzing income changes that occur repeatedly over the life cycle, and one analyzing an irregular income change.[u] Among the studies analyzing large income changes, only one (Souleles, 1999, who analyzes tax refunds) rejects the Permanent Income Hypothesis. This study involves an experiment associated with an equivalent variation barely exceeding 1%, being the smallest among the "large" studies.

The remaining two studies that find support for the Permanent Income Hypothesis analyze small, irregular changes. Coulibaly and Li (2006) find that home owners smooth consumption over their last mortgage payment, after which disposable income increases. The episode is characterized as small, because the last mortgage payment is typically not high and these households are relatively well off; from a life-cycle perspective, mortgage payments, however, constitute substantial consumption commitments and thus reductions in disposable income. The last study, by Agarwal and Qian (2014b), analyzes the

[t] In other words, z solves $11 * u[y + z] + 1 * u[y + x + z] = 12 * u\left[y + \frac{x}{12}\right]$, and the equivalent variation is calculated as $EV = z/y$.

[u] Paxson (1993) does not provide enough information to calculate the equivalent variation as in the other studies. Still, it is clear that the utility loss for farmers not smoothing income fluctuations over the year would be large in the sense of an equivalent variation exceeding 1%.

2011 Singaporean Growth Dividends, which amounted to around 500 USD per individual. This study is different from the others in that it explicitly analyzes the consumption reaction at implementation *and* announcement, and finds that consumption increases already at announcement, but remains higher for almost 1 year.

Taken together, the evidence appears to imply that households tend to behave consistently with the Permanent Income Hypothesis when the stakes are high, that is, when dealing with large or repeated changes in their income. A simple way to rationalize the different results of the papers may be to consider models that allow for monetary or psychological adjustment costs of reoptimization. Moreover, learning on the part of the consumer might play a role. Monetary or psychological adjustment costs would point to near-rationality, as defined, for example, by Cochrane (1989). The evidence in favor of the Permanent Income Hypothesis coming from the studies analyzing large income changes is in line with the natural experiment studies analyzing income shocks in Section 2.1, which all look at large shocks to income and do not find evidence against the Permanent Income Hypothesis. Moreover, in the two studies that analyze temporary price cuts, the study analyzing large price cuts (Mian and Sufi, 2012) finds evidence in favor of rational behavior, whereas the paper analyzing relatively small price cuts (Agarwal et al., 2013) finds evidence against rationality. Near-rationality is in the spirit of the concept of inattentive consumers as in Reis (2006) or of inaction inertia as discussed in, for example, Anderson (2003).[v] In Reis (2006), households with high planning costs become inattentive savers, which live according to a saving plan and let consumption absorb all income changes that are not large enough to trigger a reoptimization. Small income changes might fall into this category, and thus an inattentive saver would not adjust his or her consumption at arrival of new information on a future small income change, but rather consume the extra income at arrival. The announcement of a large future income change would instead trigger reoptimization.[w]

Perhaps the most convincing evidence in favor of adjustment costs or near rationality comes from Hsieh (2003). Hsieh (2003) uses data on Alaskan households from the consumer expenditure survey in order to analyze two natural experiments on the same set of households. The first experiment involves tax refunds also analyzed by Souleles (1999). These refunds are anticipated, because the taxpayer has to calculate them when filing the tax return. Around three quarters of all taxpayers receive refunds, and the average refund

[v] Early studies of near-rationality include Akerlof and Yellen (1985) and Mankiw (1985). For a recent study, see Hassan and Mertens (2014).

[w] The survey responses analyzed by Shapiro and Slemrod (2003) do not, however, support the implications of models of inattentive savers or inattentive consumers: in contrast to the model's prediction, individuals who report to target spending are more likely to spend the 2001 tax rebates than individuals who don't target spending, whereas individuals who report to target saving show the same propensity to save the rebate as those who don't. Also, the survey evidence by Parker (2014) does not point towards inattentiveness.

on the household level amounts to 700 USD to 850 USD (in 1982–84 USD, see Souleles, 1999). Hsieh (2003) finds that Alaskan households receiving a tax refund consume 28% of it in the quarter of receipt. He then runs a regression on the same set of households, in which he analyzes a different preannounced income change, namely, payments from Alaska's Permanent Fund. The Alaska Permanent Fund redistributes receipts from oil royalties as dividend payments to residents of Alaska. The amount of the payment has been increasing over time and varies between around 300 USD per person in 1984 and almost 2000 USD per person in 2000. Because every resident of Alaska, regardless of income and age, is entitled to this payment, the average household payment is quite high, substantially higher than the average tax refund. Hsieh (2003) finds that the same households that show significant excess sensitivity of consumption to the preannounced income changes caused by tax refunds do not show such excess sensitivity to the preannounced income changes caused by dividends from the Alaska Permanent Fund. This is strong evidence that the size of the welfare cost associated with failing to smooth the income change in question matters, because it comes from exactly the same set of households. Scholnick (2013) also reports direct evidence that the magnitude of the analyzed income change matters. He analyzes the reaction of credit card spending to the predictable changes in disposable income resulting from a household's final mortgage payment. Because the mortgage payment amounts vary by households, also relative to their income, he can analyze whether the size of the income change matters.[x] Indeed, he finds a positive reaction of credit card spending to the income increase after the final mortgage payment, in violation to the prediction of the Permanent Income Hypothesis, but the larger the preannounced income change is, the smaller the reaction.

Summarizing, the literature on the Permanent Income Hypothesis finds that liquidity constraints clearly matter for some households. For households that are not constrained, near-rationality is a likely candidate to explain their excess sensitivity to small anticipated income changes. Faced with large income changes, households seem to react in line with the Permanent Income Hypothesis and are thus forward looking when making their consumption decisions.

3. QUANTIFICATION: THE FISCAL MULTIPLIER

The size of the fiscal multiplier is a highly controversial topic in macroeconomics. The fiscal multiplier measures the size of the output change associated with a change in a fiscal instrument; that is,

[x] One might, however, be worried whether the variation in size is endogenous, and how this endogeneity would affect the estimates. In a recent working paper, Kueng (2015) similarly finds evidence for near-rationality by exploiting variation in the relative size of the income change across households relying on the same experiment as Hsieh (2003).

$$\Delta Y_{t+1} = \alpha + \beta \Delta F_{t+1} + \gamma' \Delta X_{t+1} + \epsilon_{t+1}, \tag{9}$$

where β is the fiscal multiplier, Y is a measure of output, F is a measure of the fiscal instrument, and X is a vector of potential control variables, typically including lagged growth measures.

Although, in principle, running this regression with a time series of macroeconomic data is easy, the macroeconomic literature on fiscal multipliers faces one serious challenge: the change in government spending must be exogenous to economic growth. A standard measure of total government spending is certainly subject to reverse causality, such that the assumption $Cov[\Delta F_{t+1}, \epsilon_{t+1}] = 0$ does not hold. For example, automatic stabilizers such as medicaid and unemployment insurance lead to an increase in fiscal spending precisely when output growth is low, such that $Cov[\Delta F_{t+1}, \epsilon_{t+1}] < 0$, biasing the estimate of β towards zero. On the other hand, procyclical government spending components might exist if governments have limited ability to accumulate debt, in which case $Cov[\Delta F_{t+1}, \epsilon_{t+1}] > 0$, and the estimate of β would be biased upwards.

The macroeconomic literature typically addresses the issue of endogeneity using vector auto regression (VAR) methods imposing identifying restrictions (see, eg, Blanchard and Perotti, 2002 and Mountford and Uhlig, 2009), for example, that government spending does not react to current economic conditions at the quarterly frequency, or relying on the so-called narrative approach, which establishes exogeneity of fiscal policies to current economic conditions based on government records (Romer and Romer, 2010). Relying on natural experiments provides an alternative way of establishing exogeneity: for example, a war initiated by another country may create a natural experiment that causes increased government spending not motivated by current economic conditions in the home country. Although the absence of reverse causality might be easier to argue, the approach still faces some important challenges. First, one needs a critical number of these events over time or geographical variation in order to carry out an empirical analysis. A further hurdle lies in controlling for effects of the "natural experiment" on economic growth that do not play out via government spending. For example, a war might affect patriotism in the home country, potentially increasing the demand for home-produced goods, or a war taking place in the home country likely affects the capital stock. We review two lines of this literature: the first one relies on exogenous variation in military spending, and the second one estimates local fiscal multipliers, relying on different natural experiments.

3.1 Permanent Income Hypothesis Studies and the Fiscal Multiplier

Before analyzing the use of natural experiments in establishing exogeneity of fiscal spending, we want to point out the intimate link between the literature on the Permanent Income Hypothesis and the question of the size of the fiscal multiplier. Some of the Permanent Income Hypothesis papers involving natural experiments mentioned above lend themselves naturally to answering questions about the effectiveness of fiscal policy.

Are tax rebates an effective means to stimulate the economy? The answer depends on whether households save or spend the tax rebates that they receive. However, answering this question with the studies above has four important caveats: the Permanent Income Hypothesis would predict that households adjust their consumption at *announcement* of the stimulus, whereas the papers cited above analyze consumption reaction at the *implementation* of the stimulus. In that sense, using them to test the Permanent Income Hypothesis and to at the same time analyze the response of household consumption to an economic stimulus is inconsistent. On the other hand, one can consider the estimates found in these papers as a lower bound of spending, because households could have adjusted their consumption already partly at the announcement or during the time between announcement and implementation. Agarwal and Qian (2014b), which is the only paper that explicitly analyzes consumption reactions to a temporary income increase both at announcement and at implementation, find a significant consumption response already at announcement, which carries over to the time period after receipt of the payment. Second, although the receipt of a rebate check can be considered exogenous for an individual household, for the economy as a whole, it is certainly not exogenous. For example, the 2008 Economic Stimulus Payments were explicitly designed to stimulate the economy. Third, the papers analyze only a partial equilibrium response of households, not taking into account any general equilibrium effects. Fourth, most of the cited studies analyze expenditure on nondurables, whereas for the fiscal multiplier, total spending matters.

That said, the studies that analyze fiscal policy measures find evidence for a large spending response by households. Parker et al. (2013) find that households spent between 50% and 90% of the 2008 Economic Stimulus Payment on durable and nondurable goods in the quarter following receipt, indicating that the majority of the payments were consumed, not saved. Johnson et al. (2006) find that nondurable consumption increased by 20 to 40% of the payments in the quarter following receipt of the 2001 tax rebates, and that around two thirds of the rebates were spent in total on nondurable consumption, considering the cumulative effect over the 6-months period following receipt.[y] Misra and Surico (2014) stress the heterogeneity of the consumption response to both the 2001 and 2008 episodes. They show that the aggregate consumption response is smaller once this heterogeneity is taken into account than the estimates imposing homogeneity would suggest. The total disbursements of $38 billion in 2001 and $96 billion in 2008 lead to an estimated aggregate consumption response of $16 ($26) billion in nondurable consumption in 2001 based on the heterogeneous (homogeneous) estimates, and to an increase of $15 ($56) billion in total consumption in 2008.[z] Sahm et al. (2010) use survey

[y] They do not analyze expenditure on durable goods.

[z] Kaplan and Violante (2014b) point out potential reasons for the generally lower impact of the 2008 reimbursements, among others the larger size of the individual household transfers, and the phasing out at the lowest income levels.

data on spending intentions. Their estimated spending responses are smaller than the ones estimated from actual expenditure data, indicating that around one third of the 2008 Economic Stimulus Payments were spent.[aa] Analyzing an older episode, Hausman (2015) finds that within one year, World War I veterans spent between 60% and 75% of bonuses that they received in 1936, mostly on cars and housing.

3.2 Military News Shocks as Natural Experiments

One way to address the potential endogeneity of government spending is to use military events as natural experiments. The work of Barro (1981) and Hall (1986) recognized the usefulness of military events in this regard early on. Geopolitical events leading to a large buildup of military expenditure are often plausibly exogenous, because they arise due to actions of some other nations. Thus, they can potentially be used as natural experiments to isolate exogenous changes in government spending. The first paper systematically following this approach is the study by Ramey and Shapiro (1998). Based on newspaper articles, they identify three major military news shocks in the post-World-War II area: the Korean War news shock in the third quarter of 1950, the Vietnam War news shock in the first quarter of 1965, and the Carter-Reagan buildup after the Soviet invasion of Afghanistan in the first quarter of 1980. Ramey (2011) adds to this list the shock of September 11, 2001. Because the identification is based on newspaper articles, these studies also fall under the "narrative approach," but they try to identify the dates of military shocks that can be used as natural experiments. Note that timing the news shock is not trivial, especially during the Vietnam War. Ramey and Shapiro (1998) document that newspaper articles only started arguing about a military buildup after the February 1965 attacks on the US Army barracks, long after the military coup of November 1, 1963, in Vietnam. Military actions of foreign entities caused all four events, such that the argument that they were exogenous to current economic conditions in the United States is very plausible.

However, using these events as natural experiments to analyze the size of the fiscal multiplier still poses some challenges. Specifically, these news might affect other relevant variables that influence GDP, rather than only government spending. This argument especially holds for World War II, in which rigid price controls were introduced and patriotism was strong, both of which might have had a direct effect on labor supply. For this reason, Ramey and Shapiro (1998) exclude World War II from the analysis. A thorough discussion of potential confounding factors in the other episodes is, however, somewhat missing from the literature. For example, the terrorist attacks of 9/11/2001

[aa] Using the same methodology and data, Sahm et al. (2012) find that the form of payment matters, and reducing tax withholdings leads to a smaller consumption response than explicitly distributing a rebate. Misra and Surico (2014) provide some reconciliations of the different estimates of consumption responses based on expenditure data and survey responses.

likely affected uncertainty about the future path of the economy, and uncertainty shocks can matter for economic performance (see, eg, Bloom, 2009).

The early study by Ramey and Shapiro (1998) runs a regression of GDP growth on these quarterly military event dummies with up to eight lags, whereas Ramey (2011) uses these dummies in a VAR approach. She finds that the military event dummies significantly precede increases in military spending, and concludes that traditional VAR approaches might fail to identify anticipation effects. This failure can potentially reconcile the different outcomes that the traditional VAR approach and the "narrative approach" relying on military buildups have found in the effect of government spending on private consumption and real wages: traditional VAR approaches typically find a positive effect of government spending shocks on consumption and the real wage, whereas the papers relying on military news shocks find a negative effect on these two variables. Edelberg et al. (1999) provide two robustness exercises for Ramey and Shapiro (1998): first, they show that results are robust to small disturbances in the event dates. Second, and more importantly, they run placebo exercises in the spirit of the placebo exercises discussed in Section 2.2.1 and find that using arbitrary event dates leads on average to response functions outside of the confidence bands of the true responses.

Ramey (2011) goes one step further than relying simply on dummy variables, and constructs a defense news variable that measures the change in expected net present value of future military spending at the quarterly frequency based on newspaper accounts. This variable is a strong predictor of government spending as long as World War II is included. The implied fiscal multiplier relying on a VAR estimation lies between 1.1 and 1.2, but falls to between 0.6 and 0.8 if World War II is excluded.[ab] In line with this evidence, Hall (2009) stresses that the identifying variation in these studies comes from large wars, especially World War II and the Korean War. Focusing on differential effects by spending categories, Auerbach and Gorodnichenko (2012) find that military spending is the spending variable associated with the largest multiplier.

3.3 Local Fiscal Multipliers

The literature on fiscal multipliers has recently started using natural experiments to establish the exogeneity of the fiscal instrument by relying on regional data and estimating local fiscal multipliers. These multipliers are local in the sense that they analyze the effects of changes in local spending financed by the federal administrative level, which therefore constitute windfall payments from the point of view of the localities and are not associated

[ab] In Owyang et al. (2013), this defense news variable is constructed for the United States from 1890 to 2010, and for Canada from 1921 to 2011. The authors then also analyze whether the government spending multiplier is larger in recessions than in booms, and find evidence in favor for Canada, but not for the United States. Barro and Redlick (2011) also use this variable on an annual frequency to estimate multipliers, and find somewhat smaller multipliers than in Ramey (2011).

with an increase in taxation or local debt.[ac] Importantly, this approach ignores general equilibrium effects at the national level. Nakamura and Steinsson (2014) provide a theoretical discussion of how the local fiscal multiplier estimate can be tied to a standard aggregate fiscal multiplier; we come back to this shortly at the end of this section.

A typical regression run in the local fiscal multiplier literature is the following variant of (9):

$$\Delta Y_{i,t+1} = \alpha + \beta \Delta \hat{F}_{i,t+1} + \gamma' \Delta X_{i,t+1} + \delta_i + \eta_t + \epsilon_{i,t+1}, \tag{10}$$

where subscript i stands for the local entity, δ_i are regional fixed effects, and η_t are year fixed effects.[ad]

An advantage of the local fiscal multiplier regression (10) over specification (9) is that it allows the inclusion of regional and year fixed effects. The regional fixed effects capture any time-invariant regional characteristics that could lead to systematically lower or higher growth in a respective region (eg, in urban vs rural regions).[ae] More important in the context of estimating the fiscal multiplier might, however, be the inclusion of year fixed effects. These effects allow one to control for any national fiscal and more importantly monetary policies that happen concurrently with the local fiscal policy. Monetary policy is often correlated with fiscal policy, and disentangling the effects of both is therefore a major challenge for any macro estimation of fiscal multipliers. However, because monetary policy is conducted exclusively on the national level, it can easily be controlled for by including year fixed effects in an estimation of local fiscal multipliers. Given that local fiscal multiplier studies all analyze multiple local subentities of a country, they lend themselves naturally to analyzing potential heterogeneous effects of fiscal multipliers depending on local characteristics such as business cycle conditions, openness, financial development, and so on.

3.3.1 Instrumental Variables

To address potential endogeneity of the fiscal instrument, regression (10) is estimated via instrumental variables, where $\Delta \hat{F}_{i,t+1}$ is the predicted change in fiscal spending based on a first-stage regression involving the instrument I:

$$\Delta F_{i,t+1} = \kappa + \theta I_{i,t} + \zeta' \Delta X_{i,t+1} + \varepsilon_{i,t+1}. \tag{11}$$

The challenge of the estimation is to find a valid instrument for the fiscal measure. The exclusion restriction for the instrument is that it affects output growth only through its

[ac] An exception to this rule is the paper by Clemens and Miran (2012).

[ad] Note that Corbi et al. (2014) and Shoag (2013) instead regress output growth on the level of the fiscal instrument, rather than its change.

[ae] The papers by Serrato and Wingender (2014) and Chodorow-Reich et al. (2012) are exceptions in this regard by not including regional fixed effects. The former instead includes state-decade fixed effects, with the local level being the county level. The latter one does not include a time dimension, thereby preventing the use of local fixed effects.

effect on the fiscal measure. Here is where natural experiments step in. Consider, for example, the paper by Serrato and Wingender (2014). Their instrument relies on the fact that federal spending at the local level is tied to the size of the local population. The estimates of the local population size come from different sources in different years: the census carried out every 10 years provides direct counts of the local population, whereas in the years in between two censuses, population estimates are updated based on vital statistics and estimated migration flows. As a result, substantial fluctuations occur in measured population in the year before a decennial census and the census year, which are called census "error of closure." The authors use this census error of closure to instrument the change in federal spending on the local level in the affected years.

For the census error of closure to be a valid instrument, it has to predict fiscal spending, and the exclusion restriction has to hold. The first of these two conditions can relatively easily be established by showing the first-stage regression results and running an F-test for the joint significance of the instruments. Concerning the second condition, the authors show theoretically that under classical measurement error in both census counts and administrative estimates, or under the weaker condition that both estimates are biased in the same order of magnitude, the exclusion restriction holds. Moreover, they explain in detail how the two estimates arise and what the literature concludes on their accuracy and potential biases. For example, one could imagine that the population estimates between censuses systematically underestimate population growth in fast-growing counties, such that the error of closure is always more positive in counties that experience an economic expansion. Any persistence in growth would then result in a direct effect of the error of closure on growth, violating the exclusion restriction. Controlling for past growth helps address this concern but does not rule it out completely. To provide further evidence that the exclusion restriction holds, the authors show that the census error of closure shows only minimal geographical correlation at the county level and no time-series correlation. Most importantly, it is not positively correlated with growth in the years before the error of closure should actually affect federal fiscal spending on the county level.[af] Although in the end these exercises remain suggestive, addressing potential concerns about the exclusion restriction in further evidence of this kind is good practice.

This literature uses two other interesting natural experiments. The first one, used in the paper by Acconcia et al. (2014), is an Italian law specifying the dismissal of elected local officials and their replacement with three external commissioners for 18 months upon evidence of Mafia infiltration in city councils. This replacement leads on average to sharp reductions in spending on public work at the provincial level, the reason being

[af] The error of closure should only affect fiscal spending 2 years after the census is run, given that publishing the results takes 2 years. In fact, a significant negative correlation exists between the error of closure and employment and income growth in previous years. This finding might raise the worry that spending rises in past recession areas, and that mean reversion might lead to future growth in these areas. The authors argue that controls for past growth in the second-stage regression take care of these concerns.

that this sector is typically a lucrative source of business for the Mafia. The authors show that growth rates prior to dismissal are not significantly different in treated and control provinces. The second natural experiment in the paper by Cohen et al. (2011) consists of changes in congressional committee chairmanships, which influence government spending in the state of the new chairman.[ag] Because chairmanship in a committee is largely determined by seniority, and because chair turnover results from election defeat or resignation of the incumbent, it is driven by political circumstances in other than the home state of the incoming chairman and can thus be seen as exogenous.

There exist other papers in this literature that rely on the same approach of finding a valid instrument for the fiscal measure in Eq. (10), but in which this instrument is less clearly a natural experiment. There is an obvious "grey zone" of what can be considered a natural experiment. In the spirit of our definition that a natural experiment is an historical event that provides exogenous variation to give a plausible identifying assumption, the census error of closure, the law specifying replacement of local officials upon evidence of Mafia infiltration, and the chairmanship in congressional committees, are such historic episodes. A variety of papers in this literature use instruments to identify exogenous variation in government spending, where the instruments do not rely on historical episodes and are themselves more directly linked to fiscal policies. Examples of these papers are Nakamura and Steinsson (2014), who exploit different state-level sensitivities to national military spending,[ah] Chodorow-Reich et al. (2012), who use precrisis state-level Medicaid spending to extract the exogenous component of increases in federal match components of state Medicaid expenditure during the 2009 American Recovery and Reinvestment Act (ARRA), and Wilson (2012), who uses exogenous formulary allocation factors such as federal highway miles in a state or a state's youth share to instrument government spending under the 2009 ARRA. Similarly, Clemens and Miran (2012) use fiscal institutions on the state level, specifically how strict balanced budget rules are, to identify exogenous variation in government spending. Shoag (2013) and Shoag (2015) exploit variations in returns to state pension plans.[ai] Kraay (2012) and Kraay (2014) focus

[ag] Feyrer and Sacerdote (2012) take a similar approach, relying on average seniority of House members, when analyzing the effectiveness of the 2009 American Recovery and Reinvestment Act.

[ah] Fishback and Cullen (2013) analyze the effect of state-level military spending during the Second World War, but do not use instruments for state-level military spending, but rather rely on narratives to establish exogeneity.

[ai] Both papers use the same instrument. However, the analysis in Shoag (2013) focuses on the Great Recession years 2008 and 2009, whereas Shoag (2015) exploits information from 1987 to 2008. Brückner and Tuladhar (2014) also analyze a local fiscal multiplier using data from Japanese Prefectures. Whereas their study shares the use of year and region fixed effects with the studies cited above, it addresses the issue of endogeneity of local government expenditures by using a system GMM approach. The paper by Fishback and Kachanovskaya (2015) analyzes federal spending on the state level during the Great Depression, relying on instruments similar in spirit to Nakamura and Steinsson (2014), Chodorow-Reich et al. (2012), and Wilson (2012).

on World Bank lending, in which project financing is spread out over several years after the lending decisions. In all of these cases, the instrument is quite closely related to the research question, which makes it harder to argue that the exclusion restriction holds. Therefore, all of these papers spend considerable effort on providing additional evidence for the validity of the exclusion restriction. A common strategy to establish exogeneity of the instrument is to include further controls and exploit specifics in the timing to argue that the identifying assumption holds; see, for example, Clemens and Miran (2012) and Kraay (2012).[aj] Wilson (2012) controls for a variety of variables that are potentially correlated with post-2009 growth and also 2009 ARRA spending, for example, pre-2009 employment growth.

3.3.2 Regression Discontinuity

There are only few papers in the local fiscal multiplier literature using a regression discontinuity approach. Since the exploited policy rules that generate the discontinuities are close to the research question at hand, these papers are closer in spirit to the second group of papers cited above than to the first group, which relies more obviously on natural experiments. Corbi et al. (2014) exploit the fact that, as in the United States, Brazilian federal transfers to municipal governments rely on the population at the local level. In contrast to the United States, a specific step function exists that specifies the total transfer amount for certain population classes. Thus, sharp discontinuities arise in the transfers per capita around the cut-off values in this step function, whereas all other variables should change smoothly around the cut-off. This is the identifying assumption for their regression discontinuity approach. Another advantage of their experiment is that several cut-off values exist (rather than, eg, only one cut-off value as in the paper by Trezzi and Porcelli, 2014), which gives the test high statistical power. Sixty percent of the municipalities in the sample switch the population class at least once in the sample period. Because the data show that adherence to the cut-off is not implemented 100%, and, in fact, some judiciary disputes surround them, the authors confront a fuzzy regression discontinuity design and use the theoretically predicted transfers based on the actual population count as an instrument for the actual transfers. They employ different bandwidths around the cut-off values, and also report results from regressions with a rectangular kernel. In a similar spirit, Becker et al. (2010) and Becker et al. (2013) use a regression discontinuity design to analyze the effect of EU grants on local development, relying on a discontinuity in regional GDP per capita eligibility for the grants.

3.3.3 Estimates of the Local Fiscal Multiplier

The estimates of the local fiscal multipliers in the studies described above show surprising consistency and range between 1.5 and 2, despite the different identifying restrictions

[aj] Kraay (2012) in addition uses predicted project-level disbursements, given the economic sector and the geographic region, rather than actual ones to address concerns about endogeneity.

based on natural experiments or other institutional details, different econometric approaches, different nations, and different fiscal spending measures.[ak] Nakamura and Steinsson (2014) show that an open economy New Keynesian model with sticky prices and complementarity between consumption and labor is best able to replicate these large local fiscal multipliers, which they call "open economy relative multiplier." They also show that the model implied "closed economy aggregate multiplier," which is commonly considered in the literature on fiscal multipliers, depends in its size very much on the accompanying monetary policy.

Another common feature of these studies is that the IV estimates are 5 to 15 times larger than the simple OLS estimates of Eq. (10).[al] This indicates that OLS estimates might be systematically downward biased, for example, because of automatic stabilizers (which increase spending in downturns of the economy), general endogeneity of government spending (increased discretionary spending to stimulate the economy in downturns), and interaction with monetary policy (fiscal spending might step in specifically when monetary policy does not work due to a binding zero lower bound).

4. IDENTIFICATION: CAUSAL FACTORS IN ECONOMIC GROWTH

4.1 The Fundamental Causes of Growth

In the previous two sections, we have explored a number of natural experiments that inform us about the validity of established macroeconomic models and the direction and magnitude of causal relationships that operate within them. In this section, we ask what natural experiments can teach us about the kind of models that we *should* be writing. In other words, what are the important determinants of economic outcomes that are outside of our standard models?

By far the most influential application of natural experiments in this respect is the search for the "fundamental" reasons of why some countries are rich while others are poor. Corresponding to the breadth of this question, the empirical work in this area is very diverse and much less focused than the work we covered in the previous sections. For this reason, we find it useful to first lay out a rough framework to fix ideas and organize the different strands of this literature into a coherent narrative.

To distinguish the fundamental causes from proximate causes of economic growth, consider a typical production function that relates output Y_t to the input of physical

[ak] These multipliers to windfall income are larger than the multiplier estimated by Clemens and Miran (2012), who take local tax or debt adjustments into account.

[al] For example, in Serrato and Wingender (2014), the 2SLS estimate is 15 times larger than the OLS estimate, 7 times larger in Acconcia et al. (2014), and 5 (based on regional data) to 15 (based on state data) times larger in Nakamura and Steinsson (2014).

capital K_t, human capital H_t, the number of workers L_t, and the level of labor-augmenting technology A_t:

$$Y_t = K_t^{\alpha} H_t^{\beta} (A_t L_t)^{1-\alpha-\beta}, \tag{12}$$

where $0 < \alpha < 1, 0 < \beta < 1$, and $\alpha + \beta < 1$. By dividing both sides of this expression by L, we can see that output per capita is a function of technology and the intensity of physical and human capital per worker. Eq. (12) thus describes a causal relationship: having better technology and more capital and education per worker makes a country richer.[am]

Although this statement is undoubtedly true, it is also not very helpful for understanding the large and persistent differences in income per capita across countries, without understanding the process by which countries accumulate capital and technology. This question is the object of a large theoretical literature on economic growth.

Consider, for example, the canonical growth model based on Solow (1956) and Swan (1956). In this model, A_t grows at the exogenous rate g and at every point in time households invest a fixed proportion of their income into physical and human capital according to

$$\dot{K}_t = s_k Y_t - \delta_k K_t$$

and

$$\dot{H}_t = s_h Y_t - \delta_h H_t,$$

where the savings rates s and depreciation rates δ are between zero and one, and $s_k + s_h < 1$.

Using lowercase variables to denote the level of output, physical, and human capital in terms of effective labor,

$$x_t \equiv X_t/(A_t L_t), X = Y, K, H,$$

we can then show that at the balanced growth path, consumption, output, physical, and human capital per effective unit of labor are all constant. In particular, output per effective labor is

$$y^* = \left(\frac{s_k}{g + \delta_k}\right)^{\frac{\alpha}{1-\alpha-\beta}} \left(\frac{s_h}{g + \delta_h}\right)^{\frac{\beta}{1-\alpha-\beta}}.$$

It follows directly that output per capita (as well as physical and human capital per capita) grows at the fixed rate g.

The Solow–Swan model again describes a causal relationship: having better technology and saving more for investment in human and physical capital makes a country richer. Although this relationship gives us a better idea of *how* growth happens (by saving

[am] Here we are assuming that all countries share the same production function (12) but do not otherwise interact with each other.

and accumulating capital), it does arguably little for our understanding of *why* people in a poor country like Zimbabwe use worse technology and/or invest less in physical capital and education than people in a rich country like the United States.

In the half century since the publication of the Solow (1956) and Swan (1956) papers, growth theory has made tremendous advances in understanding the mechanics of growth. Aside from endogenizing the savings rates (s), one of the major advances of the literature has been to explain the dynamics of the technology process, such that A_t becomes effectively an endogenous accumulated factor itself. With one major exception, which we will discuss in detail below, these advances, however, do not change the fundamental nature of the problem: physical capital, education, and technological progress are proximate rather than fundamental causes of growth. Understanding their dynamics helps us understand the mechanics of growth (how it happens) but conceptionally does not tell us why a poor country like Zimbabwe is fundamentally different from a rich country like the United States.

For the purposes of our following discussion, we will define the fundamental causes of economic growth as *the political, institutional, and social reasons that are preventing many countries from investing enough in technology and productive factors*. Formally, we may think of a typical growth model as producing a mapping from a vector of parameters ϕ_i governing the production and accumulation of technology and productive factors in a country i to its level of output per capita $\frac{Y_{i,t}^*}{L_{i,t}}$ on the balanced growth path:

$$F(\phi_i) \rightarrow \frac{Y_{i,t}^*}{L_{i,t}}. \tag{13}$$

Whereas we think of the proximate causes of growth as operating within the function F, the fundamental causes are the political, institutional, and social factors that generate cross-country variation in the parameters ϕ_i.

In the remainder of this chapter, we consider the evidence that natural experiments have uncovered for three such fundamental causes:

1. institutions,
2. social structure, and
3. culture.

For the purposes of our following discussion, we define as "institutions" the broad set of rules, regulations, laws, and policies that affect economic incentives and thus the incentives to invest in technology, physical capital, and human capital (Acemoglu, 2009). By social structure we mean "patterned relations," that is, the network of friendships and family ties between large groups of individuals that affects the diffusion of information and the ability of individuals to enforce contracts, as well as the system of socioeconomic stratification (eg, the class structure) of a society. As "culture" or "civic capital," we define those persistent and shared beliefs and values that help a group overcome the free-rider problem in the pursuit of socially valuable activities (Guiso et al., 2012). Note that the literature often refers to the latter two categories jointly as "social capital" (Putnam, 2000). We prefer to separate them here because both of these elements have been empirically shown to have independent effects on growth, but otherwise have no preference for one definition over another.

Taken together, these three causes determine the social environment in which economic activity takes place. Because conducting controlled experiments on this social environment at the scale of countries or even regions is generally impossible, natural experiments are arguably our best bet for making causal inference at this scale. In each case, we will first discuss a selection of natural experiments that provide evidence of the causal relationship between GDP per capita and institutions, social structure, and culture, respectively. Then, whenever available, we will discuss some of the evidence on the dynamics of each of these forces and avenues for future research. Because each of these literatures is vast, we cannot give a comprehensive overview of each of them (Guiso et al., 2012; Algan and Cahuc, 2013; Alesina and Giuliano, 2015; Nunn, 2013, and Chaney, 2014 provide excellent surveys). Instead, we focus on giving a broad overview of the types of measurement and identification issues that arise in these applications, and provide specific examples.

To our list of three fundamental causes, we add a set of natural experiments that speak to the question of whether multiplicity might exist in the mapping (13). In other words, the mechanics of economic growth may be such that two countries with identical ϕ_i may end up on different balanced growth paths by pure coincidence or luck. This scenario is the major exception mentioned above: models that generate multiple equilibria may be able to explain why Zimbabwe is poor and the United States is rich, without taking recourse to any fundamental causes of growth:

4. luck and multiple equilibria.

Here again we select papers to give a broad overview of the measurement and identification issues.

One striking feature that the studies in all four categories have in common is that they tend to make relatively little use of the structure provided by growth models. That is, most approaches relate variation in ϕ_i directly to $\frac{Y^*_{i,t}}{L_{i,t}}$, without making use of the structure of F. In this sense, the literatures on the proximate causes and fundamental causes of growth have developed relatively independently. We will comment on this issue further below.

4.2 Institutions and Political Economy

Of the three fundamental causes of economic growth, "institutions"—the rules, regulations, laws, and policies that affect the incentives to invest in accumulated factors of production—have received by far the most attention from empiricists. The reason for this attention is that institutions, and in particular the protection of property rights, fit neatly into standard ways of thinking about incentives: investors will be reluctant to invest in capital and technology if the returns from these investments are likely to disappear into the pockets of corrupt bureaucrats. Clearly, bad institutions must thus be bad for growth. A correspondingly long history of thought in economics links institutions to economic development (North and Thomas, 1973; Jones, 2003; North, 1981; Mauro, 1995; Hall and Jones, 1999; La Porta et al., 1998).

However, despite this long intellectual history, which way the causality runs is far from clear: for example, we may suspect that richer countries can also afford a better judicial system, and thus better protect property rights. Similarly, researchers disagree about what makes governments *want to* protect property rights. In practice, the set of institutions a society adopts depends in complex ways on the society's level of economic development, culture, social structure, the education of the population, and its historical experience. Identifying a causal effect of institutions on economic growth thus requires an exogenous source of variation in the type of institutions that different societies adopt.

Consider, for example, the following structural equation of interest:

$$log(Y_i) = \alpha + \beta R_i + X_i' \gamma + \epsilon_i, \tag{14}$$

where Y_i is income per capita in country i, R_i is a measure for the protection of property rights, and X_i is a vector of controls. The fundamental problem in identifying β is that R_i and Y_i are likely to be jointly determined such that $cov(R_i,\epsilon_i) \neq 0$, resulting in biased OLS estimates of (14). Unbiased estimates of β thus require exogenous variation in R_i.

In this section, we first discuss a set of natural experiments that attempt to identify such exogenous variation, and establish a causal link between institutions and growth. We then turn to the mechanism that links institutions to growth and to the dynamics of institutions.

4.2.1 The Effect of Institutions on Growth

In an influential study, Acemoglu et al. (2001), consider the natural experiment surrounding the colonization of virtually all of Africa, North and South America, Australia, and large parts of Asia by Europeans. Today, the countries that emerged from these former colonies differ widely in their level of economic development and in the functioning of their institutions—and these differences appear highly persistent over time. For example, the United States has been richer than the Congo for more than a century, and there is little evidence that this will change in the near future. Acemoglu, Johnson, and Robinson (AJR) argue that the mortality rates Europeans settling in these different colonies faced explain part of this heterogeneity: Europeans who made the trip to the Congo could expect to be plagued by malaria and yellow fever and consequently had much lower life expectancies than settlers heading for the present-day United States. This health cost that

Europeans faced when considering whether to settle in different parts of the world determined the form of colonization that each country experienced.

AJR's idea is that in countries with a disease environment that was hazardous to Europeans (eg, the Congo), the early colonizers set up institutions that would maximize the extraction of natural resources, requiring as small a European presence as possible. These institutions did not introduce much protection of property rights and did not involve checks and balances against the power of the ruling elites that were dominated by Europeans. By contrast, colonies that were attractive destinations for European settlers (eg, Australia and the United States) imported European institutions that fostered safe property rights and checks and balances in government. The resulting historical differences in institutions across countries then tended to persist to the present day, resulting in persistent differences in economic performance that last to the present day.

Fig. 2 shows the relationship between settler mortality and a contemporary measure for average expropriation risk for the 64 countries included in AJR's sample. The authors argue that this negative and highly significant relationship delivers quasi-random variation in R_i because the mortality rates of European settlers in the 17th to 19th centuries (or any omitted variables correlated with them) are unlikely to have a direct effect on GDP per capita today, other than their effect through institutions.

When instrumenting R_i with the mortality rates of soldiers, bishops, and sailors stationed in country i between 1600 and 1800 CE, AJR's estimates of the parameter β are positive and statistically highly significant. They imply that an improvement in Nigeria's level of protection of property rights to match that of Chile would, in the long-run, increase Nigeria's GDP per capita by a factor of 7. Heterogeneity in institutions may thus account for a large part of the differences that exist today in wealth between countries.

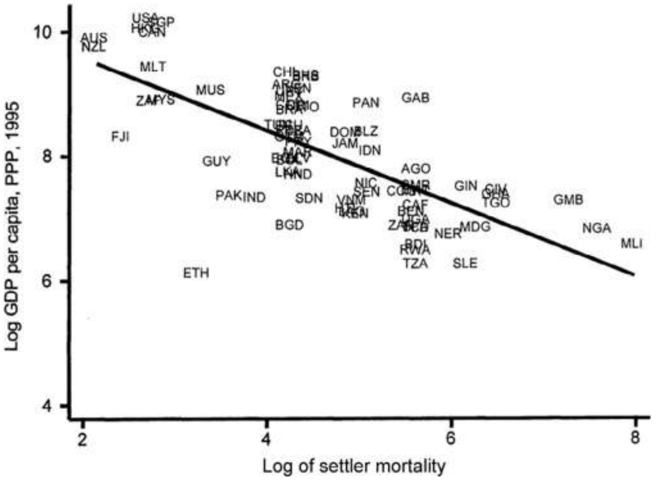

Fig. 2 Relationship between settler mortality and expropriation risk in Acemoglu et al. (2001).

In an additional application of the same natural experiment, Acemoglu et al. (2002) argue that heterogeneity in institutions can also explain the large changes in the relative prosperity that have occurred since 1500 CE. Before the onset of European colonization, civilizations in Meso-america, the Andes, India, and Southeast Asia appear to have been richer than those in North America, Australia, or New Zealand. Today, the relationship is reversed: a simple regression of GDP per capita in 1995 on urbanization in 1500 (as a proxy for historical GDP per capita) yields a negative and highly statistically significant coefficient. AJR show that differences in the institutions imposed by European colonizers can again explain this fact. When adding measures of institutions to the regression and instrumenting them with settler mortality, the negative correlation between present-day GDP per capita and historical urbanization disappears. Because settler mortality and population density in 1500 are positively correlated, European colonizers tended to introduce or perpetuate extractive institutions in places where they found a high density of local populations, while creating good institutions in places where they settled in large numbers.[an]

The main identifying assumption for a causal interpretation of the results in both papers is that, conditional on the controls included in the vector X, the mortality rates of European settlers in the 17th to 19th centuries (or any omitted variables correlated with them) have no effect on GDP per capita today, other than their effect through institutions.

This assumption raises two main concerns. First, omitted variables that are correlated with historical mortality rates could be correlated with present-day GDP per capita. The most obvious of these variables is the current disease environment. For example, places that were hard to settle historically may be difficult to live in today, resulting in lower economic growth. AJR argue that this is not the case. The historical disease environment had large negative effects on Europeans, but much smaller effects on the indigenous populations. For example, local troops serving the British army in Bengal had mortality rates that were comparable to those of British troops stationed in Britain, whereas British troops in Bengal had mortality rates that were 7 to 10 times higher. In addition, AJR's estimates for β change little when controlling for elements of the current disease environment, suggesting that the effect of the historical disease environment indeed transmits itself through differential European settlement at the time. They also show that their results are robust to controlling for other correlates of GDP per capita, such as the identity of the colonizer, the origin of the legal system, and various measures of climate conditions.

[an] For a more in-depth discussion of the merits and weaknesses of AJR (2001)'s analysis, see Easterly and Levine (2003); Glaeser et al. (2004); Olsson (2004); Rodrik et al. (2004); Acemoglu et al. (2012); Albouy (2012); Easterly and Levine (2012), and Acemoglu et al. (2014a).

The second main concern is much harder to address: the effect of European settlement may transmit itself through a range of different mechanisms that may be correlated with the protection of property rights. In particular, Europeans may also have imported their own culture and high levels of civic capital or they may have brought valuable social ties to their countries of origin. Thus, AJR are unable to distinguish the effect of institutions from the effect of other persistent variables that may be correlated with both European settlements and institutions, and in particular from the two other fundamental causes of economic growth discussed in the next two subsections. More generally, any instrumental variables approach that relies on cross-sectional variation will run into this problem.

Michalopoulos and Papaioannou (2014) attempt to make progress on distinguishing the effects of institutions and culture using data on light intensity in combination with a regression discontinuity approach. They argue that the borders between many African countries were drawn in the mid to late 19th century by Europeans who were largely uninformed about local conditions. As a result, these borders partition more than 200 historic homelands of ethnicities between two different modern-day countries in a quasi-random way, subjecting identical cultures residing in geographically homogeneous territories to different country-level institutions. Their main specification takes the following form:

$$y_{p,e,i} = \alpha + \beta IQL_i^{HIGH} + f(BD_{p,e,i}) + \gamma PD_{p,e,i} + X'_{p,e,i}\Phi + \eta_e + \epsilon_{p,e,i}, \tag{15}$$

where $y_{p,e,i}$ is a dummy variable that is 1 if pixel p (an area corresponding to about 12 × 12 km) in the historic homeland of ethnic group e in country i is lit—a simple measure of whether residents of that piece of land can afford nighttime lighting. IQL^{HIGH} is an indicator that is 1 if the pixel is in the part of the partitioned homeland that is located in the country with the relatively higher institutional quality, $f(BD_{p,e,i})$ is a polynomial of shortest distance of the pixel centroid to the country border, PD is population density, X contains additional controls, and η_e is an ethnic homeland fixed effect. Under the identifying assumption that at the country border, institutions change discretely, while all other relevant influences on $y_{p,e,i}$ (including culture and geography) change continuously, β measures the effect of relatively better institutions at the country border.

In contrast to the results of AJR (2001)'s cross-country analysis, the authors find no effect of institutions at the country border: across different variations, they cannot distinguish β from zero, suggesting that, at the border, exogenous variation in national institutions is not associated systematically with higher wealth (more light). These results may suggest that, at least for Africa, omitted factors such as culture (civic capital) or social structure might explain the strong association between institutions and GDP per capita. However, more consistent with AJR (2001)'s results, Michalopoulos and Papaioannou find a positive and significant effect of better institutions for split groups that are located close to national capitals. The absence of an effect at the border of the average African country could thus simply be explained by the fact that the influence of many African countries' governments is weak in remote regions.[ao]

In a closely related paper, Pinkovskiy (2013) also uses a regression discontinuity approach to test for discontinuities in the amount of light per capita at country borders, but applies his analysis to the entire world, rather than only to Africa. Because most borders in the world were not drawn randomly but might be determined by the location of ethnic homelands, culture, or other variables, he restricts his estimates to within 50km of the border. Within this narrow bandwidth, one may plausibly argue that the *exact* location of the border is quasi-random, even though borders outside of Africa were not drawn by largely uninformed imperial powers. In contrast to Michalopoulos and Papaioannou (2014), Pinkovskiy finds a large and statistically significant discontinuity at national borders, although it is not significant when restricting the sample to Africa. In addition, this effect of the country border becomes statistically insignificant once Pinkovskiy controls for differences in the rule of law.

4.2.2 The Effect of Institutions on Business Cycles and Conflict

Given this evidence of a causal link between institutions and growth, an obvious question is *how* this effect transmits itself in practice. One interesting, and often overlooked, piece of evidence comes from yet another application of AJR (2001)'s natural experiment. Acemoglu et al. (2003) show that countries with worse institutions (again instrumented with settler mortality) also have more volatile business cycles and are more prone to episodes of economic crises. Once the authors control for this effect of institutions, the standard macroeconomic policies that are often blamed for macroeconomic instability (eg, high government spending and high inflation rates) are no longer systematically associated with macroeconomic volatility.

The authors draw two main conclusions from this finding. First, bad macroeconomic policies are often a symptom of underlying institutional problems. Second, they are often not the primary mediating channel through which institutions affect macroeconomic stability. These results suggest that a more useful line of thought might be that policies such as excessive government spending and high inflation rates are just two of a large set of tools that politically powerful groups use to extract rents from the economy. Any policy (perhaps imposed by the IMF or another international organization) that shuts down one of these distortions but does not resolve the underlying institutional problems, may then simply result in the use of a different tool (another macroeconomic or microeconomic distortion) that achieves the same aim. Macroeconomic instability and low growth may then be thought of as collateral damage from this rent-extraction process.[ap]

[ao] There is also a technical debate on the bleeding of nighttime light across borders that may attenuate any estimated border-effect, see the discussion in Pinkovskiy (2013).

[ap] Most macroeconomic models imply that macroeconomic volatility reduces growth; see Baker and Bloom (2013) for estimates of this relationship.

In a second application of their natural experiment surrounding the quasi-random drawing of African boundaries by relatively uninformed Europeans, Michalopoulos and Papaioannou (2011) show that ill-designed institutions may also slow economic development by prompting long-term conflict. Using data on the precolonial locations of 834 ethnic groups, they show that the drawing of African boundaries indeed appears to have quasi-randomly partitioned 229 of these groups between two adjacent states: partitioned and nonpartitioned ethnicities do not appear to differ systematically in their precolonial characteristics, except that partitioned groups tended to cover larger land areas and to have historical homelands with larger areas under water. The authors then show that between 1997 and 2010, partitioned ethnic homelands had a 30% higher likelihood of experiencing political violence (eg, battles between government forces, rebel groups, and militias) and a 40% higher likelihood of experiencing violence against civilians (eg, murders, abductions, and child-soldiering raids) than nonpartitioned ethnic homelands. This higher incidence of violence is also associated with worse economic outcomes and lower provision of public goods.

4.2.3 Persistent Effects of Historical Institutions

The main conclusion from this set of studies is that dysfunctional institutions are a major obstacle to economic development because they deter investment, create macroeconomic instability, and potentially lead to violent conflict. A crucial question for policy is then whether replacing such institutions reverses these adverse effects. Several papers study this question using natural experiments surrounding the imposition and subsequent abolition of historical institutions.

Banerjee and Iyer (2005) examine the long-term impact of colonial land revenue systems in British India. In some Indian districts, British officials levied taxes on agricultural income, whereas in other districts, the collection of taxes was left to a class of native landlords who were free to set the revenue terms for the peasants under their rule and to dispossess them if they did not pay their dues. After Indian independence in 1947, all direct taxes on agricultural income (and thus both institutions) were abolished. Nevertheless, Banerjee and Iyer find that to the present day, districts that used the landlord-based system have lower agricultural yields and investment, lower public investment in health and education, as well as worse health and educational outcomes. To show that these relationships are causal, the authors instrument the choice of land revenue system with a dummy variable equal to 1 if the district was annexed between 1820 and 1856, a period during which the authors argue the British preferred the nonlandlord-based systems for political and intellectual reasons that are orthogonal to the characteristics of the annexed districts. Banerjee and Iyer argue that these adverse effects of the landlord-based system persist because of its effect on the social structure of the affected areas: it created a class-based antagonism that limits the capacity for collective action in the affected districts to the present day. As a result, these districts are relatively less able to muster the political influence to claim their fair share of expenditure in education, health care, and public goods.

Rather than focusing on heterogeneous institutions within districts that were directly controlled by the British, Iyer (2010) studies the long-term effects of direct British colonial rule vs indirect rule across 415 districts in present-day India. Although all of India was under British political control by the middle of the 19th century, the British administered directly only part of this area (British India), while Indian Kings (Princely States) who had considerable autonomy ruled the remaining parts. After the end of colonial rule in 1947, all of India then came under a uniform administrative and political structure. The major problem when attempting to estimate the causal effect of direct British control is that the British did not randomly annex areas, but presumably were more eager to annex richer than poorer areas. Iyer deals with this selection problem by using the "Doctrine of Lapse," a policy that was in place from 1848 to 1856, under which the British annexed princely states whose rulers died without a natural heir. Using lapse as an instrument for direct British rule, she finds no effect on agricultural productivity and investment, but a negative effect of direct British rule on the provision of public goods, education, and health care that lasts through the 1990s, although these persistent effects appear to be decreasing over time.

Whereas both Banerjee and Iyer (2005) and Iyer (2010) rely on instruments in their identification strategy, Dell (2010) uses a regression discontinuity design to study the long-term effects of the *mita* forced labor system that the Spanish instituted in Peru and Bolivia from 1573 to 1812. Under this system, villages within a geographically precisely determined area were required to send one seventh of their male adult population to work in silver and mercury mines. Similar to Pinkovskiy (2013), she argues that the exact location of the *mita* boundary is quasi-random within a 50km band, such that all other relevant influences on household consumption vary smoothly at the border of the *mita* area. Subject to this assumption, Dell estimates that the mita had a persistent negative effect that lowers household consumption by 25% almost 200 years after its abolition. She argues that this effect most likely transmits itself again through the lower provision of public goods and education services to these areas.

Alesina and Fuchs-Schündeln (2007) analyze the long-term effect of institutions on individual economic preferences, as opposed to economic outcomes. They explore German separation and reunification as a natural experiment to analyze how 45 years of communist rule affected individuals' attitudes toward market capitalism, and the role of the state in providing insurance and redistribution from the rich to the poor. Seven years after reunification, East Germans are still much more likely to favor a strong role of the government. This difference in preferences is larger for older cohorts, who lived under different systems for a longer time period. The micro data allow the authors to include rich controls for individual economic motives to favor a strong government, such that the difference can confidently be attributed to the effect of living under a market system vs a communist system. Similar to the convergence found in Iyer (2010), the longer East Germans live under the new market system, the more their preferences resemble those of West Germans. Under the assumption of linear convergence, full convergence will take one to two generations. This convergence is the product of two forces: around one third of the convergence is due to a shift in the cohort composition towards younger cohorts, and around two thirds can be attributed to actual convergence of preferences within individuals.[aq]

The main conclusion from this set of natural experiments is that historical institutions have long-lasting effects—even after their abolition—that transmit themselves through their effect on the distribution of political power, social structure, preferences, or some other mechanism. Although all three studies focusing on economic outcomes commit considerable effort to narrow down the potential channels of persistence, their design does not allow them to identify the exact channel. A remaining challenge for future work is thus to go beyond causal identification of the treatment effect of historical institutions and to identify natural experiments that speak simultaneously to the treatment effect and its channel of persistence.

4.2.4 Determinants and Dynamics of Institutions

If institutions have a large causal effect on economic growth, a crucial question is how countries acquire well-functioning institutions and what might determine their evolution over time. The natural experiments covered so far suggest colonization has generated large and persistent differences in the "level" of the quality of governance and institutions across countries. This view is also consistent with a large literature on the economic consequences of legal origins, which has shown that the identity of the colonizing country determines the type of legal system used in former colonies as well as its performance along a broad range of dimensions (La Porta et al., 1998, 1997, 2008). Another example of institutional change resulting from foreign domination and conquest is the abolition of feudalism and the imposition of French civil law in German states conquered during the Napoleonic wars (Acemoglu et al., 2011a).

Aside from these large-scale cross-sectional experiments, a more practical question, at least from a policy perspective, may be what determines the dynamics of institutions over time. To address this question, a large set of studies attempts to identify exogenous shocks to the political balance of power between different groups within a polity, and how these shocks may foster or retard the development of good political and economic institutions. A closely related set of studies, which we discuss in Section 4.3.3, focuses instead on identifying exogenous shocks to a society's social structure.

4.2.4.1 Shocks to the Political Balance of Power

One interesting approach to identifying exogenous shocks to the political balance of power uses shocks to the natural environment as an instrument. For example,

[aq] Fuchs-Schündeln and Schündeln (2015) similarly find evidence for the endogeneity of democratic preferences.

Brueckner and Ciccone (2011) combine information about GDP per capita and average annual rainfall with measures of democratization and constraints on the executive in sub-Saharan African countries 1981 to 2006.[ar] Because many sub-Saharan countries rely heavily on agriculture, negative rainfall shocks (droughts) may serve as a good instrument for recessions in these countries. Brueckner and Ciccone's main specification relates changes in constraints on the executive to lagged GDP per capita and a full set of time and country fixed effects, while using lagged average rainfall as an instrument for lagged GDP per capita. They find a negative and highly significant coefficient on GDP per capita. Because the specification uses only variation within countries (due to the inclusion of country fixed effects), this finding implies that transitory recessions are associated with democratization, a result that is in line with a literature that has argued theoretically that autocracies tend to become vulnerable in times of economic crisis (eg, Lipset, 1959; Huntington, 1991; Acemoglu and Robinson, 2005).

The main advantage of using changes in the natural environment rather than "man-made" historical events as an instrument is that ruling out reverse causation between GDP per capita and droughts is easy. The main disadvantage is that droughts, and shocks to the natural environment in general, may affect democratization (and many other things) through a variety of channels. Brueckner and Ciccone have two main responses to this concern. First, their standard specification relates changes in constraints on the executive to last year's GDP growth, such that the timing of the effects mitigates the possibility that droughts may affect GDP through institutions rather than the other way around. Second, they show that the reduced-form effect of rainfall on democratization is much smaller in countries that rely less on agriculture.[as]

Chaney (2013) applies a similar empirical strategy to a completely different context. He argues that in medieval Egypt, the political power of religious leaders tended to increase during years with deviant Nile floods, because economic crises increased their capacity to coordinate a revolt. His main specification shows that in years with deviant floods, Egypt's main religious figure was less likely to be replaced and that those years also showed more evidence of popular unrest. He then shows evidence from a variety of sources to distinguish his interpretation from a variety of other channels through which deviant floods might have affected Egyptian society.

Rather than using historical variation in floods over time, Hornbeck and Naidu (2014) study the effect of a single event, the Great Mississippi Flood of 1927, on the balance of power between black laborers and white landowners in the affected areas.

[ar] Constraints on the executive typically refer to the extent of institutional constraints on the decision-making powers of the chief executive, such as the president.

[as] Also see Miguel et al. (2004) and Franck (2015) for similar natural experiments. Other empirical papers studying the relationship between income and political institutions include Barro (1999); Glaeser et al. (2007); Acemoglu et al. (2005b); Persson and Tabellini (2009); Burke and Leigh (2010), and Acemoglu et al. (2014b).

In 1927, the Mississippi River broke its banks in an unprecedented flood that inundated 26,000 square miles and displaced the affected population. Hornbeck and Naidu argue that this event represented a significant shock to oppressive racial institutions that were geared towards keeping black laborers on the land and in jobs with depressed wages. Subject to the identifying assumption that flooded and nonflooded areas in the same state and with similar preflood characteristics would have developed similarly absent the flood, they show that flooded areas experienced an immediate and persistent out-migration of black laborers. In the following decades, these areas, deprived of cheap labor, modernized agricultural production and increased capital intensity relative to nonflooded areas.

Instead of shocks to a country's natural environment, a large literature on the "resource curse" studies the effect of exogenous changes in the value of countries' endowment of commodities on the quality of their institutions. For example, Caselli and Tesei (2011) calculate the flow of resource rents accruing to commodity-exporting countries. They argue that most commodity exporters are small relative to the world market, such that, for example, a change in the world price of oil is exogenous to Venezuela's political system. Their main specification relates the 1-year change in an index of the quality of a country's political institutions to the lagged, 3-year average change in the price of its principle export commodity. Their findings are consistent with the idea that an increase in the value of a nondemocratic country's natural resources tips the balance of political power in favor of the ruling elite: when autocratic countries receive a positive shock to their flow of resource rents, they tend to respond by becoming more autocratic subsequently.[at]

4.2.4.2 Popular Mobilization

The main conclusion from the set of papers studying the effect of shocks to a country's political balance of power is that some of these shocks may make it easier to place constraints on the ruling elite, and thus obtain "good" institutions. However, *how* such constraints may be imposed in practice remains unclear, particularly in nondemocratic societies that lack a functioning mechanism for replacing the ruling elite. Part of the reason for this lack of evidence is that typical measures of institutional quality vary only at the annual or lower frequency and are thus hard to tie to particular events. In a recent study, Acemoglu et al. (2015) suggest using daily financial data to measure the real-time effects of popular mobilization in street protests on investors' expectations of economic rents from future favoritism and corruption accruing to politically connected firms. Their approach generalizes the event study methodology typically used in the finance literature that estimates the value of political connections from changes in the relative stock market valuations of politically connected firms (Roberts, 1990; Fisman, 2001).

[at] Also see Brückner et al. (2012) for a similar exercise.

During Egypt's Arab Spring, street protests first brought down Hosni Mubarak's government and then ushered in an era of competition between three groups that repeatedly rotated in and out of power: elites associated with Mubarak's National Democratic Party (NDP), the military, and the Islamist Muslim Brotherhood. In their main specification, Acemoglu, Hassan, and Tahoun estimate the direct effect of street protests on the valuation of firms connected to the group currently in power relative to their effect on the valuation of nonconnected firms:

$$R_{i,t} = I'_{i,t}\beta + \left(P_t \times I'_{i,t}\right)\gamma + X'_i \times \delta_t + \delta_t + \eta_s + \epsilon_{i,t}, \tag{16}$$

where $R_{i,t}$ is the log return of firm i on day t and P_t denotes the daily number of protesters in Tahrir Square estimated from Egyptian and international print and online media. $I_{i,t}$ denotes a vector of two dummies, the first reflecting political connections to the group currently in government and the second recording connections to the two other rival (nonincumbent) power groups. X_i is a vector of firm-level controls, and δ_t and η_s denote, respectively, time and sector dummies. The coefficients of interest are the entries of the vector γ, and measure the effect of the number of protesters in Tahrir Square on the relative stock market valuation of firms connected to the incumbent group and the relative valuation of firms connected to the two rival (currently nonincumbent) groups.

The estimates of γ show a robust and quantitatively large negative effect of larger protests on the returns of firms connected to the incumbent group, but no effect on the valuation of their rivals. For example, a turnout of 500,000 protesters in Tahrir Square lowers the market valuation of firms connected to the incumbent group by 0.8% relative to nonconnected firms, but triggers no offsetting gain in the value of "rival" (nonincumbent) connected groups. These results hold even when excluding periods from the analysis during which protests may have resulted in a change in regime or any kind of formal institutions.

The main identifying assumption for a causal interpretation of the effect of protests on the relative valuation of firms connected to the incumbent group and their rivals is that (i) no omitted variables should exist that fluctuate at the daily frequency and are correlated with both stock returns and the number of protesters in Tahrir Square, and (ii) no reverse causality should result from daily differential returns on firms connected to different power groups to the intensity of protests. Key to corroborating this assumption is the daily frequency of the data and the timing of the effect: if both stock market valuations and protests respond to some other slow-moving variable, then one might expect stock returns to be correlated with future protests (the lead of protests should be statistically significant). The authors show that this is not the case in the data. Instead, stock returns respond only during and immediately after the protest. According to their preferred interpretation, these results provide evidence that popular mobilization and protests have a role in restricting the ability of connected firms to capture excess rents and thus may limit favoritism and corruption even if they do not result in changes in formal institutions or the identity of the government.

This interpretation of a causal link between popular mobilization and corruption is also in line with evidence from a natural experiment that links popular mobilization to a range of other political outcomes in the United States: Madestam et al. (2013) study the effect of the first large rallies by the Tea Party on April 15, 2009 (the day income tax filings became due). In many regions, these rallies were the first large event organized by the movement. Using rainfall on that day as an instrument, the authors show that higher attendance at these initial rallies (due to good weather) is associated with higher subsequent political support for the Tea Party's political positions, more votes for the Republican party in the midterm elections of 2010, and more conservative voting records of congressmen subsequently elected in the region.

4.3 Social Structure

A powerful idea in economic sociology is that the economic success of an entity, be it an individual, a household, or a geographic region, depends on its position in the social structure of the marketplace. Well-connected individuals who bridge "holes" in this social structure are more likely to be economically successful and may generate a competitive advantage for the firms at which they work and the regions in which they live (Loury, 1977; Burt, 1992; Granovetter, 1985, 2005). For example, one might imagine that well-connected individuals provide "social" collateral for economic transactions that would not otherwise be feasible, or reduce informational frictions by providing a credible channel for communication (Coleman, 1988; Greif, 1993; Stiglitz, 1990). According to this view, social ties that are formed and maintained for historical or personal reasons are a fundamental cause of economic growth and thus affect the economic development of entire geographic regions.

Saxenian (1999) gives an example of this view. She analyzes the biographies of Indian engineers who migrated to California in the 1970s. Following the liberalization of the Indian economy in 1991, these immigrants were in a position to leverage their social ties to relatives and friends in Hyderabad and Bangalore. Many excelled in their personal careers, managing outsourcing operations for US firms. Saxenian argues that by connecting Silicon Valley firms to low-cost and high-quality labor in their regions of origin, these Indian immigrants became instrumental in the emergence of their home regions as major hubs of the global IT services industry.

Although empirical evidence of the effect of social ties on a range of microeconomic outcomes is compelling, estimating the effect of social ties on economic growth poses additional difficulties.[au] The reason is that social ties are likely to be nonrandom across as well as within regions. Individuals who have social ties may have common unobserved

[au] These microeconomic outcomes range from education (Sacerdote, 2001) and employment (Munshi, 2003) to performance in the financial industry (Cohen et al., 2008) and agricultural yields (Conley and Udry, 2010). Also see Bertrand et al. (2000), Hochberg et al. (2007), Beaman (2012), Kuhnen (2009), Shue (2013), and Banerjee et al. (2013).

characteristics, sort endogenously across regions, or form social ties in anticipation of future economic benefits (Manski, 1993; Glaeser et al., 2002). Identifying a causal link between social ties and macroeconomic outcomes thus requires exogenous variation both in (a) the economic value of social ties and (b) the formation of these ties across geographic regions. In general, and in the Indian example above in particular, such exogenous variation either does not exist or cannot be measured.

In this section, we first discuss a natural experiment that attempts to address this identification problem, and establish a causal link between social ties and growth. We then turn to the effect of social ties on other aggregates such as trade and foreign direct investment. Compared to the large body of literature on institutions, the study of this fundamental cause of economic growth is in its infancy. In particular, we are unaware of natural experiments that study the dynamics of the formation and value of social ties over time.

4.3.1 The Effect of Social Ties on Growth

Burchardi and Hassan (2013) use the natural experiment surrounding the fall of the Berlin Wall to identify the causal effect of social ties on economic growth. They argue this setting's key advantage is that the partition of Germany was generally believed to be permanent. After the physical separation of the two German states in 1961, private economic exchange between the two Germanies was impossible. As a result, West Germans who maintained social ties with East Germans during this period did so for purely noneconomic reasons. After the fall of the Berlin Wall, trade between the two Germanies suddenly became feasible. To the extent that social ties facilitate economic exchange, the fall of the Berlin Wall thus generates exogenous variation in the value of these ties (condition (a) stated above).

In their main specification, Burchardi and Hassan study the growth in income per capita across West German regions in the 6 years following the fall of the Berlin Wall as a function of the share of the region's population that has ties to relatives in East Germany. Their structural equation of interest is

$$Y_r^{95} - Y_r^{89} = \beta T_r^{89} + Z_r' \gamma + \varepsilon_r, \tag{17}$$

where Y_r^t is log income per capita in region r in year t, T_r^{89} is a proxy for the share of the region's population that has ties to the East, and Z_r is a vector of controls that contains a complete set of federal state fixed effects, log income per capita in 1989 $\left(Y_r^{89}\right)$, the growth rate of income per capita between 1985 and 1989, and the distance from region r to the inner-German border. Because the specification controls for the pretrend in growth, the coefficient β estimates the *differential change* in the growth rate of income per capita after 1989 for regions with different intensities of social ties to the East.

Eq. (17) consistently estimates the parameter of interest if $Cov\left(T_r^{89}, \varepsilon_r\right) = 0$. However, this covariance restriction may not hold in the data, because the strength of social ties to East Germany may be correlated with differences in growth prospects across regions. An unbiased estimate of β thus requires exogenous variation in the regional distribution of social ties (condition (b) stated above). Burchardi and Hassan argue that such variation arises as the result of a large-scale migration post World War II when millions fled from East Germany to the West. An overwhelming concern for the migrants arriving in the West at the time was an acute lack of housing. During World War II, almost a third of the West German housing stock was destroyed. Variation in wartime destruction thus made settling in some parts of West Germany more difficult than in others at a time when millions of migrants were arriving from the East. Burchardi and Hassan argue that the extent of regional destruction in 1946 thus provides the exogenous source of variation in the regional distribution of social ties needed for identifying β.

Their key identifying assumption combines a difference in differences approach with instrumental variables: it states that, conditional on the covariates in Z, (i) no omitted variable drives both wartime destruction and differential changes in income growth post-1989, and (ii) wartime destruction in 1946 has no effect on changes in the growth rate of income per capita after 1989 other than through its effect on the settlement of migrants who have social ties to the East.

Using the degree of wartime destruction as an instrument for the share of the population with social ties to the East, Burchardi and Hassan then explicitly test the hypothesis that a concentration of households with social ties to East Germany in 1989 in a given West German region is causally related to a rise in the growth rate of income per capita after the fall of the Berlin Wall. They find that regions that received a one-standard-deviation larger share of migrants from the East prior to 1961 experienced a 4.6-percentage-point higher growth rate of income per capita in the 6 years following the fall of the Berlin Wall. Although both entrepreneurs and nonentrepreneurs who live in regions with strong social ties to the East experience a rise in their incomes post-1989, the incomes of entrepreneurs increase at a significantly higher rate. Moreover, the share of the population engaged in entrepreneurial activity rises in regions with strong social ties to the East. Consistent with this increase in entrepreneurial activity, West German firms that are headquartered in regions with strong social ties to the East are more likely to invest in East Germany between 1989 and 2007.

A crucial question for the interpretation of these results is whether this link between social ties and growth is a purely "microeconomic" phenomenon in the sense that a few people who have ties to the East internalize all of the benefits from this tie, or whether it is a "macroeconomic" phenomenon that involves positive spill-overs from one person's tie to the East to the income growth of unconnected individuals living in the same region.

Using household-level data, Burchardi and Hassan show that the income growth of households with ties to at least one relative in the East is on average 6 percentage points higher in the 6 years following the fall of the Berlin Wall than that of comparable households with no such ties. The authors then relate the effects of social ties on household and region-level income growth using a model in which household income is a function of direct and indirect (higher-order) social ties to the East, where individual households may benefit from having friends with ties to the East, even if they themselves have no such ties. Their preferred estimates imply that, other things equal, a direct social tie to the East has the same effect on individual household income as a 50-percentage-point (or 3.5-standard-deviation) increase in the regional share of households with such ties. From the perspective of an individual household, the incremental benefit from a direct social tie to the East is thus large compared to the incremental benefit from higher-order social interaction. Nevertheless, indirect social ties to the East account for two thirds of the aggregate effect, because all of a region's households benefit from indirect social ties, whereas only a subset of the population benefits from direct social ties.

4.3.2 The Effect of Social Ties on Trade and FDI

Aside from an interest in identifying the fundamental causes of economic growth, trade economists have long documented a strong association between social ties and the pattern of international trade and foreign direct investment (FDI) as part of a broader effort to understand the role of informal barriers in shaping economic interactions across borders (Gould, 1994).[av] The central puzzle in this literature is that geographic distance and country borders have a strong negative impact on bilateral trade flows, even after controlling for any measurable barrier to trade. Part of this puzzle may be resolved if social ties are effective means of overcoming informal barriers to trade (eg, informational frictions or problems with contract enforceability) and are negatively correlated with geographic distance and country borders.

Perhaps the most influential of these studies is Rauch and Trindade (2002), who study the effect of ethnic Chinese networks on international trade. They study Chinese networks in particular because data on the population share of ethnic Chinese are readily available and because Chinese migrants are present in most countries of the world. In their main specification, the authors estimate a conventional gravity equation that explains bilateral trade as a function of the product of the GDP of the two countries, geographic distance, and the product of the share of the population of the two countries that is ethnic Chinese. This product can be interpreted as a proxy for the strength of social ties between Chinese residents in the two countries—the probability that if one selects at random an individual in each country, both will be ethnic Chinese. Focusing on countries in which ethnic Chinese constitute at least 1% of the population (eg, as in all of Southeast Asia), this variable has remarkable predictive power for bilateral trade, suggesting trade would be on average around 60% lower in the absence of the Chinese ethnic

[av] A number of other papers show that measures of affinity between regions, such as trust, telephone volume, and patterns of historical migration, correlate strongly with other aggregate outcomes, such as foreign direct investment (Guiso et al., 2008b) and international asset flows (Portes and Rey, 2005).

network. This conditional correlation is stronger for trade in differentiated goods, which is consistent with the view that the Chinese ethnic network facilitates trade by reducing asymmetric information. Combes et al. (2005) find a similarly strong conditional correlation between the volume of trade between a given pair of French regions and the bilateral stock of migrants between the two regions, where they measure the stock of migrants as the number of individuals born in region *i* that work in region *j*. Once they add this variable to their gravity equation, the estimated effects of distance and region borders on trade are reduced to a much more reasonable level (both effects drop by about 50%). Garmendia et al. (2012) find similar results for Spain.

The main conclusion from this set of papers is that failing to account for the effect of social ties across borders and within countries may explain why traditional gravity equations have found unreasonably large effects of distance and country borders on trade. However, none of the three studies attempt to deal with potential endogeneity or reverse causality, such that the conditional correlations between trade flows and social ties that they document should not be interpreted as causal effects. In other words, the effect of social ties on trade flows is not identified in these papers for the same reason that (17) is not identified without an appropriate instrument.

Three recent studies address this issue using different natural experiments. Parsons and Vezina (2014), Cohen et al. (2014), and Burchardi et al. (2015) evaluate the causal impact of migrant networks on the variation in international trade and FDI across locations in the United States. To the extent that these papers look at trade and FDI originating from the same country, the United States, some of the concerns of reverse causality are mitigated: the regulatory environment, most direct barriers to trade and investment, as well as the ease with which migrants from different countries can emigrate are all relatively uniform.

Parsons and Vezina's strategy is similar to that of Burchardi and Hassan (2013) in the sense that they study variation in social ties that results from a historical migration that occurred while economic interaction with the migrants' region of origin was impossible. At the end of the Vietnam war, the US government imposed a trade embargo on Vietnam and evacuated 130,000 Vietnamese citizens to the United States. Upon arrival at one of four processing centers located in Arkansas, California, Pennsylvania, and Florida, charitable organizations were charged with finding sponsors who were willing to provide food and shelter for the refugees. Parsons and Vezina stress that a main objective of this process was to disperse the Vietnamese refugees as much as possible across the United States to avoid an agglomeration of refugees, similar to that of Cubans in Florida. Consistent with this view, they show that the resulting allocation of refugees is uncorrelated with a range of variables that may proxy for the potential for trade with Vietnam, which is quite plausible because of the trade embargo that was in force at the time the refugees were allocated. Instead, they argue that the variation in the allocation of refugees across states was driven by quasi-random variation in the capacity of the charitable organizations operating in different states. Importantly, Parsons and Vezina also show that the initial allocation of this first wave of refugees in 1975 is highly predictive of the location of ethnic Vietnamese in 1995, the year in which the trade embargo was finally lifted. Their structural equation of interest takes the form

$$X_i = \beta V_i + C_i'\gamma + \epsilon_i, \tag{18}$$

where X_i is the average share of exports of state i to Vietnam between 1995–2010, V_i is the stock of Vietnamese migrants in 1995, and C_i is a of controls. The standard specification uses the allocation of refugees across the United States in 1975 as an instrument for V_i. The identifying assumption for a causal interpretation of β is thus that the initial allocation of refugees is uncorrelated with ϵ_i. Subject to this assumption, Parsons and Vezina's main specification implies that a doubling of the population share of Vietnamese migrants relative to the mean increases the ratio of exports to Vietnam over GDP by 19.8%.

Cohen et al. (2014) instead use the forced relocation of ethnic Japanese into Japanese internment camps during World War II as an exogenous shock to the location of ethnic Japanese across US Metropolitan Statistical Areas (MSAs). These camps were established in remote areas (away from any industrial activity that may have been considered sensitive to the war effort) to house Japanese-Americans who lived predominantly on the West Coast prior to the bombing of Pearl Harbor. After the war, the residents were released from the camps. However, having lost their jobs and sold off their possessions in their regions of origin, they often resettled in MSAs that were geographically close to the location of their internment. Cohen et al. (2014) show that this relocation had a persistent effect on the regional distribution of the Japanese-American population that lasts to the present day: MSAs that are within a 250-mile radius of the location of a former internment camp have a 62% larger Japanese population today than other comparable MSAs. To corroborate this finding, they show, importantly, that internment camps predict higher populations of Japanese-Americans but not of other Asian-Americans.

This persistent effect on the location of Japanese-Americans has a sizable effect on the probability that firms located in a given MSA trade with Japan. Using the location of Japanese internment camps as an instrument, they show that a one-standard-deviation increase in the share of an MSA's population that are Japanese-Americans doubles the likelihood that a given firm will export to Japan. They find similarly large effects on the probability of importing, the volume of trade, and even on the likelihood that a given MSA has a sister city in Japan today.

Although both Parsons and Vezina (2014) and Cohen et al. (2014) make convincing arguments for a causal link between social ties and trade, both use natural experiments that resulted in a shock to the allocation of migrants from one particular country, such that they cannot control for unobserved destination effects as one would in a gravity equation. Assessing the external validity of these results and how they generalize to other ethnicities is therefore difficult.

To quantify the more general causal effect of social ties on US trade and FDI, Burchardi et al. (2015) instead study the natural experiment that arises from the entire history of settlement of the United States. Their strategy isolates quasi-random variation in the allocation of migrants across destinations within the United States that results from the interaction of two facts: First, migrants from different origins tended to arrive in the United States at different times. Second, the set of destinations that are most economically attractive to the typical migrant arriving in the United States changed over time.

They motivate their approach using a reduced-form dynamic model of migrations. Migrations from a given foreign origin country *o* to a given destination county *d* in period *t* depend on the total number of migrants arriving in the United States from *o* (a push factor), the relative economic attractiveness of destination county *d* to migrants arriving at the time (a pull factor), and the size of the preexisting local population of ancestry *o*, allowing for the fact that migrants tend to prefer settling near others of their own ethnicity (a recursive factor). Solving the model shows the number of residents today who are descendants of migrants from *o* is a function of simple and higher-order interactions of the sequence of pull and push factors. Burchardi et al. (2015) then use these interactions to construct instruments for each US county's present-day ancestry composition.

To prevent omitted variables that affect both migrations and FDI from driving their results, they measure the pull factor of each US destination for migrants from *o*, using the number of migrants arriving in *d* at the same time from a continent other than *o*'s continent of origin. That is, they predict a migrant's choice of destination within the United States using the revealed behavior of the average migrant arriving at the same time but from a different continent. Similarly, they measure the push factor using the total number of migrants arriving in the United States from *o* at time *t*, excluding those who settle in the vicinity of *d*. Interacting these measures of pull and push factors for each vintage of census data since 1880 isolates variation in the present-day ancestry composition of US counties that derives solely from the interaction of the staggered arrival of migrants from different origins with time-series variations in the relative attractiveness of different destinations within the United States.

In their main specification, Burchardi, Chaney, and Hassan find that doubling the number of individuals with ancestry from a given foreign country increases by 4.2 percentage points (or 237% relative to the mean) the probability that at least one firm from that US county engages in FDI with that country. The main identifying assumption for a causal interpretation of this result is that omitted variables making a given location within the United States differentially more attractive for migrants from a specific origin for both settlement and FDI do not affect the location choices of the average migrant originating from other continents and simultaneously have large effects outside of the surrounding states of the destination in question.

Flexibly applying this instrumentation strategy to the entire set of origins and destinations, the authors estimate heterogeneous effects of ancestry on FDI across origins and destinations. Across origins, they find that the effect increases with the geographic distance and the judicial quality of the origin country. Across destinations, they find consistent evidence of a positive impact of regional diversity on FDI: the more diverse and less ethnically homogeneous the local population, the larger the total effect of ancestry on FDI. Similarly, the effect of ancestry on FDI falls with the population of migrants from the same origin in neighboring counties, and from neighboring origins, so that a small minority from a distant part of the world that is not otherwise represented in the local ethnic mix has the largest marginal impact on FDI.

By instrumenting separately for each wave of immigration, Burchardi et al. (2015) are also able to distinguish the effect of first-generation immigrants from the effect of their descendants. They find a significantly smaller effect for the first generation, implying the full effect of ancestry on FDI is long lasting and takes multiple generations to fully unfold.

Simultaneously instrumenting for migration from multiple origins also enables the authors to base their estimation on a gravity equation, including destination fixed effects that control for differences in size, market access, and productivity across US destinations. Although the results with respect to FDI remain stable regardless of the inclusion of destination and other (more complicated) fixed effects, the authors find no systematic causal impact of ancestry on the patterns of international trade of US states whenever they control for destination fixed effects. This latter finding is in stark contrast to the results in Parsons and Vezina (2014) and Cohen et al. (2014), and suggest that the causal relationship between social ties and trade found in these papers may not generalize to a larger set of origin countries.

4.3.3 The Effect of Internal Social Structure on Institutions and Growth

Although the literature on social ties focuses on the external relationships of a social entity, a number of studies have also used natural experiments to assess the effect of the *internal* relationships between different groups within a given society on aggregate economic outcomes, and in particular on the ability of a society to develop a functional political system and "good" institutions.

Perhaps the most convincing of these studies is Dippel (2014), who considers the natural experiment surrounding the formation of Native American reservations. In the 19th century, the US government formed several reservations consisting of members of ethnically and linguistically homogeneous tribal bands. While respecting ethnic differences, this process largely ignored differences in historical institutions, such that some (mixed) reservations received constituents of several previously politically independent subtribal bands while others did not. Dippel shows that these mixed reservations have significantly worse contemporary economic outcomes, even when conditioning only on variation within reservations belonging to the same tribe. To account for potential confounding factors in the formation of reservations, he instruments the likelihood of a mixing of several previously independent bands with historical mining activity in the historic homeland of the tribe, where mining activity generated incentives for the US government to form fewer, and thus more likely mixed, reservations. He then shows that the majority of the divergence in economic outcomes appears only after the 1980s, when the Bureau of Indian Affairs ceded reservation governance to the local reservations. Using information on contemporary political conflict and corruption within reservations, he argues convincingly that the adverse economic effects are explained by the fact that mixed reservations tend to have more dysfunctional political institutions.

Another set of studies has linked the emergence of good institutions to the relative influence of the middle class. Acemoglu et al. (2005a) use a difference-in-differences approach to argue that Western European countries that developed a large and politically influential merchant class were able to develop constraints on the executive and safe property rights that were crucial for subsequent economic growth. Their evidence comes from a panel data set of GDP per capita, institutional quality, and the number of Atlantic voyages undertaken by each European country 1300–1850. They show that the onset of the Atlantic trade after 1500 was a major positive shock to GDP per capita in countries on the Atlantic coast. However, this shock led to an increase in constraints on the executive only in Atlantic countries that already had relatively higher constraints on the executive in medieval times: the interaction between Atlantic trade and medieval institutions explains most of the variation in institutional quality across European countries. The authors argue that these results are consistent with their view that a merchant class could only emerge in countries in which rulers were relatively constrained and did not monopolize the Atlantic trade.

Although AJR (2005) provide historical and anecdotal evidence to corroborate their interpretation, a problem with their analysis is that they do not observe the size of the merchant class directly. More generally, a major challenge for the literature attempting to establish a causal link between social structure and institutions is that consistent measures of social structure are rarely available for a sufficiently long period of time, and in particular for historical episodes in which one might observe quasi-exogenous variation in social structure.

While stopping short of claiming success at having identified a causal effect, Acemoglu et al. (2011b) make some progress in this dimension by studying the mass-murder of Jews following the Nazi invasion of Russia during World War II. Uniquely, Soviet authorities kept extensive records of the size and ethnic composition of the middle class (white-collar workers) in Russian regions (oblasts), dating back to 1926. Before the outbreak of World War II, Jews were heavily overrepresented in white-collar occupations, such that their persecution and murder by the occupying forces represented a significant shock to the size of the middle class. Using variation both within oblasts occupied by the Nazis and across occupied and nonoccupied oblasts, the authors show that oblasts in which the Holocaust most severely reduced the size of the middle class have worse political and economic outcomes today. These oblasts grew less since 1945 both in terms of population and GDP per capita, exhibited greater vote shares for communist candidates during the 1990s, and more support for preserving the Soviet Union in a referendum held in 1991. Moreover, the shock to the relative size of the middle class in oblasts most adversely affected by the Holocaust appears to persist over time, until the last Soviet census held in 1989. Acemoglu, Hassan, and Robinson argue that their evidence is consistent with the view that a shock to the size of the middle class may have permanent effects because it reduces the core constituency for policies that advance constraints on the executive and safe property rights (most notably in the form of more political support for the preservation of communism).

4.4 Trust and Civic Capital

The literature on culture and economics offers various competing definitions of social capital, culture, trust, and related concepts. For the purposes of structuring our discussion, we focus on the concept of "civic capital," which Guiso et al. (2012) define as "those persistent and shared beliefs and values that help a group overcome the free rider problem in the pursuit of socially valuable activities." We prefer to use this relatively narrow definition mainly because it allows a convenient grouping of the existing empirical literature. First, it clearly distinguishes civic capital from social structure, the focus of the literature discussed in the previous section. We may loosely think of "social capital" as the union of the two concepts. Second, it closely describes the variables used in the empirical literature, which often focuses on various measures of how much individuals are willing to trust a stranger, and other measures of beliefs about the intentions and actions of others.

The idea that the set of norms and beliefs that make cooperation among individuals easier should be a driver of economic growth has a long tradition in the social sciences, going back at least to Banfield (1967), Coleman (1988), and Greif (1993). Putnam et al. (1993) famously argued that Southern Italy is less developed economically than the North because of a lower level of civic capital, and conjectured that this difference is a result of the fact that Northern cities had a long tradition of self-rule, which fostered a tradition of civic engagement, at a time when Southern cities were tightly controlled by Norman kings.

The basic idea in this literature is that culture in general and civic capital in particular changes only slowly over time. Parents pass on beliefs and values to their children, such that civic capital is akin to a slow-moving, accumulated factor. Societies with a higher level of civic capital have a higher capacity for economic growth because they develop better tools for overcoming market failures and collective action problems.

The prime example for such a belief is trust. Even in a society with an efficient police force and functioning courts, most commercial transactions involve some element of trust (Arrow, 1972). For example, when you hire an accountant to do your taxes, you trust that she will not abuse your private information to commit credit card fraud. If you cannot trust your accountant, you might prefer to do your taxes yourself. Similarly, when you take a taxi, you trust that the driver knows how to drive, is not intoxicated, has not manipulated the meter, and will not simply lock the door, drive you off to the desert, and hold you for ransom. Although you can take accountants and taxi drivers to court, doing so will cost time and money, and even the most efficient court systems cannot enforce all the rules all the time. Other transactions that rely on trust include employment contracts in which managers cannot perfectly monitor employees, sales in which goods are delivered before or after payment is made, and many financial transactions and investment decisions. (Thinking about it this way, the amount of trust people in developed societies put in perfect strangers is remarkable!) The more complex an economy becomes, and the more labor is divided into specialized tasks, the more important may be the shared belief that strangers can generally be trusted.

4.4.1 The Effect of Trust on Growth

A number of papers have used cross-country data to document a conditional correlation between measures of civic capital and economic development. Knack and Keefer (1997) show that measures of trust and civic cooperation are strongly associated with higher GDP, higher economic growth, and higher investment-to-GDP ratios, even after controlling for education, institutions, and other factors. However, these results do not speak to causation. The obvious problem is that people who live in wealthy countries with good institutions may rationally put more trust in strangers because they know they will be partially protected by a well-functioning police force and efficient courts. Clearly, institutions, civic capital, and economic development are mutually interdependent variables. A key challenge in demonstrating a causal effect of civic capital on growth is thus not only to identify exogenous variation in civic capital, but also to separate its effect from the effect of institutions.

Three papers attempt to tackle this challenge using natural experiments that rely on the idea that civic capital depends on the experiences of each generation and is at least partially transmitted from one generation to the next.[aw] For example, one might expect individuals whose parents grew up under an authoritarian dictatorship to be less trusting than otherwise similar individuals whose parents grew up in a democracy.

Tabellini (2010) uses the fact that some Western European countries emerged as the union of several very heterogeneous historical political entities. He studies the variation in gross value added per capita across 69 regions within these countries. To the extent that present-day institutions vary only at the country level, rather than the regional level, country fixed effects absorb any differences in current institutions. He then instruments

[aw] Several studies show trust indeed has an inherited component; see Rice and Feldman (1997), Putnam (2000), and Guiso et al. (2006).

for current measures of civic capital using literacy in 1880 and a measure of constraints on the executive between 1600 and 1850, while controlling for urbanization in 1850. The key identifying assumption is that these historical instruments affect present-day economic development only through their effect on the persistent component of civic capital. Conditional on this (rather demanding) assumption, Tabellini shows that the exogenous component in civic capital has a large positive effect on regional economic development. A more conservative interpretation of the same fact, that is nevertheless interesting in its own right, is that distant political history is an important determinant of current economic performance not just across but also within countries.

Guiso et al. (2008a) consider a similar experiment within Italy. In the Northern part of Italy, some cities achieved the status of a free city during medieval times, whereas others remained under the control of a feudal lord or the Holy Roman Emperor. Consistent with the results in Tabellini (2010), they find that those cities that achieved self-rule earlier (by 1136 or 1300 CE) exhibit higher measures of social capital today. However, Guiso et al. (2008a) then go one step further by instrumenting the dummy variable for early self-rule with two variables that they argue historically affected the cost of achieving self-rule but are unlikely to affect directly the level of civic capital or the level of output today: whether the city was a seat of a bishop who may have been able to coordinate the struggle for independence, and whether the city was founded in pre-Roman (Etruscan) times and is therefore located in a geographic position that is easy to defend militarily. Using these two instruments, they confirm that a longer history of self-rule is significantly associated with higher social capital and higher GDP per capita today.

Although more robust than Tabellini (2010), the identifying assumption for a causal interpretation of the results in Guiso et al. (2008a) is still a tall order: self-rule, the two variables driving the cost of self-rule, or any omitted variables correlated with these measures cannot have a direct effect on GDP per capita today, except through their effect on civic capital. Even if formal institutions did not vary within Italy (which they do to some extent), administrative capacity, the functioning, and the quality of these institutions surely vary across regions even though they might follow the same letter of the law. As a result, both of these natural experiments may still confound the effects of civic capital and institutions or any other omitted variable that is correlated with these variables.

Two recent papers attempt to tackle this problem using clever strategies that are not natural experiments according to our definition. Algan and Cahuc (2010) use the inherited trust of descendants of US immigrants covered in the General Social Survey to recover a long time series of trust for their origin countries, reaching back to the beginning of the 20th century. This long time series then allows them to relate changes in GDP per capita to changes in inherited trust over several generations, while controlling for all of the time-invariant effects that complicate the interpretation of the results in Tabellini (2010) and Guiso et al. (2008a). In addition, they also control for time variation in the quality of institutions in order to convincingly distinguish the effect of institutions from the effect of trust. Their estimated effect of trust is positive, highly statistically significant, and quantitatively large. For example, according to these estimates, GDP per capita in Russia and Mexico would have been 60% higher had these two countries inherited the same level of trust as Swedes. Gorodnichenko and Roland (2010) also rely on the idea that cultural traits are inherited and instrument culture (in their case, a measure of individualism rater than trust) with the genetic distance of the population to the most individualist countries in the world (the United States and United Kingdom). Consistent with the other studies, they also find a large effect of culture on growth.

4.4.2 Effect of Trust on Financial Development and Other Aggregates

Although the papers surveyed in the previous section may have convincingly identified a causal effect of civic capital on growth, they have little to say about the mechanism through which this effect transmits itself and about *how* civic capital affects growth. One obvious candidate is financial development: financial contracts are arguably "trust intensive," in the sense that handing over cash to a stranger today in the hopes of receiving returns in the future requires a large amount of trust in that stranger. Higher levels of civic capital may thus enable a society to sustain a more sophisticated financial system that may then in turn facilitate economic growth. Guiso et al. (2004) study this channel.

Similar to Guiso et al. (2008a), this paper measures variation in civic capital across regions within Italy and relates these measures to the use of financial instruments by households responding to a survey by the Italian central bank. The identification strategy again relies on the idea that part of social capital is inherited from previous generations. Thus, when a household moves from one Italian region to another, the level of civic capital (but not the quality of institutions) in its region of origin still influences its behavior. In their main specification, Guiso et al. (2004) relate a household's use of financial instruments to the level of civic capital (measured as voter turnout or the volume of blood donations) in its region of origin, a set of region fixed effects, and a number of household-level controls. They find that households that originate in regions with higher levels of social capital are more likely to use checks, invest more in the stock market, and rely less on informal loans from friends and family. These effects tend to be stronger in regions with weak law enforcement.

The authors' preferred interpretation of these results is that the civic capital plays an important role in the degree of financial development across Italy. If these results generalize to the variation in financial development across countries, they may thus account for part of the observed effect of civic capital on economic growth.

Apart from this evidence of a financial channel, additional evidence on the mechanism by which civic capital affects growth is scarce, and if it exists it is largely not causally identified. A promising avenue for future applications of natural experiments may be the relationship between trust and regulation. For example, Aghion et al. (2010)

document that levels of trust and the level of government regulation are strongly negatively correlated across countries.

4.4.3 Determinants and Dynamics of Trust

The main conclusion from the series of studies that document an effect of civic capital on growth and financial development is that, from a macroeconomic perspective, we may think of civic capital as a slow-moving state variable that codetermines a society's capacity for economic growth. A crucial question then is what governs the dynamics of this state variable. That is, how do some societies end up with a high level of civic capital while others suffer from low levels of civic capital? The existing literature has examined natural experiments that identify three factors determining the dynamics of civic capital: historical institutions, experiences of violence and conflict, and the climate.

4.4.3.1 Historical Institutions

As part of their identification strategies, Tabellini (2010) and Guiso et al. (2008a) show that historical institutions appear to affect the level of trust, decades or even centuries later. Both papers show that the descendants of residents that lived in areas that had more constraints on the executive historically exhibit higher levels of trust today.

Becker et al. (2015) examine a natural experiment in which one might expect similar results. Parts of five Eastern European countries (Montenegro, Poland, Romania, Serbia, and Ukraine) were under the rule of the multiethnic Habsburg empire until the end of World War I. In some parts, this rule lasted for hundreds of years. Compared to both its contemporaries and some of its successor states, the Habsburg empire had a reputation for having a restrained and effective bureaucracy, courts, and police. The descendants of residents of areas formerly under Habsburg control thus had a longer history of living under "good" institutions in this sense than their present-day countrymen. Becker et al. (2015) study the effect of this treatment using a regression-discontinuity design.

Their main specification relates responses from a survey covering individuals in all five countries to their location relative to the former border of the Habsburg empire. They find that individuals living within 200 km of the former Habsburg side of the border are not significantly more trusting of strangers or more likely to be members of a civic organization than their countrymen on the other side of the former border. Although this finding may be due to a lack of power in their specification, they do find that individuals on the former Habsburg side are significantly more trusting of the police and less likely to pay bribes to officials.

4.4.3.2 History of Violence or Conflict

One interesting detail in the results of Algan and Cahuc (2010) is that inherited trust in Sweden increased after 1935 while it decreased in continental Europe and the United Kingdom. They conjecture that this differential change may be the effect of World Wars I and II: individuals that experience violence and conflict may pass down a lower level of trust to their descendants. Two papers examine this link between violence and trust in different historical settings.

Nunn and Wantchekon (2011) link the variation in levels of trust across individuals in Africa to the history of slave trade. They argue that the demand for slaves by Europeans (and later Americans) based predominantly in Atlantic ports created conditions that would result in distrust among the indigenous population. Particularly in the later phases of the slave trades, individuals found themselves enslaved not as the result of inland raids by foreigners but as the result of kidnappings or trickery on the part of other members of the indigenous population. By selling others into slavery, one could obtain the means to purchase iron weapons, thus protecting oneself from enslavement. A number of historical sources show that the majority of individuals were sold into slavery by kidnappers or even by their own relatives. Exposure to the slave trade may therefore have severely reduced the level of trust in the affected societies.

Nunn and Wantchekon's structural equation of interest takes the following form:

$$trust_{j,e,d,i} = \alpha_i + \beta\ slave\ exports_e + X'_{j,e,d,i}\Gamma + X'_{d,i}\Omega + X'_e\Phi + \epsilon_{j,e,d,i}, \tag{19}$$

where α_i denotes country fixed effects; *slave exports*$_e$ measures the number of slaves taken from ethnic group e during the slave trade per square kilometer of area settled by the ethnic group; $X'_{j,e,d,i}$ denotes a rich set of individual-level controls including ethnicity, education, and age; $X'_{d,i}$ controls for the ethnic composition of district d in country i; and X'_e is a vector of ethnicity-level controls that capture subnational variation in colonial rule, in particular, the disease environment and measures of precolonial prosperity.

In their main specification, Nunn and Watchenkon instrument slave exports with the distance of an ethnic group from the coast, which is where European slave traders kept their bases. Because geographic features in general are correlated with all kinds of things, they then make a careful argument that, conditional on the controls they include in their standard specification, the distance to the coast is plausibly uncorrelated with other factors that affected trust. First, they argue that Africans did not engage in overseas trade before the slave trade, such that distance to overseas trade is not a confounding factor in their case. Second, they stress the importance of the ethnicity-level controls for other forms of European contact. Third, they include additional controls for each ethnicity's historical reliance on fishing. Conditional on these controls, they argue that the exclusion restriction is plausibly satisfied. Their estimates show that a one-standard-deviation increase in exposure to the slave trade is associated with approximately a 0.2-standard-deviation decrease in various measures of trust of neighbors and trust of other ethnicities.

A fairly common problem with papers using large natural experiments such as the enslavement of Africans is that unobservables could potentially bias the result. For example, in Nunn and Wantchekon (2011), we may worry that despite the large number of controls the authors propose, differences in preexisting trust and prosperity or some other unobservable correlated with slave trade and trust may not be adequately accounted for. To assuage these concerns, Nunn and Wantchekon use a technique developed by Altonji et al. (2005) and Bellows and Miguel (2009) that calculates how much stronger selection on unobservables, relative to selection on observables, would have to be to overturn the estimated effect:

$$\hat{\beta}^R / (\hat{\beta}^R - \hat{\beta}^F),$$

where $\hat{\beta}^R$ and $\hat{\beta}^F$ are the coefficients of interest estimated with a restricted and the full set of controls, respectively. If including observable covariates does not have a large effect on the coefficient of interest, this number is large and selection on unobservables would have to be multiple times more severe than selection on observables to overturn the result. Nunn and Wantchekon find that including their full set of controls changes their coefficient of interest so little that this statistic is 3 in all of their specifications. Whatever their specifications are missing would thus have to have a very large selection effect to overturn their qualitative result.

A second paper probes the relationship between inter-state conflict and trust. Jancec (2012) uses a difference-in-differences approach to show that individuals living in regions within the present-day countries of Slovenia, Croatia, Serbia, Montenegro, Romania, and Ukraine that experienced more frequent changes in the ruling nation state between 1450 and 1945 exhibit lower trust in political institutions today. However, similar to Becker et al. (2015), he finds no effect on measures of civic behavior and trust toward strangers.

4.4.3.3 Geography and Climate

Rather than identifying "man-made" shocks, such as wars and historical migrations, Durante (2010) takes a more radical approach and links civic capital directly to environmental factors that determine the need for cooperation. The idea (similar to Ostrom, 1990) is that the earliest societies, centered around subsistence farming, would develop a culture of cooperation and trust where it is needed for survival. He argues that in regions where precipitation and temperature are highly variable from year to year, societies needed to develop civic capital to sustain investment in irrigation and other large works that facilitated survival. Similarly, in regions with very diverse climatic conditions, developing civic capital increases the probability of survival, by facilitating trade and risk-sharing. Using long-term climate data reaching back to 1500 CE, he indeed finds a significant association between trust and these climatic variables in the cross section of European regions. Interestingly, these results are robust to including country fixed effects and controlling for early institutions as in Tabellini (2010), suggesting that part of the effect of climate on trust may indeed transmit itself through civic capital.

4.5 Multiple Equilibria and Path Dependence

Some growth models that feature nonconvexities produce multiple equilibria, such that the mapping between the steady state GDP per capita and ϕ_i in (13) is not unique. For example, Murphy et al. (1989) show that multiple equilibria can arise in a simple model with monopolistic competition and a fixed cost of production. In their model, a given firm finds that incurring the fixed cost of production is profitable only if other firms do the same, due to a demand spillover. In the "bad" equilibrium, firms do not invest, because they expect that other firms will also not invest. This scenario is an example of a coordination failure—economic growth does not happen because economic actors have the "wrong" expectations and cannot coordinate to invest simultaneously. Although it seems implausible that countries might be persistently poor just because its residents cannot coordinate to simultaneously change their expectations, many more complicated models also feature multiple steady states. In these models, long-run GDP per capita is path-dependent, and once an economy finds itself on the path to a bad steady state, it may be hard to reverse its trajectory.

To our knowledge, no single natural experiment has been used to test the hypothesis that multiple steady states may explain cross-country income differentials. Part of the reason for the absence of such an experiment might be that viewing the income differential between the Congo and the United States purely as the result of a historical accident seems unsatisfactory. Instead, the literature has focused on the more modest goal of showing that the interaction of nonconvexities and historical accidents can have an effect on the sectoral composition of production or on its spatial distribution within a given country.

Juhasz (2014) uses data on 19th-century France to show a causal effect of temporary trade protection during the Napoleonic wars on the long-run location of the cotton-spinning industry in France. She argues that the continental blockade that prohibited direct shipping between Britain and France during the war differentially affected the costs of shipping goods from Britain to different regions within France. In particular, regions in Northern France that historically had relatively low costs of trading with Britain were temporarily more protected from British imports, because these imports now had to be shipped through Spain. Under the identifying assumption that more and less protected regions would have developed similarly absent the effect of the continental blockade on trade costs, she shows that relatively more protected regions significantly increased their capacity in mechanized cotton spinning (a new technology at the time). She then shows that this change in the regional distribution of the cotton-spinning industry within France persisted 30 years after the end of the blockade. Her results are thus consistent with nonconvexities in the adoption of new technologies, and the view that infant industry protection can have a lasting effect on the location of production within and possibly also across countries.[ax]

[ax] See Kline and Moretti (2014) for similar evidence from the Tennessee Valley Authority, where subsidies appear to have permanently increased the level of manufacturing employment.

A large body of work in urban economics has used natural experiments to examine this question at the scale of cities. Although the focus of this literature is not explicitly on macroeconomic variables, we summarize it briefly, keeping in mind that factors of production, in particular labor, are much less mobile at the country or region level, such that it is unclear how results would change at larger levels of aggregation. In an influential study, Davis and Weinstein (2002, 2008) use a difference-in-differences approach to show that the bombing of Japanese cities during World War II had no long-run effect on the relative size of cities and even their industrial composition, suggesting that fundamentals rather than chance govern the long-run spatial distributions of these variables. Miguel and Roland (2011) show similar results using an instrumentation strategy for the US bombing of Vietnam.

Bleakely and Lin (2012) show contrasting evidence that a temporary locational advantage can have long-lasting effects on population density. They argue that many cities in North America formed in places where natural obstacles, such as waterfalls, blocked continued water transport and thus required overland hauling. These places (portage sites) attracted transportation services and commerce such that large settlements and cities would often form. However, this natural advantage is no longer relevant today, because trains, trucks, and airplanes have supplanted ships as the primary transportation technology, and locks and canals now make hauling cargo from one ship to another unnecessary. In this sense, technological progress generated a temporary positive shock to locational fundamentals of portage sites that plausibly no longer exists today. Nevertheless, Bleakly and Lin show not only that portage sites are significantly associated with higher population density today (including large cities such as Washington DC and Philadelphia), but also that no evidence exists of a relative decline in these areas, because their natural advantage as portage sites dissipated. Their findings are thus consistent with the existence of multiple equilibria in the location of cities and towns.

A series of papers in this literature also uses the division and reunification of Germany as a natural experiment. Most directly focused on testing for multiple equilibria is Redding et al. (2011). Using a simple difference-in-differences approach on a panel of passenger-traffic data for German airports, they show that the division of Germany led to a significant increase in the growth rate of passenger traffic in Frankfurt (previously a minor destination) and to a simultaneous shrinking of passenger traffic at Berlin airport (the previous main hub). However, after reunification, this trend did not reverse, leaving Germany's main airport hub in Frankfurt. Using various methods the authors argue that this apparently permanent shift cannot be explained by fundamentals, and instead is evidence of multiple equilibria in the location of a country's main airport hub.

Two closely related papers document evidence that is consistent with a specific source of multiple equilibria—the agglomeration externalities that operate in new economic geography models. The basic idea in this literature is that consumers like locating close to firms, and that firms like being close to other firms for various reasons, most commonly to economize on commuting and trade costs (Krugman, 1991). If these agglomeration forces are strong enough relative to dispersion forces (eg, the costs of congestion), multiple equilibria may arise. One simple prediction of these models is that market access is an important driver of economic development. Redding and Sturm (2008) test this hypothesis using German division and reunification. Using a difference-in-differences approach, they find that over the 40-year period of German division, the population of West German cities close to the inner-German border declined significantly relative to other West German cities, a finding that is consistent with the predictions of the model. Their main identifying assumption is that, absent the effect of the inner-German border on market access, cities closer to and farther away from the border would have developed similarly. In Ahlfeldt et al. (2015), the authors take the analysis one step further and use the division and reunification of Berlin as a natural experiment, allowing them to quantitatively estimate agglomeration and dispersion forces at the city level. This paper is methodologically distinct from all the other papers covered in this chapter in that it focuses explicitly on structural, rather than reduced-form estimation. The authors develop a quantitative model of city structure that features multiple agglomeration and dispersion forces. They are able to separately identify these forces, because of the variation in the surrounding economic activity of city blocks that results from the division and reunification of the city. Interestingly, the identifying assumption for this structural model is just a sharper version of that used in the previous paper: that Berlin's division and subsequent reunification affects the systematic change in the pattern of economic activity across city blocks only through its effect on commuting costs and changes in access to production and residential externalities.

Taken together, these studies seem to suggest that historical accidents can have an effect on the spatial distribution of production within a given country. However, it is important to note that, conceptually, none of these studies can distinguish multiple equilibria from long-term persistence. Moreover, none of them speak to the existence of multiple equilibria at the country level.

5. CRITICAL ASSESSMENT AND OUTLOOK

In this chapter, we describe the use of natural experiments in macroeconomics for three distinct purposes: to verify underlying model premises, to quantify policy parameters, and to identify causal mechanisms that are absent from conventional models. We do this by covering the use of natural experiments in the literatures on the Permanent Income Hypothesis, on fiscal multipliers, and on the fundamental causes of growth.

An easy test of the assumption of forward-looking behavior of the Permanent Income Hypothesis can be carried out if one can identify instances when households receive payments resulting from a preannounced change in income. A series of natural experiments that identify such preannounced changes finds that agents adjust consumption at receipt, which is in contrast to the assumption of forward-looking rational behavior. Some of these experiments suggest binding liquidity constraints can partly, but not entirely, explain this finding. They tend to find that more liquidity constrained households react more strongly at receipt, but even unconstrained households appear to adjust their consumption upon receiving a preannounced payment. The pattern of results across different types of natural experiments suggests a degree of near-rational behavior: in response to large income changes, households do appear to adhere to the Permanent Income Hypothesis, and only when faced with small income changes does the evidence not line up with the model predictions. Modeling near-rationality explicitly and embedding a natural experiment directly into such a model would be useful to generate further insights. Moreover, analyzing new measures of liquidity constraints that incorporate wealthy hand-to-mouth consumers could possibly help reconcile some of the conflicting evidence on the importance of liquidity constraints. A clear disadvantage of natural experiments also becomes apparent in this application: analyzing preannounced income *decreases* would directly rule out the possibility that binding liquidity constraints drive the results, and analyzing *large* preannounced income changes would rule out near-rational behavior. Whereas a researcher running field or laboratory experiments would thus make sure any given experiment covers both features, natural episodes encompassing these two features are rare.[ay]

The literature on the fiscal multiplier faces the challenge of identifying fiscal policies that are orthogonal to current economic conditions. Two approaches involving natural experiments can help: the first uses increases in military spending caused by geopolitical events as exogenous shocks to national fiscal policies, and the second exploits cross-regional variation at the subnational level driven by historical episodes to establish exogeneity. Whereas the first approach typically estimates aggregate fiscal multipliers smaller than 1, the second approach consistently returns estimates of the local fiscal multiplier between 1.5 and 2. However, these aggregate and regional multipliers are different concepts and cannot be directly compared. A model is needed to gain further insights into their relationship.[az]

Identifying the fundamental reasons some countries are rich while others are poor is a major challenge in economics. The main empirical difficulty is that most of the likely drivers of growth, such as the accumulation of physical and human capital, the quality of institutions, the level of trust, and social structure, depend in complicated ways on the level of income and on each other. In the last two decades, natural experiments have

[ay] Replicating large income changes in a designed experiment would, however, be costly and thus also difficult.

[az] See the discussion of Nakamura and Steinsson (2014) in Section 3.

become the most widely used tool to try to resolve this question by identifying the causal determinants of economic growth. Using such large-scale natural experiments as the age of European colonization or German reunification, the literature has produced convincing evidence that the major fundamental causes of growth are outside traditional models of economic growth. Instead, cross-country variation in political and economic institutions, cultural traits, and social structure appear to explain the majority of cross-country and often even the majority of within-country variation. The literature has been less successful at distinguishing these causal channels from each other. In particular, much of the work causally linking institutions and trust to growth does not convincingly differentiate between these two channels. In addition, much work remains to be done in trying to understand the dynamics and the interaction of these fundamental causes over time. The study of social structure, meaning social ties and networks as well as the social stratification of society, as a fundamental determinant of economic growth is a new, promising field that has arisen in this context, allowing a deeper understanding of the direct effect of social structure on growth and its effect on the evolution of institutions. A common thread across the different studies identifying the fundamental causes of economic growth is that they focus almost exclusively on the reduced-form relationship between the fundamental causes and economic outcomes, but make no use of the structure of existing models of economic growth. Bridging the gap between these two literatures may prove a promising avenue for future research.

How researchers use natural experiments in practice differs between the three literatures we have covered. The literature on the Permanent Income Hypothesis employs natural experiments directly in identifying preannounced income changes, whereas the other two strands of the literature mainly rely on microeconometric techniques such as instrumental variables and regression discontinuity designs. Some studies that do not rely on specific historical events for identification also use these techniques. As a result, deciding what can and cannot be considered a natural experiment in these latter two strands of literature involves some judgment.

The fundamental challenge, however, is the same in all three literatures, namely, to argue the historical episode in question provides the quasi-random variation that is necessary to identify causal effects. Although creating a comprehensive checklist that all analyses involving natural experiments can use is impossible, we list below some common features that distinguish successful papers that rely on the use of natural experiments:

Identifying assumption: The identifying assumption underlying the study should be clearly stated. What does the reader need to believe to causally interpret the effect? What aspect of the natural experiment does the study exploit and how does it translate into exogenous variation? Why can reverse causality be ruled out? Can we think of any omitted factors that jointly affect the natural experiment and the outcome variable of interest?

Supporting evidence: Researchers should provide as much evidence as possible to corroborate the identifying assumption. Such evidence may include showing treatment and control groups do not differ on observables prior to treatment, an analysis of pre- and posttreatment trends, the timing of the effect, and the use of multiple instruments. At a minimum, a careful description of the specific historical episode is needed that makes clear the origin of the quasi-random variation and allows the reader to gauge the potential scope for endogeneity and other confounding factors. Thus, detailed institutional knowledge on the episode surrounding the experiment is required. Researchers should carefully consider and explicitly discuss which omitted factors one might reasonably worry about.

Additional methods to support a causal interpretation: If possible, researchers should use additional analyses to establish that the treatment and not other factors correlated with treatment drives the outcome variable. Specifically, placebo exercises that analyze placebo treatments can provide credibility to the claim of causality. Moreover, showing robustness to the use of different control groups if more than one is possible, and using matching methods to guarantee the control group lines up well with the treatment group in terms of observable characteristics can help assuage concerns about randomness.

Quantitative implications: Arguing convincingly in favor of a causal interpretation is usually impossible without explicitly stating the quantitative implications of the estimates. Is the size of the effect reasonable? How does it compare to the influence of other factors that are known to affect the outcome variable?

A common promising avenue for future research identified in all three strands of literature is to move beyond reduced form approaches and incorporate natural experiments into structural models. Models will be useful to identify specific mechanisms at work and channels through which effects transmit, and to argue more forcefully about the plausibility of the quantitative sizes of effects. Natural experiments could then potentially prove useful in identifying a wider variety of structural model parameters.

Our discussion of the use of natural experiments in macroeconomics has also shown the "natural" limits of this approach. Because the researcher does not create the historical episode constituting the experiment, it is often not ideally suited to analyze the question at hand. As a result, different natural experiments often produce different answers to the same question. In addition, many of the more tightly identified natural experiments leave open the question of external validity. Finally, because natural experiments rely on history for identification, they are naturally more useful for understanding the past rather than the future. Although this is not problematic in many contexts, it does preclude natural experiments from addressing the effects of unprecedented events, such as climate change.

Nevertheless, we believe that two decades of research using natural experiments have produced a range of substantial insights into the functioning of the economy, and have made major contributions to the field of macroeconomics.

APPENDIX

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Standard PIH studies								
Aaronson et al. (2012)	Minimum Wage Hikes; income increase	CEX interview survey (1982–2008); CPS (1980–2007) and SIPP (1983–2007) for data on income; proprietary dataset from national financial institution (1995–2008): credit card account and each credit card holder's auto, home equity, mortgage, and credit card balance	200,500 Household-survey observations on spending, of which 11% derive some income from minimum wage work	Spending on nondurables and durables, including separate subcategories, and change in debt (total and subcategories)	Quarterly	Reject	Households for which minimum wage labor is the source of at least 20% of household income spend 3.4 times the short-term increase in income, but mostly on cars	based on liquid assets; some evidence in favor

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Agarwal et al. (2007)	2001 Federal Income Tax Rebates; income increase	Proprietary data set from a large financial institution that issues credit cards nationally (2000–02): data on credit bureau reports, credit card spending, balance, debt	75,000 Credit card accounts open as of June 2000, followed monthly for 24 months	Credit card spending, balances, and debt, as well as credit limit	Monthly	Reject	Spending increases by 40% of the average household rebate cumulatively in the 9 months after receipt for consumers whose most intensively used credit card account is in the sample	Based on credit limit, utilization rate, and age; strong evidence in favor
Agarwal and Qian (2014b)	2011 Singapore Growth Dividends; income increase	Credit card, debit card, and bank checking account data from leading bank in Singapore (2010–12)	Random sample of all bank customers of leading Singaporean bank (180,000 observations)	Spending, debt, credit card usage	Monthly	Cannot reject	Increase in card spending by 8 cents per month for every dollar received, corresponding to a total increase of 80 cents in the 10 month period after announcement; monthly increase similar after announcement and implementation	based on liquid assets and credit card limit; liquidity constrained consumers react stronger, though also already at announcement, ie, likely incompletely binding constraints

Broda and Parker (2014)	2008 Economic Stimulus Payments; income increase	Nielsen's Consumer Panel (2008): scanned purchases in grocery stores, drugstores and mass-merchandise sectors	Data on weekly purchases of 28,937 households (1,131,208 observations)	weekly spending on household goods based on barcode scanners used by households	Weekly	Reject	3 Months cumulative increase in spending on Nielson Consumer Panel goods amounts to 7% of ESP receipt	based on income and survey question regarding the availability of easily accessible funds; evidence in favor
Browning and Collado (2001)	Spanish Bonus Payment Scheme; income increase and decrease	Spanish Encuesta Continua de Presupuestos Familiares (1985–95): data on earnings and spending	2341 Households (16,143 observations) of which about 80% are classified as bonus	Spending on nondurables and durables, including separate subcategories	Weekly	Cannot reject	Spending patterns of bonus and nonbonus groups are indistinguishable	No test
Coulibaly and Li (2006)	Last mortgage payment; disposable income increase	CEX interview survey (1984–2000)	70,593 Observations, including 286 with last mortgage payments	Spending on nondurables and durables, plus subcategories	Quarterly	Cannot reject	Homeowners do not increase consumption after the last mortgage payment	No test (none of respondents likely to be constrained)
Gelman et al. (2014)	Regular paycheck or social security check arrival; income increase and decrease	Check, a financial aggregation and service application combining information from different financial accounts (2012–13)	75,000 randomly sampled US Check users	Total spending, nonrecurring spending, and fast food and coffee shop spending	Daily	Cannot reject	Nonrecurring spending and fast food and coffee shop spending show only mild comovement with regular payments	Based on ratio of average daily balance on saving and checking account to average daily spending; strong evidence in favor

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Hsieh (2003)	Alaska Permanent Fund Payments and income tax refunds; income increase and decrease	CEX interview survey (1980–81, 1984–2001)	806 Alaskan households	Spending on nondurables and durables, and different subcategories	Quarterly	Cannot reject	A 10% increase in household income increases nondurable consumption insignificantly by only 0.002%	Based on current income; no evidence in favor
Johnson et al. (2006)	2001 Federal Income Tax Rebates; income increase	CEX interview survey (2000–02) with added questions on tax rebates	13,066 Observations on households who received the tax rebate	Spending on nondurables, strictly nondurables, and food	Quarterly	Reject	Households spend 20–40% of their rebates on nondurable consumption goods during the 3-months period in which the rebates were received, and roughly two thirds during 6-months period	Based on age, income, and liquid assets; some evidence based on income and liquid assets, not age
Mastrobuoni and Weinberg (2009)	Social Security benefits payments; income increase and decrease	Continuing Survey of Food Intake by Individuals (1994–96)	745 Observations from households in which Social Security income makes up at least 80% of total income	Caloric intake	Daily	Mixed	Retirees with savings above $5000 smooth caloric intake over the pay cycle, while those with less than $5000 in savings have 24% lower caloric intake during the final few days of pay cycle than during first week	Based on liquid assets; strong evidence in favor (see main result)

Misra and Surico (2014)	2001 Federal Income Tax Rebates and 2008 Economic Stimulus Payments; income increase	CEX interview survey (2000–02 and 2007–08) with added questions on tax rebate and stimulus payments	17,718 Household who received rebates in 2001 or 2008	Spending on nondurables and durables, plus subcategories	Quarterly	Reject	During 6-months period in which payment was received, households spent 43% of payments on nondurable consumption in 2001, and 16% on total consumption in 2008	based on high income and high mortgage debt (wealthy hand-to-mouth consumers); evidence in favor
Parker (1999)	Caps on Social Security tax and changes in Social Security tax withholding; income increase and decrease	CEX interview survey (1980–93)	133,820 Observations on 57,051 households	Spending on nondurables and durables, and different subcategories	Quarterly	Reject	When a household's Social Security contributions fall so that income rises by $1, nondurable consumption rises by 20 cents	Based on age and liquid assets; weak evidence in favor
Parker et al. (2013)	2008 Economic Stimulus Payments; income increase	CEX interview survey (2007–08) with added questions on stimulus payments	17,478 Household observations, of which 11,239 received economic stimulus payments	Spending on nondurables and durables, plus subcategories	Quarterly	Reject	During 3-months period in which payment was received, households increase their expenditures on nondurable goods by 12–39% of the payment, and on overall consumption by 50–90%	Based on age, income, and liquid assets; some evidence based on income and age, not on liquid assets

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Paxson (1993)	Seasonal income patterns in Thai agriculture; income increase and decrease	Thai Socioeconomic Surveys (1975–76, 1981, and 1986)	27,963 Economically active (ie, not retired) households that did not engage in forestry or fishing	Spending on nondurables	Monthly	Cannot reject	Spending patterns of farm and nonfarm households are indistinguishable	No test
Scholnick (2013)	Last mortgage payment; disposable income increase	proprietary data set from a Canadian bank (2004–06): credit card and mortgage accounts data	4147 Individuals who have paid off their mortgage or who have less than 1 year of mortgage payments left	Credit card expenditures	Monthly	Reject	No quantitative interpretation reported; reaction of consumption to preannounced income increase is weaker the larger the income increase	Based on households paying positive interest on credit card debt; also non liquidity constrained consumers react significantly
Shapiro (2005)	Food stamps; income increase and decrease	Continuing Survey of Food Intake by Individuals (1989–91); Nationwide Food Consumption Survey (1987–88): data on market value and nutritional characteristics of food eaten; survey conducted to document	6652 Observations from surveyed individuals who receive food stamps	Caloric intake	Daily	Reject	caloric intake declines by a statistically significant 0.40% per day after receipt of food stamps	No test

		effects of Maryland's adoption of the Electronic Benefit Transfer system (1992–93)						
Shea (1995)	Unionized wage; income increase and decrease	PSID survey (1981–86): data on food consumption matched with data on wage growth from union contracts	647 Observations drawn from 285 households whose head is a union member and can be reasonably assigned to specific union	Spending on food consumed at home and in restaurants, plus the bonus value of food stamps	Annual	Reject	A 1 percentage point increase in wage growth is associated with a 0.89 percentage point increase in food consumption	Based on liquid assets and heterogeneous reactions to increases vs decreases; mildly supportive of liquidity constraints in traditional measures; yet, reaction stronger to income decrease
Souleles (2002)	1981 Economic Recovery Tax Act (Reagan Tax Cuts); income increase	CEX interview survey (1982–83)	2399 Household-quarter observations, head aged 24 to 64	Spending on nondurables and total consumption	Quarterly	Reject	For each dollar increase in take-home pay, nondurable consumption rises by about two-thirds of a dollar	Based on age, income, and liquid assets; no evidence in favor
Souleles (2000)	Paying for college; income decrease	CEX interview survey (1980–93)	7200 Household observations with child aged 16–24, of which 1249 have positive college expenditure	Spending on nondurables	Quarterly	Cannot reject	A one dollar decrease in income due to paying college tuition leads to an 8 cent increase (not decrease) in nondurable consumption	NA

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Souleles (1999)	Income tax refunds; income increase	CEX interview survey (1980–91)	4121 Observations on households receiving income tax refunds, head aged 24 to 64	Spending on nondurables and total consumption	Quarterly	Reject	One dollar of refund receipt raises strictly nondurable consumption by 2.6 cents, and total consumption by 18 cents	Based on liquid assets; some evidence in favor
Stephens (2008)	Final payment of a vehicle loan; disposable income increase	CEX interview survey (1984–2000)	4583 Observations on households who have an expiring vehicle loan	Spending on nondurables, except for public transportation and gas and motor oil	Quarterly	Reject	A 10% increase in after-tax income increases nondurable consumption by 2.8%	Based on age, liquid wealth, and maturity of expiring vehicle loan; evidence in favor based on age and liquid assets, but not based on maturity of prior loan
Stephens (2006)	Regular paycheck receipt; income increase and decrease	UK Family Expenditure Survey: 2 week diary of all expenditures (1986–98)	12,827 Households with a dependently employed monthly paid primary earner aged 25–59	Total spending, spending on strict nondurables, food at home, and instant consumption goods	Weekly	Reject	Instant consumption increases by 5% in week when households receive monthly paychecks	Based on asset income; strong evidence in favor

Stephens (2003)	Receipt of Social Security check on "3rd of tha Month"; income increase and decrease	CEX diary survey (1986–96)	9942 consumer units which contribute a total of 123,034 potential expenditure days	Spending on instant consumption, food, and nondurables	Daily	Reject	Households that receive at least 70 percent of income from Social Security increase instant consumption and food away from home by roughly 20% in week following arrival of Social Security check	No test
Stephens and Unayama (2011)	Change in frequency of Japanese public pension payments (February 1990); income increase and decrease	Japanese Family Income and Expenditure Survey (1986–94): diary data on expenditures and income	2503 Retirees and employees before reform (pension paid once every 3 months), and 3595 after reform pension paid once every 2 months)	spending on nondurables and durables	Monthly	Reject	Nondurable consumption increases by 4% in the month of check receipt, while strict nondurable and food consumption both increase by over 2% when checks are received	Based on age, total net financial assets and demand deposits; no evidence in favor
Wilcox (1989)	Changes in Social Security amounts; income increase	aggregate data on retail sales and personal consumption expenditures (1965–85)		Total retail sales, also divided in durable and nondurable good stores, and all commodities	Monthly	Reject	An increase in benefits by 10% increases total retail sales by 1.4%, with a 3% increase in durable goods sales (mostly cars)	No test

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Liquidity constraint relaxation								
Abdallah and Lastrapes (2012)	1998 Texas constitutional amendment on home equity loans allows mortgages for nonhousing expenditures	county (1992, 1997, 2002) and state (1992–2002) level data on retail sales; American Housing Survey (1994 and 2002): household-level data on second-lien equity homes	3006 Counties/ 45 states with complete data	Retail sales (measured directly on county level, or as ratio of sales tax revenues to sales tax rates at state level)	Annual (county level: 1992, 1997, 2002 only)	NA	Real per capita spending of average Texas county increases by 2–4% due to relaxation of borrowing constraints	NA
Bertrand and Morse (2009)	2008 Economic Stimulus Payments; income increase	Customers of a payday lending chain (March to September 2008)	881 Active payday loan customers	Payday loan take-up	Weekly	NA	Payday loan customers reduce borrowing on average by $46 after receipt of the rebate check of on average $600; frequency of borrowing also falls significantly	Based on frequency of use of payday loans; no evidence in favor
Gross and Tobacman (2014)	2001 Federal Income Tax Rebates and 2008 Economic Stimulus Payment; income increase	Data set compiled based on public access to Court Electronic Records system	All consumer bankruptcy filings in 81 out of 94 US courts (1998–2008)	Chapter 7 and chapter 13 bankruptcy filings	Weekly	NA	Bankruptcies increase by 2% after 2001 rebates and 6% after 2008 rebates; also shift from chapter 13 to chapter 7 bankruptcies	Based on income, share of subprime borrowers, and home ownership rate at ZIP code level; no evidence in favor

Leth-Petersen (2010)	1992 Danish credit market reform allows mortgages for nonhousing expenditures	Danish public administrative registers: data on wealth, income, household composition, characteristics of dwelling (1987–96)	63,613 Households aged between 25 and 65 in 1991	Imputed expenditures (income minus change in wealth)	Annual	NA	Credit constrained households with an equity to house value ratio of 0.5 or higher increase their expenditure by 1–3% in the years following change in law	Based on liquid assets; some evidence in favor if equity to home value is high
Temporary price cuts								
Agarwal et al. (2013)	Sales Tax Holidays	CEX diary survey (1997–2011); proprietary credit card transactions data from a large financial institution (2003, February 8–October 20)	Over 700,000 household-date observations from CEX diaries; over 10 million consumer-date observations from credit card data	Spending on specific categories (esp. children's clothing), credit card transactions	Daily	Reject	Sales tax holidays increase daily clothing spending by $1.17 (ie, 29% of daily household clothing spending); no significant reduction in spending before/after sales tax holiday on these categories, or during sales tax holidays on other categories	No test

Table A.1 Overview of Permanent Income Hypothesis papers relying on natural experiments—cont'd

Study	Experiment	Data source	Sample	Main dependent variable	Frequency of data	PIH	Quantitative reaction at implementation	Liquidity constraint
Mian and Sufi (2012)	2009 Cars Allowance Rebate System (Cash for Clunkers)	Data on car purchases from R.L. Polk for US metropolitan or micropolitan statistical areas (2004–10), augmented by data from Census, Equifax Predictive Services, Federal Housing Finance Agency, BLS and IRS	957 Metropolitan or micropolitan statistical areas	New car purchases	Monthly	Cannot reject	Cities with lots of qualifying clunkers have significantly higher increase in car sales in months of program, but then reduce them, such that cumulative response over 12 months is zero	No test

ACKNOWLEDGMENTS

The chapter has benefitted from helpful discussions and comments from Daron Acemoglu, Jonathan Dingel, Yuriy Gorodnichenko, Chang-Tai Hsieh, Nathan Nunn, Elias Papaioannou, Matthias Schündeln, Rob Vishny, Mirko Wiederholt, and seminar participants of the Handbook of Macroeconomics Conference at Stanford and at the Deutsche Bundesbank. Leonhard Czerny, Denis Gorea, and Philip Xu provided excellent research assistance. N.F.-S. gratefully acknowledges financial support from the Cluster of Excellence "Formation of Normative Orders" and the European Research Council under Starting Grant No. 262116.

Abstract

We elaborate on the business cycle accounting method proposed by Chari et al. (2006), clear up some misconceptions about the method, and then apply it to compare the Great Recession across OECD countries as well as to the recessions of the 1980s in these countries. We have four main findings. First,

Handbook of Macroeconomics, Volume 2A
ISSN 1574-0048, http://dx.doi.org/10.1016/bs.hesmac.2016.05.002

with the notable exception of the United States, Spain, Ireland, and Iceland, the Great Recession was driven primarily by the efficiency wedge. Second, in the Great Recession, the labor wedge plays a dominant role only in the United States, and the investment wedge plays a dominant role in Spain, Ireland, and Iceland. Third, in the recessions of the 1980s, the labor wedge played a dominant role only in France, the United Kingdom, and Belgium. Finally, overall in the Great Recession, the efficiency wedge played a more important role and the investment wedge played a less important role than they did in the recessions of the 1980s.

In this chapter, we elaborate on the business cycle accounting method proposed by Chari et al. (2006), henceforth CKM, clear up some misconceptions about the method, and then apply it to compare the Great Recession across OECD countries as well as to the recessions of the 1980s in these countries. The goal of the method is to help guide researchers' choices about where to introduce frictions into their detailed quantitative models in order to allow the models to generate business cycle fluctuations similar to those in the data.

The method has two components: an equivalence result and an accounting procedure. The *equivalence result* is that a large class of models, including models with various types of frictions, is equivalent to a *prototype model* with various types of time-varying wedges that distort the equilibrium decisions of agents operating in otherwise competitive markets. At face value, these wedges look like time-varying productivity, labor income taxes, investment taxes, and government consumption. We labeled these wedges *efficiency wedges*, *labor wedges*, *investment wedges*, and *government consumption wedges*.

The *accounting procedure* also has two components. It begins by measuring the wedges, using data together with the equilibrium conditions of a prototype model. The measured wedge values are then fed back into the prototype model, one at a time and in combinations, in order to assess how much of the observed movements of output, labor, and investment can be attributed to each wedge, separately and in combinations.

Here, we use this method to study the Great Recession in OECD countries. We also compare this recession with the recessions of the early 1980s. While the exact timing of the recessions of the early 1980s differs across countries in our OECD sample, most of the countries had a recession between 1980 and 1984. Throughout we refer to the recessions of the early 1980s as the *1982 recession*. We have four main findings. First, with the notable exception of the United States, Spain, Ireland, and Iceland, the Great Recession was driven primarily by the efficiency wedge. Second, in the Great Recession, the labor wedge plays a dominant role only in the United States, and the investment wedge plays a dominant role in Spain, Ireland, and Iceland. Third, in the recessions of the 1980s, the labor wedge played a dominant role only in France, the United Kingdom, and Belgium. Finally, overall in the Great Recession, the efficiency wedge played a much more important role and the investment wedge played a much less important role than they did in the recessions of the 1980s.

We now turn to the elaborating on the equivalence results in CKM that link the four wedges to detailed models. We begin by showing that a detailed economy with fluctuations in investment-specific technological change similar to that in Greenwood et al. (1997) maps into a prototype economy with investment wedges. This result makes clear that investment wedges are by no means synonymous with financial frictions, a point stressed by CKM.

We then consider an economy that blends elements of Kiyotaki and Moore (1997) with that of Gertler and Kiyotaki (2009). The economy has a representative household and heterogenous banks that face collateral constraints. We show that such an economy is equivalent to a prototype economy with investment wedges. This result makes clear that some ways of modeling financial frictions do indeed show up as investment wedges.

Finally, we turn to an economy studied by Buera and Moll (2015) consisting of workers and entrepreneurs. The entrepreneurs have access to heterogeneous production technologies that are subject to shocks to collateral constraints. We follow Buera and Moll (2015) in showing that this detailed economy is equivalent to a prototype model with a labor wedge, an investment wedge, and an efficiency wedge. This equivalence makes the same point as does the input-financing friction economy in CKM, namely that other ways of modeling financial frictions can show up as efficiency wedges and labor wedges.

The point of the three examples just discussed is to help clarify how the pattern of wedges in the data can help researchers narrow down the class of models they are considering. If, for example, most of the fluctuations are driven by the efficiency and labor wedges in the data, then of the three models just considered, the third one is more promising than the first two.

We then turn to models with search frictions. We use these models to make an important point. Researchers should choose the baseline prototype economy that provides the most insights for the research program of interest. In particular, when the detailed economies of interest are sufficiently different from the one-sector growth model, it is often more instructive to adjust the prototype model so that the version of it without wedges corresponds to the planning problem for the class of models at hand. For example, when we map the model with efficient search into the one-sector model, that model does have efficiency and labor wedges, but if we map it into a new prototype model with two capital-like variables, physical capital and the stock of employed workers, the new prototype model has no wedges.

We then consider a search model with an inefficient equilibrium. When we map this model into the new prototype model with two capital-like variables, then the prototype model has only labor wedges. But if we map it into the original prototype model, it has efficiency wedges and (complicated) labor wedges. These findings reinforce the point that it is often more instructive to adjust the prototype model so that the version of it without wedges corresponds to the planning problem for the class of models at hand.

Taken together, these equivalence results help clear up some common misconceptions. The first misconception is that efficiency wedges in a prototype model can only come from technology shocks in a detailed model. In our judgment, by far the least interesting interpretation of efficiency wedges is as narrowly interpreted shocks to the blueprints governing individual firm production functions. More interesting interpretations rest on frictions that deliver such high-frequency movements in this wedge. For example, the input-financing friction model in CKM shows how financial frictions in a detailed model can manifest themselves as efficiency wedges. Indeed, we think that exploring detailed models in which the sudden drops in efficiency wedges experienced in recessions come from frictions such as input-financing frictions is more promising than blaming these drops on abrupt negative shocks to blueprints for technologies. The second misconception is that labor wedges in a prototype model arise solely from frictions in labor markets in detailed economies. The Buera–Moll economy makes clear that this view is incorrect. The third misconception is that investment wedges arise solely due to financial frictions. Clearly, the detailed model with investment-specific technical change shows that this view is also incorrect.

We turn now to describing our procedure. This procedure is designed to answer questions of the following kind: How much would output fluctuate if the only wedge that fluctuated is the efficiency wedge and the probability distribution of the efficiency wedge is the same as in the prototype economy? If the wedges were independent at all leads and lags, the procedure can be implemented in a straightforward manner by letting only, say, the efficiency wedge fluctuate and setting all other wedges to constants. In the data, the wedges are correlated with each other, so the straightforward implementation does not answer our question.

Our implementation views the wedges as being functions of underlying abstract events. In practice, we assume that the dimension of the underlying events is the same as the dimension of the wedges, namely four, and identify each event with one of the wedges. We then use the data to estimate the stochastic process for the underlying events. Given this estimated stochastic process, we can then answer our question by letting the wedge of interest vary with the underlying events in the same way it did in the data but assuming that all other wedges are constant functions of the underlying events. The procedure ensures that the probability distribution over the wedge of interest is the same in the prototype economy with all wedges and in the experiment.

We then briefly discuss what at first seems to be an intuitive way to proceed in which the wedges are identified with the underlying event not only in the estimation but also in the thought experiment. The problem with this procedure is that it does not make clear the conceptual distinction between underlying events and wedges. This distinction is apparent when the wedges are correlated. Indeed, in this case, this procedure makes it impossible to hold all but one wedge constant without changing the probability distribution over the wedge of interest. We note that not keeping clear the conceptual distinction between underlying events and wedges has been the source of some confusion in the literature (see, for example, Christiano and Davis, 2006).

Our business cycle accounting method is intended to shed light on promising classes of mechanisms through which primitive shocks lead to economic fluctuations. It is not intended to identify the primitive sources of shocks. Many economists think, for example, that shocks to the financial sector drove the Great Recession in developed economies, but these economists disagree about the details of the driving mechanism. Our analysis suggests that the transmission mechanism from shocks to the financial sector to broader economic activity must be different in the United States, Spain, Ireland, and Iceland than in the rest of the countries in the OECD. More precisely, our analysis shows that these shocks must manifest themselves as labor wedges in the United States, as investment wedges in Spain, Ireland, and Iceland, and as efficiency wedges in the rest of the OECD.

As CKM argue, the equivalence results provide the logical foundation for the way our accounting procedure uses the measured wedges. At a mechanical level, the wedges represent deviations in the prototype model's first-order conditions, in its relationship between inputs and outputs, and in a variable in the resource constraint. One interpretation of these deviations, of course, is that they are simply errors, so that their size indicates the goodness-of-fit of the model. Under that interpretation, however, feeding the measured wedges back into the model makes no sense. Our equivalence result leads to a more economically useful interpretation of the deviations by linking them directly to classes of models; that link provides the rationale for feeding the measured wedges back into the model.

Also in terms of method, the accounting procedure goes beyond simply plotting the wedges. Such plots, by themselves, are not useful in evaluating the quantitative importance of competing mechanisms of business cycles because they tell us little about the equilibrium responses to the wedges. Feeding the measured wedges back into the prototype model and measuring the model's resulting equilibrium responses is what allows us to discriminate between competing mechanisms.

Related Literature

The chapter most closely related to ours is Ohanian and Raffo (2012), who use a methodology similar to ours to study the Great Recession in 14 OECD countries and compare the peak-to-trough declines in output and hours across countries and recessions. In part, our findings are the same in spirit: we both find that in the Great Recession, the labor wedge plays a dominant role in the United States.

In part our findings are in contrast: they find that in Korea the labor wedge plays a large role in the Great Recession. We instead find that in Korea the efficiency wedge does. We note that both Ohanian and Raffo (2012) and Lopez and Garcia (2014) find that the labor wedge rather than the investment wedge plays a dominant role in the Great

Recession in Spain. Our findings differ from both studies in part because of differences in the treatment of the data, including, for example, how we treat consumer durables and how we deflate nominal variables to make them real. We also differ from Ohanian and Raffo (2012) in terms of methodology: we fit stochastic processes for the wedges, whereas they focus on perfect foresight models. For some related studies, see Mulligan (2009) and Ohanian (2010).

The business cycle accounting methodology has been used for many countries and time periods. For example, it has been used for Portugal by Cavalcanti (2007), for the economies of Brazil, Russia, India, and China by Chakraborty and Otsu (2013), for India by Chakraborty (2006), for the East Asian economies by Cho and Doblas-Madrid (2013), for the United Kingdom by Kersting (2008), for Japan by Kobayashi and Inaba (2006), for Asian economies by Otsu (2010), and for monetary economies by Sustek (2011) and Brinca (2013), and for a variety of countries by Brinca (2014).

1. DEMONSTRATING THE EQUIVALENCE RESULT

Here, we show how various detailed models with underlying distortions are equivalent to a prototype growth model with one or more wedges.

1.1 The Benchmark Prototype Economy

The *benchmark prototype economy* that we use later in our accounting procedure is a stochastic growth model. In each period t, the economy experiences one of finitely many events s_t, which index the shocks. We denote by $s^t = (s_0, \ldots, s_t)$ the history of events up through and including period t and often refer to s^t as the *state*. The probability, as of period 0, of any particular history s^t is $\pi_t(s^t)$. The initial realization s_0 is given. The economy has four exogenous stochastic variables, all of which are functions of the underlying random variable s^t: the *efficiency wedge* $A_t(s^t)$, the *labor wedge* $1 - \tau_{lt}(s^t)$, the *investment wedge* $1/[1 + \tau_{xt}(s^t)]$, and the *government consumption wedge* $g_t(s^t)$.

In the model, consumers maximize expected utility over per capita consumption c_t and per capita labor l_t,

$$\sum_{t=0}^{\infty}\sum_{s^t}\beta^t\pi_t(s^t)U(c_t(s^t), l_t(s^t))N_t,$$

subject to the budget constraint

$$c_t + [1 + \tau_{xt}(s^t)]x_t(s^t) = [1 - \tau_{lt}(s^t)]w_t(s^t)l_t(s^t) + r_t(s^t)k_t(s^{t-1}) + T_t(s^t)$$

and the capital accumulation law

$$(1+\gamma_n)k_{t+1}(s^t) = (1-\delta)k_t(s^{t-1}) + x_t(s^t), \tag{1}$$

where $k_t(s^{t-1})$ denotes the per capita capital stock, $x_t(s^t)$ per capita investment, $w_t(s^t)$ the wage rate, $r_t(s^t)$ the rental rate on capital, β the discount factor, δ the depreciation rate of capital, N_t the population with growth rate equal to $1 + \gamma_n$, and $T_t(s^t)$ per capita lump-sum transfers.

The production function is $A(s^t)F(k_t(s^{t-1}), (1+\gamma)^t l_t(s^t))$, where $1 + \gamma$ is the rate of labor-augmenting technical progress, which is assumed to be a constant. Firms maximize profits given by $A_t(s^t)F\left(k_t(s^{t-1}), (1+\gamma)^t l_t(s^t)\right) - r_t(s^t)k_t(s^{t-1}) - w_t(s^t)l_t(s^t)$.

The equilibrium of this benchmark prototype economy is summarized by the resource constraint,

$$c_t(s^t) + x_t(s^t) + g_t(s^t) = y_t(s^t), \tag{2}$$

where $y_t(s^t)$ denotes per capita output, together with

$$y_t(s^t) = A_t(s^t)F\left(k_t(s^{t-1}), (1+\gamma)^t l_t(s^t)\right), \tag{3}$$

$$-\frac{U_{lt}(s^t)}{U_{ct}(s^t)} = [1 - \tau_{lt}(s^t)]A_t(s^t)(1+\gamma)^t F_{lt}, \text{ and} \tag{4}$$

$$U_{ct}(s^t)[1 + \tau_{xt}(s^t)] \tag{5}$$

$$= \beta \sum_{s^{t+1}} \pi_t(s^{t+1}|s^t)U_{ct+1}(s^{t+1})\{A_{t+1}(s^{t+1})F_{kt+1}(s^{t+1}) + (1-\delta)[1 + \tau_{xt+1}(s^{t+1})]\},$$

where, here and throughout, notations such as U_{ct}, U_{lt}, F_{lt}, and F_{kt} denote the derivatives of the utility function and the production function with respect to their arguments and $\pi_t(s^{t+1}|s^t)$ denotes the conditional probability $\pi_t(s^{t+1})/\pi_t(s^t)$. We assume that $g_t(s^t)$ fluctuates around a trend of $(1+\gamma)^t$.

Notice that in this benchmark prototype economy, the efficiency wedge resembles a blueprint technology parameter, and the labor and the investment wedges resemble tax rates on labor income and investment. Other more elaborate models could be considered, such as models with other kinds of frictions that look like taxes on consumption or capital income. Consumption taxes induce a wedge between the consumption-leisure marginal rate of substitution and the marginal product of labor in the same way as do labor income taxes. Such taxes, if time-varying, also distort the intertemporal margins in (5). Capital income taxes induce a wedge between the intertemporal marginal rate of substitution and the marginal product of capital, which is only slightly different from the distortion induced by a tax on investment. We experimented with intertemporal distortions that resemble capital income taxes rather than investment taxes and found that our substantive conclusions are unaffected. (For details, see the Appendix.)

We emphasize that each of the wedges represents the overall distortion to the relevant equilibrium condition of the model. For example, distortions to labor supply affecting consumers and to labor demand affecting firms both distort the static first-order condition

(4). Our labor wedge represents the sum of these distortions. Thus, our method identifies the overall wedge induced by both distortions and does not identify each separately. Likewise, liquidity constraints on consumers distort the consumer's intertemporal Euler equation, whereas investment financing frictions on firms distort the firm's intertemporal Euler equation. Our method combines the Euler equations for the consumer and the firm and therefore identifies only the overall wedge in the combined Euler equation given by (5). We focus on the overall wedges because what matters in determining business cycle fluctuations is the overall wedges, not each distortion separately.

For the equivalence results that follow, it is notationally convenient to work with the prototype model just described. For our quantitative results, we add investment adjustment costs by replacing the capital accumulation law (1) with

$$(1+\gamma_n)k_{t+1}(s^t) = (1-\delta)k_t(s^{t-1}) + x_t(s^t) - \phi\left(\frac{x_t(s^t)}{k_t(s^{t-1})}\right), \tag{6}$$

where ϕ represents the per unit cost of adjusting the capital stock. We follow the macroeconomic literature in assuming that the adjustment costs are parameterized by the function

$$\phi\left(\frac{x}{k}\right) = \frac{a}{2}\left(\frac{x}{k} - b\right)^2,$$

where $b = \delta + \gamma + \gamma_n$ is the steady-state value of the investment–capital ratio.

1.2 The Mapping—From Frictions to Wedges

Now we illustrate the mapping between detailed economies and prototype economies for several types of wedges. We show that investment-specific technical change in a detailed economy maps into investment wedges in our prototype economy. Likewise, bank collateral constraints also map into investment wedges in our prototype economy. We then consider an economy with heterogeneous productivity and collateral constraints and show that it maps into a prototype economy with efficiency, labor, and investment wedges. Finally, we consider a search model with efficient allocations and show it maps into a prototype economy with a labor wedge and an efficiency wedge but no investment wedge. The four economies we use to illustrate this mapping are closed economies for which the associated government consumption wedge in the prototype economy is identically zero. Hence, we focus on the other three wedges and make no mention of the government consumption wedge.

We choose simple models in order to illustrate how the detailed models map into the prototypes. Since many models map into the same configuration of wedges, identifying one particular configuration does not uniquely identify a model; rather, it identifies a whole class of models consistent with that configuration. This point is seen clearly when comparing the prototype model associated with the economy with investment-specific technical change to that for the economy with bank collateral constraints. In this sense, our method does not uniquely determine the model most promising to analyze business cycle fluctuations. It does, however, guide researchers to focus on the key margins that need to be distorted in order to capture the nature of the fluctuations.

1.2.1 An Equivalence Result for a Model with Investment-Specific Technical Change

We begin with a two-sector model with investment-specific technical change and show how it maps into a prototype economy with only investment wedges.

1.2.1.1 A Detailed Economy with Investment Specific Technical Change

The detailed economy has consumption $c_t(s^t)$ and investment $x_t(s^t)$ produced according to

$$c_t(s^t) = A_t(s^t)F(k_{ct}(s^t), l_{ct}(s^t)) \text{ and } x_t(s^t) = A_{xt}(s^t)A_t(s^t)F(k_{xt}(s^t), l_{xt}(s^t), \tag{7}$$

where $k_{ct}(s^t)$ and $l_{ct}(s^t)$ denote capital and labor used to produce consumption goods, $k_{xt}(s^t)$ and $l_{xt}(s^t)$ denote capital and labor used to produce investment goods, $A_t(s^t)$ is neutral technical change, $A_{xt}(s^t)$ denotes investment-specific technical change, and F satisfies constant returns to scale. The timing is that the (total) capital stock in use at period t is chosen at the end of period $t-1$ given the shock history s^{t-1}, whereas at the beginning of each period, after the current shock s_t is realized, labor and capital are allocated between sectors. This timing gives rise to a capital accumulation rule

$$k_{t+1}(s^t) = (1-\delta)k_t(s^{t-1}) + x_t(s^t) \tag{8}$$

and adding up constraints for sectoral capital allocation,

$$k_{ct}(s^t) + k_{xt}(s^t) \leq k_t(s^{t-1}), \tag{9}$$

and sectoral labor allocation,

$$l_{ct}(s^t) + l_{xt}(s^t) \leq l_t(s^t). \tag{10}$$

The planning problem is to choose allocations to solve

$$max \sum_{s^t} \beta^t \mu(s^t) U(c_t(s^t), l_t(s^t))$$

subject to (7)–(10). Using that the production function F has constant returns to scale, the first-order conditions imply that

$$\frac{k_{ct}(s^t)}{l_{ct}(s^t)} = \frac{k_{xt}(s^t)}{l_{xt}(s^t)} = \frac{k_t(s^{t-1})}{l_t(s^t)},$$

and hence

$$F_{kc}(k_{ct}(s^t), l_{ct}(s^t)) = F_{kx}(k_{xt}(s^t), l_{xt}(s^t)) \text{ and } F_{lc}(k_{ct}(s^t), l_{ct}(s^t)) = F_{lx}(k_{xt}(s^t), l_{xt}(s^t)),$$

and we can write these marginal products as $F_k(k(s^{t-1}), l(s^t))$ and $F_l(k(s^{t-1}), l(s^t))$. The Euler equation is

$$\frac{U_{ct}(s^t)}{A_{xt}(s^t)} = \sum_{s_{t+1}} \beta\mu(s^{t+1}|s^t)\left[U_{ct+1}(s^{t+1})A_{t+1}(s^{t+1})F_k(s^{t+1}) + (1-\delta)\frac{U_{ct}(s^{t+1})}{A_{xt+1}(s^{t+1})}\right],$$

and the static first-order condition for labor is given by

$$-\frac{U_{lt}(s^t)}{U_{ct}(s^t)} = A_t(s^t)F_l(s^t).$$

If we express output in current consumption units, we can write

$$A_t(s^t)F(k_{ct}(s^t), l_{ct}(s^t)) + q_t(s^t)A_{xt}(s^t)A_t(s^t)F(k_{xt}(s^t), l_{xt}(s^t) = A_t(s^t)F(k(s^{t-1}, l(s^t)))$$

since the relative price of investment to consumption goods is $q_t(s^t) = 1/A_{xt}(s^t)$.

1.2.1.2 The Associated Prototype Economy with Investment Wedges

Now consider a prototype economy with just investment wedges. This prototype economy has a productivity shock $A_t(s^t)$ equal to that in the consumption goods sector in the detailed economy, an investment wedge equal to the reciprocal of the level of investment-specific technical change, and no other wedges.

Proposition 1 *The aggregate allocations in the detailed economy with investment-specific technical change coincide with those of the prototype economy if the efficiency wedge in the prototype economy equals the productivity shock in the consumption goods sector, the investment wedge is given by*

$$1 - \tau_{xt}(s^t) = \frac{1}{A_{xt}(s^t)},$$

and the labor wedge is zero.

Note that if we measure output in the detailed economy at base period prices rather than at current prices, the map between the detailed economy and the prototype economy is more complicated.

1.2.2 An Equivalence Result for an Economy with Bank Collateral Constraints

Here, we show the equivalence between an economy with bank collateral constraints and a prototype economy with only investment wedges.

1.2.2.1 A Detailed Economy with Bank Collateral Constraints

Consider an infinite horizon economy that blends elements of Kiyotaki and Moore (1997) with that of Gertler and Kiyotaki (2009) and is composed of a household that works and operates financial intermediaries, referred to as *banks*, together with firms and a government. Households elastically supply labor and save by holding deposits in banks and government bonds and receive dividends. Banks raise deposits from households and use these deposits plus retained earnings to invest in capital as well as to pay dividends to consumers. Firms rent capital and labor and produce output. The government finances an exogenous stream of government spending by taxing labor income and the capital stock and by selling government bonds.

Let the state of the economy be $s_t \in S$ distributed according to $\pi(s_t|s_{t-1})$. Let $s^t = (s_0, \ldots, s_t)$. The resource constraint is given by

$$C_t(s^t) + K_{t+1}(s^t) = A_t(s^t)F\left(K_t\left(s^{t-1}\right), L_t(s^t)\right), \tag{11}$$

where C_t is aggregate consumption, K_{t+1} is the capital stock, L_t is aggregate labor, and F is a constant returns to scale production function that includes the undepreciated capital stock. Throughout we use the convention that uppercase letters denote aggregates and lowercase letters denote the decisions of individual households or banks.

We follow Gertler and Karadi (2011) and Gertler et al. (2012) in the formulation of households. The decision making in each household can be thought of as being made by different entities: a measure 1 of workers and a measure 1 of bankers. The workers supply labor and return their wages to the household while each banker manages a bank that transfers nonnegative dividends to the household. The household as a whole has preferences

$$\sum_{t=0}^{\infty} \sum_{s^t} \beta^t \pi(s^t|s_0) U(c_t(s^t), l_t(s^t)), \tag{12}$$

where c_t and l_t are an individual household's consumption and labor supply. Given initial asset holdings b_{H0} and d_0, the stand-in household in the economy maximizes this utility by choosing $\{c_t, l_t, d_{t+1}\}$ subject to the budget constraint

$$c_t(s^t) + \sum_{s^{t+1}} q_{t+1}\left(s^{t+1}\right) d_{t+1}\left(s^{t+1}\right) \le w_t(s^t) l_t(s^t) + d_t(s^t) + X_t(s^t) - \frac{1-\sigma}{\sigma}\bar{n}$$

and the restrictions that

$$d_{t+1}\left(s^{t+1}\right) \ge \bar{d}, \tag{13}$$

where $\bar{d}$ is a large negative number. Here, d_{t+1} is the amount of deposits made by households in banks and q_{t+1} is the corresponding price. Also, w_t is the real wage, X_t are dividends paid by banks, and $\bar{n}$ is the amount of initial equity given to each newly formed bank of which a measure $(1 - \sigma)/\sigma$ is formed each period.

The first-order conditions for the household's problem can be summarized by

$$-\frac{U_{Lt}(s^t)}{U_{Ct}(s^t)} = w_t(s^t) \tag{14}$$

$$q_{t+1}\left(s^{t+1}\right) = \frac{\beta\pi(s^{t+1}|s^t) U_{Ct+1}(s^{t+1})}{U_{Ct}(s^t)}. \tag{15}$$

A representative firm rents capital at rate R_t from banks and hires L_t units of labor to maximize profits

$$\max_{K_t, L_t} AF(K_t, L_t) + (1-\delta)K_t - R_t K_t - w_t L_t. \tag{16}$$

The first-order conditions to this problem imply

$$AF_K(s^t) + 1 - \delta = R_t(s^t) \text{ and } AF_L(s^t) = w_t(s^t). \tag{17}$$

Next consider the banks. At the beginning of each period, an idiosyncratic random variable is realized at each existing bank. With probability σ, the bank will continue in operation until the next period. With probability $1 - \sigma$, the bank ceases to exist and, by assumption, pays out all of its accumulated net worth as dividends to the household. Also at the beginning of each period, a measure $(1 - \sigma)/\sigma$ of new banks is born, each of which is given an exogenously specified amount of initial equity $\bar{n}$ from households. Since only a fraction σ of these newborn banks survive until the end of the period, the measure of surviving banks is always constant at 1. This device of having banks die is a simple way to ensure that they do not build up enough equity to make the financial constraints that we will next introduce irrelevant.

Turning to the budget constraint of an individual bank, note first that for any non-newborn bank the budget constraint at t is

$$x_t(s^t) + k_{t+1}(s^t) - \sum_{s^{t+1}} q_{t+1}\left(s^{t+1}\right) d_{t+1}\left(s^{t+1}\right) \le R_t(s^t) k_t\left(s^{t-1}\right) - d_t(s^t), \tag{18}$$

where R_t is the rental rate for capital. We will let $n_t(s^t) = R_t(s^t)k_t(s^{t-1}) - d_t(s^t)$ denote the right side of (18) and will refer to it as the *net worth* of the bank. For a bank that is newly born at t, the left side of the budget constraint is the same and the right side of (18) is replaced by initial net worth $\bar{n}$. Banks face a *collateral* constraint for each s^{t+1},

$$d_{t+1}\left(s^{t+1}\right) \le \gamma R_{t+1}\left(s^{t+1}\right) k_{t+1}(s^t), \tag{19}$$

where $0 < \gamma < 1$, as well as nonnegativity constraints on dividends and bond holdings,

$$x_t(s^t) \ge 0. \tag{20}$$

For notational simplicity only, consider the problem of a bank born in period 0. The bank chooses $\{k_{t+1}(s^t), d_t(s^t), x_t(s^t)\}$ to solve

$$\max \sum_t^{\infty} \sum_{s^t} Q(s^t)\sigma^t[\sigma x_t(s^t) + (1-\sigma) n_t(s^t)] \tag{21}$$

subject to (18)–(20) where $n_t(s^t) = R_t(s^t) k_t\left(s^{t-1}\right) - d_t(s^t)$, $n_0\left(s^0\right) = \bar{n}$, and $Q(s^t)$ is the price of a good at date t in units of a good at date 0 after history s^t. We assume that a bank that ceases to operate pays out its accumulated net worth as dividends. Since the bank is owned by the household, it values dividends at the marginal rates of substitution of consumers, so that

$$Q(s^t) = \beta^t \pi(s^t) U_C(s^t) / U_{C0}(s^0). \tag{22}$$

From the household's first-order condition, it follows that the discount factor used by the bank is consistent with the rate of return on deposits in that $Q(s^t) = q_0(s^0) \cdots q_t(s^t)$.

The first-order conditions to the bank's problem can be written as

$$Q(s^t)\sigma^{t+1} + \eta_{xt}(s^t) = \lambda_t(s^t)$$

$$\lambda_t(s^t) = \sum_{s^{t+1}} \left[Q(s^{t+1})\sigma^{t+1}(1-\sigma)R_{t+1}(s^{t+1}) + R_{t+1}(s^{t+1})\left(\lambda_{t+1}(s^{t+1}) + \gamma\mu_{t+1}(s^{t+1})\right)\right]$$

$$-Q(s^{t+1})\sigma^{t+1}(1-\sigma) + \lambda_t(s^t)q_{t+1}(s^{t+1}) = \lambda_{t+1}(s^{t+1}) + \mu_{t+1}(s^{t+1}), \tag{23}$$

where $\lambda_t(s^t)$, $\mu_t(s^t)$, and $\eta_{xt}(s^t)$ are the multipliers on the bank budget constraint, the collateral constraint, and the nonnegative dividend constraint. We can manipulate these constraints to obtain

$$1 = \sum_{s^{t+1}} \left[R_{t+1}(s^{t+1}) q_{t+1}(s^{t+1}) \left(1 - (1-\gamma)\frac{\mu_{t+1}(s^{t+1})}{\lambda_t(s^t) q_{Dt+1}(s^{t+1})} \right) \right]. \tag{24}$$

A competitive equilibrium is defined in the standard fashion.

1.2.2.2 The Associated Prototype Economy with Investment Wedges

Consider a version of the benchmark prototype economy that will have the same aggregate allocations as the banking economy just detailed. This prototype economy is identical to our benchmark prototype except that the new prototype economy has an investment wedge that resembles a tax on capital income rather than a tax on investment. Here, the government consumption wedge is set equal to zero.

In the prototype economy, the consumer's budget constraint is

$$C_t(s^t) + K_{t+1}(s^t) = (1 - \tau_{Kt}(s^t))R_t(s^t)K_t(s^{t-1}) + (1 - \tau_{Lt}(s^t))w_t(s^t)L_t(s^t) + T_t(s^t). \tag{25}$$

The first-order condition for the investment wedge in this economy is given by

$$U_{Ct}(s^t) = \sum_{s^{t+1}} \beta\mu(s^{t+1}|s^t)U_{Ct+1}(s^{t+1})[AF_{Kt+1}(s^{t+1}) + 1 - \delta](1 - \tau_{Kt+1}(s^{t+1}). \tag{26}$$

Comparing the first-order conditions in the detailed economy with bank collateral constraints to those of the associated prototype economy leads us to set

$$\tau_{Kt}(s^t) = (1-\gamma)\frac{\mu_{t+1}(s^{t+1})}{\lambda_t(s^t)q_{Dt+1}(s^{t+1})}. \tag{27}$$

We then have the following proposition.

Proposition 2 *The aggregate allocations in the detailed economy with bank collateral constraints coincide with those of the prototype economy if the efficiency wedge in the prototype economy $A_t(s^t) = A$, the labor wedge is zero, and the investment wedge is given by (27).*

Clearly, the efficiency wedge here is just the constant level of technology A in the detailed economy. To see why there is no labor wedge, note that combining (14) and (17) gives that

$$-\frac{U_L(s^t)}{U_C(s^t)} = AF_L(s^t).$$

To derive the expression for the investment wedge, substitute for $R_{t+1}(s^{t+1})$ from the firm's first-order condition (17) and for $q_{t+1}(s^{t+1})$ from the consumer's first-order condition (15) to obtain

$$1 = \sum_{s^{t+1}} \left[\beta\mu(s^{t+1}|s^t) \frac{U_{Ct+1}(s^{t+1})}{U_{Ct}(s^t)} [AF_{Kt+1}(s^{t+1}) + 1 - \delta] \left(1 - (1-\gamma)\frac{\mu_{t+1}(s^{t+1})}{\lambda_t(s^t)q_{Dt+1}(s^{t+1})}\right)\right]$$

and compare (26) to this equation.

1.2.3 *An Equivalence Result for an Economy with Heterogeneous Productivity and Collateral Constraints*

We use an example from Buera and Moll (2015) to illustrate how a model with fluctuations in financial frictions, modeled as shocks to a collateral constraint on entrepreneurs, is equivalent to a prototype model with a labor wedge, an investment wedge, and an efficiency wedge. We think of this example as making a point identical to that in proposition 1 of Chari et al. (2006) but in a different context. That proposition showed how a detailed model with financial frictions modeled as input-financing frictions is equivalent to a prototype economy with a labor wedge, an investment wedge, and an efficiency wedge.

1.2.3.1 A Detailed Economy with Heterogeneous Productivity and Collateral Constraints

We consider an economy with only idiosyncratic shocks and exogenous incomplete markets against these shocks. A unit mass of identical workers supply labor L_t at a wage w_t, who can neither borrow nor lend, maximize

$$\sum_{t=0}^{\infty} \beta^t [\log(C_{Wt}) - V(L_t)]$$

subject to

$$C_{Wt} = w_t L_t. \tag{28}$$

The economy has a unit mass of entrepreneurs indexed by $i \in [0, 1]$ and a unit mass of identical households. An entrepreneur of type i draws an idiosyncratic shock z_{it} which is i.i.d. over time and across entrepreneurs and has density $\psi(z)$. This entrepreneur has a technology to produce output of the form $y_{it} = z_{it}^{\alpha} k_{it}^{\alpha} l_{it}^{1-\alpha}$ where k_{it} and l_{it} are the amounts of capital invested and labor hired by entrepreneur i.

The timing is that an entrepreneur's productivity in period $t + 1$, namely z_{it+1}, is revealed at the end of period t, before the entrepreneur issues new debt d_{t+1}. Written in recursive form, an entrepreneur with utility function $\sum \beta^t \log(c_t)$ solves

$$V_t(k, d, z_{-1}, z) = \max_{c, d', k'} \log c + \beta E[V_{t+1}(k', d', z, z')]$$

subject to a budget constraint

$$c + k' - d' = \Pi(z_{-1}, w, k) + (1-\delta)k - (1 + r_t)d$$

and a collateral constraint

$$d' \leq \theta_t k' \text{ with } \theta_t \in [0, 1]. \tag{29}$$

Note that (29) restricts the amount of leverage d'/k' to be less than some exogenous amount, θ_t. We use the constant returns to scale production function and the multiplicative technology shock to write total profits $\mathit{\Pi}(z_{-1}, w, k)$ as linear functions of the technology shock and the capital stock so that

$$\mathit{\Pi}(z_{-1}, w, k) = z\pi(w)k = \max_{l} (zk)^{\alpha} l^{1-\alpha} - wl,$$

where $\pi(w) = \alpha\left(\dfrac{1-\alpha}{w}\right)^{(1-\alpha)/\alpha}$.

An equilibrium consists of sequences of prices $\{r_t, w_t\}$ and quantities such that the allocations solve both the entrepreneur problem and the household problem, and markets clear in that

$$\int d_{it} di = 0 \text{ and } \int l_{it} di = L_t \tag{30}$$

$$C_{Et} + C_{Wt} + X_t = Y_t$$

$$K_{t+1} = X_t + (1-\delta)K_t,$$

where X_t denotes aggregate investment. To characterize the equilibrium, we let m_{it} denote the entrepreneur's cash on hand given by

$$m_{it} \equiv z_{it}\pi_t k_{it} + (1-\delta)k_{it} - (1 + r_t)d_{it},$$

and we let a_{it} denote the net worth of the entrepreneur,

$$a_{it} \equiv k_{it} - d_{it}.$$

We can use this notation to rewrite the dynamic programming problem of the entrepreneur as a two-stage budgeting problem: first choose how much net worth d' to carry over to the next period, and then in the second stage, conditional on d', decide how to split this net worth between capital k' and bonds $-d'$. The two-stage problem is then to solve

$$v_t(m,z) = \max_{d'}\left[\log(m-d') + \beta E v_{t+1}(\tilde{m}_{t+1}(d',z),z')\right],$$

where

$$\tilde{m}_{t+1}(d',z) = \max_{k',d'} z\pi_{t+1}k' + (1-\delta)k' - (1+r_{t+1})d'$$

subject to

$$k' - d' = a',$$

and

$$k' \leq \lambda_t d' \text{ where } \lambda_t = \frac{1}{1-\theta_t} \in [1,\infty). \tag{31}$$

This formulation immediately implies the following result.

Lemma 1 *There is a productivity cutoff for being active* $\underline{z}_{t+1}$ *defined by* $\underline{z}_{t+1}\pi(w_{t+1}) = r_{t+1} + \delta$. *Given this cutoff, capital and debt holdings are given by*

$$k_{it+1} = \left\{\begin{matrix} \lambda_t a_{it+1} & \textit{for } z_{it+1} \geq \underline{z}_{t+1} \\ 0 & \textit{otherwise} \end{matrix}\right\}, d_{it+1} = \left\{\begin{matrix} (\lambda_t - 1)a_{it+1} & \textit{for } z_{it+1} \geq \underline{z}_{t+1} \\ -a_{it+1} & \textit{otherwise} \end{matrix}\right\}, \tag{32}$$

and entrepreneurs save a constant fraction of cash on hand $a_{it+1} = \beta m_{it}$.

Note that the optimal capital choice is always at one of two corners. Sufficiently unproductive entrepreneurs lend out all their net worth for use by other entrepreneurs and receive return $r_{t+1} + \delta$, whereas sufficiently productive entrepreneurs borrow the maximal amount allowed by the collateral constraint, $\lambda_t a_{it+1}$, and invest these funds in their own projects. The marginal entrepreneur has a productivity that makes the returns from investing in capital, $\underline{z}_{t+1}\pi_{t+1}$, just equal to the returns to lending out funds, $r_{t+1} + \delta$.

We can use this characterization of decision rules together with market clearing conditions to determine the cutoff $\underline{z}_{t+1}$ as a function of the parameters of the economy. To do so, we aggregate over entrepreneurs to obtain

$$K_{t+1} = \beta[\alpha Y_t + (1-\delta)K_t] \text{ and } Y_t = A_t K_t^{\alpha} L_t^{1-\alpha},$$

where

$$A_t = \left(\frac{\int_{\underline{z}_t} z\psi(z)dz}{1-\Psi(\underline{z}_t)}\right)^{\alpha} = (E[z|z \geq \underline{z}_t])^{\alpha}, \tag{33}$$

where $\underline{z}_t$ is given by the solution to

$$\lambda_{t-1}(1-\Psi(\underline{z}_t)) = 1. \tag{34}$$

To understand the determination of the cutoff productivity level, we use the results of Lemma 1 to obtain that

$$d_{it+1}=\left\{\begin{array}{c}(\lambda_t-1)\beta m_{it}\text{ for }z_{it+1}\geq\underline{z}_{t+1}\\ -\beta m_{it}\text{ otherwise}\end{array}\right\}.$$

Using the observation that m_{it} chosen before z_{it+1} is realized and is therefore independent of z_{it+1}, we can write the market clearing condition for debt given in (30) for period $t+1$ as

$$(\lambda_t-1)\int_{\underline{z}_{t+1}}^{\infty}\psi(z)dz=\int_0^{\underline{z}_{t+1}}\psi(z)dz,$$

which, when rearranged, yields (34).

1.2.3.2 The Associated Prototype Economy with Efficiency, Labor, and Investment Wedges

Consider a version of the benchmark prototype economy that will have the same aggregate allocations as the banking economy just detailed. This prototype economy is identical to our benchmark prototype except that the new prototype economy has an investment wedge that resembles a tax on capital income rather than a tax on investment.

This economy can be mapped into our prototype economy with a period utility function of the form $U(C_t,L_t)=\log C_t-V(L_t)$ as follows. The efficiency wedge is given by (33), the labor wedge is given by

$$\tau_{Lt}=-\frac{C_{Et}}{C_{Wt}}, \tag{35}$$

and the investment wedge is defined recursively from

$$\frac{U_{ct}}{U_{ct+1}}\tau_{xt}=\beta(1-\delta)\tau_{xt+1}+\frac{C_{Wt}}{C_t}\left(\frac{C_{Wt+1}}{C_{Wt}}-\frac{C_{Et+1}}{C_{Et}}\right) \tag{36}$$

with $\tau_{x0}=0$. To derive (35), note that the labor wedge in the prototype economy is given by

$$C_tV'(L_t)=(1-\tau_{Lt})F_{Lt}. \tag{37}$$

Next, note that in the detailed economy, the first-order condition for the worker can be manipulated to yield $L_tV'(L_t)=1$. Using this condition along with $w_t=F_{Lt}$, $C_t=C_{Wt}+C_{Et}$, and $C_{Wt}=w_tL_t$ in (37) yields (35). Note that (36) can be obtained by using the result that entrepreneurs save a constant fraction of their wealth.

Proposition 3 *The aggregate allocations in the detailed economy with heterogeneous productivity and a collateral constraint coincide with those of the prototype economy if the efficiency wedge in the prototype economy is given by (33), the labor wedge is given by (35), and the investment wedge is given by (36).*

1.2.4 An Equivalence Result for an Economy with Efficient Search

Consider the efficient outcomes from a standard search model. We will show that if we view the outcomes of this model through the lens of a prototype growth model, the prototype model has a labor wedge and an efficiency wedge but no investment wedge.

1.2.4.1 A Detailed Economy with Efficient Search

For simplicity, we focus on a version of the model without aggregate uncertainty. The technology is as follows. The population is normalized to 1. In each period, measure n_t of the population is employed and the rest are unemployed. Of the employed, measure v_t is used as recruiters and $n_t - v_t$ are used in producing the single consumption–investment good. The matching technology depends on the measure of recruiters and the measure of unemployed, $1 - n_t$. The measure of new matches m_t created in any period is given by the constant returns to scale function $G(v_t, 1 - n_t)$. Existing matches dissolve at an exogenous rate δ_n so that the law of motion for the measure of employed is given by

$$n_{t+1} \leq (1-\delta_n)n_t + m_t \tag{38}$$

and the resource constraint for goods is

$$c_t + k_{t+1} \leq y_t + (1-\delta)k_t, \tag{39}$$

where c_t is consumption, k_{t+1} is the capital stock, $y_t = A_tF(k_t, n_t - v_t)$, and δ is the depreciation rate. We assume that $F = k_t^{\alpha}(n_t - v_t)^{1-\alpha}$. The utility of the stand-in household is given by

$$\sum \beta^t U(c_t, n_t). \tag{40}$$

The social planner's problem is to choose $\{c_t, v_t, n_{t+1}, k_{t+1}\}$ to maximize utility subject to (38) and (39). We summarize the key first-order conditions as

$$U_{ct} = \beta U_{ct+1}\left[\frac{\alpha y_{t+1}}{k_{t+1}} + 1 - \delta\right], \tag{41}$$

$$U_{ct}\frac{F_{nt}}{G_{1t}} = \beta U_{ct+1}\left\{\frac{F_{nt+1}}{G_{1t+1}}[(1-\delta_n) - G_{2t+1}] + F_{nt+1} + \frac{U_{nt+1}}{U_{ct+1}}\right\}, \tag{42}$$

and

$$y_t = A_tF(k_t, n_t - v_t).$$

1.2.4.2 The Associated Prototype Economy with Efficiency and Labor Wedges

Consider a prototype economy in which the production function is $y_t = \hat{A}_t k_t^{\alpha} n_t^{1-\alpha}$ where

$$\hat{A}_t = A_t\left(\frac{n_t - v_t}{n_t}\right)^{\alpha} \tag{43}$$

and the resource constraint is the same as in (39). Lagging and manipulating (42) and using

$$A_tF_{nt} = (1-\alpha)\frac{y_t}{n_t - v_t} = (1-\alpha)\frac{y_t}{n_t}\frac{n_t}{n_t - v_t},$$

we obtain

$$\frac{U_{nt}}{U_{ct}(1-\alpha)y_t/n_t} = \left(\frac{n_t}{n_t - v_t}\right)\left[\frac{U_{ct-1}}{\beta U_{ct}}\frac{F_{nt-1}}{A_tF_{nt}}\frac{1}{G_{1t-1}} - \frac{1}{G_{1t}A_t}[(1-\delta_n) - G_{2t}] - \frac{1}{A_t}\right]. \tag{44}$$

Since the labor wedge in the prototype economy is given by the right side of (44), we have the following result.

Proposition 4 *The aggregate allocations in the efficient search economy coincide with those of the prototype economy if the efficiency wedge in the prototype economy is given by (43), the labor wedge $1 - \tau_{lt}$ is given by the right side of (44), and the investment wedge is zero.*

1.3 Adjusting the Prototype Economy

So far we have always established equivalence results between a given detailed economy and the prototype one-sector growth model. When using business cycle accounting logic, one can always do that. When the underlying economy is sufficiently different from the one-sector growth model, however, it is often more instructive to adjust the prototype model so that the version of it without wedges is the planning problem for the class of models at hand.

1.3.1 An Equivalence Result for an Economy with Inefficient Search

Here, we illustrate what we mean by considering a version of the search model in which search is inefficient in that the equilibrium of the economy does not solve the planning problem just discussed. One alternative is to keep the prototype model as the one-sector growth model, in which case the wedges will simply be more elaborate versions of those just discussed. Here, we illustrate an alternative: we now measure the wedges relative to a distorted version of the social planning problem just studied.

1.3.1.1 A Detailed Economy with Inefficient Search

Consider the decentralized equilibrium of a standard search model. The matching technology is as before: the measure of new matches m_t created in any period is given by the constant returns to scale function $G(v_t, 1 - n_t)$. Letting $\theta_t = v_t/(1 - n_t)$ be the number of recruiters per unemployed worker, each firm that uses the recruiting technology attracts $\lambda_f(\theta_t) = G(v_t, 1 - n_t)/v_t$ per recruiter to the firm. Thus, a measure of recruiters v_t attracts $v_t\lambda_f(\theta_t)$ workers to the firm. The probability that an unemployment worker finds a job is $\lambda_w(\theta) = G(v_t, 1 - n_t)/(1 - n_t)$. Note for later that under constant returns to scale, $\lambda_w(\theta) = \theta\lambda_f(\theta)$.

Here, as is standard, we imagine that workers are part of a family which has idiosyncratic risk across its members. Since we abstract from aggregate shocks, the law of large numbers implies that the family solves a deterministic problem. As we did earlier, we assume that productivity deterministically varies over time. To keep notation simple, we only index the value function and the prices by time. The problem of a family written in recursive form is

$$V_t(a_t, n_t) = \max_{c,a'} U(c,n) + \beta V_{t+1}(a', n')$$

subject to the household budget constraint and the transition law for employed workers,

$$c + q_{t+1} a' = a + wn, \tag{45}$$

$$n' = (1-\delta_n)n + \lambda_w(\theta)(1-n). \tag{46}$$

In (45), a' is the quantity of goods saved at t and q_{t+1} is the price at t per unit of goods delivered at $t+1$. In (46), δ_n is the separation rate of employed workers and $\lambda_w(\theta)(1-n)$ is the measure of workers that transit from unemployment to employment.

The first-order condition for a' is

$$q_{t+1} U_{ct} = \beta V_{at+1},$$

and using the envelope condition for a, namely $V_{at} = U_{ct}$, gives

$$q_{t+1} U_{ct} = \beta U_{ct+1}. \tag{47}$$

We can use the envelope condition to derive the marginal value to the household of an additional employed worker,

$$V_{nt} = U_{ct} w_t + U_{nt} + \beta[1-\delta_n - \lambda_w(\theta_t)] V_{nt+1}(a', n'), \tag{48}$$

at the equilibrium wage w_t where n' is given from (46). The first term gives the marginal increase in utility from the increased consumption due to having an additional worker earning w_t. The second term gives the decrease in utility from increased work. The third term is the increase in the present value of utility from entering the next period with an additional worker.

In order to determine the wages in Nash bargaining, it is useful to define the value to the family of having an additional employed worker at an arbitrary current wage w. This worker will receive the equilibrium wage in all future periods if employed. This value is

$$\widetilde{V}_{nt}(a,n,w) = U_c(w - w_t) + V_{nt}(a,n).$$

The problem of the firm with a current stock of employed workers n and a current stock of capital k can be written in recursive form as

$$J_t(n,k) = \max_{v,k'} \left\{ z_t F(k, n-v) - [k' - (1-\delta)k] - w_t n + q_{t+1} J_{t+1}((1-\delta_n)n + v\lambda_f(\theta_t), k') \right\},$$

where the transition law from workers employed at this firm is

$$n' = (1-\delta_n)n + v\lambda_f(\theta_t).$$

Here, the flow profits at t are output, $z_tF(k, n - v)$, minus investment, $[k' - (1-\delta)k]$, minus the wage bill, w_tn. The firm discounts the present value of future profits from $t + 1$ on by q_{t+1}. The first-order condition for capital is $q_{t+1}J_{kt+1}(n', k') = 1$. Using the envelope condition for k, $J_{kt}(n, k) = z_tF_{kt} + (1 - \delta)$ in this first-order condition gives

$$1 = q_{t+1}[z_{t+1}F_{kt+1} + (1-\delta)]. \tag{49}$$

The first-order condition for the mass of recruiters to deploy at t is

$$z_tF_{nt} = \lambda_f(\theta_t)q_{t+1}J_{nt+1}(n', k'). \tag{50}$$

Using the envelope condition for n,

$$J_{nt}(n,k) = z_tF_n - w_t + [1-\delta_n]q_{t+1}J_{nt+1}(n', k'), \tag{51}$$

in the first-order condition for recruiters (50) gives

$$J_{nt}(n,k) = z_tF_{nt} - w_t + [1-\delta_n]\frac{z_tF_n}{\lambda_f(\theta_t)}. \tag{52}$$

The value of having an additional worker employed at an arbitrary wage w in the current period, who will receive the equilibrium wage in all future periods, is

$$\tilde{J}_{nt}(n,k,w) = w_t - w + J_{nt}(n_t, k_t).$$

Wages are determined according to Nash bargaining with the bargaining parameter ϕ for the worker and $1 - \phi$ for the firm. The bargained wage w maximizes the asymmetric Nash product by solving

$$\max_w \phi \log\left[\tilde{V}_{nt}(a_t, n_t, w)\right] + (1-\phi)\log\left[\tilde{J}_{nt}(k_t, n_t, w)\right],$$

where the first term in brackets is the value to the family of having an additional worker employed rather than unemployed at an arbitrary wage w. The first-order condition is

$$\phi\frac{\tilde{V}_{nwt}}{\tilde{V}_{nt}} + (1-\phi)\frac{\tilde{J}_{nwt}}{\tilde{J}_{nt}} = 0.$$

Using $\tilde{V}_{nwt}(a_t, n_t, w) = U_{ct}$ and $\tilde{J}_{nwt}(k_t, n_t, w) = -1$ and evaluating this first-order condition at equilibrium with $w = w_t$ so that $\tilde{V}_{nt} = V_{nt}$ and $\tilde{J}_{nt} = J_{nt}$ gives

$$\phi\frac{U_{ct}}{V_{nt}} = (1-\phi)\frac{1}{J_{nt}}. \tag{53}$$

Substituting for V_{nt} and V_{nt+1} from (53) into (48) and replacing J_{nt} with the right side of (52) gives

$$\phi\left[\left(1+\frac{1-\delta_n}{\lambda_f(\theta_t)}\right)z_tF_{nt}-w_t\right]=(1-\phi)\left[w_t+\frac{U_{nt}}{U_{ct}}\right]+\phi[1-\delta_n-\lambda_w(\theta_t)]q_{t+1}J_{nt+1}.$$

Replacing J_{nt+1} using the first-order condition for recruiters (50), we can solve for the equilibrium wage,

$$w_t=\phi[1+\theta_t]z_tF_{nt}+(1-\phi)\left(-\frac{U_{nt}}{U_{ct}}\right). \tag{54}$$

Here, hiring an unemployed worker produces a marginal value to the firm that includes both the direct value of production and the savings on recruiters' time. The wage is a weighted average of this marginal value and the marginal rate of substitution between consumption and employment for the household. Substituting the wage equation into the recruiter's first-order condition (50) gives

$$z_tF_{nt}U_{ct}=\beta U_{ct+1}\lambda_{ft}\left\{z_{t+1}F_{nt+1}\left[1+\frac{1-\delta_n}{\lambda_{ft+1}}\right]-\phi[1+\theta_{t+1}]z_{t+1}F_{nt+1}+(1-\phi)\frac{U_{nt+1}}{U_{ct+1}}\right\}. \tag{55}$$

The corresponding first-order condition for recruiters for the planner (42) can be manipulated to be

$$z_tF_{nt}U_{ct}=\beta U_{ct+1}G_{1t}\left\{z_{t+1}F_{nt+1}\left[\frac{1-\delta_n}{G_{1t+1}}-\frac{G_{2t+1}}{G_{1t+1}}\right]+z_{t+1}F_{nt+1}+\frac{U_{nt+1}}{U_{ct+1}}\right\}. \tag{56}$$

With a Cobb–Douglas matching function $G(v, 1-n)=Bv^{1-\eta}(1-n)^{\eta}$, we have that $G_{1t}=(1-\eta)\lambda_{ft}$ and $G_{2t}=\eta\theta_t\lambda_{ft}$ so that (56) becomes

$$z_tF_{nt}U_{ct}=\beta U_{ct+1}\lambda_{ft}\left\{z_{t+1}F_{nt+1}\left[1+\frac{1-\delta_n}{\lambda_{ft+1}}\right]-\eta[1+\theta_{t+1}]z_{t+1}F_{nt+1}+(1-\eta)\frac{U_{nt+1}}{U_{ct+1}}\right\}. \tag{57}$$

Clearly, these first-order conditions coincide if the Mortensen–Hosios condition is satisfied in that the worker's bargaining weight ϕ equals the elasticity of the matching function with respect to unemployment η. We can decentralize the solution to the planning problem as an equilibrium with a wage of

$$w_t^p=\eta[1+\theta_t]z_tF_{nt}+(1-\eta)\left(-\frac{U_{nt}}{U_{ct}}\right). \tag{58}$$

Notice that even in an efficient equilibrium, the wage typically equals neither the marginal product of labor z_tF_{nt} nor the marginal rate of substitution $-U_{nt}/U_{ct}$. Furthermore, the marginal rate of substitution is not equal to the marginal product of labor. These considerations suggest a different notion of a wedge relative to that used in the one-sector model. To that end, write the equilibrium wage as $w_t = (1-\tau_{lt})w_t^p$ where w_t^p is the planner's wage. Hence,

$$1-\tau_{lt} = \frac{\phi[1+\theta_t]z_t F_{nt} + (1-\phi)\left(-\frac{U_{nt}}{U_{ct}}\right)}{\eta[1+\theta_t]z_t F_{nt} + (1-\eta)\left(-\frac{U_{nt}}{U_{ct}}\right)}. \tag{59}$$

Clearly, if the Mortensen–Hosios condition is satisfied, the wedge $\tau_{lt} = 0$.

1.3.1.2 The Associated Prototype Economy with Efficiency and Labor Wedges

Consider the following prototype model. In this model, the bargaining power of the worker is equal to the elasticity η, but workers have to pay a tax τ_{lt} on their wages, investment is taxed at rate τ_{xt}, and the productivity is given by $\hat{A}_t$. Next we compare the aggregate outcomes of the prototype model and the equilibrium search model. From (47) and (49), we immediately have that the Euler equation is undistorted so that the investment wedge $\tau_{xt} = 0$. Using the production function $y_t = A_t F(k_t, n_t - v_t)$, it is immediate that $\hat{A}_t = A_t$. Thus, we have the following proposition.

Proposition 5 *The aggregate allocations in the equilibrium search economy coincide with those of the prototype economy if the efficiency wedge in the prototype economy is given by $\hat{A}_t = A_t$, the labor wedge $1 - \tau_{lt}$ is given by (59), and the investment wedge is zero.*

Note that if search is efficient, the labor wedge is zero in the two-sector prototype economy.

2. THE ACCOUNTING PROCEDURE

Having established our equivalence result, we now describe our accounting procedure at a conceptual level, discuss a Markovian implementation of it, and distinguish our procedure from others.

Our procedure is designed to answer questions of the following kind: How much would output fluctuate if the only wedge that fluctuated is the efficiency wedge and the probability distribution of the efficiency wedge is the same as in the prototype economy? Critically, our procedure ensures that agents' expectations of how the efficiency wedge will evolve are the same as in the prototype economy. For each experiment, we compare the properties of the resulting equilibria to those of the prototype economy. These comparisons, together with our equivalence results, allow us to identify promising classes of detailed economies.

2.1 The Accounting Procedure at a Conceptual Level

Recall that the state s^t is the history of the underlying abstract events s_t. Suppose for now that the stochastic process $\pi_t(s^t)$ and the realizations of the state s^t in some particular episode are known. Recall that the prototype economy has one underlying (vector valued) random variable, the state s^t, which has a probability of $\pi_t(s^t)$. All of the other stochastic variables, including the four wedges—the efficiency wedge $A_t(s^t)$, the labor wedge $1 - \tau_{lt}(s^t)$, the investment wedge $1/[1 + \tau_{xt}(s^t)]$, and the government consumption wedge $g_t(s^t)$—are simply functions of this random variable. Hence, when the state s^t is known, so are the wedges.

To evaluate the effects of just the efficiency wedge, for example, we consider an economy, referred to as an *efficiency wedge alone economy*, with the same underlying state s^t and probability $\pi_t(s^t)$ and the same function $A_t(s^t)$ for the efficiency wedge as in the prototype economy, but in which the other three wedges are set to be constant functions of the state, in that $\tau_{lt}(s^t) = \overline{\tau}_l, \tau_{xt}(s^t) = \overline{\tau}_x$, and $g_t(s^t) = \bar{g}$. Note that this construction ensures that the probability distribution of the efficiency wedge in this economy is identical to that in the prototype economy.

We compute the decision rules for the efficiency wedge alone economy, denoted $y^e(s^t)$, $l^e(s^t)$, and $x^e(s^t)$. For a given initial value k_0, for any given sequence s^t, we refer to the resulting values of output, labor, and investment as the *efficiency wedge components* of output, labor, and investment.

In a similar manner, we define the *labor wedge alone economy*, the *investment wedge alone economy*, and the *government consumption wedge alone economy*, as well as economies with a combination of wedges, such as the *efficiency and labor wedge economy*.

2.2 A Markovian Implementation

So far we have described our procedure assuming that we know the stochastic process $\pi_t(s^t)$ and that we can observe the state s^t. In practice, of course, we need to either specify the stochastic process a priori or use data to estimate it, and we need to uncover the state s^t from the data. Here, we describe a set of assumptions that makes these efforts easy. Then we describe in detail the three steps involved in implementing our procedure.

We assume that the state s^t follows a Markov process $\pi(s_t|s_{t-1})$ and that the wedges in period t can be used to uniquely uncover the event s_t, in the sense that the mapping from the event s_t to the wedges $(A_t, \tau_{lt}, \tau_{xt}, g_t)$ is one to one and onto. Given this assumption, without loss of generality, let the underlying event $s_t = (s_{At}, s_{lt}, s_{xt}, s_{gt})$, and let $A_t(s^t) = s_{At}$, $\tau_{lt}(s^t) = s_{lt}$, $\tau_{xt}(s^t) = s_{xt}$, and $g_t(s^t) = s_{gt}$. Note that we have effectively assumed that agents use only past wedges to forecast future wedges and that the wedges in period t are sufficient statistics for the event in period t. This assumption is only to make our estimation easier, and it can be relaxed.

In practice, to estimate the stochastic process for the state, we first specify a vector autoregressive AR(1) process for the event $s_t = (s_{At}, s_{lt}, s_{xt}, s_{gt})$ of the form

$$s_{t+1} = P_0 + Ps_t + \varepsilon_{t+1}, \tag{60}$$

where the shock ε_t is i.i.d. over time and is distributed normally with mean zero and covariance matrix V. To ensure that our estimate of V is positive semidefinite, we estimate the lower triangular matrix Q, where $V = QQ'$. The matrix Q has no structural interpretation. (Attempting to give Q such a structural interpretation is part of the source of some of the conceptual confusion about our approach. See Christiano and Davis (2006) for one such attempt.)

The first step in our procedure is to use data on y_t, l_t, x_t, and g_t from an actual economy to estimate the parameters of the Markov process $\pi(s_t|s_{t-1})$. We can do so using a variety of methods, including the maximum likelihood procedure described later.

The second step in our procedure is to uncover the event s_t by measuring the realized wedges. We measure the government consumption wedge directly from the data as the sum of government consumption and net exports. To obtain the values of the other three wedges, we use the data and the model's decision rules. With $y_t^d, l_t^d, x_t^d, g_t^d$, and k_0^d denoting the data and $y(s_t, k_t)$, $l(s_t, k_t)$, and $x(s_t, k_t)$ denoting the decision rules of the model, the realized wedge series s_t^d solves

$$y_t^d = y(s_t^d, k_t), \quad l_t^d = l(s_t^d, k_t), \text{ and } x_t^d = x(s_t^d, k_t), \tag{61}$$

with $k_{t+1} = (1-\delta)k_t + x_t^d$, $k_0 = k_0^d$, and $g_t = g_t^d$. Note that we construct a series for the capital stock using the capital accumulation law (1), data on investment x_t, and an initial choice of capital stock k_0. In effect, we solve for the three unknown elements of the vector s_t using the three Eqs. (3)–(5) and thereby uncover the state. We use the associated values for the wedges in our experiments.

Note that the four wedges account for all of the movement in output, labor, investment, and government consumption, in that if we feed the four wedges into the three decision rules in (61) and use $g_t(s_t^d) = s_{gt}$ along with the law of motion for capital, we simply recover the original data.

Note also that, in measuring the realized wedges, the estimated stochastic process plays a role only in measuring the investment wedge. To see that the stochastic process does not play a role in measuring the efficiency and labor wedges, note that these wedges can equivalently be directly calculated from (3) and (4) without computing the equilibrium of the model. In contrast, calculating the investment wedge requires computing the equilibrium of the model because the right side of (5) has expectations over future values of consumption, the capital stock, the wedges, and so on. The equilibrium of the model depends on these expectations and, therefore, on the stochastic process driving the wedges.

The third step in our procedure is to conduct experiments to isolate the marginal effects of the wedges. To do that, we allow a subset of the wedges to fluctuate as they do in the data while the others are set to constants. To evaluate the effects of the efficiency wedge, we compute the decision rules for the efficiency wedge alone economy, denoted $y^e(s_t, k_t)$, $l^e(s_t, k_t)$, and $x^e(s_t, k_t)$, in which $A_t(s^t) = s_{At}, \tau_{lt}(s^t) = \overline{\tau}_l, \tau_{xt}(s^t) = \overline{\tau}_x$, and $g_t(s^t) = \overline{g}$. Starting from k_0^d, we then use s_t^d, the decision rules, and the capital accumulation law to compute the realized sequence of output, labor, and investment, y_t^e, l_t^e, and x_t^e, which we call the *efficiency wedge components* of output, labor, and investment. We compare these components to output, labor, and investment in the data. Other components are computed and compared similarly.

Notice that in this experiment, we computed the decision rules for an economy in which only one wedge fluctuates and the others are set to be constants in all events. The fluctuations in the one wedge are driven by fluctuations in a four-dimensional state s_t.

By distinguishing the events to which the wedges are indexed from the wedges themselves, we can separate out the direct effect and the forecasting effect of fluctuations in wedges. As a wedge fluctuates, it directly affects either budget constraints or resource constraints. Whenever a wedge is not set to a constant, the fluctuations in the underlying state that lead to the fluctuations in the wedges also affect the forecasts of that wedge as well as those of other wedges in the future. Our experiments are designed so that when we hold a particular wedge constant, we eliminate the direct effect of that wedge, but we retain the forecasting effect of the underlying state on the future evolution of the wedge. By doing so, we ensure that expectations of the fluctuating wedges are identical to those in the prototype economy.

2.3 Distinguishing Our Procedure from Others

Since this way of separating the direct and forecasting effects of wedges is critical to our procedure, here we describe an alternative procedure that might, at first, seem like the intuitive way to proceed but does not answer the question that interests us.

Consider a simple example with just two wedges, an efficiency wedge and a labor wedge, denoted $W_t = (A_t, \tau_{lt})'$. Suppose that we used our prototype model to estimate the following vector process for them of the form $W_{t+1} = PW_t + \varepsilon_{t+1}$ where $E\varepsilon_t\varepsilon_t' = V$:

$$\begin{bmatrix} A_{t+1} \\ \tau_{lt+1} \end{bmatrix} = \begin{bmatrix} P_{AA} & P_{Al} \\ P_{lA} & P_{ll} \end{bmatrix} \begin{bmatrix} A_t \\ \tau_{lt} \end{bmatrix} + \begin{bmatrix} \varepsilon_{At+1} \\ \varepsilon_{lt+1} \end{bmatrix}, \tag{62}$$

where we have suppressed the constant terms. Suppose also that we have decision rules of the form

$$y_t = y(W_t, k_t), \quad l_t = l(W_t, k_t), \text{ and } x_t = x(W_t, k_t) \tag{63}$$

and that we have recovered the realized wedge series W_t^d along with the realized innovation series ε_{t+1}^d.

Now suppose want to answer the question: How much would output fluctuate under the following three conditions? First, only the efficiency wedge fluctuates. Second, for the event, the realized sequence of the efficiency wedges coincides with that in the data. Third, the probability distribution of the efficiency wedge is the same as in the prototype economy.

A first attempt to answer this question is to simply feed a realized innovation series $\hat{\varepsilon}_{t+1} = (\varepsilon^d_{At+1}, 0)$ for the event and to simulate the resulting shocks using

$$\begin{bmatrix} \hat{A}_{t+1} \\ \hat{\tau}_{lt+1} \end{bmatrix} = \begin{bmatrix} P_{AA} & P_{Al} \\ P_{lA} & P_{ll} \end{bmatrix} \begin{bmatrix} \hat{A}_t \\ \hat{\tau}_{lt} \end{bmatrix} + \begin{bmatrix} \varepsilon^d_{At+1} \\ 0 \end{bmatrix}. \tag{64}$$

This attempt meets our first condition but does not meet our second condition if P or V has nonzero off-diagonal elements, as we show they do in the data. Indeed, with nonzero off-diagonal elements, this procedure will not even produce a simulated $\hat{A}_t$ series that agrees with A^d_t. Moreover, this attempt clearly does not meet our third condition.

For a second attempt, suppose we choose the sequence of innovations so that the first two conditions are met. That is, we choose the sequence $\{\hat{\varepsilon}_{t+1}\}$ so that, in the event, the realized value of the efficiency wedge coincides with that in the data and the labor wedge is constant at, say, its mean value $\overline{\tau}_l$. Specifically, we choose $\{\hat{\varepsilon}_{t+1}\}$ so that $(\hat{A}_t, \hat{\tau}_{lt}) = (A^d_t, \overline{\tau}_l)$ in the event. The problem with this procedure is that agents' forecasts about future efficiency wedges are different under this procedure from what they are in the prototype economy. Hence, this procedure meets our first two conditions but not our third. To see why, note that the expected value of A_{t+1} in this procedure is given from

$$E_t \begin{bmatrix} A_{t+1} \\ \tau_{lt+1} \end{bmatrix} = \begin{bmatrix} P_{AA} & P_{Al} \\ P_{lA} & P_{ll} \end{bmatrix} \begin{bmatrix} A^d_t \\ \overline{\tau}_l \end{bmatrix}$$

so that

$$E_t A_{t+1} = P_{AA} A^d_t + P_{Al} \overline{\tau}_l \text{ and } E_t \tau_{lt+1} = P_{lA} A^d_t + P_{ll} \overline{\tau}_l. \tag{65}$$

The expectation of the underlying state s_{t+1} in the prototype economy, however, is calculated from

$$E_t \begin{bmatrix} s_{At+1} \\ s_{lt+1} \end{bmatrix} = \begin{bmatrix} P_{AA} & P_{Al} \\ P_{lA} & P_{ll} \end{bmatrix} \begin{bmatrix} s^d_{At} \\ s^d_{lt} \end{bmatrix} \tag{66}$$

to be

$$E_t s_{At+1} = P_{AA} s^d_{At} + P_{Al} s^d_{lt} \text{ and } E_t s_{lt+1} = P_{lA} s^d_{At} + P_{ll} s^d_{lt}. \tag{67}$$

Since we have identified s_{At+1} with A_{t+1} and s_{lt+1} with τ_{lt+1}, then (67) gives the expectations of the efficiency wedge and the labor wedge in the prototype economy during the event. Clearly, (65) and (67) do not agree when P_{Al} is not zero, so the procedure does not meet our third condition. Note that in some preliminary notes for Chari et al. (2006), while we were aware of the flaws in the second attempt, we followed a version of this second attempt as a quick approximation to get an initial set of answers. Christiano and

Davis (2006), unfortunately did not realize that even in our NBER working paper version we followed the correct procedure. We view their paper as a valuable exposition of why the second attempt is incorrect and of the flaws that arise when one follows it.

Next we show that our procedure meets our three conditions. In the efficiency wedge alone economy, the first two conditions are clearly met: only the efficiency wedge fluctuates, and in the event the realized efficiency wedge coincides with the measured efficiency wedge in the data. To see that the third, and more subtle, condition is met, note from (60) the probability distribution over s_{t+1}, and therefore A_{t+1} is the same in both the prototype economy and the efficiency wedge alone economy.

3. APPLYING THE ACCOUNTING PROCEDURE

Now we demonstrate how to apply our accounting procedure to the Great Recession and postwar data for the United States and a group of other OECD countries. (In Appendix, we describe in detail our data sources, parameter choices, computational methods, and estimation procedures.)

3.1 Details of the Application

To apply our accounting procedure, we use functional forms and parameter values that are familiar from the business cycle literature. We assume that the production function has the form $F(k, l) = k^{\alpha}l^{1-\alpha}$ and the utility function the form $U(c,l) = \log c + \psi \log(1-l)$. We choose the capital share α to be one-third and the time allocation parameter $\psi = 2.5$. We choose the depreciation rate δ, the discount factor β, and growth rates γ and γ_n so that, on an annualized basis, depreciation is 5%, the rate of time preference 2.5%, and the population growth rate and the growth of technology are country-specific and computed using OECD data. The adjustment cost parameter $b = \delta + \gamma + \gamma_n$ is pinned down by the previous parameters and varies across countries. For the adjustment cost parameter a, we follow Bernanke et al. (1999) in choosing this parameter so that the elasticity, η, of the price of capital with respect to the investment–capital ratio is 0.25. In this setup, the price of capital $q = 1/(1-\phi')$, so that, evaluated at the steady state, $\eta = ab$. Given η and b, we then set a accordingly.

Our prototype economy is a closed economy. When confronting the data, we let government consumption in the model correspond to the sum of government consumption and net exports in the data. The rationale for this choice is given in Chari et al. (2005), where we prove an equivalence result between an open economy model and a closed economy model in which government consumption is treated in this fashion. We then use a standard maximum likelihood procedure to estimate the parameters P_0, P, and V of the vector AR(1) process for the wedges. In doing so, we use the log-linear decision rules of the prototype economy and data on output, labor, investment, and the sum of government consumption and net exports.

In confronting the theory with the data, we need to decide how to treat consumer durables and sales taxes. At a conceptual level, we think of current expenditures on consumer durables as augmenting the stock of consumer durables, which in turn provides a service flow of consumption to consumers. Based on this idea, we reallocate current expenditures of consumer durables from consumption to investment. We then add the imputed service flow from the stock of consumer durables to consumption and output. This imputed service flow is the rental rate on capital times the stock of durables. We assume that the stock of consumer durables depreciates at the same rate as the stock of physical capital. We also adjust the data to account for sales taxes. We assume that sales taxes are levied solely on consumption. This assumption leads us to subtract sales tax revenues from both consumption and measured output.

At a practical level, it turns out that while the U.S. NIPA accounts have quarterly data on consumer durable expenditures for the 1980:1–2014:4 sample we use, the OECD has more limited data. For some of the countries in our sample, data are only available annually or are missing. For countries for which we only have annual data, we fill in quarterly estimates using maximum likelihood estimates of a state space model. For countries for which we only have quarterly data for a subsample, we regress consumer durables on investment and output and use the coefficients to construct estimates of the missing data. Once we have the quarterly series on consumer durables, we construct estimates of the capital stock using the perpetual inventory method. The service flow of durables is assumed to be 4% of the stock of durables. (For details, see the Appendix.)

We express all variables in per capita form and deflate by the GDP deflator. We then estimate separate sets of parameters for the stochastic process for wedges (60) for each of the OECD countries after removing country-specific trends in output, investment, and government consumption. The other parameters are the same across countries. The stochastic process parameters for the Great Recession are estimated using quarterly data for 1980:1–2014:4. The stochastic process (60) with these values is used by agents in our economy to form their expectations about future wedges. In Appendix, we give the details of the estimated values of the stochastic processes for each of the countries.

3.2 Findings

Now we describe the results of applying our procedure to OECD countries for the Great Recession and the 1982 Recession. Here, we focus primarily on the fluctuations due to the efficiency, labor, and investment wedges.[a]

3.2.1 The Great Recession

Here, we discuss our findings for the 24 OECD countries. The main finding is that in terms of accounting for the downturn, in the United States the labor wedge is by far the

[a] We alert the reader that the quantitative results for Spain should be treated with caution. In some robustness analysis for Spain, we found that the nonlinear labor wedge computed directly from the consumer's first-order condition (4) and found that the nonlinear labor wedge moved substantially more than the labor wedge computed using our log-linearization procedure.

most important, in Spain, Ireland, and Iceland the investment wedge is the most important, and in the rest of the countries, the efficiency wedge is the most important.

3.2.1.1 Three Illustrative Recessions

Here, we illustrate our findings for one country for which the efficiency wedge, labor wedge, and investment wedge, respectively, is the most important. In reporting our findings, we remove a country-specific trend from output, investment, and the government consumption wedge. Both output and labor are normalized to equal 100 in the base period 2008:1. Here, we focus primarily on the fluctuations due to the efficiency, labor, and investment wedges. We discuss the government consumption wedge and its components in Appendix.

3.2.1.1.1 France: Primarily an Efficiency Wedge Recession We begin with France. In Fig. 1A, we see that from 2008:1 to 2009:3, output fell about 7% while labor fell about 3% and investment fell about 18%. In Fig. 1B, we see that the efficiency wedge worsened by about 5%, the labor wedge worsened by about 1%, and the investment wedge worsened by about 5%. In Fig. 1C, we see that the efficiency wedge accounts for the bulk of the decline in output, namely about 6% of the 7% decline. Fig. 1D–E show that the efficiency and investment wedges play the most important roles in accounting for the declines in labor and investment.

Overall, these results imply that the Great Recession in France should be thought of as primarily an efficiency wedge recession with some role for the labor and investment wedges in accounting for the decline in hours and investment. This finding implies that models that emphasize fluctuations in the labor wedge in France are less promising than those that emphasize fluctuations in the efficiency and investment wedges.

3.2.1.1.2 United States: Primarily a Labor Wedge Recession Next consider the United States. In Fig. 2A, we see that output and labor both fell about 7% from 2008:1 to 2009:3 while investment fell about 23%. In Fig. 2B, we see that the efficiency wedge fell very modestly by only about 1%, while the labor wedge and the investment wedge both worsened dramatically, by about 8% and 9%, respectively. In Fig. 2C–E, we see that the labor and investment wedges play the most important role in accounting for the downturn in output and labor, while the investment wedge accounts for the bulk of the downturn in investment.

Overall, considering the period from 2008 until the end of 2011, these results imply that the Great Recession in the United States should be thought of as primarily a labor wedge recession, with an important secondary role for the investment wedge. This finding implies that the most promising models must yield significant fluctuations in the labor wedge, with some role for the investment wedge. Models that emphasize the efficiency wedge are less promising.[b]

[b] In the Appendix, we show that if we estimated the stochastic process for the wedges from 1948 to 2015, the contribution of the labor wedge rises and that of the investment wedge falls. A similar change occurs if we decrease the investment adjustment cost parameter.

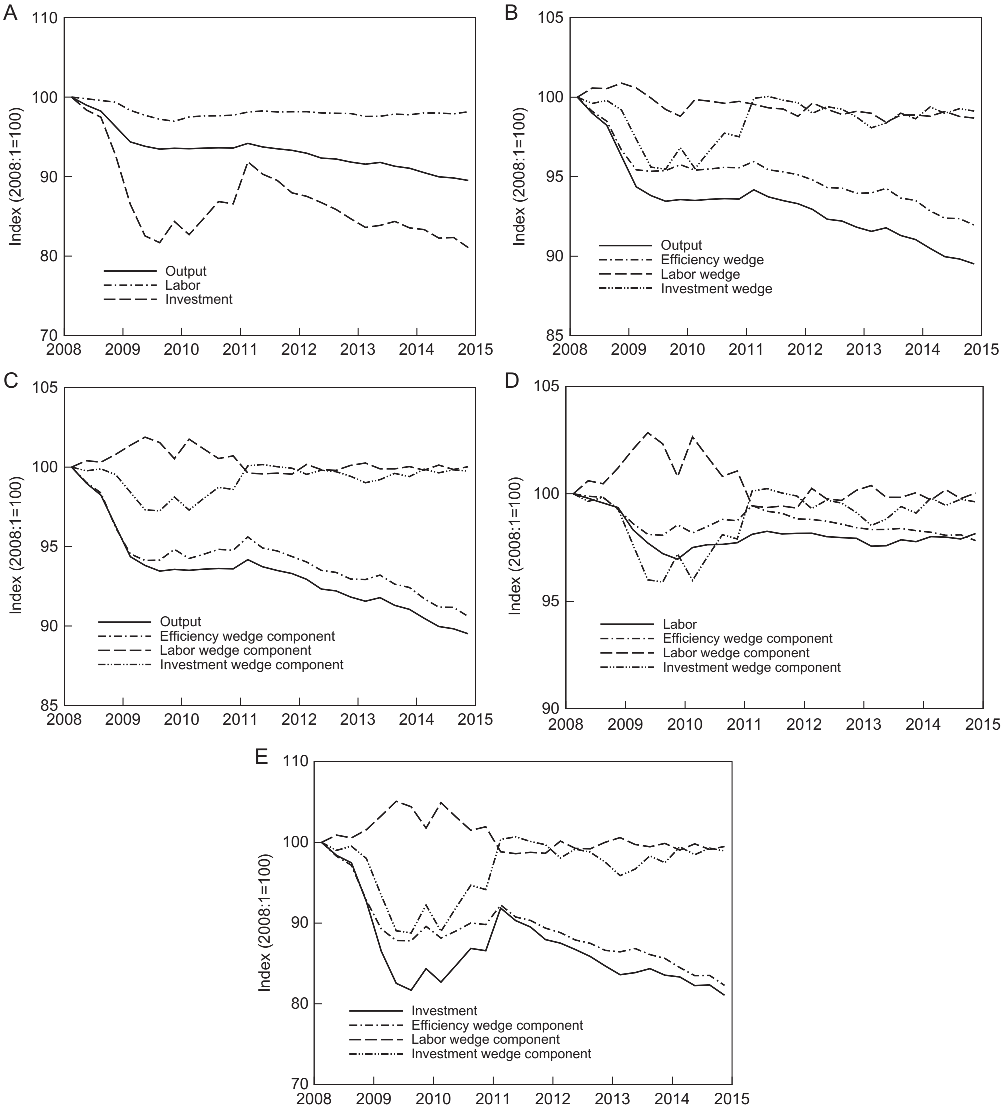

Fig. 1 (A) Output, labor, and investment for France, 2008:1–2014:4. (B) Output and three wedges for France, 2008:1–2014:4. (C) Output and output components for France, 2008:1–2014:4. (D) Labor and labor components for France, 2008:1–2014:4. (E) Investment and investment components for France, 2008:1–2014:4.

3.2.1.1.3 Ireland: Primarily an Investment Wedge Recession Finally consider Ireland. In Fig. 3A, we see that from 2008:1 to 2009:3, output fell about 13%, labor about 11%, and investment almost 50%. Fig. 3B shows that during this period, the efficiency wedge fell about 5%, the labor wedge worsened by about 10%, and the investment wedge worsened dramatically, that is, by about 20%.

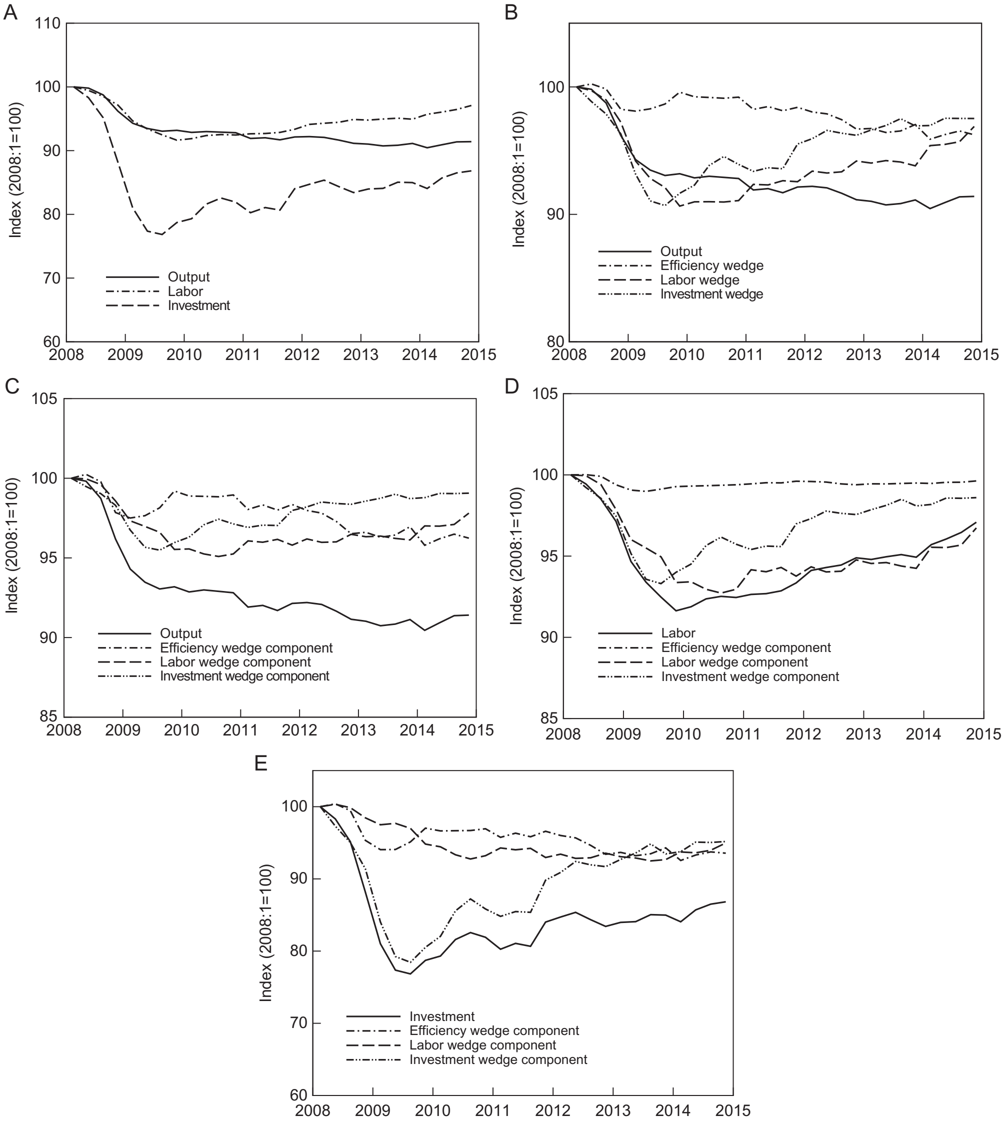

Fig. 2 (A) Output, labor, and investment for the United States, 2008:1–2014:4. (B) Output and three wedges for the United States, 2008:1–2014:4. (C) Output and output components for the United States, 2008:1–2014:4. (D) Labor and labor components for the United States, 2008:1–2014:4. (E) Investment and investment components for the United States, 2008:1–2014:4.

In Fig. 3C–E, we see that the investment wedge plays the largest role: it accounts for about half of the fall in output, about four-fifths of the fall in investment, and all of the fall in hours. Overall, these results imply that the Great Recession in Ireland should be thought of as primarily an investment wedge recession.

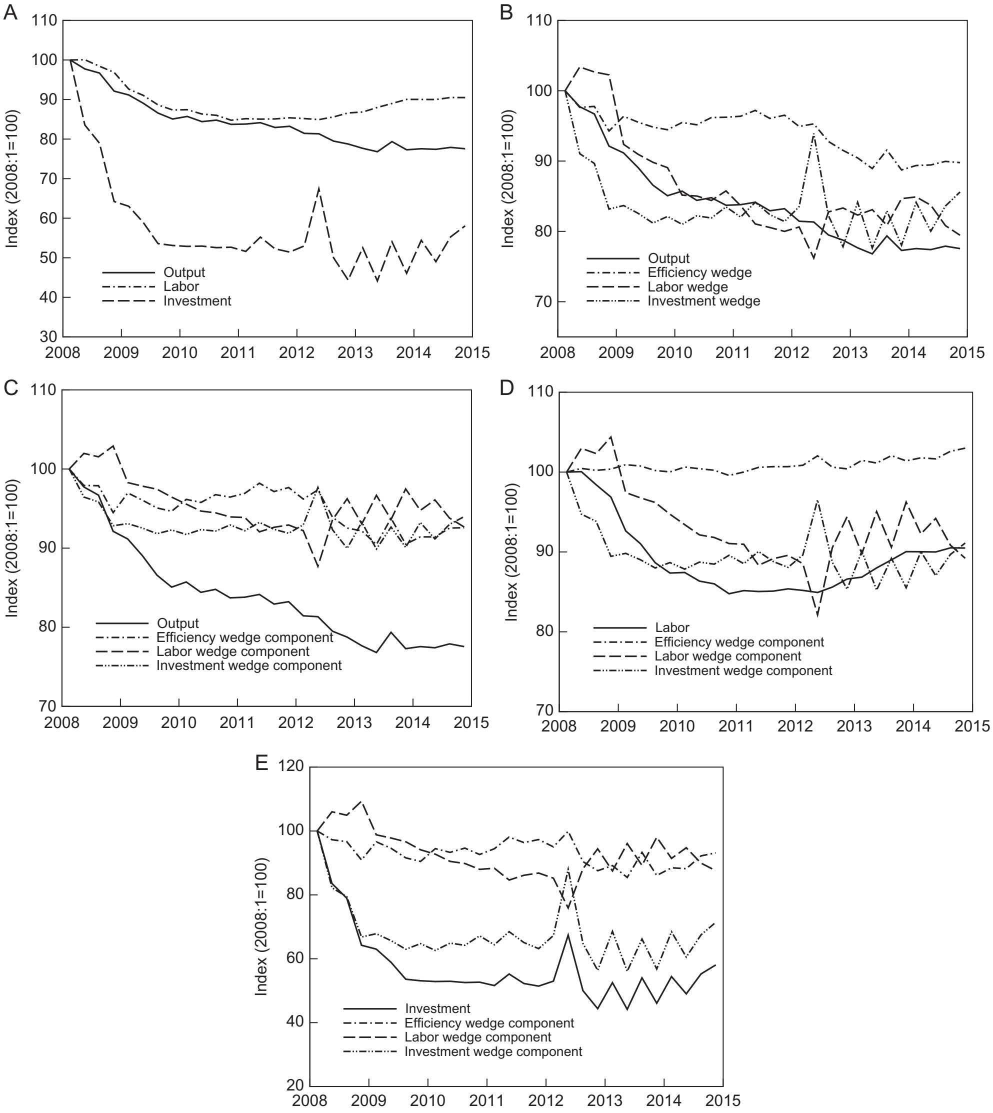

Fig. 3 (A) Output, labor, and investment for Ireland, 2008:1–2014:4. (B) Output and three wedges for Ireland, 2008:1–2014:4. (C) Output and output components for Ireland, 2008:1–2014:4. (D) Labor and labor components for Ireland, 2008:1–2014:4. (E) Investment and investment components for Ireland, 2008:1–2014:4.

3.2.1.2 Summary Statistics for Our OECD Countries

So far we have described the Great Recession in three countries. Here, we describe useful summary statistics over the period 2008:1–2011:3. One such statistic, referred to as the ϕ*statistic*, is intended to capture how closely a particular component, say, the output component due to the efficiency wedge, tracks the underlying variable, say, output. For our decomposition of output, we let

$$\phi_i^Y = \frac{1/\sum_t (y_t - y_{it})^2}{\sum_j \sum_t \left(1/(y_t - y_{jt})^2\right)},$$

where y_{it} is the output component due to wedge $i = (A, \tau_l, \tau_x, g)$. We compute similar statistics for labor and investment. The ϕ statistic has the desirable feature that it lies in [0, 1], sums to one across the four wedges, and when a particular output component tracks output perfectly, in that if $(y_t - y_{it}) = 0$ for all t, then $\phi_i^Y = 1$, that is, the ϕ statistic for the wedge reaches its maximum value of 1. Note that this statistic is the inverse of the mean-square error for each wedge appropriately scaled so that the sum across wedges adds to one.

Now consider our main finding. In Fig. 4A, we display the ϕ statistic for the efficiency wedge and labor wedge components of output. The downward-sloping lines represent

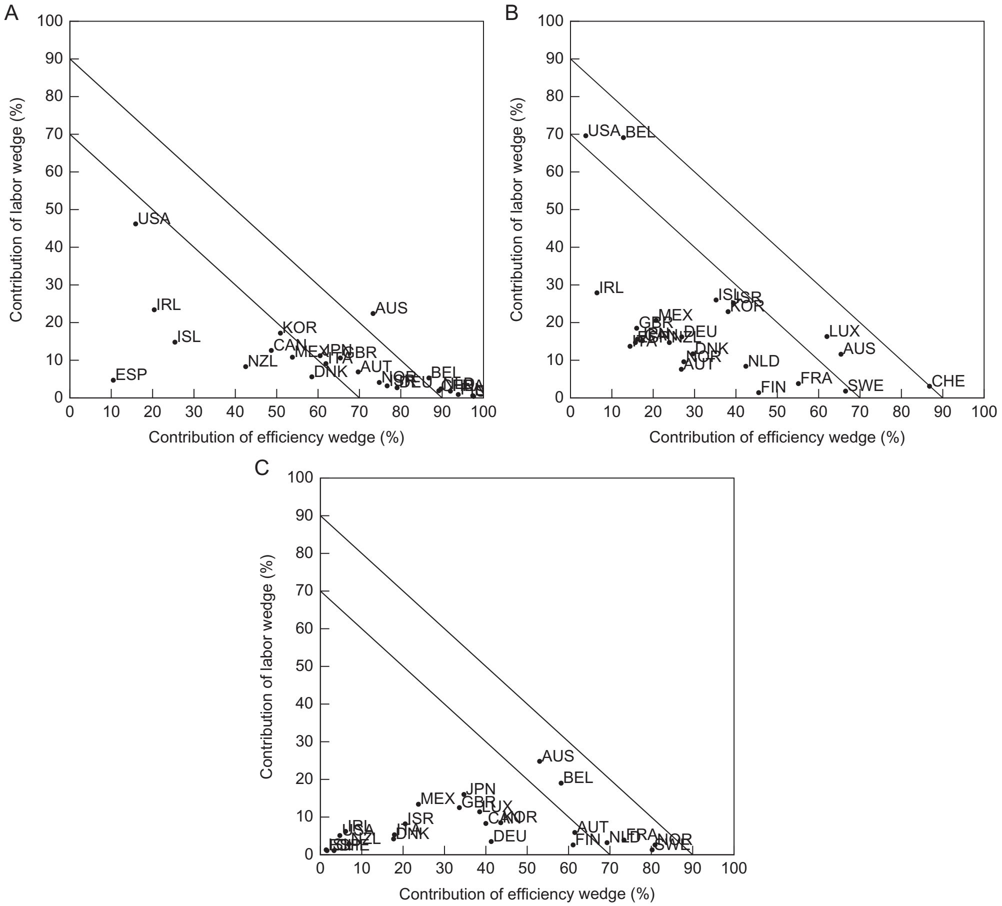

Fig. 4 (A) Decomposition of output, 2008:1–2011:3. (B) Decomposition of labor, 2008:1–2011:3. (C) Decomposition of investment, 2008:1–2011:3.

combinations for which the sum of the labor wedge and efficiency wedge components is constant at 70% and 90%, respectively. This figure shows that the United States stands out from the other countries in that the labor wedge accounts for a much greater fraction of the movements in output than it does in any other country. Specifically, the labor wedge accounts for about 46% of the movements in output in the United States but no more than 22% in any other country. In all other countries except Iceland, Ireland, New Zealand, and Spain, the efficiency wedge accounts for roughly 50% or more of the movements in output. In Table 1, we report the decompositions of output, labor, and investment for all countries. There we see that for Iceland, Ireland, New Zealand, and Spain, the investment wedge accounts for 51%, 48%, 42%, and 82% of the movements in output, respectively. In the other panels of Fig. 4, we display the ϕ statistics for the components of labor and investment.

Our main finding is also apparent if we use other ways to measure how important a given wedge is for the movements in output, labor and investment. When we discussed

Note: The date of the peak is 2008:1 for all countries.

the three illustrative recessions earlier, we compared simple peak-to-trough measures of output, labor, and investment to the corresponding measures for each of the components. In Tables 2A, 2B, and 2C, we report such measures for all of our countries. A quick perusal of these measures shows that they give the same message as the ϕ statistics do. Consider, for example, France. The ϕ statistic indicates that the efficiency wedge accounts for the bulk of the movements in output, namely about 92% of its decline. The peak-to-trough measure indicates that the efficiency wedge also accounts for the bulk of the peak-to-trough decline, namely about 5.9% of the 6.5% decline or about 91% of the decline.

3.2.2 Comparing the Great Recession with Recessions of the Early 1980s

The postwar era had essentially two periods during which most developed economies experienced recessions at roughly the same time: the early 1980s and the Great Recession

Table 2B Peak to trough declines in labor and components, Great Recession

Note: The date of the peak is 2008:1 for all countries.

of 2008. Here, we compare the recessions of the early 1980s with the Great Recession. For the United States, we use the NBER business cycle dates; for the OECD countries, we use the business cycle dates as estimated by ECRI when available and otherwise use the CEPR Euro Area Business Cycle Dates. We use the stochastic process for wedges estimated over the 1980–2014 period for both episodes. (See the Appendix for details.)

In Fig. 5A, we compare the ϕ statistics for the efficiency wedge component of output for the two recessions. This panel shows that for most of the countries, the efficiency wedge in the Great Recession played a more important role than it did during the recessions of the 1980s. In Fig. 5B, we compare the ϕ statistics for the labor wedge component of output for the two recessions. This panel shows that in the Great Recession, the labor wedge accounts for over 40% of the fluctuations in output only in the United States, while in the 1982 recession, it does so only in Belgium, the United Kingdom, and France.

Average		−23.3	−12.4	1.6	−13.2

Note: The date of the peak is 2008:1 for all countries.

In Fig. 5C, we compare the ϕ statistics for the investment wedge component of output for the two recessions. This panel shows that in most of the countries, the investment wedge played a larger role in the recessions of the 1980s than it did during the Great Recession.

In Table 3, we report the ϕ statistics for the 1982 recessions. This table shows that the efficiency wedge played the most important role for ten countries, the labor wedge for three countries, and the investment wedge for seven countries. Together with Table 1, this table broadly reinforces our two main findings for the comparison. First, the labor wedge played an important role for output in the Great Recession only for the United States, and in the 1982 recession it played a dominant role only in Belgium, France, and the United Kingdom. Second, for most countries, in the Great Recession the efficiency wedge played a more important role and the investment wedge played a less important role than they did in the recessions of the 1980s.

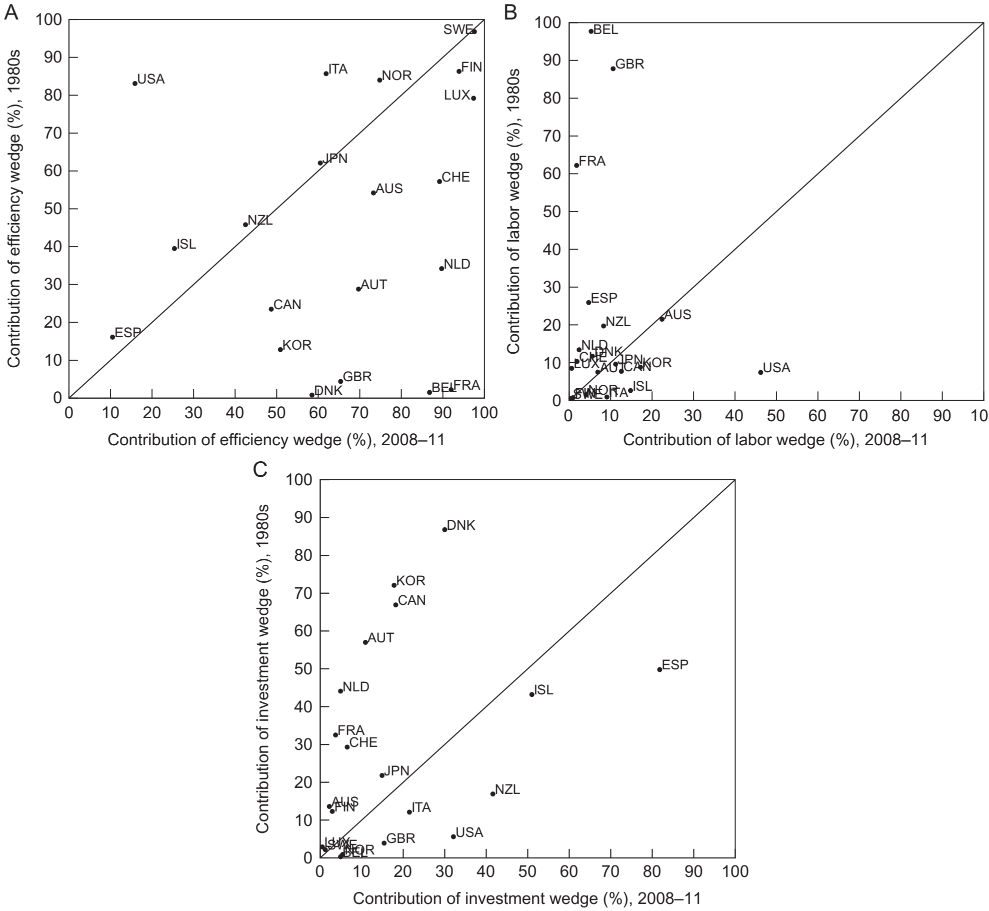

Fig. 5 (A) Efficiency component of output for two recessions. (B) Labor component of output for two recessions. (C) Investment component of output for two recessions.

In Tables 4A–4C, we report peak-trough results for the 1982 recession. Comparing Table 3 with the Tables 4A–4C, we see that the peak-trough results present the same overall picture as our ϕ statistics do. If we compare the classification of the most important wedge for each country using ϕ statistics for output to that using the peak-trough decline for output, we see that they agree in all but three cases.

3.2.3 Summary Statistics for the Entire Period

In Tables 5A–5C, we present some summary statistics for the entire period 1980:1–2014:3 about the importance of the various wedges in accounting for the movements in output, labor, and investment. In Table 5A, for example, we report the standard deviation of the output component due to each wedge relative to the standard deviation

of output during entire period, along with the correlation of each such output component with output. In Tables 5B and 5C, we report similar statistics for labor and its components and for investment and its components.

Using these statistics to infer the importance of various wedges is more subtle than using the ϕ statistics. The ϕ statistic captures in one statistic how much the component due to a wedge moves, as well as how closely this component tracks the underlying variable. Instead, to evaluate the importance of a wedge using the statistics in this table, we need to jointly consider the relative standard deviations and the correlations.

Consider, for example, France. Viewing the relative standard deviations alone suggests that the labor and investment wedges play roughly the same role in accounting for the movement in output. Indeed, the relative standard deviations of the labor and investment components of output are 93% and 92%, respectively. But the correlations of these variables with output suggest that the investment wedge plays a much more important role. Indeed, the labor component of output comoves negatively with output, whereas the investment component of output comoves positively with output.

With this perspective in mind, the averages across countries show that the efficiency wedge plays the most important role in accounting for output. The standard deviation of

Average			−20.4	−7.4	−2.7	−11.8

the efficiency component of output is 92% of output, and its correlation with output is 0.77. Even though the labor component of output is 89% as variable as output itself, it is essentially uncorrelated with output. In this sense, the labor wedge does not account for much of the movements in output.

3.2.4 The Importance of the Classification of Consumer Durables

Macroeconomists have long argued that theory implies it is appropriate to treat the expenditures on consumer durables as a form of investment that yields a flow of consumption services. This treatment requires adjustments to the national income account classification of consumption and investment to make them consistent with the theory.

Here, we show that while this adjustment is quantitatively important for some countries, for most countries it does not change the overall findings. In Fig. 6A, we contrast the ϕ statistic for the efficiency wedge component of output when this consistent adjustment is made and when it is not. Clearly, the countries with statistics most affected by this adjustment are Iceland and Spain. In Iceland, for example, the contribution of the efficiency wedge falls from 26% when durables are correctly accounted for to 12% when

they are not. In Spain, the contribution of the efficiency wedge increases from 11% when durables are correctly accounted for to 29% when they are not.

In Fig. 6B and C, we contrast the analogous ϕ statistics for the labor wedge component of output and for the investment wedge component of output. In panel C, we see that in Iceland and Spain, the contribution of the investment wedge to output is 51% and 82% when durables are correctly accounted for and 65% and 35% when they are not.

3.2.5 Comparing Our Procedure with a Perfect Foresight Procedure

Some authors implement a perfect foresight version of our procedure in which agents have perfect foresight about the future evolution of the wedges. The equilibrium conditions for the deterministic version of our prototype model are

Average	0.35	1.55	1.58	0.04	0.43	0.39

Notes: The entire sample is 1980:1–2014:4. Series are first logged and detrended with the filter of Hodrick and Prescott (1997).

$$c_t + x_t + g_t = y_t, \tag{68}$$

$$y_t = A_t F\left(k_t, (1+\gamma)^t l_t\right), \tag{69}$$

$$-\frac{U_{lt}}{U_{ct}} = [1-\tau_{lt}]A_t(1+\gamma)^t F_{lt}, \text{ and} \tag{70}$$

$$U_{ct}[1+\tau_{xt}] = \beta U_{ct+1}\{A_{t+1}F_{kt+1} + (1-\delta)[1+\tau_{xt+1}]\}. \tag{71}$$

Clearly, the efficiency wedge, the labor wedge, and the government consumption wedge can be recovered from the static relationships in (68), (69), and (70). Recovering the investment wedge, however, requires solving the difference equation implied by the Euler equation (71). To do so, we need to impose either an initial condition or a terminal condition. In practice, we imposed an initial condition that the investment wedge begins at zero.

Notes: The entire sample is 1980:1–2014:4. Series are first logged and detrended with the filter of Hodrick and Prescott (1997).

In Fig. 7A–C, we plot the ϕ statistics for the perfect foresight procedure against the same statistics for our procedure. These panels show that for a significant number of the countries, the ϕ statistics are very different. In particular, the perfect foresight procedure greatly exaggerates the importance of the labor wedge for the United States and Spain. Under perfect foresight, the labor wedge accounts for 92% and 72% of the movements in output for the United States and Spain, while under the standard business cycle accounting procedure, the labor wedge accounts for only 46% and 5%, respectively.

We highlight two important sources for these differences. One is that in the perfect foresight procedure, private agents anticipate the evolution of future wedges perfectly and thus react in the current period to actual future worsening or improvement of the wedges. In this sense, the perfect foresight procedure brings with it all the undesirable properties of the simple "news" models by which an anticipated worsening of, say, the

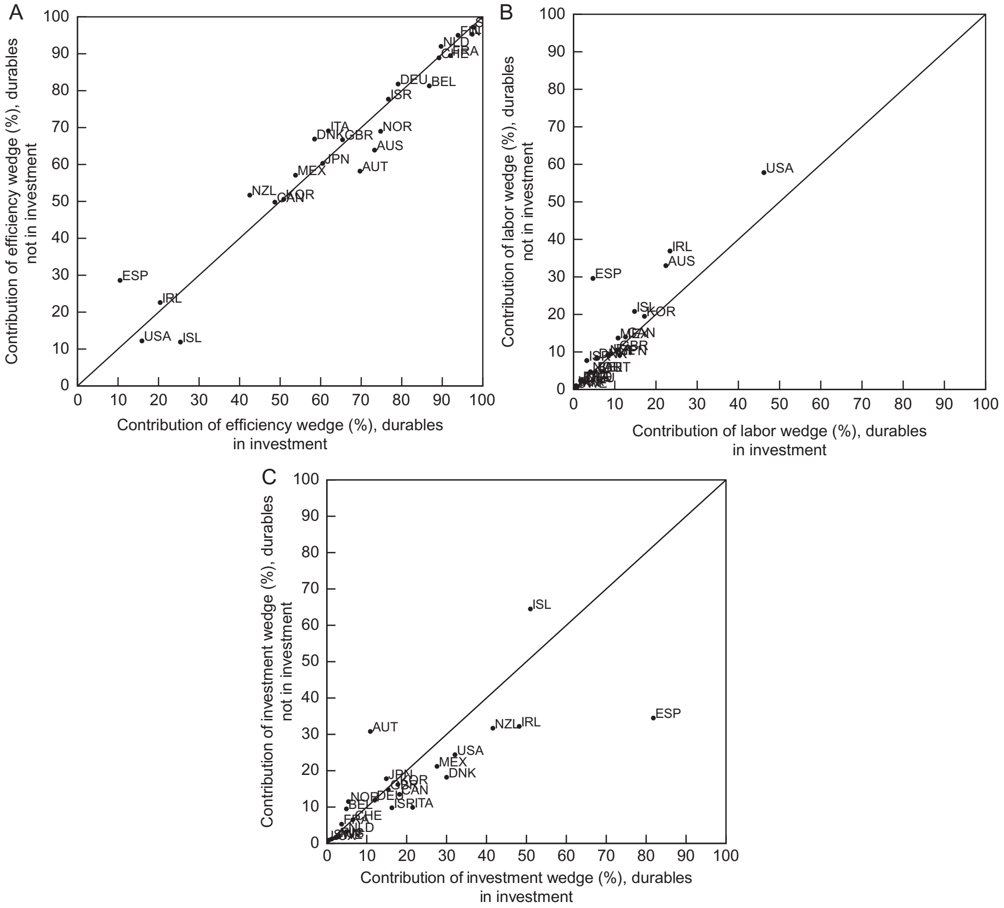

Fig. 6 (A) Efficiency component of output for two investment measures. (B) Labor component of output for two investment measures. (C) Investment component of output for two investment measures.

labor wedge leads to a current boom as households choose to increase labor supply before times worsen. The other is that, as we noted earlier, the perfect foresight procedure uses the nonlinear version of the first-order conditions (68)–(71) to compute the wedges while our procedure uses log-linearized versions of these conditions.

4. CONCLUSION

We have elaborated on the business cycle accounting method proposed by CKM, cleared up some misconceptions about the method, and applied it to compare the Great Recession across OECD countries as well as to the recessions of the 1980s in these countries.

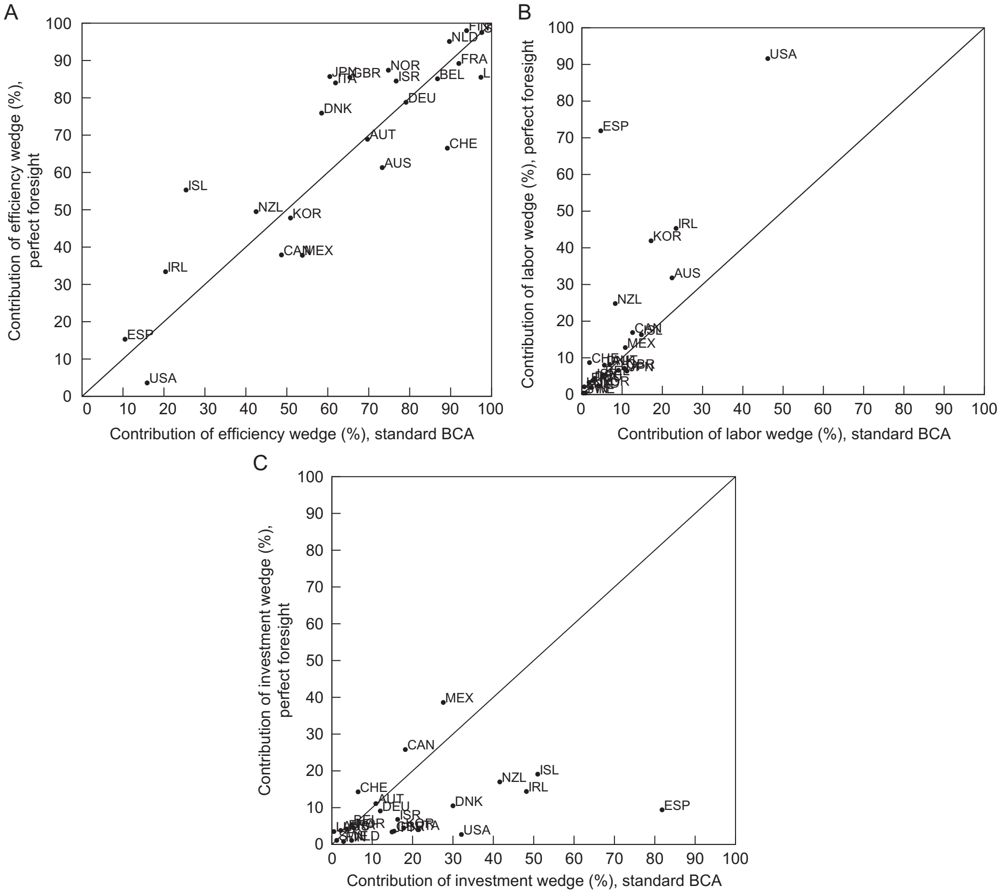

Fig. 7 (A) Efficiency component of output for two expectational assumptions. (B) Labor component of output for two expectational assumptions. (C) Investment component of output for two expectational assumptions.

We documented four findings. First, with the notable exception of the United States, Spain, Ireland, and Iceland, the Great Recession was driven primarily by the efficiency wedge. Second, in the Great Recession, the labor wedge plays a dominant role only in the United States, and the investment wedge plays a dominant role in Spain, Ireland, and Iceland. Third, in the recessions of the 1980s, the labor wedge played a dominant role only in France, the United Kingdom, and Belgium. Finally, overall in the Great Recession, the efficiency wedge played a much more important role and the investment wedge played a much less important role than they did in the recessions of the 1980s.

APPENDIX

A.1 Data and Sources

The data used for the business cycle accounting exercises throughout the chapter come mainly from OECD (variable codes in parenthesis). The time span is from 1980 to the end of 2014 and, unless mentioned otherwise, at the quarterly frequency. For some countries (such as Germany, Ireland, Israel, and Mexico), data for most series were only available starting later than 1980Q1 and thus the business cycle accounting exercises were performed for shorter samples.

- Economic Outlook 98
  - Gross domestic product, value, market prices (GDP)
  - GDP deflator, market prices (PGDP)
  - Gross capital formation, current prices (ITISK)
  - Government final consumption expenditures, value, expenditure approach (CG)
  - Exports of goods and services, value, national accounts basis (XGS)
  - Imports of goods and services, value, national accounts basis (MGS)
  - Hours worked per employee, total economy (HRS)
  - Total employment (ET)
- System of Quarterly National Accounts
  - Durable goods (subcategory of CQRsa: private final consumption expenditure by durability, national currency, current prices)
- Tax on goods and services
  - Taxes on goods and services as a share of GDP, annual (TAXGOODSERV, PCGDP)
- Population and Labor Force
  - Population 15–64, persons, annual

All data are deflated by the GDP deflator. Data on durables are available for different time spans and frequency. When data were available at a quarterly frequency, the series of durables were computed by regressing durables on a constant, gross capital formation (ITISK) and gross domestic product (GDP) in logs, for the available time span, and then using the coefficient estimates to compute the series for durables from the beginning of sample. When data on durables were only available at the annual frequency, quarterly observations were estimated using maximum likelihood estimates of a state space model and, as before, series on gross capital formation and gross domestic product. Once we get durables at the quarterly frequency, we extend the series to the beginning of sample by the method described above. Population data are available at annual frequency and thus is interpolated to quarterly frequency using cubic splines. All other transformations are standard and described in detail below:

- per capita output (y): real GDP $-$ sales taxes $+$ services from consumer durables (with annualized return at 4% $+$ depreciation of durables at an annualized rate of 25%) deflated by the GDP deflator and divided by population 16–64.
- per capita hours (h): hours worked*total employment, divided by population 16–64.

- per capita investment (x): gross capital formation + personal consumption expenditures on durables net of sales taxes, all deflated by the GDP deflator and divided by population 16–64.
- per capital government consumption (g): government final consumption expenditures + Exports of goods and services − Imports of goods and services, all deflated by the GDP deflator and divided by population 16–64.

A.2 Parametrization and Calibration

Table A.1 Parameters held fix across countries

β	δ	ψ	σ	θ
0.975	0.05	2.5	1	0.33

where β is the (annualized) and δ the (annualized) depreciation rate of capital.

Other parameters are specific to each country and shown in the Table A.2 below, where γ_n is the average growth rate of population, γ the growth rate of labor augmenting technology and a the adjustment costs coefficient. To compute γ, we set it so that detrended log output is mean zero over the sample period.

Table A.2 Parameters that are specific to each country

Note also that there are other parameters which are country specific, namely the elements of the P_0, P and Q matrices that result from the maximum likelihood estimation procedure that models expectations. These estimates are available at http://pedrobrinca.pt/2016-accounting-for-business-cycles/

A.3 Replication Instructions

Replication files are available at http://pedrobrinca.pt/2016-accounting-for-business-cycles/. We also make available an extensive Appendix that includes all the tables and figures in the chapter and country reports which include additional tables and figures regarding each of the business cycle accounting exercises performed, for both the Great Recession period and the recessions in the 1980s. The Appendix also includes the elements of the P_0, P, and Q matrices that result from the maximum likelihood estimation procedure that models expectations for each country.

CHAPTER 14

Incomplete Information in Macroeconomics: Accommodating Frictions in Coordination

Abstract

This chapter studies how incomplete information helps accommodate frictions in coordination, leading to novel insights on the joint determination of expectations and macroeconomic outcomes. We review and synthesize recent work on global games, beauty contests, and their applications. We elaborate on the distinct effects of strategic uncertainty relative to fundamental uncertainty. We demonstrate the potential fragility of workhorse macroeconomic models to relaxations of common knowledge; the possibility of operationalizing the notions of "coordination failure" and "animal spirits" in a manner that unifies unique- and multiple-equilibrium models; and the ability of incomplete information to offer a parsimonious explanation of important empirical regularities. We provide a general treatment of these ideas, as well as specific applications in the context of business cycles, financial crises, and asset pricing.

Keywords

Informational frictions, Higher-order beliefs, Strategic uncertainty, Coordination failure, Animal spirits, Aggregate demand, Business cycles, Financial crises, Global games, Beauty contests

1. INTRODUCTION

Modern economies are vastly complex networks, in which the decisions of any given agent are highly dependent on expectations of the decisions of many other agents. For instance, how much a firm wants to hire and invest depends on the firm's expectations of the future demand for its product, which in turn depends on the spending plans of the consumers who are likely to buy the product of that firm; but consumer plans themselves depend on expectations of income and labor-market conditions, which in turn depend on the decisions of other firms and other consumers, and so on. Markets, the government, and other social institutions help facilitate the coordination of these expectations, and of the associated decisions, but only up to a point.

The limits to such coordination are rarely acknowledged in macroeconomics. Workhorse models are constructed as if all economic agents could confer with one another, reach a unanimous consensus on the current state and future prospects of the economy, and effortlessly coordinate on a commonly known profile of actions, or allocation, at all times.[a] Importantly, this is not just about theory: such models form the basis for both the interpretation of the data and the guiding of policy.

How would the predictions of these models differ if there were nontrivial frictions in the agents' ability to reach such a consensus and to coordinate their actions? What are useful ways for formalizing and operationalizing such frictions in the first place? And how does the accommodation of such frictions affect our interpretation of the observed phenomena and the guidance we may offer to policy makers?

This chapter reviews and synthesizes recent advances made in addressing these questions. We argue that incomplete information offers a useful method for introducing frictions in coordination and for enriching the dynamics of expectations in macroeconomic models. This enrichment leads to the questioning of existing interpretations of, and helps shed new light on, important phenomena such as business cycles and crises.

[a] This allocation need not be a socially desirable one; it only has to be consistent with equilibrium.

1.1 Background and Key Ideas

Before reviewing the contents of this chapter, we need to clarify the benchmark from which we depart, and the nature of the departure.

It is useful to start with the textbook RBC model. This model, like other workhorse models in macroeconomics and finance, is based on the Arrow–Debreu paradigm. In this paradigm, agents attain perfect communication: the general equilibrium is akin to the Nash equilibrium of a game of complete information, in which the players attain common knowledge, not only about exogenous fundamentals such as preferences and technology, but also about endogenous outcomes such as employment, output, and asset prices.[b]

While modern macroeconomic models often depart from the Arrow–Debreu paradigm by allowing for monopolistic power, sticky prices, credit constraints, search frictions, and so forth, they typically impose that all agents share the same information. This assumption, together with standard equilibrium concepts, tends to trivialize the problem of forecasting the actions of other agents and the associated macroeconomic outcomes: in equilibrium, all agents share the same "state of mind" about where the economy is heading to. It is in this sense that perfect coordination of beliefs and actions is imposed.

This property is evident in unique-equilibrium DSGE models that pin down equilibrium outcomes as functions of commonly known fundamentals such as preferences and technologies. But it also applies to certain multiple-equilibrium models that aimed to capture the idea that recessions, bank runs, and liquidity crises are the product of "coordination failures," such as Diamond (1982), Bryant (1983), Cooper and John (1988), Diamond and Dybvig (1983), Calvo (1988), and Obstfeld (1986, 1996).

Let us explain. The models in the aforementioned papers boil down to static coordination games that admit multiple equilibria. Some of these equilibria can be interpreted as coordination failures because they are welfare-inferior to other equilibria. Nevertheless, the following property holds in *any* of the equilibria of these models: the agents know, not only which strategy profile has been selected, but also the particular actions played by all other agents. This represents a certain oxymoron: although a coordination failure obtains *across* equilibria, coordination remains flawless *along* any given equilibrium.[c]

[b] Whenever we say "fundamentals," the game theorist can read "payoff types;" and whenever we say "endogenous outcomes" or "economic activity," the game theorist can read "actions."

[c] These points are exact in static coordination models, such as those studied in the aforementioned works, but become fussy in dynamic sunspot models. See the remark at the end of Section 3.4; see also Aumann et al. (1988) and Peck and Shell (1991) on the relation between sunspot equilibria in dynamic macroeconomic models and correlated equilibria in games.

The oxymoron gets worse: once we allow the coordination that obtains along any given equilibrium to be imperfect, in the manner that we formalize in the sequel, the multiplicity of equilibria may vanish; and when this happens, the conventional formalizations of "coordination failures" and "animal spirits" fall apart. This underscores the potential fragility of the predictions of standard macroeconomic models—and of the associated interpretations of macroeconomic phenomena—to the kind of friction we are after.

Nonetheless, we also show that this friction offers a new, refined, version of the aforementioned concepts. Interestingly, this new version helps unify unique- and multiple-equilibria models. Most importantly, it leads to new insights into the nature of important phenomena, including financial crises, business cycles, and asset-price fluctuations; and to new lessons for policy.

But how can one operationalize the sought-after friction in coordination? We propose that incomplete information offers a useful method for doing so.[d]

We thus depart from standard macroeconomic models in one crucial respect: we let agents have differential information about the aggregate shocks hitting the economy. This transforms the macroeconomic models of interest into games of incomplete information, thereby also opening the door to rich higher-order beliefs.

Once we look at the equilibria of the modified models, we find that there is no more a unanimous consensus about where the economy is heading: agents fail to reach the same equilibrium beliefs about one another's actions and the associated macroeconomic outcomes. In this sense, coordination has become imperfect.

Shedding light on how this imperfection affects the predictions of macroeconomic models and our interpretation of macroeconomic phenomena is the goal of this chapter.

1.2 Preview and Main Lessons

Our analysis alternates between two modes: one abstract, seeking to highlight general properties; and another applied, spelling out concrete lessons in the context of specific applications.

In Section 2, we set up our baseline framework. The framework is highly stylized: it boils down to a static game with a continuum of agents. Yet, the framework is sufficient for our purposes. First, it encapsulates the fixed-point relation between expectations of economic outcomes and actual behavior that is at the core of most macroeconomic models. Second, it facilitates a sharp analysis of how the theoretical properties of this fixed point, and the implied restrictions on the observables of the model, vary with the information structure. Last but not least, it helps clarify the language employed throughout this chapter.

[d] By "incomplete information" we refer to situations in which agents have dispersed private information about, and lack common knowledge of, aggregate shocks. Our preferred definitions of this and other key concepts are provided in Section 3, after the introduction of our framework.

In Section 3, we offer our preferred definitions of key concepts such as "fundamentals," "incomplete information," and "imperfect coordination." We next distinguish the uncertainty that the agents face about the behavior of others and the associated macroeconomic outcomes, hereafter referred to as "strategic uncertainty," from the uncertainty they face about fundamentals such as preferences and technologies. We finally elaborate on how incomplete information helps disentangle these two types of uncertainty and how it helps formalize the sought-after friction in coordination.

For the remainder of the chapter, we concentrate on two special cases of our framework, each of which corresponds to a different class of models. The first class, which is introduced in Section 4, is known in the literature as "global games." second class, which is introduced in Section 7, is often referred to as "beauty contests." classes exhibit strategic complementarity and use incomplete information to accommodate a friction in coordination; what differentiates them is the strength of the coordination motives and the potential impact of the friction on the determinacy of the equilibrium.

In Section 4, we thus review the following result from the literature on global games, which was initiated by Carlsson and Van Damme (1993a,b) and was further advanced by Morris and Shin (1998, 2001, 2003). Take a classic coordination model, as in Diamond (1982), Diamond and Dybvig (1983), Calvo (1988), and Obstfeld (1986, 1996). Modify it by introducing idiosyncratic noise in the agents' observation of the fundamentals. In the limit as this noise vanishes, the modified model is indistinguishable from the original model in the sense that every agent has nearly perfect knowledge of the underlying fundamentals. And yet, the modified model admits a unique equilibrium.

At the core of this result is the subtle difference between perturbations of mutual knowledge (everybody knows A) and perturbations of common knowledge ("everybody knows A," "everybody knows that everybody knows A," … ad infinitum). The friction may be small in the sense that every agent faces little uncertainty about the underlying fundamentals; and yet it can have a sizable effect on equilibrium outcomes insofar as it shatters common knowledge.

Notwithstanding this subtlety, the result reveals a discontinuity in the predictions of a large body of applied work to perturbations of the informational assumptions. At first glance, this discontinuity is quite troubling: the interpretations of certain phenomena and the related policy implications that macroeconomists have developed on the basis of multiple-equilibria models appear to be in jeopardy.

We argue that this worry is largely not warranted.

First, equilibrium multiplicity is no more needed in order for economic outcomes to be fragile, for self-fulfilling beliefs to matter, and for coordination failures to occur. For instance, we show that small exogenous shocks can still trigger large changes in equilibrium outcomes because, and only because, they trigger large changes in the equilibrium expectations that agents hold about one another's choices.

Second, the determinacy of the equilibrium under incomplete information is sensitive to the particular way that the information structure is modeled. For instance, if market signals such as prices create sufficient correlation in beliefs, or approximate common knowledge, multiplicity may survive the kind of perturbations that would have induced equilibrium uniqueness in the absence of such endogenous signals.

These observations help resuscitate the spirit of the earlier, complete-information models. But this is not the endgame. By offering a more structured way for modeling expectations, the global-games methodology qualifies existing applied lessons and leads to new ones.

In Section 5, we expand on these lessons within the context of several applications. Some of these applications regard bank runs, currency attacks, and sovereign debt crises; others are in the context of business cycles, market freezes, and bubbles. Inter alia, we highlight a number of novel lessons regarding the adverse effects of big speculators, the effectiveness of lenders of last resort such as the IMF, and the role of bank regulation in preventing coordination failures.

We also discuss a few extensions that endogenize the information structure in global games. This permits us to elaborate on the robustness and the empirical content of the uniqueness result. More importantly, it leads to new applied lessons, such as the possibility that an informed policy maker finds herself trapped in a situation where her policy actions are shaped by market expectations rather than the other way around.

Summing up, although the global-game methodology does not offer a panacea for equilibrium uniqueness, it helps open "the black box" of expectations and coordination. This leads to useful applied lessons that were not possible in the context of the earlier, complete-information, literature on coordination failures.

In Section 6, we review two contributions that shift attention to a dynamic issue, the ability of the agents to *synchronize* their choices. The first contribution, which is by Frankel and Pauzner (2000) and Burdzy et al. (2001), uses a friction as in Calvo (1983) to introduce asynchronous choice in a dynamic coordination game and shows that this helps select a unique equilibrium, even when the Calvo-like friction is vanishingly small. The second contribution, which is by Abreu and Brunnermeier (2003), is also concerned with a dynamic coordination game; but instead of adding a Calvo friction, it introduces asynchronous awareness of a shock in the environment; it is then shown that such asynchronous awareness results, not only in asynchronous responses to the aforementioned shock, but also in significant delay of these responses. We discuss how these contributions connect to the global-games literature and how they shed light on the subtle relation between synchronization and coordination.

In Section 7, we shift gears and study a class of models that feature a weaker form of coordination motives than that in the global-games literature. These games, which are often described as beauty contests, have linear best-response conditions and admit a unique equilibrium, features shared by the type of (log)linear DSGE models commonly used to study business cycles and macroeconomic policy, as well as by certain asset-pricing models.

In this class of models, equilibrium determinacy is no longer an issue and the key preoccupation is with the stochastic properties of the equilibrium. Accordingly, the questions we pose are the following: How does an economy respond to innovations to fundamentals? How does this response depend on strategic uncertainty as opposed to fundamental uncertainty? Do coordination motives matter for level and the nature of aggregate volatility? Can one discern a role for "animal spirits" and "self-fulling beliefs"?

The core of Section 7 is devoted to answering the above questions in a relatively abstract manner. The analysis builds heavily on Morris and Shin (2002b), Angeletos and Pavan (2007), and Bergemann and Morris (2013), although we adapt and extend the results of those papers in ways that suit our purposes. Inter alia, we establish the following three general points.

First, incomplete information can help generate significant rigidity, or inertia, in the response of macroeconomic outcomes to aggregate shocks to fundamentals. This inertia can be quantitatively significant even if the noise in the observation of the fundamentals is small, a finding that underscores the distinct role played by strategic uncertainty, or imperfect coordination, relative to fundamental uncertainty.

Second, inertia may obtain at the macro level even if it is largely absent at the micro level. This finding may help liberate macroeconomists from ad hoc adjustment costs that DSGE models have to use in order to match the inertia in the estimated responses of macroeconomic variables to identified shocks to fundamentals. It also highlights a subtle difference between incomplete information and the formalizations of "inattention" found in Sims (2003), Reis (2006), and Gabaix (2014): whereas these formalizations are designed so as to introduce inertia at the microeconomic level, the friction we accommodate in this chapter is uniquely positioned to generate inertia at the macroeconomic level.

Third, this friction can also manifest as extrinsic volatility, that is, as volatility in equilibrium outcomes that is not spanned by the volatility in either the fundamentals or beliefs thereof. It follows that the traditionally dichotomy between models that admit multiple equilibria and those that do not may no longer be central to the understanding of "animal spirits" and "self-fulfilling beliefs": the same type of volatility can now obtain in either class of models.

In Section 8, we consider several applications. In our first application, which is based on Angeletos and La'O (2010), we show how incomplete information can induce rigidity in the response of employment and output to technology shocks. This helps reconcile the RBC paradigm with facts that have so far been considered prima-facia evidence against that model and in favor of the New-Keynesian model (Gali, 1999). We also discuss other works that use informational frictions to generate real rigidities in other contexts.

Our second application concerns nominal rigidity. In particular, we review Woodford (2003), who shows how inertia in higher-order beliefs can be a potent, if not superior, substitute to sticky prices. We also discuss the connection to the complementary works of Mankiw and Reis (2002) and Maćkowiak and Wiederholt (2009), as well as to the seminal contribution by Lucas (1972).

We proceed to review some recent empirical work that uses surveys of economic forecasts to measure the role of frictions in information, most notably by Coibion and Gorodnichenko (2012). We argue that this work provides important evidence in support for the main ideas reviewed in this chapter; but we also highlight certain caveats in the mapping from this evidence to the theory.

In another application, we argue that incomplete information helps accommodate the notion of demand-driven fluctuations without the need for either nominal rigidity or constraints on monetary policy. We also discuss how the incorporation of plausible higher-order belief dynamics in DSGE models can help match salient features of the business-cycle data.

We then turn to a review of applications in finance, which have indicated how incomplete information can also offer a parsimonious explanation to asset-pricing puzzles such as momentum, excess volatility, and the disconnect between exchanges rates and macroeconomic fundamentals.

Section 9 concludes our analysis by touching upon certain normative questions. We first review a notion of constrained efficiency that helps dissect the normative properties of the equilibrium in the class of incomplete-information models we are concerned with. We then discuss two sets of applications: a literature that characterizes optimal monetary policy in the presence of informational frictions; and a literature that studies the welfare effects of the information disseminated by markets, policy makers, or the media.

1.3 Additional Points and Position in the Literature

We now offer a few additional remarks about the theme of our chapter and its position in the literature.

1. The hallmark of the friction we accommodate in this chapter is the inability of agents to reach a consensus about the state of the economy. Along with it comes a certain disentanglement of the uncertainty agents face about endogenous economic outcomes such as employment, output, and asset prices, from their uncertainty about exogenous fundamentals such as preferences and technologies. This disentanglement is made possible with the help of certain types of private information, which permit higher-order beliefs of fundamentals to diverge from the corresponding first-order beliefs. This divergence, in turn, is instrumental to understanding the equilibrium properties of the models we study. However, once equilibrium is imposed, higher-order beliefs become a sideshow: all that matters for the behavior of an agent is the equilibrium expectations (first-order beliefs) she forms about the relevant economic outcomes. Furthermore, for the applications we have in mind, it seems easier

to detect and quantify this kind of expectations, as opposed to the underlying belief hierarchies. These observations explain why the focal point of our analysis is the joint determination of equilibrium outcomes and expectations thereof: higher-order beliefs is the machinery, not the essence, of what we are after.

2. The uncertainty agents face about economic outcomes is tightly connected to the one they face about the behavior of other agents, which is often referred to as "strategic uncertainty" in game theory. Starting from a complete-information model, one notes that the equilibria of such a model rule out any uncertainty about the behavior of others conditional on payoffs.[e] One may then seek to accommodate such uncertainty by relaxing the solution concept. Alternatively, one may maintain the solution concept and instead engineer the sought-after uncertainty with the help of incomplete information. The approach taken in this chapter is the latter. Whenever we talk about strategic uncertainty in the sequel, we therefore refer to the uncertainty that agents face about the actions of others *on* equilibrium, due to incompleteness of information.
3. The frictionless coordination of beliefs and actions that is embedded in standard macroeconomic models hinges on the rational-expectations equilibrium concept just as much as it hinges on the conventional assumption of complete information. It follows that the relaxation of the latter assumption—the approach favored in this chapter—can also be seen as a substitute for relaxing the solution concept. We elaborate on this point in due course.
4. The preceding remarks help distinguish our chapter from the recent literature on "news" and "noise shocks" that has followed Beaudry and Portier (2006).[f] This literature extends workhorse models by letting agents observe noisy signals of future fundamentals, but typically maintains the assumption that all agents share the same information. In so doing, it fails to accommodate the type of friction we are after. In short, it enriches the stochasticity in expectations of fundamentals, but does not disentangle uncertainty of endogenous economic outcomes from uncertainty of exogenous fundamentals. The same point applies to Bloom (2009) and the subsequent literature on "uncertainty shocks."
5. Similar observations help position our chapter also vis-a-vis a strand of the literature that studies various forms of inattention. Consider, in particular, Sims (2003), Reis (2006), and Gabaix (2014). These papers study single-agent problems in which it is

[e] Strictly speaking, this statement applies only to Nash equilibria in pure strategies. However, mixed strategies are not relevant in our context, because we study settings in which there is no loss in ruling out mixed strategies. Also, the statement need not apply to the broader class of *correlated* equilibria, but this precisely because this solution concept departs from complete information.

[f] See, inter alia, Barsky and Sims (2011, 2012), Blanchard et al. (2013), Christiano et al. (2008), Jaimovich and Rebelo (2009), and the baseline model in Lorenzoni (2009). See also the related work by Collard and Dellas (2010) on imperfect observability of current fundamentals.

costly for an agent to acquire information about an exogenous payoff-relevant variable (or otherwise make her action covary appropriately with that variable). In so doing, these papers provide useful decision-theoretic foundations of informational frictions. But they also bypass the distinction between fundamental and strategic uncertainty, for such a distinction is meaningful only in settings in which agents interact with one another.

6. Applied work often confounds the aforementioned two types of uncertainty. To some extent, this is unavoidable: in many applications, accommodating uncertainty about the actions of others *requires* uncertainty about fundamentals. Yet, not only are the two types of uncertainty conceptually distinct, but they can also have different implications. For instance, in the class of global games we study in Sections 4 and 5, what matters for equilibrium determinacy is the strategic uncertainty that is induced by incomplete information, not the underlying fundamental uncertainty. Furthermore, as we elaborate in Sections 7 and 8, incomplete information and the resulting strategic uncertainty can help operationalize the notions of coordination failure and animals spirits within unique-equilibrium models, in a manner that no kind of fundamental uncertainty alone can do. An integral part of our analysis is therefore to disentangle the two types of uncertainty as much as possible. We hope that this will help clarify, not only the theoretical underpinnings, but also the empirical implications of the blossoming macroeconomics literature on informational frictions.
7. The aforementioned literature contains many strands. This chapter occupies only the subspace in this literature that relates to coordination, higher-order beliefs, and strategic uncertainty. For complementary reviews of the literature, see Sims (2010), Mankiw and Reis (2011), and Veldkamp (2011).
8. Models with search and trading frictions are occasionally interpreted as models with imperfect coordination; see, eg, Diamond (1982) and Shimer (2005). This is not what *we* have in mind. To the extent that these models maintain common knowledge of aggregate fundamentals and aggregate outcomes, for our purposes they impose the same level of coordination as the Arrow–Debreu framework.[g]
9. We are more sympathetic to the notion that asynchronous choice impedes coordination. We expand on this point in Section 6 by uncovering a subtle connection between the role of incomplete information and that of a Calvo-like friction in settings with strategic complementarities.
10. Our treatment of incomplete information is consistent with standard treatments in Bayesian games. In particular, our baseline framework specifies information in terms of Harsanyi types: the signal of an agent encodes, not only her beliefs about payoffs (fundamentals), but also her beliefs, or "state of mind," regarding the types of other

[g] That said, trading frictions can be instrumental for sustaining lack of common knowledge: accommodating incomplete information *requires* a departure from the Arrow–Debreu framework.

agents. We nevertheless adjust some of the definitions in manners that suit our applied purposes. We also bypass a number of deeper theoretical issues that are beyond the scope of this chapter, such as the equivalence between Harsanyi types and belief hierarchies (Mertens and Zamir, 1985) and the approximation of common knowledge with common beliefs (Monderer and Samet, 1989; Morris and Shin, 1997), as well as all the concerns of epistemic game theory (Dekel et al., 2015).

11. In our baseline framework, as well as in various applications, we favor a broad interpretation of incomplete information: signals are allowed to capture subjective states of mind about the beliefs and actions of others. For certain questions, however, a more narrow interpretation may be appropriate: when we study the aggregation of information through markets or other channels, or when we touch upon the desirability of central-bank communication, it is safer to assume that signals represent hard information.

2. FRAMEWORK

In this section we introduce our main framework. Although it is static and abstract, the framework is quite flexible and stylizes role of general-equilibrium interactions, and of coordination, in a variety of applications. Furthermore, it facilitates the formalization of a number of key concepts in the next section; it helps illustrate how the predictions of standard macroeconomic models hinge on strong assumptions about the determination of beliefs; and it paves the way to a number of applications presented later on.

2.1 Actions and Payoffs

Consider a one-shot game, or "economy," with a large number of players, or "agents," indexed by $i \in [0,1]$. Each agent i chooses an action $k_i \in D_k \subseteq \mathbb{R}^n$, with $n \geq 1$. His payoff is given by

$$u_i = U(k_i, \mathbf{K}, \theta_i), \tag{1}$$

where $\mathbf{K} \in D_{\mathbf{K}}$ denotes the distribution of actions in the cross section of the population (the aggregate economic activity), $\theta_i \in D_\theta \subseteq \mathbb{R}^m$, $m \geq 1$, summarizes any exogenous variable that is payoff-relevant to agent i (her fundamental), and U is a function, which will be further specified as we proceed.

As we move on, we will discuss a number of applications that can be nested either directly in the above framework or in appropriate extensions of it. In some of the applications, the players are speculators deciding whether to attack a currency, or depositors deciding whether to run against a bank. In others, they are firms making production and pricing choices, or consumers choosing how much to spend. Also note that the specification assumed in condition (1) allows an agent's payoff to depend on the entire distribution of actions in the cross-section of the population. In applications, however, the first and second moments (ie, the mean and the dispersion) often suffice. Furthermore, although we momentarily allow for both the actions and the fundamentals to be multidimensional, we will soon restrict attention to settings where $n = m = 1$. In such a case, we let $K \equiv \int k d\mathbf{K}(k)$ and $\sigma_k \equiv \sqrt{\int (k-K)^2 d\mathbf{K}(k)}$ denote, respectively, the mean action and the cross-sectional standard deviation of actions.

Remark 1 One may find it more appealing to represent the macroeconomy as a network where each agent is connected to a small set of other agents as opposed to the entire population. The ideas we develop in this chapter apply in such settings as well. For our purposes, the fact that the economy is modeled as a complete and symmetric network is mostly a simplification. For other purposes, however, it may be important to abandon this simplification. For instance, an important question that we will not address is how the effects of strategic uncertainty on observables depend on the network structure.

Remark 2 Recall that the question of interest for us is the equilibrium expectations of economic outcomes. In the static framework we introduce in this section, this question is reduced to the question of the equilibrium expectations of the *contemporaneous* actions of others. In dynamic applications in which decisions are forward-looking, the relevant expectations also regard the actions of others in *future* periods.

Remark 3 Notwithstanding the previous remark, there is an important multiperiod setting that defies the aforementioned distinction and can be readily nested in our static framework: an Arrow–Debreu economy, with a complete market for time- and state-contingent goods. In such an economy, θ_i captures the preferences and endowments of agent i, k_i captures her net demand of the various goods, and the dependence of the agent's utility on $\mathbf{K}$ emerges from the dependence of equilibrium prices on the net demands of other agents. Importantly, because in a complete Arrow–Debreu market all agents get to observe all the relevant prices, it is *as if* they also observe the actions of other agents. This underscores that the Arrow–Debreu framework and many workhorse macroeconomic models that are based on it are, in effect, a particular class of static, complete-information games. Conversely, accommodating incomplete information in macroeconomic models requires some kind of market incompleteness (such as missing forward markets).

2.2 Examples

We now use two simple examples to illustrate how the abstract payoff structure assumed above corresponds to a reduced-form representation of more concrete applications. The first example is a neoclassical economy similar to those studied in Angeletos and La'O (2010, 2013), Benhabib et al. (2015b), Sockin and Xiong (2015), and Huo and Takayama (2015a). The second is a monetary economy similar to those studied in Woodford (2003), Mankiw and Reis (2002), and Maćkowiak and Wiederholt (2009). Later on, we will explore the implications of a certain kind of informational friction in these and other examples. For now, we abstract for the informational friction and focus on demonstrating how these examples can be nested in our framework. Apart from providing concrete interpretations of the framework, these examples help clarify that, for our purposes, strategic interaction is often synonymous to market-based general-equilibrium effects.

2.2.1 An Neoclassical Economy

There is a continuum of "farmers," which can be interpreted as both firms and consumers, and a continuum of differentiated consumption goods. Each farmer specializes in the production of a single good but consumes all the goods in the economy. We let $i \in [0, 1]$ index both the farmer and the good she produces. There are two stages. Production takes places in stage 1; trading and consumption take place in stage 2. Preferences are given by

$$u_i = v(c_i) - n_i, \tag{2}$$

where v is a strictly increasing and strictly concave function, n_i denotes labor, and c_i is a CES aggregator of the farmer's consumption of all the goods. That is,

$$c_i = \left[\int c_{ij}^{1-\eta} dj \right]^{\frac{1}{1-\eta}}$$

where c_{ij} denotes the consumption of good j by household i and $\frac{1}{\eta}$ is the elasticity of substitution across goods. The budget constraint of any farmer i is given by $\int p_j c_{ij} dj = p_i q_i$, where p_j denotes the (nominal) price of good j and q_i the farmer's output. Finally, production is given by

$$q_i = A_i n_i,$$

where A_i is the farmer's exogenous productivity.

As is well known, the CES specification implies that the optimal consumption bundle of farmer i satisfies

$$\int p_j c_{ij} dj = P c_i \quad \text{and} \quad \frac{c_{ij}}{c_i} = \left(\frac{p_j}{P} \right)^{-1/\eta} \quad \forall j,$$

where $P \equiv \left[\int p_j^{1-1/\eta} dj \right]^{\frac{1}{1-1/\eta}}$ is the ideal price index. Market clearing imposes $\int c_{ji} dj = q_i \;\; \forall i$. Using this yields the following relation between the market-clearing prices and the quantities produced:

$$p_i = P \left(\frac{q_i}{Q} \right)^{-\eta} \quad \forall j, \tag{3}$$

where $Q \equiv \left[\int q_j^{1-\eta} dj\right]^{\frac{1}{1-\eta}}$ measures aggregate output. The budget constraint, on the other hand, gives $c_i = \frac{p_i q_i}{P} = Q^\eta q_i^{1-\eta}$. It follows that the utility of farmer i reduces to the following:

$$u_i = v(c_i) - n_i = v\left(Q^\eta q_i^{1-\eta}\right) - \frac{q_i}{A_i}.$$

We conclude that the example we have introduced here can be readily nested in our framework if we let

$$U(k_i, \mathbf{K}, \theta_i) = v\left(\left[\int \exp(x)^{1-\eta} d\mathbf{K}(x)\right]^{\frac{\eta}{1-\eta}} \exp(k_i)^{1-\eta}\right) - \exp(k_i - \theta_i), \tag{4}$$

with $k_i \equiv \log q_i$ and $\theta_i \equiv \log A_i$. That is, the economy under consideration can be interpreted as a game in which the players are the farmers, the actions are the quantities these farmers produce, the fundamentals are their exogenous productivities, and the payoffs are given by (4).[h]

2.2.2 A Monetary Economy

The structure of the economy is as above, except for the following two modifications. First, the farmers set nominal prices in stage 1 and commit to accommodate any quantity demanded in stage 2 at these prices. Second, the level of nominal GDP is given by

$$PQ = M, \tag{5}$$

where M is an exogenous variable. In line with much of the related literature, one may interpret the variation in M as monetary shocks.

Following similar steps to those above, we can solve for quantities as functions of prices (rather than the other way around). In particular, using (3), (5), and the budget constraint, we get

$$q_i = Q\left(\frac{p_i}{P}\right)^{-1/\eta} = MP^{1/\eta - 1} p_i^{-1/\eta} \quad \text{and} \quad c_i = \frac{p_i q_i}{P} = MP^{1/\eta - 2} p_i^{1-1/\eta}.$$

[h] Note that k_i and θ_i could have been defined as the absolute levels of q_i and A_i, rather than their logarithms. We opt for the logarithmic transformation because of the following reason: when we assume that productivities are log-normally distributed and that the available information is Gaussian, the power specification of preferences and technologies in this example guarantees the existence of a unique equilibrium in which $k_i \equiv \log q_i$ can be expressed as a linear function of the firm's expectation of $\theta_i \equiv \log A_i$ and K, with K itself being equal to $\log Q$ plus a constant. This in turn means that the neoclassical economy under consideration maps into the specific class of games we study in Sections 7 and 8.

The present example is nested in our framework by letting $k_i \equiv \log p_i$, $\theta_i \equiv (\theta_{i1}, \theta_2) \equiv (\log A_i, \log M)$, and[i]

$$U(k_i, \mathbf{K}, (\theta_{i1}, \theta_2)) = v\left(\exp(\theta_2)\left[\int \exp(x)^{1-1/\eta} d\mathbf{K}(x)\right]^{\frac{1/\eta-2}{1-1/\eta}} \exp(k_i)^{1-1/\eta} \right) \\ - \exp\left(\theta_2 - \theta_{i1} - \frac{1}{\eta} k_i\right)\left[\int \exp(x)^{1-1/\eta} d\mathbf{K}(x)\right]^{-1}. \tag{6}$$

That is, the actions now are the nominal prices set by the farmers and the fundamentals are the productivity and monetary shocks. Note that in this example, productivity is allowed to have both an idiosyncratic and an aggregate component, whereas the monetary shock has only an aggregate component. Woodford (2003) and Mankiw and Reis (2002) are then nested by shutting down all the productivity shocks, whereas Maćkowiak and Wiederholt (2009) is nested by letting the productivity shocks be purely idiosyncratic.

Remark 4 The above two examples can be thought as representing two diametrically opposite cases: in the first, firms set quantities and let prices adjust; in the second, firms set prices and let quantities adjust. This difference is inconsequential when the firms face no uncertainty, but matters for both positive and normative issues if the firms are uncertain about either the relevant exogenous fundamentals or the choices of other firms. We elaborate on these points in Sections 8 and 9.

Remark 5 Although our examples are populated by "farmers," one should of course not take this too literally. Starting with Lucas (1972), various authors have considered models that feature more appealing micro-foundations along with informational frictions. The key question for our purposes is whether these models make room for nontrivial strategic, or higher-order, uncertainty. This is what distinguishes the more recent works mentioned above from Lucas' earlier contribution: as further explained in Section 8.3, the specific model used in Lucas (1972) shuts down the effects we are after in this chapter.

2.3 Shocks and Information

So far, we have specified actions and payoffs. To complete the description of the framework, we must specify the exogenous stochastic structure (shocks and information) and must also pick a solution concept. We complete these two tasks in, respectively, the present section and Section 2.4.

We let $\omega_i \in D_\omega \subseteq \mathbb{R}^l$ denote the signal received by agent i, where by "signal" we mean the entire information set of the agent, or equivalently her Harsanyi type. We denote by $\mathbf{\Omega}$ the distribution of ω_i in the cross-section of the population, and by $\mathbf{\Theta}$ the cross-sectional distribution of θ_i. We let $D_{\mathbf{\Omega}}$ and $D_{\mathbf{\Theta}}$ denote the sets of the possible

[i] The logarithmic transformation is used for the same reason as in footnote h.

values for, respectively, $\mathbf{\Omega}$ and $\mathbf{\Theta}$. We let $\mathbf{S}$ denote the distribution that Nature uses to draw, in an i.i.d. fashion, a pair $s_i = (\omega_i, \theta_i)$ for each i, and let $D_{\mathbf{S}}$ denote the set of possible values for $\mathbf{S}$. We assume that a version of the law of large numbers applies, so that $\mathbf{S}$ is also the cross-sectional distribution of s_i in the population. It follows that $\mathbf{\Theta}$ and $\mathbf{\Omega}$ are also the marginals of $\mathbf{S}$ in, respectively, the θ and ω direction. We introduce aggregate uncertainty by allowing $\mathbf{S}$ (and hence also $\mathbf{\Theta}$ and $\mathbf{\Omega}$) to be random, drawn from the set $D_{\mathbf{S}}$ according to some fixed distribution $\mathcal{P}$, which constitutes the common prior.

One can thus describe the "moves of Nature" as follows. First, Nature draws $\mathbf{S}$ according to $\mathcal{P}$. Next, Nature uses $\mathbf{S}$ to draw, in an i.i.d. manner, a pair $s_i = (\theta_i, \omega_i)$ for each agent i. Finally, Nature reveals ω_i (and only that) to agent i.

The objects $\{U, D_k, D_{\mathbf{K}}, \mathcal{P}, D_\theta, D_\Theta, D_\omega, D_\Omega, D_{\mathbf{S}}\}$ and all the aforementioned facts are common knowledge. What may not be common knowledge is the realization of $\mathbf{S}$, and therefore also the realizations of $\mathbf{\Theta}$ and $\mathbf{\Omega}$. Different specifications of the stochastic structure—that is, of the prior $\mathcal{P}$ and the associated domains for the fundamentals and the signals—can accommodate different scenarios about how much each agent knows, not only about her own fundamentals, but also about the fundamentals and the information of other agents. Importantly, we can accommodate aggregate and idiosyncratic shocks, not only to fundamentals, but also to information.

To give a concrete example, consider the neoclassical economy introduced earlier on and let $\theta_i \equiv \log A_i = \overline{\theta} + \xi_i$, where $\overline{\theta}$ and ξ_i are independent Normally distributed variables with mean zero and variances, respectively, σ_θ^2 and σ_ξ^2, and ξ_i is i.i.d. across i. Then, variation in $\overline{\theta}$ represents aggregate TFP shocks, whereas variation in ξ_i represents idiosyncratic TFP shocks. Concerning the information structure, we could then let $\omega_i = (x_i, z)$, where $x_i = \theta_i + \epsilon_i$, $z = \overline{\theta} + \zeta$, and ϵ_i and ζ are Normally distributed, independent of one another, of $\overline{\theta}$, and of ξ_i for all i, with mean zero and fixed variances σ_ϵ^2 and σ_ζ^2. This would mean that the information set of an agent is given by the pair of two signals, a private signal of her own TFP and a public signal of the aggregate TFP. Finally, because all the relevant cross-sectional distributions, namely $\mathbf{\Theta}$, $\mathbf{\Omega}$, and $\mathbf{S}$, are now Normal distributions with fixed variances, we can think of the aggregate shocks in terms of the pair $(\overline{\theta}, \zeta) \in \mathbb{R}^2$ rather than of the high-dimensional objects $(\mathbf{\Theta}, \mathbf{\Omega})$ or $\mathbf{S}$.

In the example described above, x_i is a signal, not only of θ_i, but also of $\overline{\theta}$; and since $\overline{\theta}$ is the mean of the realized distribution of x_j for $j \neq i$, it follows that x_i is also signal of the signals of others. More generally, note that different realizations of $\mathbf{S}$ correspond to different conditional distributions for ω_i, which means that ω_i is a signal of $\mathbf{S}$ and hence also of $\mathbf{\Omega}$.[j] This underscores that ω_i shapes the agent's belief, not only about her own

[j] Note that ω_i is also a signal of $\mathbf{\Theta}$, the fundamentals of others. This, however, is not relevant per se. An agent cares only about her own fundamental and the actions of others. In equilibrium, the latter are pinned down by their information. What is relevant is therefore only the information that ω_i contains about the agent's own fundamental and the information of others.

payoff, but also about the *information* of others. Once we impose equilibrium, the latter will mean that ω_i shapes the beliefs about the *actions* of others.

We can now offer the following definitions, which help fix the language we use in this chapter.

Definition 1 The realized *fundamentals* are given by $\mathbf{\Theta}$, the distribution of the exogenous payoff characteristic θ_i in the cross-section of the population. The realized *information* is given by $\mathbf{\Omega}$, the corresponding distribution of the signal ω_i. The *state of Nature* is given by $\mathbf{S}$, the joint distribution of (ω_i, θ_i).[k]

Note that the above objects, as many others we introduce below, refer to the cross-section of the population, as opposed to any specific agent. This reflects merely our focus on macroeconomic outcomes, as opposed to the behavior of each individual player.

We now introduce our notation for first- and higher-order beliefs. Let b_i denote the belief of agent i about her own fundamental and the aggregate fundamentals, that is, the posterior of $(\theta_i, \mathbf{\Theta})$ conditional on ω_i. This belief encapsulates the agent's information about the payoff structure of the environment and is also known as her *first-order* belief (of the underlying fundamental). Clearly, b_i is a function of ω_i. Let $\mathbf{B}$ denote the realized distribution of b_j in the cross-section of the population; this is a function of $\mathbf{\Omega}$. Define the *second-order* belief of agent i as her posterior about $\mathbf{B}$ and denote it by b_i^2. Since $\mathbf{B}$ is a function of $\mathbf{\Omega}$ and since ω_i pins down i's belief about $\mathbf{\Omega}$, ω_i pins down b_i^2 as well. Let $\mathbf{B}^2$ denote the cross-sectional distribution of second-order beliefs. We can then iteratively define, for any $h \geq 3$, the hth order belief of i, b_i^h, as her belief about $\mathbf{B}^{h-1}$; and the object $\mathbf{B}^h$ as the cross-sectional distribution of b_j^h. To ease notation, we also let $b_i^1 \equiv b_i$ and $\mathbf{B}^1 \equiv \mathbf{B}$.

Definition 2 The (aggregate) *beliefs of fundamentals* are given by $\mathbf{B}$, the cross section of the first-order beliefs of own and aggregate fundamentals. The corresponding belief hierarchy is given by $\left\{\mathbf{B}^h\right\}_{h=1}^{\infty}$. An agent faces *higher-order uncertainty* (about the fundamentals) if she is uncertain about $\left\{\mathbf{B}^h\right\}_{h=1}^{\infty}$.

Because $\left\{\mathbf{B}^h\right\}_{h=1}^{\infty}$ is pinned down by $\mathbf{\Omega}$, we can think of $\mathbf{\Omega}$ interchangeably either as the cross-sectional profile of information or as a summary statistic of the belief hierarchy. If $\mathbf{\Omega}$ is known to an agent, then so is $\left\{\mathbf{B}^h\right\}_{h=1}^{\infty}$. Conversely, uncertainty about $\mathbf{\Omega}$ helps accommodate higher-order uncertainty about fundamentals. Importantly, once we impose equilibrium, such higher-order uncertainty helps induce *first-order* uncertainty about the actions of others, ultimately capturing the coordination friction we are after.

Remark 6 For the rest of this chapter, and unless otherwise stated, the terms "higher-order beliefs" and "higher-order uncertainty" refer to the kind of higher-order beliefs of fundamentals defined above, as opposed to higher-order beliefs of either Harsanyi types (beliefs of beliefs of... $\mathbf{\Omega}$) or actions (beliefs of beliefs of... $\mathbf{K}$). In general, these three

[k] Note that $\mathbf{S}$ is the joint distribution of $s_i = (\theta_i, \omega_i)$, not just the pair of the corresponding marginals: $\mathbf{S}$ contains more information than the pair $(\mathbf{\Theta}, \mathbf{\Omega})$.

types of higher-order beliefs are distinct from one another. For instance, in Aumann (1974, 1987), private information about payoff-irrelevant variables (correlation devices) helps sustain higher-order uncertainty about the information and the actions of others, while maintaining common knowledge of fundamentals.[1] Furthermore, the distinction is central to epistemic game theory. For the purposes of this chapter, however, one can think of the three types of higher-order uncertainty as different facets of one and the same departure from workhorse macroeconomic models. Indeed, in the applications we study in this chapter, and insofar as the equilibrium is unique, the equilibrium beliefs of actions is pinned down by the hierarchy of beliefs of fundamentals. It follows that the friction we are after can be accommodated only by introducing higher-order uncertainty about fundamentals.

Remark 7 Whenever we use the terms "expectations," "beliefs," or "uncertainty" without the explicit qualifier "higher-order" in front of these terms, we refer to first-order beliefs.

Remark 8 In game theory, it is a standard practice to write the payoff of a player as function of her Harsanyi type. This could be done here by recasting payoffs as $V(k_i, \mathbf{K}, \omega_i) \equiv \int U(k_i, \mathbf{K}, \theta_i) db(\theta_i|\omega_i)$, where $b(\theta_i|\omega_i)$ is the posterior belief about θ_i conditional on ω_i. We have opted to express payoffs as functions of θ_i rather than ω_i in order to disentangle fundamentals from information sets and to accommodate the possibility that the econometrician observes θ_i but not ω_i.

2.4 Equilibrium

Let us now turn to the solution concept. In line with the vast majority of macroeconomic research, we assume that agents play according to Rational-Expectations Equilibrium. In the present framework, this means the following.

Definition 3 A *rational-expectations equilibrium* (or, simply, an equilibrium) is a strategy $k^* \in D_\omega \to D_k$ and a mapping $\mathbf{K}^* : D_\Omega \to D_\mathbf{K}$ such that:

(i) the strategy k^* is the best response to the mapping $\mathbf{K}^*$, that is,

$$k^*(\omega) \in \arg\max_{k \in D_k} \mathbb{E}[U(k, \mathbf{K}^*(\Omega), \theta)|\omega] \quad \forall \omega; \tag{7}$$

(ii) for any $\mathbf{\Omega}$, $\mathbf{K}^*(\mathbf{\Omega})$ is the distribution of k that obtains when the distribution of ω is $\mathbf{\Omega}$ and $k = k^*(\omega)$.

This definition is essentially the same as the definition of Bayesian-Nash Equilibrium in games. This, however, does not mean that the agents themselves engage in strategic reasoning. The context we have in mind is a large market-based economy, in which there

[1] With our notation, this corresponds to situations where $\mathbf{B}$ is commonly known, but $\mathbf{\Omega}$ is not. This is because $\mathbf{\Omega}$ contains correlation devices about which agents have private information. By the same token, although higher-order beliefs collapse to first-order beliefs in the case of fundamentals, the same is not true in the case of actions.

is myriad of firms and consumers, each one trying to predict economic outcomes such as aggregate employment and output. This is quite different from an arms race or other contexts in which it may be more appealing to think that each player is explicitly trying to second guess the moves of other players. We thus envision that each agent treats $\mathbf{K}$ as an exogenous stochastic process and we seek to understand the predictions that any given model makes about this process.

Under this interpretation, the adopted solution concept imposes that all agents perceive the same stochastic process for $\mathbf{K}$, as well as that this commonly perceived process coincides with the actual one generated by the joint behavior of all agents. Furthermore, ω_i becomes a signal of the realized value of $\mathbf{K}$. By the same token, we can think of ω_i as the agent's "state of mind" about what is going on in the economy. Importantly, insofar as different agents do not share the same ω_i, they also do not need to share the same expectations about the endogenous outcomes of interest.

Summing up, we have that ω_i can play any subset of the following three modeling roles. First, it shapes the agent's beliefs about her own fundamental. Second, it shapes the agent's beliefs about the information of others and thereby also her higher-order beliefs of the fundamentals. Third, it shapes the agent's equilibrium expectations about the actions of others and thereby about the endogenous outcomes of interest. The first two modeling roles are by construction; the third rests on imposing the adopted solution concept.

Some of the applied literature on informational frictions relies on the first modeling role: it removes knowledge of θ_i and lets ω_i be a noisy signal of θ_i, often in settings that rule out strategic interactions. In this chapter, by contrast, we are primarily concerned with the other two modeling roles, which are themselves relevant only in the presence of strategic interactions.[m]

Remark 9 Once the equilibrium concept has been imposed, higher-order beliefs become a sideshow: in equilibrium, an agent's signal ω_i pins down her posterior about the joint distribution of θ_i and K, which is all that matter for her behavior. Therefore, the equilibrium can be characterized without ever invoking higher-order beliefs. However, understanding the structure of higher-order beliefs turns out to be instrumental to understanding the structure of the entire equilibrium set and its sensitivity to variations of the information structure. This will become evident as we proceed.

Remark 10 When we move on to dynamic settings, the equilibrium concept we use is essentially the same as Perfect Bayesian Equilibrium. The only difference—and a useful simplification—is that we do not always need to specify out-of-equilibrium beliefs. This is because, in the typical macroeconomic setting, each private agent is too small to trigger

[m] With this point in mind, in the sequel we will often consider specifications of the information structure that help isolate the stochastic variation in the equilibrium expectations of economic outcomes from the stochastic variation in beliefs of fundamentals.

deviations that are detectable by, and payoff-relevant to, any other agent. An important exemption to this rule, however, is settings with big players, such as the government.

Remark 11 While we have introduced the notation and the concepts needed for our purposes, we have not spelled out the mathematical structure of the underlying probability space and have swept under the rug technical issues regarding measurability and existence. We hope that this simplifies the exposition without obstructing the understanding of the more substantive issues. If the reader is annoyed by this imprecision, he/she can read the next section as if the sets of actions, fundamentals, and signals were finite. In subsequent sections, we will impose enough assumptions on the stochastic structure and the function U to guarantee the existence of an equilibrium, as well as its tractable characterization.

3. IMPERFECT COORDINATION

In this section, we use our framework to define certain key notions and to elaborate on the central theme of this paper. We also discuss how equilibrium expectations and outcomes are determined under incomplete information, and contrast them to their complete-information counterparts. The complete-information case defines the benchmark relative to which equilibrium expectations are enriched.

3.1 Some Key Notions

Macroeconomic models are typically used to provide a structural interpretation of the data, or to deliver counterfactuals that can help guide policy. To clarify what this means within our framework, we start by distinguishing the exogenous objects that the theorist can specify "at will" from the endogenous objects that she wishes to predict. The exogenous objects are the payoff function U together with the stochastic structure of the fundamentals and the information sets introduced in the previous section. The endogenous objects are the actions of the agents and the realized payoffs. Because the payoffs are themselves pinned down by the fundamentals and the actions, the only "true" endogenous objects are the actions. With this in mind, we adopt the following definition.

Definition 4 The *economy's outcome*, or the economy's endogenous state, is given by $\mathbf{K}$, the distribution of actions in the cross-section of the population.

In the context of an application, $\mathbf{K}$ may represent the hiring choices of the firms, the spending choices of consumers, or the capital stock of the economy (which is itself the product of past investment choices by firms and consumers). What a model ultimately does is to impose certain restrictions on the joint distribution of these endogenous objects with the exogenous shocks to fundamentals and information sets.

Suppose that the data that are available for testing or quantifying the model regard *at most* the following objects: the fundamentals, the agents' expectations of their fundamentals, their expectations of the endogenous state, and their actions. Then, the testable implications, or predictions, of the model are the restrictions that it imposes on the joint distribution of these objects. Of course, one can expand this list of objects by including the information sets and/or the higher-order beliefs. For applied purposes, however, this seems redundant, because data on information sets and higher-order beliefs are hardly available, in contrast to data on choices and on forecasts of economic outcomes. With these points in mind, we let π_i denote the expectation of agent i about $\mathbf{K}$; we let $\mathbf{\Pi}$ denote the distribution of such expectations in the population; and we adopt the following definition.

Definition 5 The *predictions* of the model are the restrictions it imposes on the joint distribution of $(\theta_i, b_i, \pi_i, k_i, \mathbf{\Theta}, \mathbf{B}, \mathbf{\Pi}, \mathbf{K})$.

One can thus think of any model as a "box" that takes the joint distribution of $(s_i, \mathbf{S})$ as an input and delivers a joint distribution for $(\theta_i, b_i, \pi, k_i, \mathbf{\Theta}, \mathbf{B}, \mathbf{\Pi}, \mathbf{K})$ as an output. Depending on the question of interest and/or the available data, one can then look at certain conditionals or marginals of the aforementioned distribution, or certain moments of it. One can thus also answer the following type of applied questions: How much does individual activity respond to idiosyncratic shocks to fundamentals? What is the corresponding response of aggregate activity to aggregate shocks to fundamentals? Are expectations of economic outcomes pinned down by expectations of fundamentals? What is the volatility in aggregate economic activity and how much of it is explained by volatility in fundamentals?

To illustrate, consider our earlier neoclassical economy from Section 2.2, in which case θ_i captures the exogenous TFP of an agent (farmer, firm, or island) and k_i captures her production level. Assume that TFP is log-normally distributed in the cross section, let $\overline{\theta}$ denote the aggregate log-TFP, and assume $\omega_i = (\theta_i, \overline{\theta})$; the latter means that every agent knows perfectly both her own TFP level and the aggregate TFP level. These assumptions, in conjunction with the power-form specification of preferences and technologies, imply that the equilibrium levels of output at the individual and the aggregate level are given by, respectively,

$$\log q_i \equiv k_i = \kappa_1(\theta_i - \overline{\theta}) + \kappa_2\overline{\theta} \quad \text{and} \quad \log Q \equiv K = \kappa_2\overline{\theta},$$

where κ_1 and κ_2 are fixed scalars, pinned down by the underlying preference and technology parameters. Equilibrium outcomes are therefore pinned down by fundamentals—and so are equilibrium expectations. Furthermore, the joint distribution of $(\theta_i, b_i, \pi_i, k_i, \mathbf{\Theta}, \mathbf{B}, \mathbf{\Pi}, \mathbf{K})$ is now conveniently summarized by the distribution of $(\theta_i, k_i, \overline{\theta}, K)$, Turning to some of the applied questions raised above, note that the "micro" elasticity of the response of individual output to idiosyncratic TFP shocks is given by κ_1, whereas the corresponding "macro" elasticity is given by κ_2. Finally, note that

$$\kappa_1 = \frac{Cov(k_i, \theta_i | \overline{\theta})}{Var(\theta_i | \overline{\theta})} \quad \text{and} \quad \kappa_2 = \frac{Cov(K, \overline{\theta})}{Var(\overline{\theta})},$$

which illustrates how the joint distribution of $(\theta_i, k_i, \overline{\theta}, K)$ contains the model's predictions about the two elasticities of interest.[n]

Later on, we will explore how this kind of predictions change as one departs from standard informational assumptions. Importantly, we will draw a distinction between two kinds of departure: those that regard the information, or beliefs, agents have about their fundamentals; and those regard the information, or beliefs, agents have about one another's beliefs and the associated friction in coordination (or lack thereof).

To do so, we need to introduce a few additional definitions. We start by distinguishing the two kinds of uncertainty mentioned in the Introduction.

Definition 6 An agent faces *fundamental uncertainty* if and only if, conditional on her information, she is uncertain about the value of $(\theta_i, \mathbf{\Theta})$.

Definition 7 An agent faces *uncertainty about the actions of others*, or about the economy's outcome, if and only if, conditional on her information, she is uncertain about the value of $\mathbf{K}$.

As noted in the Introduction, the latter type of uncertainty is connected to the notion of strategic uncertainty in games. In what follows, we use the term "strategic uncertainty" to refer to the type of uncertainty defined in Definition 7 and proceed to study how incomplete information helps accommodate such uncertainty in equilibrium. This is consistent with Morris and Shin (2002a, 2003). Note, however, that the same term is often used in game theory to refer to a distinct object, namely the uncertainty that agents may face about the strategies of others outside equilibrium.

Also note that Definitions 6 and 7 refer to the uncertainty the agents face in the interim stage, after they have received their information, as opposed to the stochasticity that exists at the ex ante stage. For instance, consider the neoclassical economy introduced in Section 2.2 and suppose that TFP is random but perfectly observed. We would say that the agents in this economy face no fundamental uncertainty.[o]

The aforementioned definitions invite us to put ourselves in the shoes of a particular agent and to examine the uncertainty the agent faces conditional on her information. The next definition, instead, invites us to inspect the cross-section of agents conditional

[n] Macroeconomists are primarily interested in the macro elasticity, κ_2. Empirical studies that use macro data, such as the paper by Gali (1999) reviewed in Section 8.1, seek to estimate this elasticity directly. By contrast, studies based on cross-sectional data concentrate on the identification of the micro-level elasticity, κ_1 (where "micro" may mean either at the level of an individual firm/household, or at the level of a region). The difference between the two types of elasticities reflects general-equilibrium effects that operate at the aggregate level and can thus not be identified from the cross section. See, however, Section 8.2 for a discussion of how incomplete information can help reduce this difference in the short run.

[o] One has to be careful with the extension of this notion to dynamic applications: in the RBC model (with capital), we would say that fundamental uncertainty is absent when the agents know, not on current TFP, but also future TFP.

on the state of nature. It then asks the following question: have the agents been able to reach a common belief about the relevant economic outcomes?

Definition 8 *Coordination is imperfect* in state **S** if and only if, in that state, a positive measure of agents fail to reach the same belief about **K**.

To see what motivates this definition, consider the following hypothetical scenario. Prior to playing an equilibrium, the agents get together in the same room and communicate with one another until they reach common knowledge, not only of the fundamentals, but also of their intended actions and the relevant economic outcomes (ie, of **K** in our setting). We think of this situation as being conducive to "perfect coordination." Conversely, we say that there is a friction in coordination if agents are unable to reach a common belief about one another's actions and thereby about the relevant economic outcomes.

The following remark helps refine the friction we are after. In our framework, once we impose equilibrium, reaching the same belief about the choices of others means facing no uncertainty about them. The last property, however, is an artifact of the static nature of our framework. In dynamic settings, agents may face uncertainty about the *future* choices of others, even if they do not face any uncertainty about the *current* choices of others. Reaching a common belief about the relevant economic outcomes is therefore distinct from facing no uncertainty about them. In particular, standard macroeconomic models accommodate for uncertainty in future economic activity, due to uncertainty in future fundamentals; they nevertheless impose that agents always hold exactly the same equilibrium beliefs about all future economic outcomes. It is this restriction—the unanimous consensus about the current state and the future prospects of the economy—that we interpret as perfect coordination and that we seek to depart from.

We can now also elaborate on our earlier claim that some of the related applied literature either confounds the roles of payoff and strategic uncertainty, or is exclusively concerned with fundamental uncertainty. When Sims (2003), Reis (2006), and Gabaix (2014) introduce different (but also complementary) formalizations of "inattention," they focus on single-agent decision problems, thus precluding a meaningful distinction between the two types of uncertainty.[p] When Bloom (2009), Bloom et al. (2014), and Arellano et al. (2012) study the role of "uncertainty shocks," or when Jaimovich and Rebelo (2009), Christiano et al. (2008), Beaudry and Portier (2006), Barsky and Sims (2011, 2012), and Blanchard et al. (2013) study the role of "news" and "noise shocks," they consider different facets of fundamental uncertainty,

[p] The same applies to many of the recent applications of rational inattention, including Luo (2008), Matejka (2015a,b), and Matejka et al. (2015); but not to those that let rational inattention be, in effect, a specific micro-foundation of strategic uncertainty, such as Maćkowiak and Wiederholt (2009, 2015). See Section 8.5 for further discussion.

but do not accommodate the kind of strategic uncertainty, or the friction in coordination, that we are after in this chapter.[q]

By contrast, when Aumann (1974, 1987) introduced the concept of correlated equilibrium and formalized its connection to Bayesian rationality in games, he ruled out fundamental uncertainty and used incomplete information to model *exclusively* uncertainty about the actions of others. A similar point applies to Rubinstein's (1989) "email game": an imperfection in communication was introduced in order to inhibit coordination, not to add uncertainty in payoffs.

The preceding observations help clarify the theme of this chapter. However, as noted in the Introduction, a sharp separation between fundamental and strategic uncertainty may not always be possible, especially once we impose equilibrium.

For instance, in the models we study in Sections 7 and 8, the equilibrium is a unique irrespective of the information structure and the action of each agent is pinned down by her hierarchy of beliefs about the fundamentals. It follows that uncertainty about the equilibrium value of $\mathbf{K}$ can obtain in any particular state if and only if the agents lack common knowledge of fundamentals in that state, which in turns means that at least some of them face fundamental uncertainty in some state of nature.

What is more, suppose that all agents share the same fundamental, namely $\theta_i = \overline{\theta}$ for all i, and that the information of each agent i consists of a single private signal $x_i = \overline{\theta} + \epsilon_i$, where ϵ_i is idiosyncratic noise that is drawn from a commonly known distribution and that washes out at the aggregate level. Under these assumptions, $\overline{\theta}$ becomes a sufficient statistic for $\mathbf{\Omega}$, the profile of information in the cross section, and thereby also for the equilibrium profile of actions. One we impose equilibrium, no *apparent* difference therefore remains between the two types of uncertainty: predicting $\mathbf{K}$ is the same as predicting $\overline{\theta}$.

To better appreciate the role of strategic uncertainty, it is therefore useful to do one, or both, of the following: (i) consider sufficient rich information structures that make sure that the uncertainty agents face about $\mathbf{K}$ is not spanned by their uncertainty about fundamentals; (ii) momentarily drop equilibrium and, instead, contemplate the kind of higher-order reasoning that may justify certain forecasts of $\mathbf{K}$ on the basis of the common knowledge of the environment and of the rationality of the agents. Both of these paths will be explored throughout this chapter.

[q] The same statement applies to the baseline model in Lorenzoni (2009): the key mechanism in that paper rests on the uncertainty consumers face about future fundamentals (TFP) and the deviation of monetary policy from replicating flexible-price allocations. The paper contains also an extension that features dispersed information. This extension is used to justify higher fundamental uncertainty and to raise the quantitative potential of the aforementioned mechanism. It also makes a contribution to the literature we are concerned with, because of the elegant ways in which the author deals with the geography of information and the dynamics of learning. Yet, the key mechanism does not rest on the dispersion of information, and is therefore outside the scope of our chapter.

Remark 12 No matter the information structure, once equilibrium is imposed, the distinction between the two forms of uncertainty becomes blurred in the eyes of the agents inside the model: both the fundamentals and the endogenous outcomes are treated by each agent as exogenous stochastic processes. In the eyes of the outside observer, however, the two forms of uncertainty can be distinguished by the different marks they leave on the observables of the model. Dissecting this difference is an integral part of this chapter.[r]

3.2 Informational Friction

As noted in the Introduction, the present chapter views incomplete information as a device for introducing frictions in coordination, rather than as a device for introducing uncertainty about payoff-relevant fundamentals such as technology and preferences. In this context, we now proceed to clarify two distinct forms of informational friction and to point out which one is more relevant for our purposes.

Definition 9 Information is said to be *perfect* if $(\theta_i, \mathbf{S})$ is known to all agents in all states $\mathbf{S}$. If the converse is true, information is said to be *imperfect*.

Definition 10 Information is said to be *complete* if $\mathbf{\Omega}$ is known to all agents (or at least to all but a zero-measure set of agents) in all states of nature. If the converse is true, information is said to be *incomplete*.

This terminology differs somewhat from the one typically found in the related applied literature, where terms "informational friction" and "imperfect," "dispersed," or "heterogeneous" information are often used to refer to either of the two concepts defined above. The problem is that, although many papers depart from the clearly defined benchmark of perfect information, it is not always clear whether their key departure is (i) the introduction of some type of fundamental uncertainty or (ii) the relaxation of common knowledge and the associated strategic uncertainty. With the above two definitions, we seek to clarify the difference between two important types of informational frictions.[s]

Note, in particular, that perfect information imposes common knowledge of both $\mathbf{\Omega}$ and $\mathbf{\Theta}$, whereas complete information imposes only common knowledge of $\mathbf{\Omega}$.[t] For example, suppose that $\mathbf{\Omega}$ is commonly known, but $\mathbf{\Theta}$ is not. Then, information is *imperfect*

[r] This remark is consistent with the Bayesian approach to games (eg, Harsanyi, 1967-1968; Aumann, 1987; Aumann and Heifetz, 2002); but it also reinforces why we treat incomplete information and higher-order beliefs as instruments for generating first-order uncertainty about equilibrium outcomes, rather than objects of independent interest.

[s] Note that our notion of incomplete information is the same as the one found in game theory, but our notion of imperfect information is distinct. Although we regret this discrepancy, we believe that the definitions we adopt here help clarify both the language used in macroeconomics and the mechanisms featured in different applications.

[t] To be precise, our definition of complete information requires only *mutual* knowledge of $\mathbf{\Omega}$. But since $\mathbf{\Omega}$ is the entire profile of Harsanyi, mutual knowledge of $\mathbf{\Omega}$ implies common knowledge of $\mathbf{\Omega}$.

in the sense that the agents are uncertain about one another's fundamentals, and yet information is *complete* in the sense that the agents face no uncertainty about one another's information sets. Finally, note that our definition of complete information rules out private information about aggregate shocks, but allows for private information about idiosyncratic shocks; that is, complete information imposes that all agents share the same beliefs about both $\mathbf{\Theta}$ and more generally about $\mathbf{S}$, but allows each agent to know more than others about the idiosyncratic component of her fundamental.[u]

3.3 Imperfect Coordination Equals Incomplete Information

So far, the notions of imperfect coordination, strategic uncertainty, and incomplete information have been defined in a manner that allows them to be disconnected from one another. However, once equilibrium is imposed, these notions become essentially the same.

Proposition 1 (Information and Coordination) *The following are true only when information is incomplete:*

(a) *higher-order beliefs of fundamentals diverge from first-order beliefs;*

(b) *agents face uncertainty about the actions of others in any given equilibrium;*

(c) *coordination is imperfect in any given equilibrium.*

We prove this by showing that complete information rules out (a), (b), and (c). Recall first that first-order beliefs $\mathbf{B}$ are pinned down by $\mathbf{\Omega}$. If information is complete, meaning that $\mathbf{\Omega}$ is commonly known, then so is $\mathbf{B}$. The common-prior assumption then imposes that higher-order beliefs collapse to first-order beliefs. Next, note that, in any given equilibrium, the endogenous outcome $\mathbf{K}$ is given by a known function $\mathbf{K}^*$ of the realized $\mathbf{\Omega}$. If the latter is commonly known, then so is $\mathbf{K}$.[v] That is, complete information rules out strategic uncertainty in equilibrium. Finally, note that the equilibrium beliefs of $\mathbf{K}$ are pinned down by the beliefs of $\mathbf{\Omega}$, which themselves collapse to a Dirac on the true $\mathbf{\Omega}$

[u] The last point underscores that the heterogeneity, or dispersion, of information that is relevant for our purposes is the one that regards aggregate shocks, as opposed to the one that is at the center of the Mirrlees literature (aka New Public Finance): that literature introduces private information about idiosyncratic fundamentals in order to accommodate certain incentive problems, but maintains the assumption that all aggregate shocks (including the cross-sectional distribution of information sets) are commonly known, thus ruling out all the effects that are of interest to us in this chapter.

[v] If there are multiple equilibria, the function $\mathbf{K}^*$ varies across equilibria, but it is commonly known to the agents in any given equilibrium. This is true even in the case of sunspot equilibria; this case is nested by allowing ω_i to contain a publicly observed sunspot. Finally, if we consider correlated equilibria with imperfect correlation, the function $\mathbf{K}^*$ is still commonly known in any equilibrium, but now different agents have different beliefs about the realized $\mathbf{K}$, simply because they have private information about the underlying correlation devices and therefore also about $\mathbf{\Omega}$.

when information is complete. It follows that all agents share the same belief about $\mathbf{K}$, which means the friction in coordination vanishes.

These arguments prove that incomplete information is necessary for obtaining (a), (b), and (c) in Proposition 1. Sufficiency is also true, provided we consider nontrivial forms of incomplete information; this will become clear as we proceed.[w] Furthermore, one can strengthen part (b) to read as follows: a agent can face uncertainty about $\mathbf{K}$ even if she knows $\boldsymbol{\Theta}$, or even if she knows both $\boldsymbol{\Theta}$ and $\{\mathbf{B}^h\}_{h=1}^H$ up to any finite H. This illustrates the richness of the uncertainty that agent can face about one another's equilibrium actions and the associated economic outcomes when, and only when, information is incomplete.

Apart from clarifying how complete information rules out the friction we are after in this chapter, the above result also highlights the following point.

Fact Workhorse macroeconomic models typically rule out imperfect coordination, not only because they assume complete information, but also because they impose a strong solution concept.

This is due to the fact that the Rational-Expectations Equilibrium concept *itself* rules out uncertainty about the *strategies* of other agents, regardless of the information structure and the number of equilibria. It follows then that the agents can face uncertainty about the actions of others in equilibrium if and only if they do not share the same information, which is how incomplete information is defined.

Yet, this does not mean that incomplete information must be taken literally: as hinted in the Introduction, one can view incomplete information also as a substitute for relaxing the equilibrium concept.

Let us elaborate on what we have in mind. Fix a standard macroeconomic model, such as the textbook RBC model or its New-Keynesian sibling. These models deliver certain predictions about the nature of the business cycle, namely about the comovement of key economic outcomes such as employment, consumption, and investment with one another, as well as with the underlying shocks to TFP or other fundamentals. These predictions rely, not only on features of the micro-foundations such as the Frisch elasticity of labor supply and the degree of price stickiness, but also on the combination of a strong solution concept with strong informational assumptions—a combination that imposes flawless coordination in beliefs.

Macroeconomists have long debated about the elasticity of labor supply, the degree of nominal rigidity, and numerous other aspects of the micro-foundations of macroeconomic models, but have paid relatively little attention to the bite that the aforementioned combination has on the predictions of their models, and thereby on their interpretation of the data. By contrast, it is precisely this combination which we are uncomfortable with and whose bite we would like to relax. Incomplete information

[w] See also Weinstein and Yildiz (2007a).

is a vehicle for doing so and, in this sense, it is also as a substitute for relaxing the solution concept.[x]

Summing up, we have now formalized the following point, which was anticipated in the Introduction.

Fact Incomplete information is a modeling device that expands the sources of uncertainty the economic agents face about endogenous economic outcomes and that allows the expectations of these outcomes to deviate from the expectations of fundamentals.

We conclude this section by noting that, for our purposes, the uncertainty agents may face about their *own* fundamentals is of little consequence on its own right. To formalize this point, let

$$\hat{U}(k_i, \mathbf{K}, b_i) \equiv \int U(k_i, \mathbf{K}, \theta_i) db(\theta_i, \Theta),$$

where b_i is the agent's first-order belief.[y] The following is then immediate.

Proposition 2 *The equilibrium set of the original model coincides with the equilibrium set of a variant model in which the agents are always perfectly informed about their own fundamentals. In this variant games, payoffs are given by $\hat{U}(k, \mathbf{K}, \hat{\theta}_i)$, individual fundamentals by $\hat{\theta}_i \equiv b_i$, and aggregate fundamentals by $\hat{\Theta} \equiv \mathbf{B}$.*

In this sense, we can always recast any given model as one in which the agents are perfectly informed about their own fundamentals. Of course, this does not mean that uncertainty about fundamentals is irrelevant. There is a long tradition in macroeconomics that studies different kinds of fundamental uncertainty within complete-information, and often representative-agent, models. Examples include a voluminous literature on the equity premium, as well as the recent literatures on news and uncertainty shocks. The sole role of the above result is to underscore, once more, the type of uncertainty that we are interested in. For our purposes, it is not relevant per se whether each agent knows her *own* fundamental; what is relevant is whether agents have common knowledge of *aggregate* fundamentals. To isolate the latter channel, we will therefore occasionally consider examples in which every agent *i* knows her own θ_i perfectly, but not necessarily $\mathbf{\Theta}$. By contrast, the leading example in the literature shuts down heterogeneity ($\theta_i = \theta$ for all *i*)

[x] In this regard, the approach we take in this chapter can be viewed as complementary to, albeit distinct from, the approaches taken by Evans and Honkapohja (1999, 2009), Guesnerie (1992, 2008), Fuster et al. (2010), Kurz (1994, 2012), and Sargent (2008). See also the review in Woodford (2013). What is common between our approach and these alternative approaches is the desire to relax, or enrich, the stochastic structure of beliefs.

[y] Note that the definition of $\hat{U}$ treats $\mathbf{K}$ as a deterministic variable: the possibility that $\mathbf{K}$ correlates with $\mathbf{\Theta}$ in equilibrium is not relevant here. By the same token, $\hat{U}$ depends on b_i only through the marginal of b_i over θ_i; that is, it depends on the agent's belief about her *own* fundamental, but is otherwise invariant to her belief about the *aggregate* fundamentals.

and confounds the lack of common knowledge of aggregate fundamentals with uncertainty about own fundamentals.

3.4 Complete-Information Benchmark and Coordination Motives

Section 3.3 clarified the sense in which incomplete information introduces a friction in coordination. To elaborate on the observable implications of this friction and the applied value of the approach taken in this chapter, we will have to get more concrete. This is what we do in Sections 4–8. As a prelude to this, however, it is useful to work out the complete-information benchmark of our abstract framework. We do so in this section with the help of additional, simplifying, assumptions on the action space D_k and the payoff function U. We then use this benchmark to identify a feature that distinguishes the type of models studied in Sections 4–6 ("global games" and their applications) from those studied in Sections 7 and 8 ("beauty contests" and their applications), namely a feature that regards the strength of coordination motives.

With the function $\hat{U}$ defined as before, we impose the following:

Assumption 1 D_k is a closed interval in $\mathbb{R}$ and $\hat{U}$ is strictly concave and twice differentiable in k.

This simplifies the analysis by letting the action be uni-dimensional and by guaranteeing both the existence and the uniqueness of a solution to the individual's decision problem, that is, to the choice of k_i that is optimal for given beliefs of fundamentals and of the actions of others. We express this solution as follows:

$$k_i = \gamma(\mathbf{K}, b_i) \equiv \arg\max_k \hat{U}(k, \mathbf{K}, b_i).$$

Note here that agent i faces no uncertainty about $\mathbf{K}$, not only because information is complete, but also because she knows that others play a given equilibrium. That is, as anticipated, strategic uncertainty has been ruled out by the combination of a strong informational assumption with a strong solution concept.

With this in mind, we have the following result.

Proposition 3 (Complete Info) *Suppose information is complete. There exists a function Γ, which depends only on the function $\hat{\mathrm{U}}$, such that the following is true: in any equilibrium and any state of nature, $\boldsymbol{K}$ solves*

$$\mathbf{K} = \Gamma(\mathbf{K}, \mathbf{B}). \tag{8}$$

This result follows trivially from letting $\Gamma(\mathbf{K}, \mathbf{B})$ be the distribution of k that obtains when $k = \gamma(\mathbf{K}, b)$ and by noting that the function γ is essentially exogenous, in the sense that it is pinned down by the function $\hat{U}$. When the equilibrium is unique, this result means that equilibrium actions are pinned down *exclusively* by first-order beliefs of fundamentals. When, instead, there are multiple equilibria, the theory makes room for sunspots, that is, for random selections across the multiple solutions of condition (8). For any such selection, however, the equilibrium value of $\mathbf{K}$ remains tied to $\mathbf{B}$ through condition (8). Furthermore, whether the equilibrium is unique or not, the heterogeneity in the cross-section of actions is pinned down by the heterogeneity in beliefs of own fundamentals.[z] Finally, if information is perfect (which, recall, is a stronger requirement than the requirement of complete information), nothing essential changes: we merely need to replace b_i with θ_i and $\mathbf{B}$ with $\mathbf{\Theta}$.

By contrast, these restrictions are relaxed when information is incomplete: equilibrium outcomes, whether at the aggregate level or in the cross section, may depend on higher-order beliefs, which themselves may differ from first-order beliefs. What exactly this implies for the observables of any given model will be explored in the subsequent sections of this chapter. For now, we continue with the complete-information benchmark.

To further sharpen the analysis, we next impose the following:

Assumption 2 $\hat{U}_k$ depends on $\mathbf{K}$ only through the mean action K and is differentiable in it.

We can then rewrite the best response of agent i as $k_i = g(K, b_i)$, where g is a function that is differentiable in K and that is implicitly defined by the solution to $\hat{U}_k(g(K,b),K,b)=0$. Aggregating gives

$$K = G(K,\mathbf{B}),$$

where the function $G: D_k \times D_{\mathbf{B}} \to D_k$ is defined by $G(K,\mathbf{B}) \equiv \int g(K,b)d\mathbf{B}(b)$. This is essentially the same as Proposition 3 above, except for the fact that we now have a fixed-point relation in the mean action K alone as opposed to the entire distribution $\mathbf{K}$.

Since g is differentiable in K, G is also differentiable in K (as well as continuous in it). This, together with the compactness of D_k, guarantees the existence of equilibrium. To characterize the determinacy of the equilibrium, we introduce the following notions.

Definition 11 The economy exhibits *strategic substitutability* if and only if $G_K(K, \mathbf{B}) < 0$ for all $(K, \mathbf{B})$; and *strategic complementarity* if and only if $G_K(K, \mathbf{B}) > 0$ for all $(K, \mathbf{B})$.

Definition 12 Strategic complementarity is of the *weak* form if $G_K(K, \mathbf{B}) \in (0, 1)$ for all $(K, \mathbf{B})$, and of the *strong* form if $G_K(K, \mathbf{B}) > 1$ for some $(K, \mathbf{B})$ such that $K = G(K, \mathbf{B})$ and K is in the interior of D_k.

We have the following result.

Proposition 4 (Equilibrium Determinacy) *Suppose information is complete.*

(i) *An equilibrium always exists.*

(ii) *The equilibrium is unique if the economy exhibits either strategic substitutability or weak strategic complementarity.*

(iii) *There exist multiple equilibria if the economy exhibits strong strategic complementarity.*

[z] To see this, note that $k_i = \gamma(\mathbf{K}, b_i)$ can differ across two agents only if these agents have a different b_i; and because all agents have the same beliefs about $\mathbf{\Theta}$, different b_i means different beliefs about θ_i.

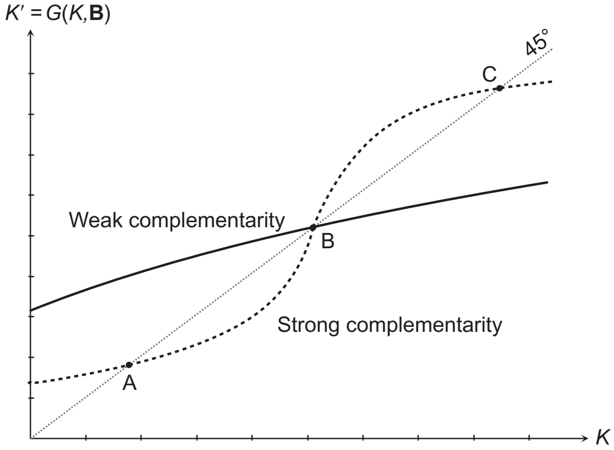

Fig. 1 Best responses with weak and strong complementarity.

We illustrate these possibilities in Fig. 1 for two examples. In both examples, we fix a particular realization of $\mathbf{B}$ and draw $G(K, \mathbf{B})$ against K. The case of weak complementarity corresponds to the solid curve, which intersects only once with the 45-degree line; point B then gives the unique equilibrium value of K, for a given value of $\mathbf{\Theta}$. The case of substitutability is similar and is thus omitted. The case of strong complementarity, on the other hand, corresponds to the dotted curve, which intersects three times with the 45-degree line; points A and C then give the two stable equilibrium outcomes of the economy, whereas point B represents an unstable equilibrium outcome.[aa]

The above categorization anticipates the two classes of models we study in the sequel: Section 4 introduces a class of models that feature strong complementarity and that have been used to study self-fulfilling crises; Section 7 turns attention to a class of models that feature weak complementarity and that are commonly used to study business cycles and asset prices. These two classes of models behave quite differently, not only under complete information, but also under incomplete information. This is because the impact of higher-order uncertainty depends on how essential coordination is in the first place. As a result, higher-order uncertainty has a more pronounced effect in the former class than in the latter one.[ab]

We conclude this section by noting how complete information ties "animal spirits" to equilibrium indeterminacy. To formalize this point, we define the notion of animal spirits as follows.

[aa] The notion of stability used here is that of iterated best responses.

[ab] In particular, the beauty contests studied in Section 7 pass Weinstein and Yildiz's (2007b) criterion of "global stability under uncertainty," which means that beliefs of sufficiently high order have a vanishing effect. This is not the case with either the static global games of Section 4, or the related dynamic games of Section 6.

Definition 13 The economy features *animals spirits* if there are two states ($\mathbf{S}_1$, $\mathbf{S}_2$), with respective beliefs of fundamentals ($\mathbf{B}_1$, $\mathbf{B}_2$) and respective outcomes ($\mathbf{K_1}$, $\mathbf{K}_2$), such that $\mathbf{B}_1 = \mathbf{B}_2$ and $\mathbf{K}_1 \neq \mathbf{K}_2$.

This definition is consistent with those found in Cass and Shell (1983) and the extant macroeconomic literature on sunspot fluctuations: it simply says that equilibrium actions can vary without any variation in the agent's beliefs of the fundamentals. For instance, if we consider the textbook RBC model, animal spirits would require that employment, investment, and consumer spending vary without any commensurate variation in the firms' and the consumers' beliefs of preferences and technologies.[ac]

Note now that the action of any given agent is always pinned down by her belief of her fundamental and her belief of the actions of others. It follows that two states can be associated with different equilibrium outcomes even when they contain the same beliefs about the fundamentals only if the two states are associated with different equilibrium beliefs about the endogenous outcomes themselves. In this sense, the notion of animal spirits is inherently tied to the notion of self-fulfilling beliefs. Finally, the following is true.

Corollary 1 *Suppose information is complete. The economy can feature animal spirits if and only if it admits multiple equilibria.*

This result highlights more generally the tendency in the profession to associate the notion of animal spirits with models that admit multiple equilibria, and to treat this notion as inconsistent with the class of unique-equilibrium DSGE models often used in the study of business cycles and monetary policy. In this context, a key point of our analysis will be to show how incomplete information blurs the distinction between multiple- and unique-equilibrium models in two complementary ways: first, by inducing equilibrium uniqueness in models that admit multiple equilibria under complete information; and second, by allowing animal spirits to obtain despite a unique equilibrium.[ad]

Remark 13 Recall that our definition of complete information requires that agents share the same information, not only with regard to the underlying fundamentals, but also with regard to *everything* else. This allows for public sunspots but rules out *imperfect* correlation devices as in Aumann's (1974; 1987) work on correlated equilibrium. If, instead, one imposes common knowledge of fundamentals but allows private information about payoff-irrelevant variables, then one can devise examples in which (i) there is a unique correlated equilibrium and (ii) this equilibrium features animal spirits because agents respond to their private information about the underlying correlation devices in this equilibrium. To see this, consider a three-player variant of the "matching pennies" game

[ac] Our notion of animal spirits should therefore not be confused with the less-common notion adopted in Lorenzoni (2009) and Barsky and Sims (2012): in these papers, "animal spirits" are defined as the noise in a public signal of future TFP, that is, as a particular shock to beliefs of fundamentals.

[ad] An alternative approach, which will not be considered in this paper, is to formalize "animal spirits" as a deviation from individual rationality. See, eg, Akerlof and Shiller (2010).

in which there is no (Nash) equilibrium in pure strategies, but there is a correlated equilibrium in which the two players coordinate on playing a jointly mixed strategy against a mixed strategy of the third player. Although this example is too contrived to be of any practical relevance, it clarifies the following point: in general, incomplete information can help sustain "animal spirits," not only by introducing higher-order uncertainty about the fundamentals, but also by sustaining strategic uncertainty even in settings that maintain common knowledge of fundamentals.

Consider now an overlapping-generations macroeconomic model in which the fundamentals are common knowledge and remain constant over time, but a different sunspot is realized in every period. Even if the sunspot is publicly observed in the period that is realized, the model is akin to a game with imperfect correlation devices, because the generation of agents that acts in any given period does not see the sunspot upon which future generations can condition their choices. This example underscores that the concept of sunspot equilibria in *dynamic* macroeconomic models is closely related to the concept of correlated equilibria, which itself allows for incomplete information. As a consequence, the sunspot volatility that has been documented in prior work does not *strictly* require equilibrium multiplicity. For a more detailed discussion of these issues, we refer the reader to Aumann et al. (1988) and Peck and Shell (1991); see also Jackson and Peck (1991) and Solomon (2003) for two applications of these ideas.

4. GLOBAL GAMES: THEORY

In this section, we restrict attention to a special case of our framework that imposes strong complementarity. We view this case as representative of a variety of multiple-equilibrium models that were developed in order to formalize the idea that macroeconomic outcomes are driven by coordination failures, self-fulfilling beliefs, and animal spirits.[ae] Of course, our framework is too stylized to capture either the rich micro-foundations or the intricate dynamics of some of these models. Nonetheless, the case studied contains two key features from the related literature: the role of coordination and the existence of multiple self-fulfilling equilibria under complete information.

The main theme of this section is to show how the introduction of incomplete information in such settings can induce a unique equilibrium, possibly one in which outcomes are pinned down merely by the underlying fundamentals. In addition, we establish the existence of a certain type of discontinuity in equilibrium outcomes as we move from the complete-information benchmark to a perturbation with arbitrarily small noise in the

[ae] See, inter alia, Azariadis (1981), Benhabib and Farmer (1994, 1999), Cass and Shell (1983), Cooper and John (1988), Cooper (1999), Diamond and Dybvig (1983), Farmer (1996), Farmer and Woodford (1997), Guesnerie (1992), Howitt and McAfee (1992), Murphy et al. (1989), Matsuyama (1991, 1995), Obstfeld (1986, 1996), Shell (1977, 1987), and Woodford (1986, 1991).

agent's information of the fundamentals. Combined, these results provide a sharp illustration of the potential sensitivity of the predictions of the theory the kind of friction we study in this chapter. They also highlight that the driving force is the uncertainty faced by agents about one another's actions, rather than their uncertainty about the underlying fundamentals. With this in mind, we then proceed to describe the distinct role that private and public information play in shaping the level of strategic uncertainty.

The analysis in this section builds heavily on the influential contributions of Carlsson and Van Damme (1993a,b) and Morris and Shin (1998, 2001, 2003). Carlsson and Van Damme's work highlighted the possible fragility of multiple equilibria by showing how small perturbations of the payoff and information structures can guarantee a unique rationalizable outcome within arbitrary two-by-two games (two players, two actions). This outcome was also shown to coincide with the one selected by the risk-dominance criterion proposed by Harsanyi and Selten (1988). Morris and Shin's work extended this type of result to models that were better suited for macroeconomics and finance, thus paving the way to a large applied literature; it also expanded the theoretical foundations.

Remark 14 The closely related contributions of Chamley (1999), Frankel and Pauzner (2000), and Burdzy et al. (2001) were made at roughly the same time as those of Morris and Shin. An important precedent to all these works is Rubinstein (1989), which first highlighted the fragility of coordination to perturbations of common knowledge.

Remark 15 The term "global game" was introduced by Carlsson and Van Damme (1993b) within the context of two-by-two games that had the following key features: first, information was incomplete; second, types could be ordered in such a way that one action is dominant for sufficiently low types and another action is dominant for sufficiently high types. In the subsequent literature, the number of players and actions is often larger, and strategic complementarity is often imposed, yet appropriate versions of the aforementioned key features are maintained. For the purposes of our paper, we restrict attention to a particular class of games that are often referred to in the literature as "games of regime change."

4.1 Setup

Throughout this section, we impose that actions are binary, that there is no heterogeneity in fundamentals, and that payoffs take a particularly simple form.

Assumption 3 (Global Game) $D_k = \{0, 1\}$ and $D_\theta = \mathbb{R}$. Furthermore, θ_i is identical across i and is henceforth denoted simply by θ. Finally,

$$u_i = U(k_i, K, \theta) = \begin{cases} k_i(b-c) & \text{if } K \geq \theta \\ -k_i c & \text{if } K < \theta \end{cases}$$

where K is the average action (equivalently, the fraction of the population that chooses $k = 1$) and where b and c are known positive scalars, and b > c.

The key feature of this specification is that it represents environments with strong strategic complementarity. As long as the agent faces no uncertainty about either K or θ, her best response is given by $k = G(K, \theta)$, where

$$G(K,\theta) \equiv \arg \max_{k \in \{0,1\}} U(k,K,\theta) = \begin{cases} 1 & \text{if } K \geq \theta \\ 0 & \text{if } K < \theta \end{cases}$$

It is therefore as if the best response of an agent has infinite slope in a neighborhood of $K = \theta$.

Remark 16 The definition of strong complementarity that we introduced in Section 3.4 requires that G is continuous and that it has slope higher than one in a point where it crosses the 45^o line. Here, G is discontinuous, so the earlier definition does not apply anymore, but the essence remains the same. Also, note the following slight abuse of notation: before, G was a function of $\mathbf{B}$, the entire cross-sectional distribution of first-order beliefs; now, it is a function of θ, because the latter happens to be sufficient statistic for $\mathbf{B}$ under the specification we consider in this section.

4.2 Interpretation

To ease the transition to applications, and following Angeletos et al. (2007), we interpret the aforementioned payoff specification as a "game of regime change."

There are two possible regimes, the status quo and an alternative. Each agent can choose between an action that is favorable to the alternative regime and an action that is favorable to the status quo. We henceforth refer to these actions as, respectively, "attack" and "not attack." We denote the regime outcome with $R \in \{0, 1\}$, where $R = 0$ represents the survival of the status quo and $R = 1$ represents its collapse. We similarly denote the action of an agent with $k_i \in \{0, 1\}$, where $k_i = 0$ represents "not attack" and $k_i = 1$ represents "attack." Next, we normalize the payoff from not attacking to zero and let the payoff from attacking be $b-c > 0$ if the status quo is abandoned and $-c < 0$ - otherwise. This means that it is individually optimal to attack the status quo if and only if the latter is expected to collapse. Finally, we assume the status quo is abandoned ($R = 1$) if and only if

$$K \geq \theta,$$

which means that θ identifies the minimal size of attack that is needed for the status quo to be overturned. It then follows that the payoff of the agent can be expressed as in Assumption 3.

One may wish to interpret the above game as a model of revolutions and political change.[af] Perhaps more interestingly for macroeconomics, the above game can be used to capture the role of coordination in the context of financial crises.

[af] See, eg, Atkeson (2000) and Edmond (2013) for related interpretations.

Consider, in particular, the literature on self-fulfilling currency attacks, such as Obstfeld (1996). In this context, the players can be interpreted as speculators choosing whether to attack a currency peg or not; θ represents the resources (eg, reserves) that are available to the central bank for defending the peg, or more generally, the ability and the willingness of the policy maker to withstand a speculative attack; c represents the interest-rate differential between domestic and foreign assets, or other costs suffered by a speculator when short-selling the domestic currency; b represents the gains of an attacking speculator in the event of devaluation; and a "regime change" occurs when a sufficiently large mass of speculators attacks the currency, forcing the central bank to abandon the peg.

Similarly, in models of self-fulfilling bank runs, such as Diamond and Dybvig (1983), θ may represent the liquidity of a bank or of the financial system at large. A "regime change" occurs once a sufficiently large number of depositors decides to withdraw their deposits, forcing the bank to suspend its payments.

In models of self-fulfilling debt crises, such as Calvo (1988), θ may represent the long-run profitability of a firm or the growth potential of a country, and "regime change" occurs when the firm's/country's creditors decline to roll over its outstanding short-term debt because they fear that other creditors will refuse to roll over, forcing the firm/country into default.

Finally, regime change can also mean the "big push" in Murphy et al. (1989), that is, a situation where the incentives of an agent to switch from one technology to another, or to leave the village for the city, or to enter a particular industry, depend crucially on how many other agents are doing the same.

Remark 17 The aforementioned papers assume complete information. The more recent literature that incorporates incomplete information in such applications is discussed in the next section. Also, the applications we have in mind are intrinsically dynamic. One may thus question whether it is appropriate to model them as one-shot games. We will revisit this issue at the end of the next section.

4.3 Complete Information and Multiple Equilibria

Suppose for the moment that information is complete. Without any serious loss, suppose further that information is perfect, meaning that the true realization of θ is known to all agents in all states of Nature.

Let $\theta_L \equiv 0$ and $\theta_H \equiv 1$. For $\theta \leq \theta_L$, the fundamentals are so weak that the regime is doomed with certainty and the unique equilibrium has every agent attacking. For $\theta > \theta_H$, the fundamentals are so strong that the regime can survive an attack of any size and the unique equilibrium has every agent not attacking. For intermediate values, $\theta \in (\theta_L, \theta_H]$, the regime is sound but vulnerable to a sufficiently large attack and there are multiple equilibria sustained by self-fulfilling expectations. In one equilibrium, individuals expect everyone else to attack, so they then find it individually optimal to attack, the status quo is abandoned and expectations are vindicated. In another, individuals expect no one else to attack, they thus find it individually optimal not to attack, the status quo is spared and expectations are again fulfilled.

Proposition 5 (Multiple Equilibria) *Suppose information is complete (θ is common knowledge). When $\theta \leq \theta_L$, the unique equilibrium outcome is $K = R = 1$. When $\theta > \theta_H$, the unique equilibrium outcome is $K = R = 0$. And when $\theta \in (\theta_L, \theta_H]$, both $K = R = 0$ and $K = R = 1$ are equilibrium outcomes.*

The interval $(\theta_L, \theta_H]$ thus represents the set of "critical fundamentals" for which multiple equilibria are possible under complete information. Each equilibrium is sustained by different self-fulfilling expectations about what other agents do.

Under the assumed payoff function, the two equilibria can be readily ranked: the equilibrium with $K = R = 1$ is Pareto superior to that with $K = R = 0$. One can thus associate the latter equilibrium with a "coordination failure." More generally, which equilibrium represents a coordination failure varies depending on the context of interest. In the context of self-fulfilling currency attacks, for example, a coordination failure is the no-attack equilibrium from the perspective of foreign speculators, whereas it is the attack equilibrium from the perspective of domestic agents. Regardless of which perspective is adopted, however, the notion of coordination failure is associated with a particular selection across multiple equilibria.

In Sections 4.4 and 4.5, we will show how allowing information to be incomplete can remove the indeterminacy of the equilibrium. In fact, we will show that this can be true even if the noise in the available information is arbitrarily small. While this implies that a realistic perturbation of standard models can potentially destroy the *traditional* view of coordination failures and animal spirits, we will argue that these notions can be meaningfully resurrected even in models with a unique equilibrium.

4.4 Incomplete Information and Unique Equilibrium

Following Morris and Shin (1998, 2001), we restrict the stochastic structure as follows. Nature draws θ from a uniform distribution over the entire real line.[ag] Conditioning on θ, Nature draws a private signal for each agent i. This signal is given by

$$x_i = \theta + \sigma\epsilon_i,$$

[ag] This specification of the common prior about θ is only for simplicity. For the results that follow, it suffices to consider any smooth prior over an interval that strictly contains the critical region and to let σ, the noise in the signal, be small enough. What the assumption of a uniform (or uninformative) prior does is to guarantee that uniqueness obtains for any σ, not just for σ small enough. The role of precise priors, or the related role of public information, is discussed later.

where ϵ_i is an idiosyncratic noise term and $\sigma > 0$ parameterizes the level of noise. The noise is independent of θ and is drawn from a smooth distribution over the real line, with a strictly increasing c.d.f. denoted by Φ. These facts are common knowledge, but the realizations of θ and the signals are not; instead, the information set, ω_i, of agent i is simply the signal x_i. Without any loss, we will assume that an agent attacks whenever she is indifferent between attacking and not attacking.[ah]

Note that the scalar σ parameterizes how informed each agent is about the realization of θ. When σ is *exactly* zero, the model reduces to the complete-information benchmark. When, instead, σ is positive but small enough, every agent is nearly perfectly informed, and we have a seemingly tiny perturbation in the exogenous primitives of the environment. One may have expected that such a tiny change in the assumptions of the model would imply a tiny difference in its predictions. This turns out not to be the case: the predictions of the theory are discontinuous at $\sigma = 0$.

Proposition 6 (Morris-Shin) *There is a unique equilibrium for all $\sigma > 0$. In this equilibrium, the size of the attack K is monotonically decreasing in θ, and regime change occurs ($R = 1$) if and only if $\theta < \theta^*$, where $\theta^* = 1 - c/b \in (0, 1)$.*

This result highlights the sharp discontinuity mentioned above: a seemingly tiny perturbation in a model's assumptions regarding the agents' information implies a huge difference in the model's predictions. This discontinuity seems troubling as it calls into question the insights and policy lessons obtained in the large multiple-equilibria literature of the 80s and 90s.

We prove this result in Section 4.5. We then proceed to elaborate on its robustness, its theoretical underpinnings, and its implications for applied work.

4.5 Proof of Equilibrium Uniqueness

The proof is based on the procedure of iterated deletion of dominated strategies. For any $\hat{x} \in [-\infty, +\infty]$, let $K_{\hat{x}}(\theta)$ denote the size of aggregate attack when every (or almost every) agent attacks if and only if $x \leq \hat{x}$. Next, define the function

$$V(x,\hat{x}) = \mathbb{E}[\ \ U(1, K_{\hat{x}}(\theta), \theta) - U(0, K_{\hat{x}}(\theta), \theta)\ \ |\ \ x\ \ ].$$

This is the difference in utility between attacking and not attacking for an agent who has private information x and expects the other agents to attack if and only if their signals fall below $\hat{x}$.

Let us determine V. First, note that, when other agents follow a threshold strategy with threshold $\hat{x}$, the resulting size of the attack is given by the following:

[ah] This assumption resolves an indeterminacy that obtains in a zero-probability event, namely when the private signal x takes the particular value x^* characterized in the proof of Proposition 6 below.

$$K_{\hat{x}}(\theta) = Prob(x \leq \hat{x}|\theta) = Prob(\theta + \sigma\epsilon \leq \hat{x}|\theta) = Prob\left(\epsilon \leq \frac{1}{\sigma}(\hat{x} - \theta)\right) = \Phi\left(\frac{1}{\sigma}(\hat{x} - \theta)\right).$$

By implication, the regime collapses ($R = 1$) if and only if $\theta < \hat{\theta}$, where $\hat{\theta} = \hat{\theta}(\hat{x})$ is the unique solution to $K_{\hat{x}}(\hat{\theta}) = \hat{\theta}$, or equivalently the inverse of the following:

$$\hat{x} = \hat{\theta} + \sigma\Phi^{-1}(\hat{\theta}).$$

It follows that the agent with signal x attaches the following probability to the event of regime change:

$$Prob(R = 1|x) = Prob(\theta \leq \hat{\theta}|x) = Prob(\theta - x \leq \hat{\theta} - x) = Prob\left(\epsilon \geq \frac{1}{\sigma}(x - \hat{\theta})\right)$$
$$= 1 - \Phi\left(\frac{1}{\sigma}(x - \hat{\theta})\right).$$

We can express the payoff V as follows:

$$V(x, \hat{x}) = b - b\Phi\left(\frac{1}{\sigma}[x - \quad \hat{\theta}(\hat{x})]\right) - c,$$

where $\hat{\theta} = \hat{\theta}(\hat{x})$ is the aforementioned unique solution to $K_{\hat{x}}(\hat{\theta}) = \hat{\theta}$.

Before we proceed, we wish to emphasize that the specific functional form of V is not essential. As it will become clear below, the result is driven by the monotonicity and continuity properties of the function V and of the related function h that we introduce below.

With this point in mind, note $\hat{\theta}$ is increasing in $\hat{x}$. It follows that $V(x, \hat{x})$ is increasing in $\hat{x}$: The more aggressive the other agents are, the higher the expected payoff from attacking. Moreover, $V(x, \hat{x})$ is decreasing in x: The higher the value of the private signal, the lower the expected payoff from attacking.

Next, note that $V(x, \hat{x})$ is continuous in x and satisfies $V(x, \hat{x}) \to b - c > 0$ as $x \to -\infty$ and $V(x, \hat{x}) \to -c < 0$ as $x \to +\infty$. We can thus define a function h such that $x = h(\hat{x})$ is the unique solution to $V(x, \hat{x}) = 0$. Because $V(x, \hat{x})$ is continuous in both arguments, decreasing in x, and increasing in $\hat{x}$, $h(\hat{x})$ is continuous and increasing in $\hat{x}$.

The function h defined above summarizes best responses within the set of monotone strategies: assuming that agents $j \neq i$ attack if and only if $x_j \leq \hat{x}$, agent i finds it optimal to attack if and only if $x_i \leq h(\hat{x})$. By the same token, the fixed points of h identify the set of monotone equilibria: if there is an equilibrium in which an agent attacks if and only if $x < x^*$, then x^* solves $x^* = h(x^*)$.

Finally, note that $x^* = h(x^*)$ if and only if $V(x^*, x^*) = 0$. Using the definition of V, and letting $\theta^* = \hat{\theta}(x^*)$, we have that $V(x^*, x^*) = 0$ if and only if $\theta^* = 1 - c/b$. It follows that there exists a *unique* threshold x^* such that $x^* = h(x^*)$. This proves that there exists a unique equilibrium in monotone strategies.

We next prove that there is no other equilibrium. In fact, we prove a stronger result: the only strategy that survives iterated deletion of dominated strategies is the monotone equilibrium strategy identified by the aforementioned threshold.

Construct a sequence $\{\underline{x}_j\}_{j=0}^{\infty}$ by $\underline{x}_0 = -\infty$ and $\underline{x}_j = h(\underline{x}_{j-1})$ for all $j \geq 1$. In particular, letting $\underline{\theta}_{j-1}$ be the solution to

$$\underline{x}_{j-1} = \underline{\theta}_{j-1} + \sigma\Phi^{-1}(\underline{\theta}_{j-1}), \tag{9}$$

we have

$$V(x, \underline{x}_{j-1}) = b - b\Phi\left(\frac{1}{\sigma}(x - \underline{\theta}_{j-1})\right) - c$$

and thus

$$\underline{x}_j = \underline{\theta}_{j-1} + \sigma\Phi^{-1}\left(1 - \frac{c}{b}\right). \tag{10}$$

Hence, $\underline{x}_0 = -\infty$, $\underline{\theta}_0 = 0$, $\underline{x}_1 = \frac{1}{\sqrt{\alpha_x}}\Phi^{-1}\left(\frac{b-c}{b}\right)$, and so on. Clearly, the sequence $\{\underline{x}_j\}_{j=0}^{\infty}$ is increasing and bounded above by x^*. Hence, the sequence $\{\underline{x}_j\}_{j=0}^{\infty}$ converges to some $\underline{x}$. By continuity of h, the limit $\underline{x}$ must be a fixed point of h. But we already proved that h has a unique fixed point. Hence, $\underline{x} = x^*$.

Next, construct a sequence $\{\bar{x}_j\}_{j=0}^{\infty}$ by $\bar{x}_0 = +\infty$ and $\bar{x}_j = h(\bar{x}_{j-1})$ for all $j \geq 1$. Note that this sequence is decreasing and bounded below by x^*. Hence, the sequence $\{\bar{x}_j\}_{j=0}^{\infty}$ converges to some $\bar{x}$. By continuity of h, $\bar{x}$ must be a fixed point of h. But we already proved that h has a unique fixed point. Hence, $\bar{x} = x^*$.

What is the meaning of these sequences?

Consider $\underline{x}_1$. If nobody else attacks, the agent finds it optimal to attack if and only if $x \leq \underline{x}_1$. By complementarity, if some people attack, the agent finds it optimal to attack *at least* for $x \leq \underline{x}_1$. That is, for $x \leq \underline{x}_1$, attacking is *dominant*. Next, consider $\underline{x}_2$. When other agents attack if and only if it is dominant for them to do so, that is, if and only if $x \leq \underline{x}_1$, then it is optimal to attack if and only if $x \leq \underline{x}_2$. By complementarity, if other agents attack at least for $x \leq \underline{x}_1$, then it is optimal to attack *at least* for $x \leq \underline{x}_2$. That is, attacking becomes dominant for $x \leq \underline{x}_2$ after the second round of deletion of dominated strategies.

More generally, for any $j \geq 1$, we have that attacking becomes dominant $x \leq \underline{x}_j$ after the j round of deletion of dominated strategies. Hence, $\{\underline{x}_j\}_{j=0}^{\infty}$ represents iterated deletion of dominated strategies "from below." Symmetrically, $\{\bar{x}_j\}_{j=0}^{\infty}$ represents iterated deletion of dominated strategies "from above."

To recap, the only strategies that survive j rounds of iterated deletion of dominated strategies are functions k such that $k(x) = 1$ for all $x \leq \underline{x}_j$ and $k(x) = 0$ for $x > \bar{x}_j$. The value of $k(x)$ is still "free" at the jth round only for $x \in (\underline{x}_j, \bar{x}_j)$. But we already proved that both $\underline{x}_j$ and $\bar{x}_j$ converge to x^* as $j \to \infty$. Hence, in the limit, the only strategy that survives is the function k such that $k(x) = 1$ for $x \leq x^*$ and $k(x) = 0$ for $x > x^*$.

We have thus proved that there exists a unique rationalizable strategy, and hence a fortiori also a unique equilibrium. In this equilibrium, an agent attacks if and only if $x \leq x^*$, and the status quo collapses if and only if $\theta \leq \theta^*$, where the pair (x^*, θ^*) is the unique fixed point to the iteration defined in (9) and (10). From this last fact, it is then immediate that $\theta^* = \frac{b-c}{b}$.

Remark 18 The property that the best-response function h is increasing and admits a unique fixed point means, in effect, that the incomplete-information game under consideration features weak complementary. But recall that the complete-information counterpart features strong complementarity. It follows that the introduction of incomplete information has effectively transformed the game from one of strong complementarity to one of weak complementarity, which in turn helps explain the uniqueness result. See Vives (2005), Van Zandt and Vives (2007), and Mathevet (2010) for a further discussion of this point, and for complementary analyses of how the uniqueness result can be understood via either super-modular methods (Vives, 2005; Van Zandt and Vives, 2007) or a contraction mapping argument (Mathevet, 2010).

4.6 The Role of Public Information

In the preceding analysis, we assumed that the common prior about θ was uninformative (ie, an improper uniform over entire real line). If the prior is not uniform, uniqueness obtains for σ small enough, but may not obtain otherwise. A similar property applies if we introduce a public signal: to the extent that there is sufficient public information, multiplicity survives the introduction of dispersed private information.[ai]

To illustrate this point consider the following modification of the information structure. The private signal is now given by

$$x_i = \theta + \sigma_\epsilon \epsilon_i,$$

where ϵ_i is drawn from a standardized Normal distribution (with mean 0 and variance 1). Similarly, the public signal is given by

$$z = \theta + \sigma_\zeta \zeta,$$

where ζ is an aggregate noise term that is also drawn from a standardized Normal distribution. The scalars σ_ϵ and σ_ζ parameterize the level of noise in the two signals.

One can establish the following:

[ai] In terms of strategic uncertainty, there is no difference between a public signal and the common prior: when studying the hierarchy of beliefs and/or solving for the equilibrium strategies, one can always re-cast a public signal as part of the common prior. The distinction between the prior and a public signal is therefore useful only for applied purposes.

Proposition 7 (Public Info) *The equilibrium is unique if and only if* $\sigma_\epsilon \leq \sqrt{2\pi}\sigma_\zeta^2$.

The distinct nature of the two types of information can be further illustrated by comparing the limit as $\sigma_\epsilon \to 0$ (for fixed $\sigma_\zeta > 0$) to that as $\sigma_\zeta \to 0$ (for fixed $\sigma_\epsilon > 0$). In either limit, the beliefs of every agent about θ converge in probability to the true θ. Both limits therefore approach "perfect knowledge" with regard to fundamentals, and are indistinguishable from the perspective of how informed the agents are about the fundamentals. Yet, the two limits look very different from the perspective of how well the agents can predict one another's actions. Because of this, they also make very different predictions about economic behavior.

Proposition 8 (Limits)

(i) *In the limit as* $\sigma_\epsilon \to 0$ *for given* $\sigma_\zeta > 0$, *the probability of regime change converges to 1 for all* $\theta < \theta^*$ *and to zero for all* $\theta > \theta^*$, *where* $\theta^* = 1 - c/b$.

(ii) *Pick an arbitrary compact subset of the critical region,* $A \subset (\theta_L, \theta_H]$. *In the limit as* $\sigma_\zeta \to 0$ *for given* $\sigma_\epsilon > 0$, *there is an equilibrium in which the probability of regime change converges to 1 for all* $\theta \in A$, *as well as an equilibrium in which the probability of regime change converges to 0 for all* $\theta \in A$.

Part (i) recasts Proposition 7 as a particular limit in which private information is infinitely precise *relative* to public information. Part (ii), by contrast, recasts the complete-information benchmark as the limit in which it is the relative precision of public information that is infinite. In combination, these two results therefore underscore the distinct role played by the two types of information in shaping the equilibrium beliefs that agents form about one another's actions and in determining their ability to coordinate.

Remark 19 Recall the function h from the proof of Proposition 6 in Section 4.5; that function described best responses within the set of monotone strategies. In that proof, we saw that h admitted a unique fixed point. We then commented that this property meant that the introduction of private information had transformed the game from one of strong complementarity to one of weak complementary. The role of public information is the exact opposite: when public information is sufficiently precise relative to private information, the function h admits multiple fixed points. That is, sufficiently precise public information brings back strong complementarity.[aj]

4.7 Intuition and Take-Home Lessons

A deeper understanding of the precise logic behind the preceding results requires a review of important advances in game theory, an endeavor which is beyond the scope of this paper. We refer the interested reader to Rubinstein (1989) for an early seminal contribution that highlighted the fragility of coordination to perturbations of common

[aj] These points can be inferred from the proof of Proposition 7 in Appendix, noting that the function G in that proof is a transformation of the function h from the space of strategies (as indexed by the threshold x^*) to the space of regime outcomes (as indexed by θ^*).

knowledge; to Monderer and Samet (1989, 1996) and Kajii and Morris (1997a,b) for what it means to have "approximate" common knowledge and the related robustness of equilibria to incomplete information; to Morris et al. (1995) for the contagious effects of higher-order uncertainty; to Morris and Shin (1997, 2003), Frankel et al. (2003), and Mathevet and Steiner (2013) for extensions of the global-games uniqueness result to richer settings than the simple one we have studied in this section; to Mathevet (2010) for a variant proof based on a contraction mapping argument; to Vives (2005) and Van Zandt and Vives (2007) for related techniques from supermodular games; to Weinstein and Yildiz (2007a) for a powerful result that we discuss briefly in Section 4.8; and to Morris et al. (2016) for the importance of "rank beliefs" (the probability the players assign to their signal being higher than that of their opponents) and for the common belief foundations of global games. For our purposes, it suffices to emphasize the following key intuitions.

First, note that equilibrium imposes that agents know one another's *strategies*, that is, they know the mappings from their information sets (or Harsanyi types) to their actions. If we assume that all agents share the same information, then this imposes that all agents face no uncertainty about their actions. The absence of this kind of strategic uncertainty is conducive to multiple equilibria: it is "easy" to coordinate on one of many equilibrium actions when the agents are confident that other agents will do the same. But once information is incomplete, the agents may face uncertainty about one another's actions, and this type of uncertainty can hinder coordination. It follows that the determinacy of the equilibrium hinges on the level of strategic uncertainty: the higher the level of strategic uncertainty, the harder to sustain multiple equilibria.

Next, note that the level of strategic uncertainty is not necessarily tied to the level of fundamental uncertainty: the uncertainty an agent faces about the beliefs and actions of other agents has to do more with the heterogeneity of the information and the associated higher-order uncertainty, and less with the overall level of noise in the observation of the fundamentals. In fact, when private information becomes more precise, the uncertainty that an agent i faces about the fundamentals necessarily decreases, yet it is possible that her uncertainty about beliefs and actions of any other agent j increases. This is because an increase in the precision of private information implies that the beliefs and actions of agent j become more anchored to her own private information, which is itself unknown to agent i. This anchoring effect in turn explains why private information can exacerbate higher-order uncertainty and thereby hinder coordination.

This intuition can be formalized as follows. First, note that, when information is complete, the equilibrium belief of any agent about K is a direct measure of the realized value of K. That is, agents are perfectly informed about the size of the attack in equilibrium, irrespective of the equilibrium selected. Next, note that, in the diametrically opposite scenario where an agent is completely agnostic about the size of the attack, her belief about K is uniform over the $[0, 1]$ interval. Finally, consider what happens under incomplete information. Let σ_ϵ be small enough so that the equilibrium is unique and consider the "marginal" agent, that is, the type who is indifferent between attacking and not attacking in equilibrium. Morris and Shin (2003) show that the following is true.

Proposition 9 *In the limit as private information becomes infinitely precise (namely, $\sigma_\epsilon \to 0$ for given $\sigma_\zeta > 0$), the marginal agent's belief about* K *converges to a uniform distribution over* [0, 1]. *That is, the marginal agent learns perfectly the fundamental in the limit, and yet she remains completely uninformed about the actions of others.*

The sharpness of this last result hinges on focusing on the beliefs of the marginal agent, or of agents whose distance from the marginal agent vanishes as $\sigma_\epsilon \to 0$, as opposed to agents sufficiently far from the threshold x^*. Nevertheless, the combination of this result with the preceding observations helps explain why private information contributes to equilibrium uniqueness, whereas public information is conducive to multiplicity.

To summarize, in settings with coordination motives, information plays a dual role: it shapes the beliefs of each agent, not only about the exogenous payoff-relevant fundamentals, but also about the endogenous actions of the others. In the preceding result, it is the second channel that matters most. Private and public information are similar vis-a-vis the first function, but are distinct vis-a-vis the second function.

We close this section by discussing the nature of private and public signals.

For certain applied purposes, one may seek a rather literal interpretation of these signals. For instance, the private signal x_i may correspond to the proprietary information of a hedge fund, the "local" knowledge that a bank may have about the entire financial network, or the information a firm or consumer extracts about the aggregate economy from its own transactions. Similarly, the public signal z may be a proxy for financial news in the media, announcement or choices made by policy makers, or market signals such as prices. We discuss some of these interpretations, and the additional lessons they can lead to, in Section 5.

A literal interpretation of the signals is therefore useful to the extent that the researcher can envision empirical counterparts to them, and potentially even measure them. It is also useful if one wishes to study questions relating either to the collection and aggregation of information or to the welfare effects of the signals disseminated by markets, the media, and policy makers—issues that we address latter on.

That said, the mapping from the theory to the real world may not be as easy as suggested by the sharp dichotomy between private and public information employed above. For instance, suppose that the noise in the private signals happens to be the sum of two components, one idiosyncratic and one aggregate: $x_i = \theta + u + \epsilon_i$, where u is the aggregate noise and ϵ_i is the idiosyncratic noise. Suppose further that we introduce a public signal of the aggregate noise u, as opposed to a public signal of the fundamental θ. Then, this public signal will only increase the reliance of individual decisions on the private signals, which in turn may contribute to higher strategic uncertainty.

The above example may appear to be esoteric, but once one starts thinking about applications, the distinction between "fundamentals" and "noise" can get fussy. For instance, in the context of asset markets, should one think of shocks to discount factors as "noise" or as "fundamentals"? This question that can be meaningfully addressed only within the context of a fully-specified micro-founded model.

Finally, a literal interpretation of the signals is too narrow for some of the issues we have in mind. In the real world, and especially in the context of macroeconomic phenomena, it seems hard to measure, or even comprehend, all the ways in which economic agents collect and exchange information about either their idiosyncratic circumstances or the overall state of the economy. More generally, it is unclear, at least to us, why the most useful explanations of real-world phenomena are those based on models that rule out any friction either in how agents form beliefs about the relevant economic outcomes or in how they coordinate their behavior—which is what workhorse macroeconomic models typically do. From this perspective, the signal structures we employ throughout this chapter are ultimately modeling devices that permit the researcher to "open up the black box" of how agents form expectations about endogenous economic outcomes and how they coordinate their behavior. In our view, this basic point is central to understanding the precise applied value, and the testable implications, of incorporating incomplete information in macroeconomics.[ak]

4.8 Extensions and Additional Lessons

The preceding analysis has focused on a rather narrow class of binary-action games that can be described as games of regime change. Morris and Shin (2003) extend the global-games uniqueness result to a broader class of binary-action games, allowing for a more flexible form of payoff interdependence. Frankel et al. (2003) provide a generalization of the global-games uniqueness result to settings where the action belongs to an arbitrary, finite set, while maintaining strategic complementarity (appropriately defined in terms of supermodularity). Guimaraes and Morris (2007) consider an application with a continuous action (a portfolio choice). Goldstein and Pauzner (2005) consider an example that relaxes the assumption of strategic complementarity, in exchange for a weaker single-crossing condition[al] and the assumption that both the prior about the fundamentals and the distribution of the idiosyncratic noise are uniform.

[ak] Bergemann and Morris (2013) corroborate this point in the related class of games studied in Section 7, by showing that the equilibrium outcomes that can be sustained by any Gaussian information structure can be replicated by those that are sustained under the assumed private and public signals. For two alternative approaches within the global-games literature, see Cornand and Heinemann (2009) and Izmalkov and Yildiz (2010). The first paper studies a model with multiple group-specific signals; the second uses a heterogeneous-prior specification of the belief hierarchy.

[al] This single-crossing condition is the following: $u(K, x)$ crosses zero once, going from negative to positive, as K varies from 0 to 1, where $u(K, x)$ is the net payoff from attacking when the agent receives signal x and knows K.

Morris and Shin (2003) also establish the result in Proposition 9, namely that the marginal agent is agnostic about the size of the attack in the limit as private information becomes infinitely precise—a property to which they refer as "Laplacian belief." Whether this property is realistic or not is open for debate. Morris and Shin (2003) argue that this is a "plausible" restriction the theorist can impose in order to sharpen the predictions he can deliver. By contrast, Atkeson (2000), Angeletos and Werning (2006), Angeletos et al. (2006, 2007), and others have argued that, for many applications of interest, the endogeneity of the available information may lead to situations where this property is violated: market signals such as prices, and past economic outcomes, may endogenously limit the uncertainty that agents, including the marginal agent, face about one another's actions. More on this in the next section.

The aforementioned works, as well as the applications considered in the next section, limit attention to specific payoff and information structures. Weinstein and Yildiz (2007a) aim for greater generality and obtain a revealing result: for any given game and any given rationalizable action *a* of any given type in the Universal Type Space, there is a nearby game in which the given action *a* becomes the unique rationalizable action for a perturbed version of the original type.[am] A corollary of this is that equilibrium multiplicity can be viewed as a knife-edge situation, which can always be eliminated by considering an arbitrarily small perturbation of the payoff and information structures.

At first sight, Weinstein and Yildiz's result may appear to deliver a deathblow to multiple-equilibria models and their applications: multiplicity is degenerate! However, the actual meaning of the result is different. The result applies to *every* rationalizable action of the original game. It follows that, whenever we have a model with multiple equilibria, we can find small perturbations—indeed, open sets of such perturbations—that select *any* of the original equilibrium outcomes as the unique rationalizable outcome.

For applied purposes, this means the following. In models that admit multiple equilibria, the inability of theorist to tell which equilibrium is selected should be interpreted as follows: the theorist is unable to reach sufficiently sharp predictions on the basis of the assumptions he has made in his model (that is, on the basis of his prior knowledge about the environment). While Weinstein and Yildiz (2007a) result suggests that this type of multiplicity is fragile, the inability to make sufficiently sharp prediction about the equilibrium remains: but it now concerns lack of knowledge about the details of the information structure rather than lack of knowledge about which equilibrium is played.[an]

What lesson can be drawn? The global-games methodology is not a panacea for getting rid of multiple equilibria, or for giving policy makers the satisfaction of sharp policy

[am] What "nearby" and "perturbed" mean can be delicate; see Weinstein and Yildiz (2007a) for details.

[an] To put it differently, the common thread is that the variation in the observable outcomes of the model is not panned by either the underlying payoff relevant fundamentals or the agent's beliefs about them. In the original, multiple-equilibrium, model, the residual variation is attributed to a pure sunspot. In the perturbed, unique-equilibrium, model, the residual variation is attributed to higher-order uncertainty and rich "noise" in the information structure.

advice. Instead, the applied value of the global-games uniqueness result rests on elucidating the mechanics of coordination and on highlighting the importance of information, and communication, for the questions of interest. We try to give concrete examples of this value later in Section 5.

5. GLOBAL GAMES: APPLICATIONS

In this section, we review recent applications of global games to macroeconomics and finance. Many of these applications can be classified into two broad categories. The first one treats the information structure as exogenous, makes assumptions that guarantee equilibrium uniqueness, and uses this to shed new light on phenomena such as bank runs, financial crises, and business cycles and on related policy questions. The second one endogenizes the information structure in manners that seem empirically relevant, studies how this can bring back multiple equilibria, and sheds further light on applied questions.

Sections 5.1–5.6 review the first set of applications. Sections 5.7–5.9 turn to the second set. Section 5.10 mentions additional research that does not necessarily fit in the previous two categories.

5.1 Currency Crises and Bank Runs

In the paper that popularized the global-games approach, Morris and Shin (1998) introduced incomplete information in the currency-attack model of Obstfeld (1996). Although multiple equilibria exist when the fundamentals (such as reserves) are common knowledge, a unique equilibrium is obtained by adding a small amount of idiosyncratic noise in the speculators' information about the fundamentals. The size of the attack and the devaluation outcome no longer depend on sunspots but may exhibit a strong nonlinearity (or near-discontinuity) with respect to the fundamentals. A large attack can thus be triggered by small changes in the underlying fundamentals, helping reconcile the uniqueness of the equilibrium with the fact that speculative attacks are abrupt and often happen without a significant change in measured fundamentals. Moreover, policy analysis can now be conducted without the difficulties associated with multiple equilibria and arbitrary, ad hoc, selections. The paper shows how a marginal increase in a "tax" on capital outflows or in domestic interest rates can curtail a speculative attack, a policy conclusion that would not be have been obtained in the presence of multiple equilibria.[ao]

Turning to the context of bank runs, Goldstein and Pauzner (2005) "globalize" Diamond and Dybvig (1983) and proceed to study the implications for the design of the optimal deposit contract. To understand the contribution of this paper, note first that the characterization of optimal contract in Diamond and Dybvig (1983) is based on the assumption that a self-fulfilling run never takes place. This entails a particular equilibrium selection, which is possible in the original, complete-information, setting of Diamond

[ao] The original paper had a mistake in the characterization of the comparative statics of the equilibrium with respect to the aforementioned tax. See Heinemman (2000) for the correction.

and Dybvig, but not once incomplete information is introduced. Instead, the unique equilibrium now makes self-fulfilling runs *inevitable* for sufficiently low bank fundamentals. Goldstein and Pauzner's key contribution is therefore to study how this inevitability reshapes the design of the optimal design contract. The paper shows that the optimal contract under incomplete information penalizes early withdrawals relative to the complete-information benchmark. This entails a welfare cost in terms of providing less insurance to "impatient" consumers; but this cost is now justified by the reduction in the probability and the size of a bank run.

The broader lesson emanating from this paper, as well as from Morris and Shin (1998), is the following: just as the optimal contract characterized in Diamond and Dybvig is dependent on the complete-information assumption, many of the policy recommendations found in the literature are dependent on shutting down frictions in coordination and are often driven by arbitrary equilibrium selections. By contrast, the global-games methodology offers a way to study policy without these caveats.

We finally refer the reader to Goldstein and Pauzner (2004) and Goldstein (2005) for global-games applications that study the role of contagion effects and the phenomenon of "twin crises" (ie, the coincidence of currency crises and bank runs); to Goldstein et al. (2011) for how strategic complementarity among speculators can be the by-product of the signal-extraction problem faced by the central bank when the latter is uncertain about the underlying fundamentals; and to Kurlat (2015) for the optimal stopping problem that such a central bank has to solve in the midst of a speculative attack.

5.2 Big Players and Lenders of Last Resort

Corsetti et al. (2004) sheds new light on the role of large players in speculative markets. The model is similar to the one in Morris and Shin (1998), except for one key difference: a large speculator (Soros) coexists with a continuum of small investors.

When a small speculator chooses whether to attack, she takes the probability of devaluation as exogenous to her own choice. When, instead, the large player chooses whether to attack, she takes into account that she has a nontrivial impact on the probability of devaluation. Other things equal, this effect makes the large speculator more aggressive than any small speculator.[ap] Perhaps more interestingly, the presence of a large player facilitates more coordination among the small players, even if her actions are not observable: because it is known that the large player is more aggressive, each small player finds it optimal to be more aggressive for any realization of her own signal, each small player expects the same from other small players, and so on. What is more, as the small players get more aggressive, the large player finds it optimal to become even more aggressive, and so on. It follows that the introduction of a large player in market can have a disproportionately strong effect on equilibrium outcomes, even if her actions are not

[ap] In effect, the large player is like a pool of small players that have managed to act in a coordinated fashion, thus overcoming the friction faced by other small players.

observable. Allowing the small players to observe the actions of the large player further amplifies this property.

Davila (2012) studies the role of a different type of large players in a different context: the role of large banks in the context of the subprime crisis. The starting point of the analysis is Farhi and Tirole (2012), who identified the following collective moral hazard problem: because the government is more likely ex post to bailout an individual bank when the entire banking system is in trouble, each bank is ex ante more willing to expose itself to an aggregate risk when it expects other banks to do the same. In Farhi and Tirole (2012), this collective moral hazard problem is modeled as a complete information coordination game that ultimately features multiple equilibria: one with low "systemic risk" and another with high.[aq] By contrast, Davila (2012) uses a global-game adaptation to obtain a unique equilibrium. The presence of large banks is shown to intensify the severity of the collective moral hazard problem, increase economy-wide leverage, and make the crisis occur for a large set of fundamentals. The intriguing policy implication is then that systemic risk can be reduced by breaking up the large banks into multiple small ones.

Rochet and Vives (2004) considers a bank-run model in which investors may refuse to renew their credit on the interbank market during the liquidity crisis. In their "globalized" model the equilibrium is unique and the probability of a crisis is linked to the fundamentals. In this unique equilibrium, there is an intermediate range for bank's fundamentals in which in the absence of the government intervention the bank is solvent but may still fail if too large a proportion of investors withdraw their money. In other words, there exists a potential for coordination failure. The authors proceed to study the interaction between ex ante regulation of solvency and liquidity ratios and ex post provision of emergency liquidity assistance. They show that liquidity and solvency regulation can solve the coordination problem, but typically the cost is too high. These prudential measures must be complemented with emergency discount-window loans.

Corsetti et al. (2006) build a similar model as the one in Rochet and Vives (2004), featuring liquidity crises caused by the interaction of bad fundamentals and self-fulfilling runs. The authors focus on the "catalytic" effects of the liquidity provision from the official lender. Drawing on the results of Corsetti et al. (2004) about the role of large players, the paper models the official creditor (IMF) as a large player in the world economy. Even if IMF by its own does not have enough resources to close the large financing gaps generated by speculative runs, the range of economic fundamentals over which liquidity crises do not happen is enlarged through the "catalytic" effect. As a result, liquidity provision during crisis is justified even if it exacerbates debtor's moral hazard problem. A similar point is made in an independent, contemporaneous contribution by Morris and Shin (2006).

[aq] Note that this rests on the government lacking commitment: if the government could commit ex ante not to bail out the banking system ex post, it could alleviate the problem. See Ennis and Keister (2009) for a related point on how the ex post optimal policy response to a bank run distorts ex ante incentives, raising the occurrence of self-fulfilling runs.

The policy lessons that emerge from these papers rely on the uniqueness of the equilibrium. They therefore could not have been obtained in the complete-information versions of the relevant models. However, these lessons also hinge on abstracting from the possibility that policy actions, when made intentionally, convey valuable information about the willingness and ability of the policy maker to defend the status quo (a currency peg, a particular bank, or the entire banking system). As we discuss later on, this possibility is explored in Angeletos et al. (2006) and is shown to lead to a potentially very different lessons.

5.3 Debt runs, Default Premia, and Credit Ratings

Morris and Shin (2004a) globalize the coordination problem among creditors of a distressed borrower in an otherwise conventional debt-run model a la Calvo (1988). There are three periods. The borrower—who is interpreted as a firm but could also be a country—owns a long-term investment project and owes a certain level of short-term debt. The return of the project materializes in period 3. The debt expires in period 2 and must be rolled over to period 3, or else the borrower "dies" and the project is destroyed. There is a large pool of lenders, each of whom is too small relative to the size of the borrower. It follows that the borrower can survive if and only if enough lenders coordinate on rolling over their debts in period 2. By the same token, a coordination failure is possible: even when the borrower's fundamentals are sound, a creditor's fear of other creditors' premature foreclosure may lead to pre-emptive action, thus undermining the project.

Incomplete information guarantees that this coordination failure materializes when the profitability of the project is positive but not high enough: there exists a unique equilibrium in which default takes place in period 2, not only when the project is unprofitable, but also when profitability is positive but not high enough to preclude a self-fulfilling debt run. In period 1, market price debt anticipating that outcomes in period 2 will be determined in the aforementioned fashion. It follows that thanks to the uniqueness of the equilibrium default outcome, there is now also a unique equilibrium price—a property that is not shared by the complete-information version of the model. Furthermore, the equilibrium default risk can be now decomposed in two components: one that measures insolvency (the probability that the project is unprofitable), and another that measures roll-over risk (the probability that a coordination failure materializes).

In a follow-up paper, Zabai (2014) endogenizes the behavior of borrowers and shows how optimal borrowing internalizes the effect that the size of debt has on the probability of coordination failure and thereby on default premia. Together, these papers therefore answer two important questions: how the risk of coordination failure is priced; and how policy makers can influence it.

In another related paper, Holden et al. (2014) study the role of credit-rating agencies. By influencing the behavior of creditors, the ratings published by such agencies affect the probability of default, which in turn affects the ratings of other agencies. Through this feedback effect, the presence of credit-rating agencies can exacerbate volatility and reduce welfare.

Finally, He and Xiong (2012) study the dynamics of debt runs in a model that obtains uniqueness with the help of the techniques found in Frankel and Pauzner (2000) and Burdzy et al. (2001). More specifically, the paper characterizes how the occurrence and the dynamics of debt runs depend on the level fundamental volatility, the presence of credit lines, and the debt maturity structure. Interestingly, they find that commonly used measures that are meant to ease runs, such as temporarily keeping the firm alive and increasing debt maturity, can actually backfire and exacerbate runs—yet another example of how policy conclusions drawn from complete-information models can go wrong.

5.4 "Liquidity Black Holes" and "Market Freezes"

Morris and Shin (2004b) study how the incompleteness of information can help explain sudden drops in asset prices and liquidity in otherwise smoothly functioning markets. A set of sophisticated, risk-neutral traders (who can be thought as "hedge funds") interact with a representative unsophisticated, risk-averse, trader. This means that the value of the asset, and hence also its price, is higher when it is held by the former rather than by the latter. Importantly, the sophisticated traders have short horizons and face privately known loss limits. When the price of the asset is sufficiently above the loss limits of the sophisticated traders, their trades are strategic substitutes: the less the other traders buy of the asset, the cheaper (and more attractive) it becomes for an individual trader to buy. However, once the price of the asset falls sufficiently close to, or below, the loss limits, sales of the risky asset become strategic complements: the more the others sell, the more one has to sell "in distress." This opens the door to a "liquidity black hole" analogous to the run equilibrium in Diamond and Dybvig (1983). A global-game specification is then used to select a unique equilibrium and to obtain a unique trigger point in the fundamentals, below which the liquidity black hole comes into existence. The paper proceeds to show how this helps generate a sharp V-shaped pattern in prices around the time of the liquidity black hole and connect to historical experiences.

Bebchuk and Goldstein (2011) study a debt crisis model in which a credit-market freeze—a situation in which banks abstain from lending to good firms—may arise because of the banks' self-fulfilling expectations that other banks will not lend. The authors "globalize" the model to study the effectiveness of alternative government interventions, including interest rate cuts, infusions of capital into banks, direct lending to operating firms, and provisions of government capital or guarantees to encourage privately managed lending. See also Liu (2016) for an application that explains the joint occurrence of systemic credit runs and interbank market freezes.

5.5 Safe Assets

He et al. (2016) study the pricing of sovereign debt when debt valuations depend on both insolvency and roll-over risk. Their model features two countries that issue sovereign bonds on the international capital markets. An investor's valuation of a sovereign bond depends not only on the country's fundamental, but also on the number of other investors who purchase that bond. For a country's bonds to be safe, the number of investors who invest in the bond must exceed a threshold. As a result, investor actions feature a strategic complementarity similar to the one found in Section 4. What is new is that the model also features strategic substitutability when the number of investors who invest in the bonds exceeds the threshold required to roll over debts: above the threshold, more demand for the bond drives up the bond price, leading to lower returns. Recall that a similar feature was present in Goldstein and Pauzner (2005).

He et al. (2016) "globalize" the environment by removing common knowledge of the relative fundamental of the two countries. Under certain conditions, they prove the existence of a unique, monotone equilibrium. In this equilibrium, a sovereign's debt is more likely to be safe if its fundamentals are strong relative to the other country, but not necessarily strong on an absolute basis. Investors coordinate to invest in the country with relatively better fundamentals, and thus relative valuation determines which country's bonds have less rollover risk and, in this sense, more safety. This prediction may help explain why the valuation of US debt may increases despite a deterioration in its fiscal conditions: the fact that other countries are in even worse shape means that US roll-over risk has gotten smaller.

An additional insight is that a higher level of debt may, perhaps paradoxically, carry a higher price. This happens when the global demand for assets is strong. When this is true, investors are attracted to the country with the highest level of debt, because this helps to satisfy their high demand for assets. But this means that the country with the higher level of debt faces lower roll-over risk, which in turn means that the bond of this country is safer and commands a higher price. By contrast, when the global demand for safe assets is low, investors coordinate on the country with the smallest debt size.

Finally, the authors use their results to evaluate the recent proposal for "Eurobonds," that is, of a common bond for a club of countries. When a significant amount of such bonds is issued, all countries within the club can benefit by reducing the overall roll-over risk. It follows that Eurobonds can be beneficial for, say, both Germany and Greece. For the same reason, however, they can also upset the dominance of US debt as the international benchmark for safety.

5.6 Business Cycles and the Great Recession

A few papers sought to use the global-games methodology to shed light on business-cycle phenomena. The first attempt was Chamley (1999), which studies the dynamics of regime switches in a relatively abstract investment game. A related attempt was made by Frankel and Burdzy (2005), using the technique reviewed in Section 6.1.

More recently, Schaal and Taschereau-Dumouchel (2015) develop a global-games adaptation of the RBC framework and use it to study the Great Recession. We find this paper to be particularly interesting because it succeeds to merge the more abstract global-games literature with the more canonical business-cycle paradigm. What is more, it takes up the challenge of confronting the theory with the data. Below, we briefly explain the key ingredients of the paper.

Firms have the option to pay a fixed cost in order to increase their productivities and reduce their variable costs. This option introduces a nonconvexity in technology. The combination of this nonconvexity with monopolistic competition and aggregate demand externalities introduces a coordination problem that is akin to the one we have formalized in our binary-action regime-change setting: a firm is willing to pay the aforementioned fixed cost if and only if it expects aggregate demand to be sufficiently high, which in turn is true if and only if enough other firms also pay the aforementioned fixed cost.

Under complete information, the model admits multiple equilibria. Schaal and Taschereau-Dumouchel consider a perturbation that maintains common knowledge of past outcomes (including the capital stock) but removes common knowledge of the current TFP level. This permits them to obtain, not only a unique equilibrium, but also tractable dynamics. Although the equilibrium is now unique, there are two locally stable steady states, leading to very different dynamics from those in the standard RBC model. In particular, a large transitory shock may push the economy into a quasi-permanent recession, helping explain the slow recovery and other salient features of the Great Recession. Importantly, these outcomes are the product of a coordination failure. But since this coordination failure is not the symptom of arbitrary equilibrium selection, a meaningful policy analysis is also possible. In particular, the framework justifies certain types of fiscal stimuli when the economy is transitioning between steady states.

A complementary policy point is made in Guimaraes et al. (2014). Similarly to the above paper, this paper studies a micro-founded model with a nonconvexity in production; but it abstracts from capital and productivity shocks. This precludes the type of quantitative assessment that Schaal and Taschereau-Dumouchel (2015) are after; but it also facilitates a sharper analysis of the equilibrium effects of fiscal policy. The key contribution of the paper is then to formalize and characterize the expectational/coordination channel of fiscal policy—a channel that is customarily invoked in real-world policy debates but does not have a sufficiently meaningful counterpart in standard macroeconomic models.

5.7 Prices and Other Endogenous Public Signals

The preceding applications have treated the information structure as exogenous and have used it primarily as a device to select a unique equilibrium. In fact, the literature on applied global games has often focused attention on the limit in which public information is minimal and strategic uncertainty is maximal, in the sense defined earlier on. During times of crises, however, it is unlikely that agents are in the dark. On the contrary, they are closely monitoring the activity of others.

More broadly, agents may have access to various public signals of the underlying fundamentals and/or the actions of others. Think of the price of a peso forward in the context of currency crises, or of media reports about long ATM queues in the context of bank runs. Alternatively, think of speculators observing the actions of a policy maker who is anxious to preempt a speculative attack. How does this kind of information affect the determinacy of the equilibrium and the observables of the model? In the remainder of this section, we briefly review a few papers that have sought to answer this question.

We start with Angeletos and Werning (2006). This paper augments the basic coordination game introduced in Section 4.1 with two kinds of endogenous public signals. The first public signal is a price of an asset whose dividend is correlated either with the fundamental, θ, or the size of attack, K. The second signal is a direct signal of the size of the attack. One can think of a country's stock market or the forward foreign exchange market as examples of the first type, and the ATM queues or the size of protests as examples of the second. In what follows, we focus on the second type, because it can easily be accommodated by our framework; the first type leads to similar lessons.

The payoff structure is the same as in Section 4.1, and so is the specification of private information. In particular, agent i's private signal is once again given by $x_i = \theta + \sigma_\epsilon \epsilon_i$, where the noise $\epsilon_i \sim N(0,1)$ is i.i.d. across agents and $\sigma_\epsilon > 0$. The only change is in the specification of the public signal. The latter is now given by a noisy signal of the size of the attack:

$$z = S(K, \zeta),$$

where S is a monotone function, K is the size of attack, and $\zeta \sim N(0,1)$ is noise independent of θ and $\{\epsilon_i\}$.

Equilibrium can now be defined as follows.

Definition 14 An equilibrium consists of an endogenous signal, $z = Z(\theta, \zeta)$, an individual attack strategy, $k(x, z)$, and an aggregate attack, $K(\theta, \zeta)$, such that

$$k(x,z) \in \arg \max_{k \in \{0,1\}} \mathbb{E}[\, U(k, K(\theta,z), \theta) \,|\, x, z \,] \quad \forall (x,z) \tag{11}$$

$$K(\theta,z) = \mathbb{E}[\, k(x,z) \,|\, \theta, z \,] \quad \forall (\theta,z) \tag{12}$$

$$z = S(K(\theta,z), \nu) \quad \forall (\theta, \zeta, z) \tag{13}$$

Condition (11) requires individual choices to be optimal given all available information, including the one contained in the realized signal z. Equation (12) aggregates. Equation (13) imposes that the signal is generated by the joint equilibrium behavior of the agents. The only novelty in the above definition relative to Definition 3 is the fixed-point relation between the way that agents react to their available information and the way some of that information (namely the signal z) is generated in the first place. This fixed-point relation is standard in noisy rational-expectations models, including those used in the context of financial markets (eg, Grossman and Stiglitz, 1980; Hassan and Mertens, 2014a).

Note that, in equilibrium, K is correlated with θ. It follows that, *in equilibrium*, z becomes also a signal of θ. This fact permits to map the equilibrium analysis of the present model to that of Section 4. What is different from before is that the precision of the information contained in z about θ is now endogenous to the actions of the agents.

To preserve Normality of the endogenous information structure, Angeletos and Werning (2006) impose the following functional form for the S function:

$$S(K,\zeta) = \Phi^{-1}(K) + \sigma_\zeta \zeta,$$

where Φ^{-1} is the inverse of the c.d.f. of the standardized Normal distribution and σ_ζ is a scalar parameterizing the *exogenous* noise in the signal. This functional form, which was first proposed by Dasgupta (2007), guarantees the existence of equilibria in which the observation of z is equivalent to the observation of a Gaussian signal of the following form:

$$\tilde{z} = \theta + \tilde{\sigma}_\zeta \zeta,$$

for some scalar $\tilde{\sigma}_\zeta$, which is itself determined as part of the equilibrium. Taking $\tilde{\sigma}_\zeta$ as given, the equilibrium strategies and the regime outcome can be characterized in exactly the same fashion as in the case where information was exogenous (modulo replacing the scalar σ_ζ that appears in the analysis of Section 4 with the scalar $\tilde{\sigma}_\zeta$ introduced herein). What remains then is to characterize the equilibrium value of $\tilde{\sigma}_\zeta$.

To complete this task, we must solve the fixed-point relation between the strategies and the information. Intuitively, the sensitivity of $k(x, z)$ to x determines the sensitivity of $K(\theta, z)$ to θ, which in turn determines the precision of the signal $\tilde{z}$ with respect to θ, which in turn determines the sensitivity of $k(x, z)$ to x, and so on. Solving this fixed-point problem ultimately yields the following relation between the endogenous $\tilde{\sigma}_\zeta$ and the exogenous parameters of the model:

$$\tilde{\sigma}_\zeta = \sigma_\epsilon \sigma_\zeta.$$

In other words, the precision of the endogenous public signal is proportional to the precision of the exogenous private signal, and inversely proportional to the exogenous noise in the observation of the size of attack.

The intuition is simple. When private signals are more precise, individual decisions are more sensitive to private information. As a result, the equilibrium aggregate attack reacts relatively more to the underlying fundamental θ than to the common noise ζ, thus also conveying more precise information about θ.

This elementary observation has important implications for the determinacy of equilibria and the volatility of outcomes. As the precision of private information increases, the *endogenous* increase in the precision of the available public information permits agents to better forecast one another's actions and thereby makes it easier to coordinate. Consequently, uniqueness need not obtain as a perturbation away from the perfect-information benchmark. Indeed, in the present model, multiplicity obtains when noise is small.

Proposition 10 *In the model described above, an equilibrium always exists. There are multiple equilibria if* either *of the exogenous noises is small, namely if* $\sigma_\zeta^2 \sigma_\epsilon < 1/\sqrt{2\pi}$.

This result does not upset the theoretical insights developed earlier: it remains true that uniqueness obtains if and only if strategic uncertainty is sufficiently high, which in turn is true if and only if private information overwhelms public information. It nevertheless weakens the empirical relevance of the global-games uniqueness result: in many applications of interest, there may be good reasons to expect that the information structure may be such that multiplicity obtains or, more generally, that outcomes remain highly sensitive to shocks that are largely or totally unrelated to the underlying fundamentals.

Angeletos and Werning (2006) reinforce this message by showing the following result: even if we restrict attention to the region of the parameter space in which the equilibrium is unique (namely, the region of σ_ζ and σ_ϵ such that $\sigma_\zeta^2 \sigma_\epsilon > 1/\sqrt{2\pi}$), a local reduction in either σ_ϵ or σ_ζ leads to an increase in the sensitivity of the equilibrium regime outcome to ζ relative to θ. In short:

Corollary 2 *Less exogenous noise can contribute to more nonfundamental volatility, not only by opening the door to multiple equilibria and sunspot volatility, but also by raising the sensitivity of the equilibrium outcome to higher-order uncertainty even when the equilibrium outcome is unique.*

This result, a variant of which we will encounter in Section 7, contrasts with results in single-agent decision-theoretic settings: in such settings, less noise, whether in the form of more information or in the form of lower cognitive friction, contributes to fewer "mistakes" and less nonfundamental volatility in outcomes. A similar property holds in noisy rational-expectations models of financial markets as those studied in Grossman and Stiglitz (1980) and Hassan and Mertens (2014b): in these settings, less exogenous noise, either in the form of a lower volatility in the demand of noise traders or in the form of more precise information in the hands of sophisticated traders, typically leads to more informative asset prices and less nonfundamental volatility in investment. What differentiates these settings from the models we study in this chapter is the absence of strategic complementarity. Once such complementarity is present, the "paradoxical" result reviewed above emerges, whether we consider models that are prone to multiple equilibria (as those studied presently) or models that are prone to equilibrium uniqueness (as those studied in Section 7).

We conclude by mentioning a few additional papers that also concern the informational role of markets in global-games settings: Hellwig et al. (2006), Tarashev (2007), and Ozdenoren and Yuan (2008). Each of these papers focuses on different institutional details and offers additional insights. They nevertheless share the same core message with Angeletos and Werning (2006): there are good reasons to think that the price mechanism, or other endogenous signals of the actions of others, may "tame" the level of strategic uncertainty relative to what is assumed in Morris and Shin (1998, 2001), thus contributing to nonfundamental volatility. Somewhat complementary is also the paper by Iachan and Nenov (2015), which studies how the quality of private information can contribute to instability, even if one holds constant the precision of public information.

We conclude with a basic but important point, which is neatly illustrated in the work of Hellwig et al. (2006). In many applications of interest, strategic complementarity emerges because, and potentially only because, of the effect that the actions of others have on prices. It follows that strategic uncertainty is relevant in such applications only insofar as agents face uncertainty about the relevant prices. Hellwig et al. (2006) explore the implications of this basic observation within the context of self-fulfilling currency crises. More broadly, the take home message is that the price mechanism plays a dual role: it is the *source* of strategic uncertainty, in the sense that it induces agents to care about the actions of others; but it is also the *regulator* of strategic uncertainty, in the sense that the observability of prices controls the magnitude of the relevant strategic uncertainty.

5.8 Policy Interventions

All the applications reviewed earlier on contain important policy insights. They nevertheless abstract from the possibility that active policy interventions may reveal valuable information about the state of the economy and/or the objectives and intentions of the policy maker. Importantly, because such policy interventions are highly visible, they could affect the level of strategic uncertainty, opening the door to effects that were assumed away in the aforementioned applications.

Motivated by this elementary observation, Angeletos et al. (2006) and Angeletos and Pavan (2013) study global-game settings that add a policy maker, who is informed about the underlying fundamentals and can take an action that may influence the size of attack. Think of a central bank trying to preempt a speculative attack by raising domestic interest rates or imposing a tax on capital outflows; or think of a dictator deploying the police or the army to quell a protest. Such actions are likely to reveal that the status quo is neither too strong nor too weak: if the status quo were sufficiently strong, the policy maker would not bother to intervene, for there would be little risk of an attack; and if the status quo were sufficiently weak, it would be pointless to pay the cost of such interventions, for the status quo would be doomed in any case.

Angeletos et al. (2006) thus show that such policy interventions may induce high common belief that the fundamental θ is within the critical region, even if they do not reveal precise information about the exact value of θ. They then proceed to show how this can open the door to multiple equilibria, not only in the regime outcome, but also in the policy action itself. In a certain sense, the policy maker therefore may find himself trapped in a situation in which he has to conform to market expectations that are beyond his control, as opposed to being able to shape economic outcomes with seemingly powerful tools such as taxes and interest rates.

While this result raises an important caveat to policy applications of global-games results, it does not necessarily eliminate the predictive power of the global-games approach. Angeletos and Pavan (2013) show that, even though the signaling role of policy interventions brings back multiple equilibria, the resulting multiplicity is “much smaller" than the one that is present in the complete-information benchmark. We refer the reader to that paper for the explanation of what this "much smaller" means. The bottom line, however, is that a number of concrete policy predictions emerge that are robust across all equilibria and that could not have been reached without the introduction of incomplete information.

Edmond (2013) studies a different kind of policy interventions: interventions that can manipulate the information that is available to the agents, without however directly signaling information to them. The particular application concerns a dictator manipulating the media or the internet in an attempt to preempt a revolution. The action of the dictator is not directly observable. Instead, it is confounded with the signal the agents observe about the underlying fundamentals. This helps preserve equilibrium uniqueness. Yet, the nature of the optimal manipulation hinges on the effect it has on strategic uncertainty, as opposed to merely the information the agents extract about the fundamentals.

Combined, these papers indicate more generally how policy can interact with frictions in coordination, in manners that are absent from workhorse macroeconomic models. Exploring this possibility within a business-cycle context seems an interesting direction for future research.

5.9 Dynamics

The framework studied in Section 4 is static, and so are the applications we have studied so far. The preceding analysis has thus abstracted from the possibility that agents take multiple shots against the status quo and that their beliefs about their abilities to induce regime change vary over time. Yet, these two possibilities are important from both an applied and a theoretical perspective. First, crises are intrinsically dynamic phenomena. In the context of currency crises, for example, speculators can attack a currency again and again until they force devaluation; and their expectations about the ability of the central bank to defend the currency in the present may naturally depend on whether the bank has successfully defended it in the past. Second, learning in a dynamic setting may critically affect the level of strategic uncertainty (ie, uncertainty about one another's actions) and thereby the dynamics of coordination and the determinacy of equilibria.

Motivated by these considerations, Angeletos et al. (2007) study a repeated version of the regime-change game considered in the previous section. Whenever the regime survives an attack, it leads to common knowledge (or at least a strongly correlated belief) that the regime is "not too weak," or else it would not have survived the attack. This kind of endogenous shift in beliefs opens again the door to multiple equilibria, but it also leads to a number of distinct predictions. First, fundamentals may predict the eventual regime outcome but not the timing or the number of attacks. Second, equilibrium dynamics tend to alternate between phases of *tranquility*, where no attack is possible, and phases of *distress*, where a large attack can occur. Finally, attacks take the form of relatively infrequent and acute changes in the level of economic activity.

Costain (2007) provide a complementary result, showing how the public observation of past actions can lead to herding as well as to multiplicity. By contrast, Heidhues and Melissas (2006), Dasgupta (2007), Dasgupta et al. (2012), and Kováč and Steiner (2013) study settings where learning is private, helping preserve the uniqueness of the equilibrium; these papers then proceed to study questions that have to do with the structure of the dynamics, such as the role of irreversible actions, the option value of waiting-to-see, and the synchronization of actions.

Other dynamic global-games applications that maintain the uniqueness of the equilibrium include Chamley (1999), Giannitsarou and Toxvaerd (2006), Guimaraes (2006), He and Xiong (2012), Huang (2014), Mathevet and Steiner (2013), Steiner (2008), and Toxvaerd (2008). Finally, Chassang (2010) studies a dynamic exit game in which multiplicity survives but is much "smaller" than the one that obtains under complete information, thus helping deliver sharper predictions—a message echoed in Angeletos et al. (2007) and Angeletos and Pavan (2013).

Finally, He and Manela (2016) consider a variant of Abreu and Brunnermeier (2003) that derives interesting dynamics from the interaction of the same two features as in Angeletos et al. (2007): the public signal generated by the fact that the regime has survived past attacks, and the arrival of new private information over time. An important difference, however, is the arrival of private information is endogenous: the paper studies the incentives of acquiring information and show how this endogenously leads to the possibility of a new run after an unsuccessful one.

5.10 Other Related Research

We conclude our review of the global-games literature by briefly mentioning three additional lines of research, one theoretical and two empirical.

The first line endogenizes the acquisition of information in global games. Important contributions include Hellwig and Veldkamp (2009) and Yang (2015). The first paper restricts the agents' information choice in a fixed set of private and public Gaussian signals. The second paper considers an attention-allocation problem as in Sims (2003): the agents are free to choose any signal they wish, including a non-Gaussian signal, at a cost that is proportional to the entropy reduction attained by the chosen signal structure. Both papers reach a similar conclusion: because strategic complementarity raises the incentive to observe the *same* information, there is yet another reason why multiplicity may survive. See, however, Denti (2016) and Morris and Yang (2016) for important qualifications to this conclusion and for even more flexible specifications of the information-acquisition technology.

The second line focuses on testing the empirical implications of global games. Prati and Sbracia (2002) use data on consensus forecasts for six Asian countries to measure the cross-sectional heterogeneity of beliefs in the context of speculative attack; they then proceed to document that both the level effect of this heterogeneity and its interaction with measures of fundamentals is consistent with the predictions of global games. Bannier (2006) and Tillmann (2004) provide complementary reduced-form evidence on the role of informational disparities and belief heterogeneity. Daníelsson and Pe naranda (2011) offer a structural estimation of a global game within the context of carry trades in the yen-dollar market. Chen et al. (2010) use mutual fund data to provide evidence that strategic complementarities among investors contribute to financial-market fragility, and interpret this evidence under the lenses of a global game. Nagar and Yu (2014) provide evidence on the coordinating role of public information, interpreting accounting data as a form of public signal. Finally, Nimark and Pitschner (2015) provide complementary evidence on the endogenous correlation of the information disseminated by newspapers.

The third line is also interested in testing the predictions of global games, but does so within the context of laboratory experiments. See Cabrales et al. (2007), Cornand (2006), Duffy and Ochs (2012), Heinemann et al. (2004, 2009), and Shurchkov (2013).

6. COORDINATION AND SYNCHRONIZATION

So far we have focused on settings where incomplete information impedes coordination within any given period. We now shift attention to another aspect: the agents' ability to synchronize their choices.

More specifically, we review two important contributions. The first one, which is by Frankel and Pauzner (2000) and Burdzy et al. (2001), studies the role of adding a Calvo-like friction in a dynamic game of regime change. By preventing synchronous choice, this friction is shown to help select a unique equilibrium. Importantly, this is true even when the friction is vanishingly small. The second contribution, which is by Abreu and Brunnermeier (2003), is also concerned with asynchronous choice. However, the primitive friction is now the asynchronous awareness of a change in the environment, as opposed to a Calvo-like friction in the agents' ability to act. Such asynchronous awareness is shown to cause a significant delay in the response of the economy, even if all agents become aware pretty fast. We discuss how these contributions shed light on the subtle relation between synchronization and coordination; how they are connected to the global-games literature as well as to one another; and how they illustrate, once again, importance of strategic uncertainty and the potentially fragility of standard macroeconomic models.

6.1 The Calvo Friction, Asynchronous Choice, and Coordination

In this section we discuss the contribution of Frankel and Pauzner (2000) and Burdzy et al. (2001). Unlike the "canonical" example in the global-games literature, these papers study dynamic games of regime change in which the fundamental is perfectly observed in every period. They then proceed to show how equilibrium uniqueness can be induced by the combination of persistent shocks to the fundamentals together with a Calvo-like friction in the ability of the agents to reset their actions.

At first glance, this result appears to be distinct from the one in the global-games literature, and possibly of higher relevance. A closer look, however, reveals a tight connection. We elaborate by reviewing Frankel and Pauzner (2000). Burdzy et al. (2001) contains an extension that may be useful for applications but is not needed for our purposes.

The model in Frankel and Pauzner (2000) is a stochastic version of the two-sector model in Matsuyama (1991), which itself a dynamic variant of the "big-push" model of Murphy et al. (1989). Time is continuous, indexed by $t \in [0, \infty)$, and agents are infinitely lived. At each point of time, each agent can be in one of two idiosyncratic states, state 0 or state 1. Let $k_{i,t} \in \{0, 1\}$ denote the state at which agent i is at time t. The interpretation is analogous to the interpretation of the actions in our static framework. In the aforementioned papers, for example, $k_{it} = 0$ corresponds to living in the village and working in agriculture, whereas $k_{it} = 1$ corresponds to living in the city and working in manufacturing. Furthermore, there is again strategic complementarity: it is more profitable to "attack," that is, to live in the city and work in manufacturing, when enough other agents do the same. What is different is that each agent can not instantaneously switch between "attacking" and "not attacking," which in turn explains why k_{it} is a state variable rather than a control variable.

Let $K_t \in [0, 1]$ denote the fraction of the population that rests at state 1 (city/manufacture) at time t. The life-time utility of agent i is given by

$$\int_0^\infty e^{-\rho t} U(k_{it}, K_t, \theta_t)\, dt,$$

where $\rho > 0$ is the discount rate, θ_t is an exogenous fundamental that affects the relative return to being in the village/agriculture, and $U(k_{it}, K_t, \theta_t)$ is the flow utility. The latter is given as in Assumption 3: the flow payoff from $k_{it} = 0$ is normalized to zero, whereas the flow payoff from $k_{it} = 1$ is given by $b - c > 0$ whenever $K_t \geq \theta_t$ and by $-c < 0$ otherwise.[ar]

We introduce stochasticity in the underlying fundamental by assuming that θ_t follows a Brownian motion with zero drift and volatility parameter $\sigma > 0$: $d\theta_t = \sigma dv_t$. For future reference, we note that the case of no aggregate shocks can be approximated by taking the limit as $\sigma \to 0$. We also let $\theta_L \equiv 0$ and $\theta_H \equiv 1$; these points identify the

[ar] Frankel and Pauzner (2000) allow the net payoff from $k_{it} = 1$ to be a more general function $A(\theta_t, K_t)$ that is increasing in K_t and decreasing in θ_t. The restriction we adopt is only for expositional simplicity. Also, we have changed the notation to make it consistent with the one we use in the rest of the chapter. In particular, note that θ_t equals $-z_t$ in their notation: our fundamental is the opposite of theirs. This explains why the functions κ_L, κ_L, and κ^* below have the opposite monotonicity that the corresponding functions in the original paper.

boundaries of dominance regions in the static benchmark (the one-shot game we studied in Section 4).

Unlike the rest of this chapter, we rule out private information: the realized values of both the exogenous aggregate state θ_t and the endogenous aggregate state K_t are public information at t. Instead, the key friction is idiosyncratic inertia of the same type as in Calvo (1983): each agent's option to switch follows an idiosyncratic Poisson process with arrival rate $1/\lambda$. The scalar λ therefore parameterizes the level of inertia in individual adjustment: the higher λ is, the more likely that an agent is "stuck" in her current location for a while. For future reference, note that instantaneous adjustment is approximated by the limit $\lambda \to 0$.

For comparison purposes, let us momentarily consider the knife-edge case in which $\sigma = 0$ and $\lambda = 0$. By this we do not mean the double limit of the aforementioned model as $\sigma \to 0$ and $\lambda \to 0$. Rather, we mean a variant that *literally* shuts down both the shocks to fundamentals and the Calvo-like friction. The following is then trivially true.[as]

Proposition 11 *Suppose $\lambda = \sigma = 0$ and let $\theta \in (\theta_L, \theta_H]$. For any t, and regardless of the history of past play, there is an equilibrium in which all agents "attack" (locate in the city/work in manufacture), as well as an equilibrium in which all such agents choose the opposite.*

This is essentially a multiperiod version of the multiplicity result we encountered in Section 4.3. The only novelty, in terms of observable implications, is that the multiplicity can take the form of rich fluctuations over time: there can be equilibria in which K_t is constant at either 0 or 1 forever, as well as equilibria in which K_t jumps up and down at arbitrary points of time. In short, sunspot volatility manifests in the time series of aggregate economic activity.

Consider next the case in which $\sigma > 0$ but $\lambda = 0$. That is, allow for shocks to fundamentals, but continue to rule out idiosyncratic inertia. Clearly, the multiplicity result survives. The only minor difference is that the possibility of sunspot volatility may now vary over time, depending on whether the current value of the fundamental happens to lie within the critical region $(\theta_L, \theta_H]$.

Consider next the diametrically opposite case in which $\lambda > 0$ but $\sigma = 0$. That is, introduce the Calvo friction, but rule out shocks to fundamentals. Now, K_t becomes a state variable, which moves slowly over time. This expands the regions over which it is dominant for an agent to choose either location. In particular, if K_t is close enough to 1, then it is dominant for an agent to choose city/manufacture in a neighborhood of θ_t above 0, simply because that agent knows that many other agents will be "stuck" in the same location for a while; and symmetrically, when K_t is close enough to 0, it is dominant to choose village/agriculture in a neighborhood of θ_t below 1. Nonetheless, at least insofar as λ is not too high, multiplicity survives.

[as] The solution concept is Perfect Bayesian Equilibrium.

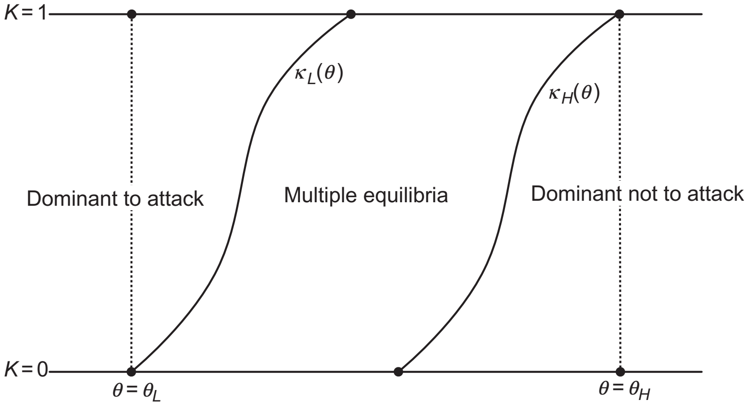

Fig. 2 Multiple equilibria with $\lambda > 0$ and $\sigma = 0$.

This case is illustrated in Fig. 2. One can readily show that there exist increasing mappings $\kappa_L : [\theta_L, \theta_H] \to [0,1]$ and $\kappa_H : [\theta_L, \theta_H] \to [0,1]$, illustrated by the solid lines in the figure, such that the following properties are true. Consider the agents who have the option to act at time t. If $K_t < \kappa_L(\theta_t)$, it is dominant to attack (ie, choose village/agriculture). If $K_t > \kappa_H(\theta_t)$, it is dominant not to attack (ie, choose city/manufacture). Finally, if $\kappa_L(\theta_t) < K_t < \kappa_H(\theta_t)$, there is an equilibrium in which all current agents choose village/agriculture, as well as an equilibrium in which all current agents choose city/manufacture. These equilibria are sustained by the expectation that all *future* agents will do the same as the current agents. In short, the mappings κ_L and κ_H identify the boundaries of, respectively, the lower and the upper dominance regions. For any $\lambda > 0$, we have that $0 < \kappa_L(\theta)$ and $\kappa_H(\theta) < 1$ for all $\theta \in (\theta_L, \theta_H)$. This fact reflects the expansion of the dominance regions mentioned above. But as λ converges to 0, these dominance regions converge uniformly to the dominance regions of the aforementioned variant model in which $\lambda = 0$. The latter are identified by the dotted vertical lines in the figure.

Let us now consider the case of interest, which is the case in which both λ and σ are strictly positive (although potentially arbitrarily small). The following is then true.

Proposition 12 (Frankel–Pauzner) *Suppose $\lambda > 0$ and $\sigma > 0$. There exists a unique, and increasing, mapping $\kappa^* : \mathbb{R} \to [0,1]$ such that the following is true in equilibrium: all the agents who have the option to act at time* t *choose not to attack (ie, locate in the city/work in manufacture) whenever the current aggregate state satisfies $K_t > \kappa^*(\theta_t)$, whereas they make the opposite choice whenever $K_t < \kappa^*(\theta_t)$.*

This result is illustrated in Fig. 3. The two dashed lines give the boundaries of the dominance regions; the solid line gives the mapping κ^*, which of course lies strictly in between the two dominance regions. Different realizations of the Brownian motion may induce the aggregate state (θ_t, K_t) to travel anywhere in the space $\mathbb{R} \times [0,1]$. However, the path of K_t is uniquely pinned down by the path of θ_t. In particular, K_t has a

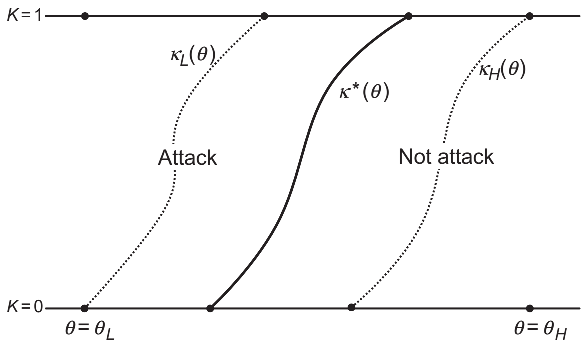

Fig. 3 Unique equilibrium with $\lambda > 0$ and $\sigma > 0$.

positive drift whenever (θ_t, K_t) is on the left of κ^*, and a negative drift on the right of κ^*. In the limit as shocks vanish, K_t therefore converges either to 0 or to 1, depending on initial conditions.

The above result applies even when λ and σ are vanishingly small. This means that the multiplicity result in Proposition 11 is fragile: a small perturbation selects a unique equilibrium.

Furthermore, if we take the limit as the level of idiosyncratic inertia becomes arbitrarily small, we obtain the following sharp characterization of the unique equilibrium.

Proposition 13 *Let* $\theta^* \equiv 1 - \frac{c}{b}$*, fix any* $\sigma > 0$*, and let* $\lambda \to 0$*. The following properties hold in this limit:*

(i) *The mapping* κ^* *becomes vertical at* θ^**:* $\kappa^*(\theta) \to 0 \;\; \forall \;\; \theta < \theta^*$ *and* $\kappa^*(\theta) \to 1 \;\; \forall \;\; \theta > \theta^*$*.*

(ii) *The distribution of* K_t *conditional on* θ_t *converges to a Dirac at* 1 *for all* $\theta_t < \theta^*$ *and to a Dirac at* 0 *for all* $\theta_t > \theta^*$*.*

This result is qualitatively the same as the Morris–Shin limit result in Proposition 8: in essence, every agent is "attacking" whenever the current fundamental is below θ^*, and nobody is attacking whenever the current fundamental is above θ^*, regardless of the history of either past fundamentals or past play. What is more, the threshold θ^* that shows up here is exactly the same as the one that shows up in Proposition 6.

At first glance, this coincidence is surprising, even mysterious. The perturbation considered here is of a different nature than the one considered before: instead of removing common knowledge of fundamentals and introducing private information and strategic uncertainty, we only had to assume (a bit of) idiosyncratic inertia at the individual level along with aggregate shocks to fundamentals. How could it be that two very different perturbations lead to essentially the same selection?

The answer is that there is a deep connection: the combination of idiosyncratic inertia and aggregate shocks transforms the dynamic model under consideration to a game that has a similar mathematical structure as the static global game we have studied in the preceding sections. This fact is most evident if one compares the proof of the uniqueness result in Frankel and Pauzner (2000) with the proof of the uniqueness result that Frankel et al. (2003) provide for a class of static global games with multiple actions: the proofs in the two papers are essentially the same!

To economize space on space and effort, we do not dwell into the formal details. Instead, we provide a sketch of the proof of the uniqueness result in Proposition 12 and relate it to the proof of Proposition 6.

Let us start with the following preliminary observations. At any given point of time, both the exogenous fundamental θ_t and the endogenous state variable K_t are publicly known to all agents. Yet, the mass of agents that have the option to act at any point of time is zero. We can therefore reinterpret the model as one in which a single agent acts at each moment. Because this agent will be "stuck" at her currently chosen action for a while, she must forecast the actions of the agents that will act in the near future. But these agents must themselves forecast the actions of other agents that will move further away in the future. It follows that we can understand the behavior of an agent as a function of her hierarchy of beliefs about the actions of other agents that will have the option to act in either the near or the far future.

These forward-looking higher-order beliefs would not have been relevant if λ were identically zero: it is essential that choices are asynchronous (due to the Calvo-like friction). This, however, does not necessarily mean that the role of higher-order belief vanishes as λ converges to zero from above. As long as both λ and σ are positive, the agents moving at any given point face higher-order uncertainty; and because we are in an environment with strong complementarities, higher-order uncertainty can leave its mark on equilibrium outcomes even if both λ and σ become vanishingly small.

To elaborate, let us fist make the following elementary observation. No matter how small σ is, as long as σ is strictly positive, the fundamentals can drift away over time to either very low or very high levels. As a result, the aggregate state variable (θ_t, K_t) can eventually enter either one of the two dominance regions, even if it is currently far away from both of them.

Consider a moment in time such that the aggregate state is outside the dominance regions but arbitrarily close to one of them, say, the upper one. An agent who acts at that moment does not have a dominant action. However, this agent expects the aggregate state to drift into the upper dominance region with probability close to 1/2, at which point it becomes dominant for future agents to attack (ie, choose village/agriculture). Given this, it becomes optimal–indeed, iteratively dominant–for the current agent to attack as well.

Repeating this argument gives a process of iterated deletion of dominated strategies from "above," which is similar to the one we encountered in the proof of Proposition 6. The only difference is that the process is now over the space of (θ, K), whereas before it was over the space of the private signal x_i. This underscores that the current value of the aggregate state plays a similar role as private information plays in global games.

One can construct a symmetric process of iterated deletion from "below" and can then attempt to prove the uniqueness result by showing that both processes converge to the same point, namely to the strategy described by the mapping κ^*. As it turns out, it is more convenient to consider a modification of the one of the two processes; see Frankel and Pauzner (2000). The substance, however, remains the same: as with the global games, the key mechanism is the impact of higher-order uncertainty, manifested as a contagion effect from the dominance regions.

A natural question is then the following. In global games, uniqueness obtains when private information is sufficiently precise, whereas multiplicity survives if public information is sufficiently precise. Is there an analogue in the present context?

Frankel and Pauzner do not provide an answer to this question. We nevertheless conjecture that multiplicity survives if the fundamental is mean-reverting towards a point in the critical region and, importantly, the mean reversion is sufficiently strong relative to λ and σ. Our intuition is that strong mean reversion in the fundamental has a similar coordinating effect as public information: it helps the current and future agents reach a high common belief about the state.[at]

To recap, the results of Frankel and Pauzner (2000) underscore that, once combined with strategic complementarity and changing fundamentals, asynchronous choice in the form suggested by Calvo (1983) can be interpreted as a friction in coordination.

At some level, this idea is not entirely surprising. In the context of New-Keynesian models, the Calvo friction—and staggered pricing more generally—captures, not only price-stickiness at the individual level, but also the asynchronous price adjustment. It is this asynchronicity that one can reasonably interpret as a friction in coordination, even if one knows nothing about either the global-games literature or the related work of Frankel and Pauzner (2000) and Burdzy et al. (2001).

Yet, the findings of these papers indicate that the workings of the Calvo friction can be more subtle than those understood so far. They also raise the following questions. If the Calvo friction is meant to capture frictions in coordination, does it make sense to impose it *only* on the price-setting behavior of firms, or should we impose it on real choices as well? Also, if the Calvo friction is a proxy for a more primitive friction, what is the latter? Is it menu costs? Or is it an informational friction?

These questions add to the motivation for a later topic of our chapter, namely the study of business-cycle models in which nominal rigidity originates from incomplete information as opposed to Calvo-like asynchronicity. For now, we conclude with few remarks.

Remark 20 In the model described above, equilibrium outcomes are discontinuous in λ at $\lambda = 0$, reflecting the nonvanishing impact of beliefs of arbitrarily high order. This kind

[at] Burdzy et al. (2001) allow for mean-reversion, but take the limit as $\lambda \to 0$. This seems akin to allowing for public information but taking the limit as private information becomes infinitely precise.

of discontinuity, which is similar to the one encountered in global games, rests on the underlying strategic complementarity being of the strong form. If, instead, complementarity is of the weak form, as in the beauty contests and the business-cycle applications we study in Sections 7 and 8, the impact of beliefs of order h vanishes as $h \to \infty$ at a rate high enough that the aforementioned discontinuity does not emerge.[au]

Remark 21 The methods developed in Frankel and Pauzner (2000) and Burdzy et al. (2001) should appeal to macroeconomists, because equilibrium uniqueness is obtained with the help of two familiar modeling ingredients: aggregate shocks to fundamentals and a Calvo-like friction. It is then somewhat surprising that this approach has not attracted more attention in applied research. Exemptions include Frankel and Burdzy (2005) on business cycles, Guimaraes (2006) on currency attacks, and He and Xiong (2012) on debt runs.

Remark 22 The Calvo friction helps captures asynchronous choice in a brute way. A possible alternative is that asynchronous choice is the byproduct of an information friction. Dasgupta et al. (2012) offer an analysis that has such a flavor: they study a dynamic global game in which there is value to synchronize actions and show how lack of common knowledge can impede synchronization. An important earlier contribution in the same vein is Abreu and Brunnermeier (2003), which we review next: in that paper, asynchronous choice is the byproduct of asynchronous awareness.

6.2 Asynchronous Awareness and Coordination (with Application to Bubbles)

We now turn attention to Abreu and Brunnermeier (2003), an important contribution that highlights how asynchronous awareness breaks common knowledge and how this in turn may cause significant delay in the response of equilibrium outcomes to changes in the environment. The particular application considered in Abreu and Brunnermeier (2003) regards asset bubbles: asynchronous awareness is shown to delay the burst of a bubble. The lessons that emerge, however, extend well beyond the particular application.

The model is unlike the ones we have studied so far, because it admits a unique equilibrium regardless of whether information is complete or incomplete. It nevertheless shares a similar contagion mechanism working through higher-order beliefs. The paper's key contribution is to show how this kind of mechanism can help explain why a bubble may persist long after every trader has recognized that the price is unsustainable.

More specifically, the paper studies a continuous-time model in which a unit mass of sophisticated traders, each with relatively shallow pockets, decide whether to ride or attack an asset bubble. If enough of them attack the bubble, then the bubble will burst immediately. If, instead, enough of them choose to ride the bubble, then the bubble will

[au] See Weinstein and Yildiz (2007b) for a formalization of this kind of intuition, albeit within the context of a static game.

survive for a while—but not forever. In particular, the bubble will burst at some random date $t = T$, even if no trader ever attacks it.

Before we proceed, we should clarify what a bubble means. In Abreu and Brunnermeier (2003), a bubble is defined in terms of two possible price paths. The first path, which is interpreted as the "bubble path," features both a higher level and a higher growth rate than the second, the "fundamental path." Both of these paths are exogenous. What is endogenous is only the crash of the bubble, that is, the transition from the first to the second path. The contribution of the paper rests in the characterization of this transition.

This transition is characterized under two scenarios. In the first scenario, Nature publicly announces at $t = 0$ the aforementioned date T to all traders at once. In the second scenario, Nature gradually reveals this date to the traders over a small time interval of length δ; think of this as each trader becoming aware of, or "wakening up" to, the fact that there is a bubble, without however knowing right away how many other traders have also waken up. The two scenarios lead to different predictions, even when δ is arbitrarily small. This is because in the first scenario the aforementioned fact becomes common knowledge instantly, whereas in the second scenario asynchronous awareness implies that common knowledge of the aforementioned fact is not achieved even long time after every single agent has herself become aware of the fact.

Let us elaborate. To start, consider the first scenario, in which all agents wake up simultaneously. In this case, the bubble bursts immediately (at $t = 0$). The proof is as follows. Suppose that a trader believes that no other trader will ever attack. Then, this trader knows that the asset will continue to have abnormal returns for any $t < T$ and that its price will jump down exactly at T. It is then optimal for the trader to ride the bubble up to $t = T - \epsilon$ and sell the asset just at that moment.[av] But if all traders do the same, then the bubble will burst at $T - \epsilon$ rather than T, in which case it becomes optimal for the individual trader to sell the asset at $t = T - 2\epsilon$ rather than at $t = T - \epsilon$. Repeating this argument proves that the bubble bursts immediately, no matter how far in the future T happens to be.

Consider next the second scenario, in which agents wake up in an asynchronous manner. In this case, the bubble can persist for long time after *all* traders have waken up. To explain why, suppose that it takes half of the traders to attack in order for the bubble to burst before T. It follows that the bubble will survive at least till $t = \delta/2$, because not enough traders are awake prior to this point for a coordinated attack to trigger a crash. (Recall that δ denotes the length of time it takes for all traders to wake up; think of δ as small relative to T.)

[av] Although the model is in continuous time, it helps to recast it in discrete time, letting ϵ denote the length between any two consecutive points of time and thinking of ϵ as arbitrarily small.

Consider a trader who just woke up. At this moment, the trader does not know whether she is the first in line to wake up or the last one. As long as she is strictly below the middle of the line, she is better of riding the bubble, because it will take more time for half of the traders to be awake and therefore for a crash to be possible. But if this is true, it is optimal for the trader to ride the bubble even if she happens to be on or just above the middle of the line. Iterating, it is possible to prove that a trader who just woke up finds it optimal–indeed dominant—not to attack the bubble right away.

We can now use this fact to initiate a process of iterated deletion of dominated strategies from "below": given that it is dominant for a trader not to attack at the moment she wakes up, it becomes iteratively dominant for a trader to delay attacking for a certain time interval after she has woken up, which in turn makes it iteratively dominant not to attack for an even bigger time interval, and so on. The opposite process, the one from "above," gets initiated from the fact that it is dominant for a trader to attack once she reaches date $t = T - \epsilon$, for arbitrarily small ϵ.

Abreu and Brunnermeier (2003) prove that the aforementioned two processes converge to the same point, which means that the equilibrium is unique and is associated a critical threshold τ^* such that the following is true: the trader keeps riding the bubble until τ^* units of time have passed since she woke up, and starts attacking the bubble thereafter. It follows that the bubble bursts at date $t = t^* \equiv \delta/2 + \tau^*$, which is how long it takes for exactly 1/2 of the traders to attack. Importantly, t^* can be much larger than δ, although, of course, it has to be smaller than T. It follows that the bubble can survive for long time after it has become known—but not common knowledge—to all traders that the bubble will burst.

To recap, the unraveling that triggers the immediate burst of the bubble in the first scenario hinges on the assumption that traders can instantaneously reach common knowledge of the fact that there is a bubble that can be burst by a coordinated run. Once this assumption is relaxed by allowing for asynchronous awareness of the aforementioned fact, there can be significant delay in the kind of coordinated action that is needed for the bubble to burst and the market price to get in line with the asset's fundamental valuation.

Remark 23 We will encounter similar delay effects within the class of "beauty contests" and the related business-cycle applications that we study in Sections 7 and 8. In that context, the relevant delay effects will manifest as rigidity, or inertia, in the response of certain outcomes to innovations in the underlying fundamentals.

Remark 24 As anticipated, the effects of asynchronous awareness that we reviewed here have a similar flavor as the effects of asynchronous choice—or the Calvo friction—that we discussed in Section 6.1. This supports our earlier claim, namely that there is a tight relation between asynchronous choice and informational frictions. Understanding the exact nature of this relation is an open question; applying the insights to business-cycle settings is another fruitful direction for future research.

7. BEAUTY CONTESTS: THEORY

In this section we turn attention to a class of games that feature weak complementarity and linear best responses. The incomplete-information versions of these games are often referred to as "beauty contests," due to a resemblance with Keynes' parable for financial markets. For applied purposes, one can think of this class of games as a stylization of unique-equilibrium macroeconomic models whose equilibrium conditions can be represented as, or at least be approximated by, a system of (log)linear equations. The lessons we develop in the present section are therefore relevant for canonical business-cycle models of either the RBC or the New-Keynesian type, as well as for a class of asset-pricing models. Such applications are discussed in the next section; here, we develop some basic insights, building in part on the analyses of Morris and Shin (2002b), Angeletos and Pavan (2007, 2009), and Bergemann and Morris (2013).

Remark 25 The settings studied in this and the next section differ from those studied in Sections 4–6 in two related respects. First, they admit a unique equilibrium—in fact, a unique rationalizable outcome—irrespective of the structure of information. Second, they let higher-order beliefs matter in a more modest manner than in global games: beliefs of order h have a vanishingly small effect as $h \to \infty$.

7.1 Setup

In this section we use the framework introduced in Section 2 and impose the following restrictions.

Assumption 4 (Beauty Contest) $D_k = D_\theta = \mathbb{R}$ and U is quadratic in (k, K, θ). Furthermore, U satisfies the following restrictions: $U_{kk} < 0$, $0 \leq -U_{kK}/U_{kk} < 1$, and $U_{k\theta} > 0$.

The first restriction, $U_{kk} < 0$, imposes concavity at the individual level, ensuring that best responses are well defined. The second restriction, $0 \leq -U_{kK}/U_{kk} < 1$, is equivalent to imposing that the slope of best responses with respect to aggregate activity is positive but less than one. This means that strategic complementarity is of the weak form and guarantees that the equilibrium is unique. The last restriction, $U_{k\theta} > 0$, is innocuous: it means that, other things equal, a higher fundamental causes the agent to take a higher action. (If the converse had been true, we could have simply redefined θ as $-\theta$).

Remark 26 Although in this section we restrict attention to the case of weak strategic complementarity (namely $0 \leq -U_{kK}/U_{kk} < 1$), many of the key lessons, including those about the role of incomplete information in sustaining inertia and animal spirits, extend also to the case of strategic substitutability (namely $-U_{kK}/U_{kk} < 0$).

7.2 Complete-Information Benchmark

As in the case of global games, we start by studying the benchmark of complete information, which in turn nests the case of perfect information.

Proposition 14 (Complete Info) *There exist coefficients* $(\kappa_0, \kappa_1, \kappa_2)$*, pinned down by the payoff function U, such that the following is true: whenever information is complete, the equilibrium action is given by*

$$k_i = \kappa\left(\mathbb{E}_i\theta_i, \mathbb{E}_i\overline{\theta}\right) \equiv \kappa_0 + \kappa_1\mathbb{E}_i\theta_i + \kappa_2\mathbb{E}_i\overline{\theta}, \tag{14}$$

where $\overline{\theta} \equiv \int \theta d\Theta(\theta)$ *is the average fundamental and* $\mathbb{E}_i$ *is the rational expectation conditional on* ω_i.

The coefficients $(\kappa_0, \kappa_1, \kappa_2)$, which are characterized in the Appendix, depend on U and thereby on the micro-foundations of the particular application that lies behind U. Understanding what determines these coefficients and how they can be identified in the data is important within any individual application.[aw]

Recall that complete information means common knowledge of the distribution of information, $\mathbf{\Omega}$, but allows for the possibility that agents face uncertainty either about their own fundamental (θ_i) or about the aggregate fundamentals ($\mathbf{\Theta}$, or $\overline{\theta}$). This explains why the forecast of the fundamentals, $\mathbb{E}_i\theta_i$ and $\mathbb{E}_i\overline{\theta}$, show up in the above characterization. Trivially, the case of perfect information is then nested simply by letting $\mathbb{E}_i\theta_i = \theta_i$ and $\mathbb{E}_i\overline{\theta} = \overline{\theta}$. That is, as we move from perfect information to imperfect but complete information, all we have to do is to replace the actual fundamentals with the forecasts of them. This offers a sharp illustration of the more general point we made in Section 3: insofar as strategic uncertainty is ruled out, it makes little difference whether the agents face uncertainty about the fundamentals or know them perfectly.

7.3 Equilibrium with Incomplete Information

Suppose now that information is incomplete. In this case, equilibrium actions need not be pinned down by fundamentals (or forecasts of fundamentals), because the latter are generally not sufficient for forecasting the actions of others. This makes equilibrium outcomes vary away from, and around, their complete-information counterparts, in a manner that is formalized in the next two propositions.

Proposition 15 (Equilibrium and Coordination) *The equilibrium satisfies the following fixed-point relation*

[aw] For instance, in the context of the neoclassical economy introduced in Section 2, κ_1 measures the "micro" elasticity of the response of a farmer's output to an idiosyncratic shock to her own productivity, whereas $\kappa_1 + \kappa_2$ measures the "macro" elasticity of the response of aggregate output to an aggregate productivity shock. The former is representative of ZIP- or state-level elasticities that are estimated in Mian et al. (2013), Mian and Sufi (2014), and Nakamura and Steinsson (2014) on the basis of appropriate cross-sectional variation in the data; the latter is what macroeconomists are most often concerned with; the two differ because of general-equilibrium effects, which are captured here by the dependence of U (and of U_K in particular) on K.

$$k_i \;=\; \mathbb{E}_i\left[\kappa\left(\theta_i,\overline{\theta}\right)\right]+\alpha\cdot\mathbb{E}_i\left[K-\kappa\left(\overline{\theta},\overline{\theta}\right)\right], \tag{15}$$

where $\alpha \equiv -U_{kK}/U_{kk} \in [0, 1)$.

Proposition 16 (Equilibrium and Higher-order Beliefs) *Suppose that each agent knows her own fundamental. Then, the equilibrium action of agent* i *is given by*

$$k_i=\kappa_0+\kappa_1\theta_i+\kappa_2\mathbb{E}_i\left\{\sum_{h=0}^{\infty}(1-\alpha)\alpha^h\bar{\mathbb{E}}^h[\overline{\theta}]\right\}, \tag{16}$$

where $\bar{\mathbb{E}}^h[\overline{\theta}]$ *denotes the* h*th order average forecast of the mean fundamental.*[ax]

Proposition 15 highlights the dependence of equilibrium allocations on beliefs regarding aggregate activity (forecasts of the actions of others). To understand condition (15), recall that $\mathbb{E}_i\left[\kappa\left(\theta_i,\overline{\theta}\right)\right]=\kappa\left(\mathbb{E}_i\theta_i,\mathbb{E}_i\overline{\theta}\right)$ is the action agent *i* would have taken in equilibrium had information been complete. How much an agent deviates from this benchmark when information is incomplete depends on $\mathbb{E}_i\left[K-\kappa\left(\overline{\theta},\overline{\theta}\right)\right]$, which is her forecast of the deviation of the average action of the rest of the population from this benchmark, weighted by the coefficient α. In this sense, the coefficient α measures how much each *individual* cares about aligning her action with that of others, or equivalently the private motive to coordinate: it identifies the degree of strategic complementarity.

Proposition 16 then restates this result in terms of the hierarchy of beliefs (forecasts of the forecasts of others). For this part we have added the restriction that each agent knows her own fundamental. This restriction allows us to isolate the uncertainty that agents face about one another's actions from the uncertainty that each agent may face about her own preferences and technologies: we shut down the latter and concentrate on the former. Comparing the above result to Proposition 14, we then see that the key difference as we move from complete to incomplete information is that $\mathbb{E}_i\overline{\theta}$ has been replaced by $\mathbb{E}_i\left\{\sum_{n=0}^{\infty}(1-\alpha)\alpha^h\bar{\mathbb{E}}^h[\overline{\theta}]\right\}$, a weighted average of the entire hierarchy of beliefs about the underlying aggregate fundamental. This is because an agent's first-order belief of the aggregate shock is no longer sufficient for forecasting the equilibrium level of aggregate activity; the agent needs to forecast the forecasts of others. The coefficient α then determines the sensitivity of the equilibrium action to higher-order beliefs: the stronger the degree of complementarity, the stronger the impact of higher-order beliefs relative to first-order beliefs.

That said, note that the specifics of higher-order beliefs do not matter per se: if we change, say, the 3rd and the 7th order belief of an agent while keeping $\mathbb{E}_i\left\{\sum_{n=0}^{\infty}(1-\alpha)\alpha^h\bar{\mathbb{E}}^h[\overline{\theta}]\right\}$ constant, then her optimal action does not change. This is

[ax] The operator $\bar{\mathbb{E}}^h$ is defined recursively by letting, for any variable X, $\bar{\mathbb{E}}^0[X]=X$, $\bar{\mathbb{E}}^1[X]\equiv\bar{\mathbb{E}}[\bar{\mathbb{E}}^0[X]]\equiv\int\mathbb{E}_i[X]di$ and $\bar{\mathbb{E}}^h[X]\equiv\bar{\mathbb{E}}\left[\bar{\mathbb{E}}^{h-1}[X]\right]=\int\mathbb{E}_i\left[\bar{\mathbb{E}}^{h-1}[\overline{\theta}]\right]di \;\; \forall h\geq 2$.

because the agent's best response depends merely on her first-order belief of K, not the details of either the belief hierarchy about the fundamentals or the underlying information structure. This underscores, once again, that incomplete information and higher-order uncertainty are modeling devices that allow the researcher to accommodate interesting, and potentially testable, variation in the agents' expectations (first-order beliefs) of economic outcomes. We will discuss how this can be understood in a manner that is robust to the underlying micro-foundations.

7.4 Simplifying Assumptions

To simplify exposition, we make a few additional assumptions. First, we rescale the fundamental so that the following is true.

Assumption 5 $\kappa_0 = 0$ and $\kappa_1 + \kappa_2 = 1$.

Using the characterization of the coefficients κ_1 and κ_2 (equation (A.6) in the Appendix), one can then show that $\kappa_1 = 1 - \alpha$ and $\kappa_2 = \alpha$. This means that, under complete information, $1 - \alpha$ measures the *micro* elasticity of the individual's action to her own fundamental, α measures the general-equilibrium feedback in the case of aggregate shocks; and $1 = (1 - \alpha) + \alpha$ measures the *macro* elasticity of the aggregate action to an aggregate shock. It also implies that the agent's best response under incomplete information, or equation (15), reduces to the following:

$$k_i = (1-\alpha)\mathbb{E}_i[\theta] + \alpha \cdot \mathbb{E}_i[K]. \tag{17}$$

To simplify the exposition and also to stay close to the applied literature, we rule out payoff heterogeneity and assume a Gaussian specification for the underlying common fundamental and for the information the agents receive about it.

Assumption 6 There is a common fundamental: $\theta_i = \overline{\theta} = \theta$, for all i and all states of nature.

Assumption 7 The fundamental θ is drawn from a Normal distribution with mean 0 and variance $\sigma_\theta^2 > 0$.[ay] Each agent observes two signals, a private one and a public one. The private signal takes the form

$$x_i = \theta + u + \epsilon_i,$$

where u and ϵ_i are common and idiosyncratic noises that are independent of one another as well as of θ, and are drawn from Normal distributions with mean 0 and variances, respectively, $\sigma_u^2 \geq 0$ and $\sigma_\epsilon^2 \geq 0$. The public signal takes the form

$$z = \theta + \zeta,$$

[ay] Allowing for a nonzero prior mean for θ only adds a constant in the equilibrium action, without affecting any of the positive properties we document below.

where ζ is noise, independent of θ, u and all ϵ_i, and drawn for a Normal distribution with mean 0 and variance $\sigma_\zeta^2 \geq 0$.

Incomplete information requires $\sigma_\epsilon > 0$ and $\sigma_\zeta > 0$, that is, nontrivial private information about the aggregate fundamental, but does not necessarily require $\sigma_u > 0$. In fact, much of the related literature (eg, Morris and Shin, 2002b; Angeletos and Pavan, 2007) is nested here by restricting $\sigma_u = 0$, that is, by shutting down the correlated noise, u, in the private signal. The reason why we allow for such correlation is twofold. First, it helps mimic the correlation in beliefs that emerges as agents talk to their neighbors or participate in localized markets. Second, the noise u in combination with the noise ζ allow us to disentangle the aggregate variation in beliefs of aggregate activity from the variation in either the fundamental or the beliefs of it.

To formalize this point, consider the residuals of the projection of $\bar{\mathbb{E}}\theta$ and $\bar{\mathbb{E}}K$ on θ.[az] From Proposition 17 and Proposition 18 (see below), we have that the two residuals are linear transformations of u and ζ. When u is shut down, as is done in much of the existing literature, the two residuals become proportional to one another, implying that the noise in beliefs of endogenous economic outcomes is perfectly correlated, and thus indistinguishable from the noise in the beliefs of the fundamentals. When instead u is switched on, as we do here, the two residuals cease to be perfectly correlated, thus permitting us to disentangle the two types of noise. By the same token, the introduction of u helps accommodate a strong form of "animal spirits": as emphasized in Proposition 19 below, expectations of economic activity (and actual activity) can fluctuate holding constant *both* the true fundamentals and the agents' beliefs of them.

It is also worth noting that the assumed information structure is less restrictive than it seems. Let A be the set of joint distributions for $(\theta, \bar{\mathbb{E}}\theta, K, \bar{\mathbb{E}}K)$ that can be obtained in equilibrium under the assumed information structure, for some $(\sigma_u^2, \sigma_\epsilon^2, \sigma_\zeta^2)$. Next, let B be the set of joint distributions for $(\theta, \bar{\mathbb{E}}\theta, K, \bar{\mathbb{E}}K)$ that can be obtained in equilibrium under *arbitrary* Gaussian information structures. The latter nests cases in which the agents observe an arbitrary collection of Gaussian signals, not only about the underlying fundamental (θ), but also about the endogenous outcome (K) or even about one another's signals; it can also nest situations where the agents talk to one another, either directly, or through some market mechanism. Using a similar argument as in Bergemann and Morris (2013), one can show that $A = B$. One can thus think of the assumed signal structure merely as a convenient parameterization of the type of outcomes that can be obtained under arbitrary information structures, as opposed to seeking a literal interpretation of it.

Unless stated otherwise, we impose σ_ϵ, σ_ζ, $\sigma_u > 0$.

[az] To ease notation, we henceforth let $\bar{E}X$ be a short-cut for $\bar{\mathbb{E}}[X]$, for any variable X.

7.5 The Structure of Higher-Order Beliefs

As a stepping stone towards the characterization of the equilibrium, we next study how the hierarchy of beliefs varies with the underlying aggregate shocks, namely the fundamental θ and the noises ζ and u.

Proposition 17 (Higher-Order Beliefs) *For every $h \geq 1$, there exist positive scalars $(\omega_\theta^h, \omega_u^h, \omega_\zeta^h)$ such that the* h*th order average expectation of the fundamental is given by*

$$\bar{\mathbb{E}}^h[\theta] = \omega_\theta^h \theta + \omega_\zeta^h \zeta + \omega_u^h u,$$

for every realization of (θ, ζ, u). Furthermore, for every $h \geq 1$,

$$1 > \omega_\theta^h > \omega_\theta^{h+1} > 0 \quad \text{and} \quad 0 < \frac{Var\left(\bar{\mathbb{E}}^h[\theta]\middle|\theta\right)}{Var\left(\bar{\mathbb{E}}^h[\theta]\right)} < \frac{Var\left(\bar{\mathbb{E}}^{h+1}[\theta]\middle|\theta\right)}{Var\left(\bar{\mathbb{E}}^{h+1}[\theta]\right)} < 1.$$

This result means that beliefs of any given order h vary with the fundamental, θ, and the two sources of noise, u and ζ; but the higher the order h is, the smaller the absolute response of the hth order belief to the fundamental; and the higher the contribution of the noise relative to that of the fundamental in driving the volatility in hth order beliefs. The first property, namely the lower response to the fundamental, is the mirror image of the fact that higher-order beliefs are more anchored to the prior (which of course does not move with the realized fundamental) than lower-order beliefs. The second property, on the other hand, means that higher-order beliefs are more "noisy" than lower-order beliefs, in the sense that the R-square of the projection of the former on the fundamental is lower than that of the projection of the latter on the fundamental.

These properties have been established here only for a very specific information structure. However, using methods similar to those of Bergemann and Morris (2013), it is possible to show that these properties are shared by essentially any Gaussian information structure. By the same token, the positive implications we document next are not driven by any ad-hoc specifications of the information structure; rather, they are *generic* to the incompleteness of information.

7.6 Positive Implications

We now proceed to translate the preceding properties of higher-order beliefs into those of the observables of the model. To this goal, we must first take a stand on what the model's observables are. For the purposes of the present exercise, we envision that the researcher collects data on the exogenous fundamental θ, the endogenous aggregate outcome K, and possibly the average beliefs of these objects, namely $\bar{\mathbb{E}}\theta$ and $\bar{\mathbb{E}}K$. For instance, in the context of the neoclassical economy introduced in Section 2 and taken up again in the next section, K corresponds to aggregate output and θ to labor productivity. The researcher can observe these variables in standard macroeconomic data sets, and can extract information about agents' beliefs of these objects from surveys of expectations.

Definition 15 The model's observables are $(\theta, \bar{\mathbb{E}}\theta, K, \bar{\mathbb{E}}K)$. The model's predictions are the restrictions the model imposes on the joint distribution of $(\theta, \bar{\mathbb{E}}\theta, K, \bar{\mathbb{E}}K)$.

Note that the stochastic properties of θ and $\bar{\mathbb{E}}\theta$ are dictated directly by the assumptions the researcher makes about shocks and information. A model's essence is in the "cross-equation restrictions" it imposes on the stochastic properties of the endogenous objects K and $\bar{\mathbb{E}}K$. We now characterize these restrictions.

Proposition 18 (Positive Properties) *For any given information structure, there exist positive scalars* $(\phi_\theta, \phi_u, \phi_\zeta)$ *and* $(\psi_\theta, \psi_u, \psi_\zeta)$, *such that the aggregate outcome and the average forecast of it satisfy the following:*

$$K = \phi_\theta \theta + \phi_\zeta \zeta + \phi_u u \quad \textit{and} \quad \bar{\mathbb{E}}[K] = \psi_\theta \theta + \psi_\zeta \zeta + \psi_u u.$$

Furthermore,

$$1 > \phi_\theta > \psi_\theta > 0, \tag{18}$$

and

$$0 < \frac{Var\,(K|\theta)}{Var\,(K)} < \frac{Var\,\left(\bar{\mathbb{E}}[K]\middle|\theta\right)}{Var\,(\bar{\mathbb{E}}[K])} < 1. \tag{19}$$

This result represents the equilibrium counterpart of Proposition 17. To interpret it, note that ϕ_θ identifies the slope of the aggregate outcome to the fundamental, ψ_θ identifies the corresponding slope of the average forecast of the aggregate outcome, and finally the (normalized) slope of either object under complete information is 1. Condition (18) therefore means the average forecast under-reacts relatively to the actual outcome, and that both of them under-react relative to the complete-information benchmark. Condition (19), on the other hand, means that the average forecast of K is relatively more noisy than the actual K, in the sense that the relative contribution of the noises ζ and u to the volatility of $\bar{\mathbb{E}}K$ is larger than those to the volatility of K. In this sense, forecasts under-react to fundamentals but overreact to noise.

This result suggests a unifying explanation for two seemingly contradictory sets of facts: the *under-reaction* of forecasts documented in Coibion and Gorodnichenko (2012); and the *overreaction* of forecasts documented in Greenwood and Shleifer (2014) and Gennaioli et al. (2015). We expand on the relation to Coibion and Gorodnichenko (2012) in the next section; we leave the potential connection to Greenwood and Shleifer (2014) and Gennaioli et al. (2015) to future work.

We also note that the actual level of aggregate activity and the average belief of it are positively but only imperfectly correlated:

$$1 > Corr(K, \bar{\mathbb{E}}[K]) > 0.$$

By contrast, when information is complete, the above correlation becomes perfect.

Pushing this observation a bit further, we have the following result.

Proposition 19 (Animal Spirits) *The economy features "animal spirits," not only in the sense of Definition 13, but also in the sense that*

$$Var\left(K|\theta,\bar{\mathbb{E}}\theta\right)>0.$$

Furthermore, the following is necessarily true:

$$Var\left(\bar{\mathbb{E}}K\middle|\theta,\bar{\mathbb{E}}\theta\right)>0 \quad \text{and} \quad Cov\left(K,\bar{\mathbb{E}}K\middle|\theta,\bar{\mathbb{E}}\theta\right)>0.$$

Recall that Definition 13 identified animals spirits with situations in which outcomes vary without commensurate variation in the agents beliefs of their *own* fundamentals. In the present context, own and aggregate fundamentals coincide ($\theta_i=\overline{\theta}$ for all i and all states of nature). It follows that animal spirits obtain in the sense of Definition 13 if and only if $Var(K|\bar{\mathbb{E}}\theta)>0$.

The first part of Proposition 19 reinforces this possibility by showing that variation in outcomes can obtain holding constant, not only the beliefs of the fundamental, but also the realized fundamental. This helps disentangle "animal spirits" from the noise in beliefs of the fundamental: aggregate activity varies while holding constant both the true fundamental and the aggregate error in beliefs of the fundamental. It also underscores that the notion of "animal spirits" used here, and the related notion found in Angeletos and La'O (2013), is both conceptually and empirically distinct from that used in Lorenzoni (2009) and Barsky and Sims (2012): in these papers, "animal spirits" is defined as noise in beliefs of fundamentals. Instead, the notion used here is closely connected to the one used in the literature on multiple equilibria and sunspot fluctuations; as noted before, the only difference is that we engineer animal spirits with the help of rich higher-order beliefs as oppose to multiple equilibria and correlation devices.

The second part of Proposition 19 states that the volatility attributed to "animal spirits" is features positive comovement between actual and expected outcomes, underscoring once more its self-fulfilling nature.

We conclude that incomplete information allows the researcher to rationalize empirically relevant imperfections in the comovement of fundamentals, economic outcomes, and beliefs thereof—thereby accommodating a number of facts that may be prima-facie inconsistent with workhorse macroeconomic models. We elaborate on this point in the next section, within the context of specific applications.

7.7 Complementarity, Information, and Volatility

Before moving to the applications, we study how the degree of strategic complementarity α affects the different kinds of volatility in the model's observables. Clearly, the stochastic properties of θ and $\bar{\mathbb{E}}\theta$ are invariant to α; we thus need to consider only the effect of α on the stochastic properties of K and $\bar{\mathbb{E}}K$, which is what the next proposition does.

Proposition 20 (The Effect of Complementarity) *Stronger strategic complementarity (higher α) results in all of the following:*

(i) *Less covariation between the fundamental and either the aggregate outcome or the average belief of it:*

$$\frac{\partial Cov\,(K,\theta)}{\partial\alpha}<0 \quad and \quad \frac{\partial Cov\,(\bar{\mathbb{E}}K,\theta)}{\partial\alpha}<0$$

(ii) *Higher portion of volatility driven by noise:*

$$\frac{\partial}{\partial\alpha}\left(\frac{Var\,(K|\theta)}{Var\,(K)}\right)>0 \quad and \quad \frac{\partial}{\partial\alpha}\left(\frac{Var\,(\bar{\mathbb{E}}K|\theta)}{Var\,(\bar{\mathbb{E}}K)}\right)>0$$

(iii) *More room for animal spirits, not only in the sense of Definition 13, but also in the stronger sense defined in Proposition 19:*

$$\frac{\partial Var\,(K|\theta,\bar{\mathbb{E}}\theta)}{\partial\alpha}>0 \quad \frac{\partial Var\,(K|\theta,\bar{\mathbb{E}}\theta)}{\partial\alpha}>0 \quad and \quad \frac{\partial}{\partial\alpha}\left(Cov\left(K,\bar{\mathbb{E}}K\middle|\theta,\bar{\mathbb{E}}\theta\right)\right)>0$$

To appreciate this result, note that under the maintained normalization $\kappa_1+\kappa_2=1$, the value of α is completely immaterial for aggregate outcomes when information is complete. The above result therefore reveals how incomplete information interacts with strategic complementarity (or general-equilibrium effects) to shape the covariation of actual economic outcomes and their forecasts. To put it differently, this result hinges entirely on strategic uncertainty.

We conclude by noting that while incomplete information helps accommodate animal spirits and overreaction to certain forms of noise, it can do so only at the expense of dampening the overall volatility.

Proposition 21 (Volatility Bound) *The unconditional variance of* K *under incomplete information is lower than its perfect-information counterpart.*

This result follows from the basic fact that the variance of the forecast of any variable is always lower than the variance of the variable itself. Applying this fact recursively gives that the variance of higher-order forecasts is lower than the variance of lower-order forecasts, which in turn is lower than the variance of the fundamental. Because the equilibrium K is a weighted average of the hierarchy of forecasts, it then follows that the volatility of K is maximal when information is perfect.

That said, we wish to emphasize that this result concerns the *unconditional* variance of K, whereas researchers are often interested in certain *conditional* moments, such as those conditional on certain shocks or, in dynamic contexts, on certain past outcomes. When it comes to this kind of conditional moments, incomplete information may actually contribute to more volatility.[ba] Finally, although the volatility of the average fundamental

[ba] As a trivial example, recall that $Var(K|\bar{\mathbb{E}}\theta)>0$ and $Cov(K,\bar{\mathbb{E}}K)<1$*only* when information is incomplete: with complete information, $Var(K|\bar{\mathbb{E}}\theta)=0$ and $Cov(K,\bar{\mathbb{E}}K)=1$.

places an upper bound on the volatility of the aggregate outcome in the current setting, this bound can be relaxed in settings that allow for local interactions and/or idiosyncratic shocks; see Angeletos and La'O (2013) and Bergemann et al. (2015).

7.8 Dynamics and Learning

So far the analysis has been confined to a static framework in order to deliver key insights in a sharp and transparent manner. In applications, however, it is often central to allow for two different kinds of dynamics. The first has to do with learning over time (the dynamics of beliefs). The second has to do with intertemporal payoff interdependences, which make the decisions depend on past and/or future actions (backward- and/or forward-looking effects).

7.8.1 Slow Learning and Inertia

To illustrate the role of the dynamics that obtain from slow learning, we now consider a repeated variant of our static beauty contest game. In this variant, the best responses remain static, in the sense that they depend only on the contemporaneous actions of others. Yet, interesting dynamics obtain because the fundamental is persistent and there is slow private learning about it.

Example 1 The fundamental of each agent i follows a Gaussian random walk:

$$\theta_{it} = \theta_{it-1} + \nu_t + \xi_{it},$$

where $\nu_t \sim N(0, \sigma_\nu^2)$ is an aggregate innovation and $\xi_{it} \sim N(0, \sigma_\xi^2)$ is an idiosyncratic one. Furthermore, in every period t, player i observes a private signal of her own fundamental:

$$x_{it} = \theta_{it} + \epsilon_{it} \tag{20}$$

where $\epsilon_{it} \sim N(0, \sigma_\epsilon^2)$ is an idiosyncratic noise.

The optimal action of agent i is still given by

$$k_{it} = \mathbb{E}_{it}[(1-\alpha)\theta_{it} + \alpha K_t].$$

What is novel relative to our static setting is only the dynamic evolution of beliefs implied by the combination of persistent fundamentals and noisy learning.

To see how these features matter for the observables of the model, let us first consider the special case in which there is no complementarity ($\alpha = 0$). In this case, equilibrium outcomes depend merely on first-order beliefs of fundamentals. Furthermore, thanks to the Gaussian specification, the dynamics of first-order beliefs can be shown to obey the following rule:

$$\mathbb{E}_{it}\theta_t = \mathbb{E}_{it-1}\theta_{it} + \lambda[x_{it} - \mathbb{E}_{it-1}x_{it}],$$

for some $\lambda \in (0, 1)$ that depends on the standard deviations of the innovations in the fundamental and the noise in the signal. This result is an application of the Kalman filter, with

λ being the Kalman gain.[bb] Using $\mathbb{E}_{it-1}x_{it} = \mathbb{E}_{it-1}\theta_{it}$ and rearranging gives $\mathbb{E}_{it}\theta_{it} = (1-\lambda)\mathbb{E}_{it-1}\theta_{it-1} + \lambda x_{it}$. Aggregating implies that

$$\bar{\mathbb{E}}_t\theta_t = (1-\lambda)\bar{\mathbb{E}}_{t-1}\theta_{t-1} + \lambda\theta_t.$$

Finally, when $\alpha = 0$, we have that $K_t = \bar{\mathbb{E}}_t\theta_t$. It follows that we can express the dynamics of K_t as follows:

$$K_t = (1-\lambda)K_{t-1} + \lambda\theta_t,$$

When information is perfect ($\sigma_\epsilon = 0$), λ becomes 1 and the expression above reduces to $K_t = \theta_t$, implying that K_t follows a random walk, just as the underlying fundamental. When instead information is imperfect ($\sigma_\epsilon > 0$), λ is strictly lower than 1, implying that K_t features sluggish response to the innovation in the fundamental. In particular, if we let IRF_j denote the cumulative effect of an aggregate innovation on the level of aggregate activity j periods after the innovation occurs,[bc] we have the following characterization:

$$IRF_0 = \lambda, \quad IRF_1 = \lambda[1 + (1-\lambda)], \quad IRF_2 = \lambda\left[1 + (1-\lambda) + (1-\lambda)^2\right], \quad \text{etc.}$$

Note then that IRF_j is an increasing sequence that starts from λ and converges to 1, with a higher speed of convergence when λ is higher. Combining this observation with the fact that λ is decreasing in σ_x, we infer that more noise (higher σ_x) induces more inertia in the response of the aggregate outcome K to any innovation in the underlying fundamental.

It is important to recognize that, when $\alpha = 0$, the information that matters is only the one that each agent has about her *own* fundamental, not the one about the aggregate fundamental. What explains the inertia documented above is therefore the lack of (first-order) knowledge of own fundamentals, not the lack of common knowledge of aggregate fundamentals. By the same token, this kind of inertia can be quantitatively important only insofar as the agents are sufficiently uninformed about their own fundamentals.

We can summarize all these points as follows.

Proposition 22 *Slow learning can induce inertia* by itself*, even if $\alpha = 0$ (ie, in the absence of strategic, or general-equilibrium, interdependence). However, the following properties hold whenever $\alpha = 0$:*

(i) *The inertia that is present at the aggregate level (in the response of aggregate outcomes to aggregate shocks) coincides with the inertia that is present at the individual level (in the response of idiosyncratic outcomes to idiosyncratic shocks).*

(ii) *Both types of inertia vanish as the agents learn their own fundamentals, regardless of the information they may or may not have about aggregate economic conditions.*

[bb] Strictly speaking, λ should be allowed to be a deterministic function of t, reflecting the dependence on the initial prior. But as time passes, the impact of the prior vanishes, and λ_t converges to a constant, which identifies the steady-state solution of the Kalman filter. Here, as in most of the applied literature, we focus on this solution.

[bc] Formally, for any $j \geq 0$, $IRF_j = \partial\mathbb{E}[K_{t+j}|K_{t-1}, v_t]/\partial v_t$.

By contrast, when $\alpha > 0$, inertia can result from lack of common knowledge of the aggregate fundamental and can be quantitatively important, even if each agents is arbitrarily well informed about both her own or the aggregate fundamentals. This is because higher-order beliefs are less sensitive to innovations in fundamentals than lower-order beliefs, not only contemporaneously (which is the effect already documented in the static setting), but also in terms of their dynamic adjustment.

We illustrate this property with the following modification of the preceding example.

Example 2 The fundamental of each agent i is given by $\theta_{it} = \overline{\theta}_t + \xi_{it}$, where $\xi_{it} \sim N\left(0, \sigma_{\xi}^2\right)$ is an idiosyncratic shock and $\overline{\theta}_t$ is the aggregate fundamental. The latter follows a random walk:

$$\overline{\theta}_t = \overline{\theta}_{t-1} + \nu_t,$$

where $\nu_t \sim N\left(0, \sigma_{\nu}^2\right)$ is an aggregate innovation. Finally, in every period t, agent i observes her own fundamental, θ_{it}, along with the following additional private signal about the aggregate fundamental:

$$x_{it} = \overline{\theta}_t + \epsilon_{it},$$

where $\epsilon_{it} \sim N\left(0, \sigma_{\epsilon}^2\right)$ is idiosyncratic noise.

We can then show the following.

Proposition 23 (Complementarity and Inertia) *When $\alpha = 0$, $K_t = \overline{\theta}_t$. When instead $\alpha \in (0, 1)$,*

$$K_t = \gamma_K K_{t-1} + \gamma_{\theta} \overline{\theta}_{t-1} + \gamma_{\nu} \nu_t,$$

for some scalars $\gamma_K, \gamma_{\theta}, \gamma_{\nu}$ that depend on $(\alpha, \sigma_{\epsilon}, \sigma_{\xi}, \sigma_{\nu})$.

This result follows from Angeletos and La'O (2010)'s adaptation of Woodford (2003). Woodford (2003) studies an environment where there is no payoff heterogeneity, thus combining two mechanisms: the inertia induced by mere lack of knowledge of own fundamentals, with the inertia induced by strategic complementarity and lack of common knowledge of the aggregate fundamentals. By contrast, Angeletos and La'O (2010) and the closely related example we study here isolate the second mechanism by imposing perfect information about own fundamentals. The dependence of K_t on K_{t-1} and $\overline{\theta}_{t-1}$ documented in the above result therefore reflects the endogenous persistence introduced by, *and only by*, the friction in coordination.[bd]

To gain further insight, we consider a numerical example. Fig. 4, which is borrowed from Woodford (2003), illustrates the dynamic response of the average first- and higher-order forecasts of $\overline{\theta}_t$ to a positive innovation in it. For any order h, the response of $\overline{\mathbb{E}}_t \overline{\theta}_t$,

[bd] The exact characterization of this dependence was elusive to both Woodford (2003) and Angeletos and La'O (2010), but becomes possible with the method developed in Huo and Takayama (2015a,b).

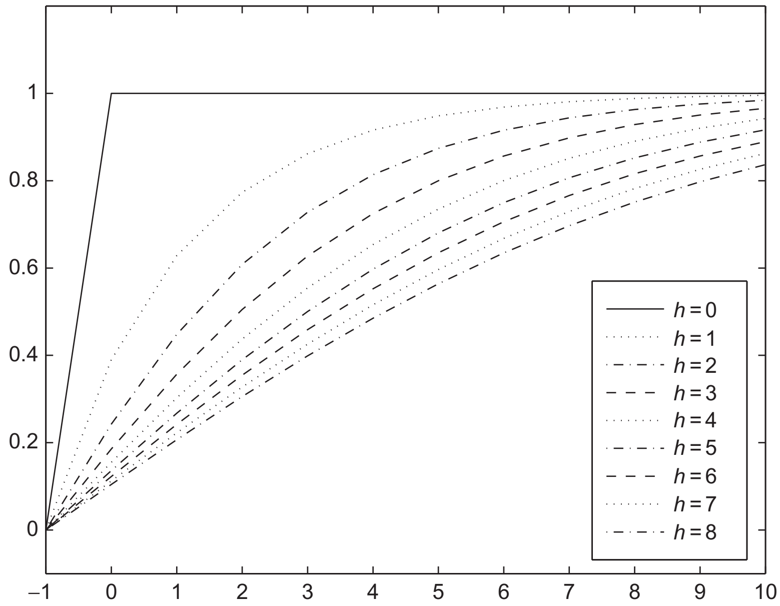

Fig. 4 Dynamics of first- and higher-order beliefs.

the *h*th order forecast, eventually converges to 1 as time passes, reflecting the accumulation of more and more information over time. Yet, in any finite period after the innovation has occurred, higher-order beliefs remain further away from 1 than lower-order beliefs, mirroring the property documented in Proposition 17 on the static framework. What is more, higher-order beliefs converge to 1 more slowly than lower-order beliefs. All in all, Fig. 4 therefore reveals that higher-order beliefs exhibit, not only lower sensitivity on impact, but also more sluggishness over time.

The translation of these properties to the observables of the model is straightforward. Importantly, if we fix the information structure (and hence also fix the dynamics of first- and higher-order beliefs) but increase the degree of strategic complementarity, we obtain both a smaller immediate response and a more sluggish adjustment of the equilibrium level of activity.

Last but not least, note that the mechanism we have documented above operates at the aggregate level but not at the idiosyncratic level (or in the cross section): because the agents are perfectly informed about their own fundamentals, they exhibit no inertia at all in their response to idiosyncratic shocks.

In the next section, we present two applications of this mechanism: one in the context of an RBC economy hit by technology shocks, another in the context of New-Keynesian economy hit by a monetary shock. Moving beyond these examples, the broader lesson is the following.

Fact Frictions in coordination, modeled as incomplete information coupled with strategic complementarity, can help generate significant inertia in the response of aggregate outcomes to aggregate shocks to fundamentals, even when the available information about the fundamentals is precise and even when there is no such inertia in the response of idiosyncratic outcomes to idiosyncratic shocks.

Remark 27 As anticipated in Section 6.2, the inertia we have documented here is of a similar nature as the delay effects documented in the asynchronous-awareness setting of Abreu and Brunnermeier (2003). In both cases, the key is that higher-order beliefs adjust more slowly that first-order beliefs–or, equivalently, that agents continue to lack confidence on whether others will adjust to a change in the environment long after they have themselves become confident that this change took place.

7.8.2 Intertemporal Payoff Interdependencies

We now turn attention to the role of intertemporal payoff interdependencies. In particular, we have in mind settings in which an agent's actions in any given period depend on her expectations of the actions of other agents, not only in the same period, but also in the future. Such forward-looking features are standard in dynamic macroeconomic models. Importantly, these features expand the room for higher-order beliefs.

Consider, for example, the textbook RBC model. In this model, the labor-supply and consumption-saving choices of a household in any given period depend, not only on the current wage and interest rate, but also on her expectations of wages and interest rates in all subsequent periods. Furthermore, the wage and the interest rate that clear the relevant markets in any given period depend on the joint behavior of all consumers and firms, which in turn depend on their own expectations of future wages and interest rates, and so on. It follows that the kind of high-order beliefs that are relevant can be vastly richer than the one we have allowed so far. In particular, even if the past and current fundamentals are common knowledge, one can sustain frictions in coordination by introducing private information about future fundamentals.

To illustrate these points, consider a dynamic game in which the best-response function of player i happens to take the following form:

$$k_{it} = \mathbb{E}_{it}[g(\theta_{it}, K_t; \theta_{it+1}, K_{t+1})], \tag{21}$$

where g is a linear function. The dependence of g on θ_{it} and K_t mirrors the one accommodated in our earlier static analysis; the novelty here is the inclusion of the next-period variables θ_{it+1} and K_{t+1}. This inclusion captures the forward-looking aspects of the environment.

To give an example, let us consider a monetary model that merges Woodford (2003) with Taylor (1979, 1980). In particular, firms face two frictions in their price-setting behavior: first, they have incomplete information about aggregate economic conditions (as in Woodford); and second, they can reset their prices only every two periods (as in

Taylor). In the absence of these two frictions, the optimal price in period t would have been given (after an appropriate log-linearization) by

$$p_{it}^{*} \equiv (1-\alpha)\theta_{it} + \alpha P_t$$

where θ_{it} summarizes exogenous demand and supply shocks hitting the firm in period t, P_t is the endogenous price level in period t, and α is the degree of strategic complementarity in pricing decisions. When only the first friction (incomplete information) is present, the optimal price set by firm i is

$$p_{it} = \mathbb{E}_{it} p_{it}^{*} = \mathbb{E}_{it}[(1-\alpha)\theta_{it} + \alpha P_t]. \tag{22}$$

When instead both of the aforementioned frictions are present, the optimal reset price is given by

$$\begin{aligned} p_{it} &= \mathbb{E}_{it}\left[\frac{1}{1+\beta} p_{it}^{*} + \frac{\beta}{1+\beta} p_{it+1}^{*}\right] \\ &= \mathbb{E}_{it}\left[\frac{1}{1+\beta}((1-\alpha)\theta_{it} + \alpha P_t) + \frac{\beta}{1+\beta}((1-\alpha)\theta_{it+1} + \alpha P_{t+1})\right] \end{aligned} \tag{23}$$

where β is the firm's discount factor. Clearly, while equation (22) is nested in our static framework, (23) is nested in the dynamic extension we have just introduced.[be]

Now we go back to the general set up, equation (21). We will show that strategic uncertainty can originate, not only from differential *current* information about the current and future fundamentals, but also from uncertainty of the information that others may receive in the *future*. To isolate the second channel, we shut down the former by restricting $g_2 = 0$. In other words, only future actions of other agents, not current actions of others, matter for an agent's best response. For simplicity, we also assume that there are no idiosyncratic shocks, so that $\theta_{it} = \theta_t$. Then, using the linearity of g and aggregating, we get

$$K_t = g_1 \bar{\mathbb{E}}_t \theta_t + g_3 \bar{\mathbb{E}}_t \theta_{t+1} + g_4 \bar{\mathbb{E}}_t K_{t+1}. \tag{24}$$

Next, let

$$\tilde{\theta}_t \equiv \theta_t + \frac{g_3}{g_1}\theta_{t+1},$$

[be] As already noted, the example considered here is a hybrid of Woodford (2003) and Taylor (1979, 1980). If one considers hybrids of Woodford (2003) and Calvo (1983), like those studied in Angeletos and La'O (2009) and Nimark (2011), the key difference is that p_{it} then depends on the expectation of $(\theta_{i\tau}, P_\tau)$, not only for $\tau \in \{0, 1\}$ as in the present example, but also for $\tau > 1$. This enriches the type of strategic uncertainty that is relevant, which can be important for quantitative purposes; but it only reinforces the message we wish to convey here.

Clearly, we can then rewrite the above as

$$K_t = g_1 \bar{\mathbb{E}}_t \widetilde{\theta}_t + g_4 \bar{\mathbb{E}}_t K_{t+1}. \tag{25}$$

With some abuse of notation, we henceforth redefine θ_t as $\widetilde{\theta}_t$. This indicates that the appropriate interpretation of what the "period-t fundamentals" mean in the theory is neither the exogenous payoff relevant variables that happen to get realized in period t nor the exogenous shocks that enter the period-t flow payoff of an agent; rather, it is the collection of all payoff-relevant variables that are relevant for period-t decisions, regardless of the time the values of these variables materialize or appear in the player's flow payoffs.

Notwithstanding these observations, let us now solve for the equilibrium K_t. To this goal, let $z_t^0 \equiv \bar{\mathbb{E}}_t \theta_t$ and, for all $j \geq 1$, let

$$z_t^j \equiv \bar{\mathbb{E}}_t z_{t+1}^{j-1} = \bar{\mathbb{E}}_t \{ \bar{\mathbb{E}}_{t+1} \{ \ldots \{ \bar{\mathbb{E}}_{t+j} \{ \theta_{t+j} \} \} \ldots \} \}.$$

Iterating (25) yields

$$K_t = g_1 \sum_{j=0}^{+\infty} (g_4)^j z_t^j. \tag{26}$$

It follows that K_t depends not only on today's forecasts of fundamentals (the forecasts captured in z_t^0) but also on today's forecasts of *tomorrow*'s forecasts of fundamentals (the forecasts captured in z_t^1), on today's forecasts of tomorrow's forecasts of forecasts two period ahead (z_t^2), and so on. Uncertainty about the information that others may receive in the *future* can thus serve as an independent source of higher-order uncertainty in the *present*. Nevertheless, there is no need to get lost in the wilderness of higher-order beliefs. If we put aside condition (26) and go back to (24), we can readily see that, conditioning on the equilibrium first-order beliefs of K_t and K_{t+1}, the actual outcome K_t is invariant to the underlying hierarchy of beliefs about the fundamentals. As with our static framework, it therefore remains true that the practical value of incomplete information is to enrich the testable restrictions on the observables of the model.

7.9 Endogenous Information Acquisition

We now discuss a strand of the literature that endogenizes the acquisition of information, or the allocation of attention, within beauty contests. We follow Myatt and Wallace (2012) and Pavan (2015) because their framework is essentially the same as ours. Other notable contributions include Hellwig and Veldkamp (2009), Vives (2016), Chahrour (2014), Colombo et al. (2014), Llosa and Venkateswaran (2015), Yang (2015), and Denti (2016).

This line of work is closely related to the one on rational inattention, such as Sims (2003) and Maćkowiak and Wiederholt (2009). It nevertheless departs from it in that it pays attention to the following fact: economic agents may wish to collect information that is useful for predicting and tracking the actions of others, even if that information is not particularly useful for predicting and tracking the underlying fundamentals.

We use the payoff structure introduced in Section 7, along with the simplifying assumptions introduced in Section 7.1 and 7.4. The only novelty is the introduction of an "information technology," by which we mean the following.

Each agent i has access to $N \in \mathbb{N}$ potential sources of information about θ, the underlying common fundamental, which is drawn from $N\left(0, \sigma_\theta^2\right)$. We let $\pi_\theta \equiv \sigma_\theta^{-2}$ denote the precision of the common prior about θ. The information contained in each source $n \in \{1, \ldots, N\}$ is given by

$$y_n = \theta + \epsilon_n,$$

where $\epsilon_n \sim N\left(0, \eta_n^{-1}\right)$ is i.i.d. Normally distributed noise, independent of θ. By paying attention $z^i = \left(z_n^i\right)_{n=1}^N \in \mathbb{R}_+^N$ to the available sources, agent $i \in [0,1]$ then receives private signals $x^i \equiv \left(x_n^i\right)_{n=1}^N \in \mathbb{R}^N$ as

$$x_n^i = y_n + \xi_n^i,$$

where $\xi_n^i \sim N\left(0, \left(t_n z_n^i\right)^{-1}\right)$ is i.i.d. Normally distributed noise, independent of θ and $\epsilon \equiv (\epsilon_n)_{n=1}^N$. Myatt and Wallace (2012) and Pavan (2015) interpret the parameter η_n as the *accuracy* of the source (the "sender's noise"), and the parameter t_n as the *transparency* of the source (how a marginal increase in the attention increases the precision of private signal that each agent ultimately obtains from "listening" to the source).

Agents incur a cost when paying attention to any given source. In particular, payoff are now given by

$$U(k_i, K, \theta) - C\left(z^i\right) \tag{27}$$

where U is as in Section 7 and C is an increasing and continuously differentiable function.

To simplify exposition, we normalize $U_{kk} = -1$ and restrict attention to the case in which attention is perfectly substitutable across different sources in the following sense.[bf]

Assumption 8 $C\left(z^i\right) = c\left(\sum_{n=1}^N z_n^i\right)$, where $c(\cdot)$ is strictly increasing, strictly convex, and differentiable.

One can then establish the following result regarding the equilibrium allocation of attention.

Proposition 24 *There exists a threshold* $\Delta > 0$ *such that, in the unique symmetric equilibrium,*

$$z_n = \frac{\eta_n max\left\{\left(\Delta - \frac{1}{\sqrt{t_n}}\right), 0\right\}}{(1-\alpha)\sqrt{t_n}}.$$

[bf] See Myatt and Wallace (2012) and Pavan (2015) for the more general case.

Proposition 24 follows from proposition 2 in Myatt and Wallace (2012), as well as from proposition 1 and corollary 1 in Pavan (2015). Transparency (t_n) determines whether a source of information will receive any attention and also how much attention it receives. Accuracy (η_n) instead only influences how much attention each information source receives, conditional on that source being used. The intuition why accuracy does not play a role in determining whether an information source receives positive attention is as follows. When z_n is small, the total amount of noise from information source n is dominated by the receiver noise, ξ_n^i. As a result, when thinking about which information source to pay attention, a player starts with the most transparent source.

Let us now define the *publicity* of an information source as the correlation of the noises in signals that two different agents receive from this source[bg]:

$$\rho_n \equiv corr\left(x_n^i, x_n^j | \theta\right) = \frac{z_n t_n}{z_n t_n + \eta_n}$$

We can now state the following result, which is due to Myatt and Wallace (2012) and regards the interaction of the coordination motive with the acquisition of information.

Proposition 25 *As the degree of strategic complementarity* α *rises, attention moves away from more private signals and towards more public signals: there is a* $\hat{\rho}$ *such that the attention paid to source n is locally increasing in* α *if and only if* $\rho_n > \hat{\rho}$.

Intuitively, public signals act as effective focal points for players' coordination. As the desire for coordination strengthens, agents pay more attention to such signals.

Pavan (2015) investigates the question of whether the equilibrium allocation of attention is efficient from the perspective of a social planner that is interested in maximizing ex ante welfare. This complements the earlier work by Angeletos and Pavan (2007), which studied the efficiency of the equilibrium use of information, taking the latter as exogenously given. We refer the reader to these works for an analysis of these normative questions; and to Angeletos and La'O (2012), Llosa and Venkateswaran (2015), and Paciello and Wiederholt (2014) for applications related to business cycles and macroeconomic policy.

We close this section by circling back to the connection between the present framework and the rational inattention literature. The applications of this literature that relate to monetary policy are briefly noted in Section 8.5; for a more extensive review, see Sims (2010). Here, we instead focus on two conceptual issues: the sense in which the framework we study can nest the works of Sims (2003) and Maćkowiak and

[bg] This is related to the notion of the *commonality* of information used in Angeletos and Pavan (2007). See that paper for how this notion helps understand both the positive and the normative properties of the class of games we have been studying.

Wiederholt (2009); and the sense in which it allows for an important departure from these works.

Let $x^i = (x^i_1, \ldots, x^i_N)$ and $y = (y_1, \ldots, y_N)$. Next, assume that instead of facing a cost for paying attention to different sources of information, the agents face a "capacity constraint" of the following form:

$$\Gamma\left(x^i, y\right) \leq \overline{\Gamma}, \tag{28}$$

for some function Γ. The agent's attention-allocation problem is then to choose z^i so as to maximize

$$\mathbb{E}\left[U(k_i, K, \theta) - \lambda\Gamma\left(x^i, y\right)\right]$$

where $\lambda \geq 0$ is the Lagrange multiplier associated with the capacity constraint. This is obviously nested in our present framework by letting $C(z^i) = \lambda\Gamma\left(x^i, y\right)$, no matter what the function Γ is.

To nest the information-acquisition problems studied by Sims (2003) and much of the related rational-inattention literature, we need to make two assumptions. The first is that Γ is the function that measures the mutual information between two random variables; in a Gaussian context like the one we are studying here, this means letting $\Gamma\left(x^i, y\right) = \frac{1}{2} log\left[det\left[V(x^i)\right] / det\left[V(x^i|y)\right]\right]$, where $\det[\cdot]$ denotes the determinant of a matrix, $V\,(x^i)$ denotes the covariance matrix of the random variable x^i, and $Var(x^i|y)$ denotes the covariance matrix of x^i conditional on y.

The second assumption is that there is a single and perfect source of information about the fundamental: $y = \theta$. This means that the attention-allocation problem reduces to one of trying to track *only* the fundamental, as opposed to various sources of information. This is not a serious limitation in a single-agent, decision-theoretic context. In a context with strategic, or general-equilibrium interactions, however, this restriction means there is no more a useful distinction between tracking the fundamental and tracking the actions of others: under this restriction, all the noise in the private signals of the agents becomes *purely* idiosyncratic, implying that the equilibrium value of **K** is pinned down by the fundamental θ. In equilibrium, predicting **K** is therefore the same as predicting θ.

It is this last property that is more relevant for our purposes. If none of the available sources of information is perfect, the underlying noise in the sources becomes correlated noise in the private signals received by different agents. As noted before, such correlated noise helps disentangle the expectations of endogenous outcomes from the expectations of exogenous fundamentals, for it accommodates aggregate shocks in the gap between first- and higher-order beliefs. The more flexible forms of information acquisition proposed by Myatt and Wallace (2012) and Pavan (2015) are therefore best suited for understanding how strategic, or general-equilibrium interaction may *endogenously* lead to more correlated noise.[bh]

On the other hand, an important feature of Maćkowiak and Wiederholt (2009) that is missing from both Myatt and Wallace (2012) and Pavan (2015) is the trade off in allocating attention to idiosyncratic vs aggregate shocks. Merging the two frameworks is an interesting venue for future research.[bi]

7.10 A Note on Solution Methods

Dynamic models with time-varying fundamentals and dispersed information can be hard to solve. Townsend (1983) first suggested that a finite state space solution for the equilibrium dynamics need not exist, reflecting an infinite-regress problem in forecasting the forecast of others.

To circumvent the problem, Townsend (1983) proposed the following short-cut: let the exogenous state of nature become common knowledge after T periods, where $T \geq 1$ is potentially large but finite. Then, for a class of linear models, one can guess and verify the existence of an equilibrium in which aggregate outcomes can be expressed as linear functions of the history of shocks over the last T periods, along with the relevant commonly-known state variables prior to that period.[bj]

It is worth noting here that Townsend (1983) was concerned with settings in which there were no strategic complementarity in actions and higher-order beliefs entered

[bh] We refer the reader also to Denti (2016) for an analysis that covers games with either a finite number or an infinity of players. See in particular the discussion in Section 9.4 of that paper regarding the significance of allowing for noise in the underlying sources of information if one wishes to obtain nonfundamental volatility in games with an infinity of players, like those studied in the present chapter.

[bi] Myatt and Wallace (2012) and Pavan (2015) restrict attention to settings where, as in the analysis above, there is a single fundamental that is common to all agents. Maćkowiak and Wiederholt (2009) study a setting in which there are two types of fundamentals: an aggregate monetary shock, and a purely idiosyncratic TFP shock. They study the optimal allocation of attention across these two types of fundamentals, under the restriction that each agent observes an pair of independent noisy private signals for the two fundamentals (as opposed to observing a joint signal of both fundamentals). Denti (2016) considers a more general structure that allows for arbitrary correlation among the fundamentals of different players, but does not focus on the aforementioned trade off and, unlike Myatt and Wallace (2012) and Pavan (2015), rules out the noise in the underlying sources of information.

[bj] For instance, if we consider Example 1 from Section 7.8, this would mean expressing K_t as a linear function of θ_{t-T-1} and of $(\nu_{t-T}, \ldots, \nu_{t-1}, \nu_t)$. More generally, one would have to include the values of any endogenous state variable (such as capital), as well as any aggregate shock to information (such as the noise in public signals), not just fundamentals.

decisions only though a signal-extraction problem.[bk] The method, however, readily extends to the class of environments we are interested in. For recent applications, see Bacchetta and van Wincoop (2006), Hellwig (2005); Hellwig and Venkateswaran (2009), and Lorenzoni (2009).

It is tempting to interpret Townsend's short cut as an approximate solution for the situation in which the past shocks never become common knowledge. However, the conditions under which this is true are not completely understood. On the one hand, Hansen and Sargent (1991) and Kasa (2000) verify that this is indeed the case for the leading example in Townsend (1983).[bl] On the other hand, Rondina and Walker (2014) present a version of Singleton's (1987) asset-pricing model in which the equilibrium is perfectly revealing when the lag T is finite (no matter how large), but not when T is infinite.

An alternative approximation method involves a truncation of the hierarchy of beliefs, rather than a truncation of the history of shocks. Nimark (2011) pursues this method. He also shows that the approximation error vanishes as the truncation gets larger for a class of dynamic linear models that exhibit a similar "stability" property as the static games studied in Weinstein and Yildiz (2007b), namely the property that the impact of higher-order beliefs on actions vanishes at an exponential rate as the order increases. Notwithstanding the theoretical appeal of this method, its computational efficiency and its comparison to Townsend's approach remain unclear.

Barring the above kinds of shortcuts and approximations, the literature has long struggled to obtain *exact* finite-state solutions for models with infinite horizons and perpetually dispersed information. A few papers have considered special examples in which it is possible to guess and verify the existence of such a solution using the Kalman filter; see Pearlman and Sargent (2005), Singleton (1987), and Woodford (2003). Another line of work has obtained analytic characterizations of the equilibrium by transforming the problem into the frequency domain; see Futia (1981), Kasa (2000), Kasa et al. (2007), Acharya (2013), and Rondina and Walker (2014). These papers have therefore been able to provide important insights into the dynamics of higher-order beliefs, often in settings

[bk] More specifically, Townsend (1983) used two examples. In the first example, there are two industries, each trying to extract a signal about the underlying fundamental from the price of the other industry. In the second, there is a continuum of industries, each trying to extract a signal of the underlying fundamental from aggregate outcomes. Townsend suggested that an infinite-regress problem exists in both examples, because an agent's signal extraction depends on the actions of others, which in turn depend on their signal extraction, and so on. However, Hansen and Sargent (1991) points out that the apparent infinite-regress problem vanishes in the first example: the solution turns out to be perfectly revealing due the limited dimensionality of the underlying uncertainty. The problem remains in the second example, which is the one that Townsend (1983) actually concentrates on, thanks to the fact that available signals are contaminated by measurement error.

[bl] That is, the example with a continuum of industries studied in section VIII of Townsend (1983).

with endogenous signals. Yet, the results of these papers appear to rest on special settings, which has limited their applicability and has not helped advance quantitative work.

A significant breakthrough was recently made by Huo and Takayama (2015a,b). The authors show that a finite-state space solution is possible for a large class of linear models insofar as the observed signals are exogenous and the underlying shocks (fundamentals and noises) follow ARMA processes. In particular, the solution itself has an ARMA structure, although typically of a higher order than those of the underlying shocks. The method may still be computationally intensive if there are multiple endogenous state variables and multiple shocks, but it is flexible and powerful.[bm]

A more radical approach is proposed in Angeletos et al. (2015). The key idea is to use a heterogeneous-prior specification that helps proxy the dynamics of higher-order beliefs that are induced by incomplete information, while bypassing all the computational difficulties. Each agent is assumed to believe that there is a bias in the signals of others. Variation in this perceived bias moves higher-order beliefs without moving first-order beliefs. The noise is taken to zero, shutting down noisy learning and forcing a low-dimensional representation of the stochastic process of the entire belief hierarchy. All in all, Angeletos et al. (2015) are able to augment a large class of DSGE models with rich yet highly tractable higher-order belief dynamics: the belief-augmented models can be solved and structurally estimated with the same ease and computational efficiency as standard, representative-agent models.[bn]

We review two related applications of the last two methods in Section 8.7 and use them to argue that the waves of optimism and pessimism that are rationalized by higher-order belief dynamics can offer a quantitatively potent explanation of business-cycle phenomena. Additional works that seek to push the quantitative frontier of the literature include Melosi (2014), who estimates a version of Woodford (2003); Mankiw and Reis (2007); Kiley (2007), and Reis (2009), who estimate DSGE models with sticky information; Maćkowiak and Wiederholt (2015), who study the quantitative performance of a DSGE model in which both firms and consumers are rationally inattentive; and David et al. (2014), who use firm-level data to gauge the cross-sectional misallocation of inputs caused by informational frictions.

[bm] The method also rules out signals of endogenous outcomes. This need not be a serious limitation for certain quantitative purposes, because the informational content of endogenous signals can be mimicked by appropriately chosen exogenous signals. Furthermore, an extension of the method can be used to obtain an approximate solution to models with endogenous signals; see Huo and Takayama (2015b) for details.

[bn] The potential downside is that this method gives the researcher the freedom to specify higher-order beliefs “at will” (ie, without the restrictions imposed by the combination of the common-prior assumption and specific information structures). How this freedom is used in practice is a delicate balancing act. Angeletos et al. (2015) propose that data on forecasts can offer much of the needed discipline, but do not pursue this idea in detail.

8. BEAUTY CONTESTS: APPLICATIONS

The analysis of the previous section has indicated that incomplete information has two key positive implications. First, it dampens the response of equilibrium actions to changes in the underlying fundamentals. Second, it accommodates forces akin to animal spirits along the unique equilibrium. In this section we explore what these properties mean within the context of specific applications; how they can help accommodate important facts that are inconsistent with certain workhorse macroeconomic models; and how they can inform policy. We also make a digression to discuss the connection between the mechanisms we study here and those in the complementary literature on sticky information (Mankiw and Reis, 2002; Reis, 2006) and rational inattention (Sims, 2003; Maćkowiak and Wiederholt, 2009).

8.1 Real Rigidity and Technology Shocks

In this section we discuss how frictions in coordination can be the source of real rigidity at the macro level[bo] and how this in turn can help reconcile the RBC paradigm with Gali (1999).

Gali (1999) argues that a key implication of the RBC model regarding the response of employment to technology shocks is grossly inconsistent with the data. More specifically, Gali uses a structural VAR method to estimate the impulse response functions of macroeconomic aggregates to an identified technology shock in US data: he run a VAR on key macroeconomic variables and identified the technology shock as the only shock that drives labor productivity in the long run.[bp] He then compares the impulse response functions obtained in the data with those predicted by the model.

Fig. 5, which is a replica of fig. 4 in Gali (1999), depicts the impulse responses of labor productivity, output, and employment obtained in the data. As it is evident in the first panel, the identified shock in the data triggers an immediate and persistent increase in productivity. This makes the identified shock in the data comparable to the theoretical technology shock in the RBC model. And yet, as seen in the last panel, the identified technology shock leads to a decline in hours/employment in the short run, which is exactly the opposite of what the RBC model predicts.

Gali (1999) proceeds to argue that this fact is consistent with the New-Keynesian framework. Suppose that prices are sticky. Suppose further that monetary policy fails

[bo] By "real rigidity" we refer to inertia in the response of real quantities, such as employment and output, to shocks in fundamentals, such as preferences and technology. See Angeletos et al. (2016b) for a complementary discussion of the sense in which incomplete information can be the source of either real or nominal rigidity (or of both) in the related applied literature.

[bp] Gali (1999) run a baseline bivariate VAR on hours and labor productivity; the same finding obtains in a five-variable VAR on hours, labor productivity, money supply, interest rates and price level. Fig. 5 below is based on the five-variable specification.

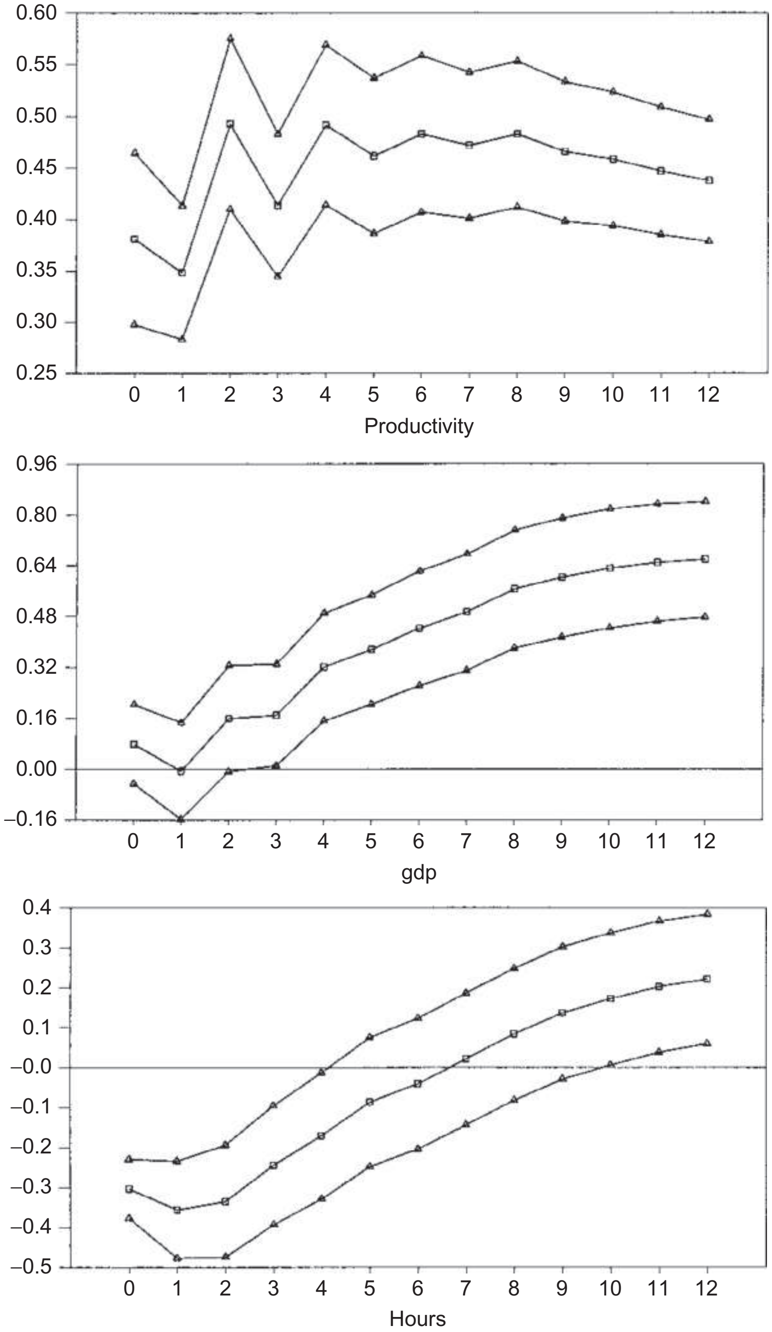

Fig. 5 Estimated impulse responses to a technology shock. Point estimates and ± 2 standard error confidence intervals; variables given in percentages. *Source: From Gali, J., 1999. Technology, employment, and the business cycle: do technology shocks explain aggregate fluctuations?. Am. Econ. Rev. 89 (1), 249-271.*

to "accommodate" the technology shock, that is, it responds to it by contracting aggregate demand *relative* to the level that would have obtained under flexible prices. Finally, suppose that this contractionary effect is strong enough. Then, aggregate output may increase less than productivity. By the same token, equilibrium employment may fall under sticky prices, even though it would have increased under flexible prices.

It remains debatable whether this is a satisfactory theoretical explanation, as well as whether the fact itself is robust to alternative empirical methodologies: see Gali and Rabanal (2005) for complementary evidence, Christiano et al. (2003) and McGrattan (2004) for criticisms. Here, we take the fact for granted and proceed to make two points: one regarding its structural interpretation and one regarding its policy implications.

The first is that, while the fact is inconsistent with the standard, complete-information, RBC model, it is not necessarily inconsistent with an incomplete-information extension of it. The reason is the dampening effect documented in Proposition 18: lack of common knowledge may cause significant inertia in the response of aggregate output, perhaps even a negative initial response in employment.

The second is that this dampening can be a reflection of the efficient use of the information that is dispersed in the economy.[bq] This contrasts the New-Keynesian explanation, which prescribes the observed fact to a failure of the monetary authority to replicate flexible-price allocations. To put it differently, the success of the New-Keynesian model in matching the fact in Gali (1999) is, in the context of that model, a manifestation of the failure of the policy maker to do the right thing. By contrast, augmenting the RBC model with a friction in coordination can help rationalize the fact without any policy failure.

These points are formalized in Angeletos and La'O (2010) by studying an incomplete-information version of the neoclassical economy we introduced in Section 2.2. This economy is essentially the same as the textbook RBC model, except for three modifications. First, capital is assumed away in order to simplify the analysis. Second, product differentiation is introduced, giving rise to strategic complementarity. Lastly, information is incomplete, giving rise to imperfect coordination.

More specifically, the economy is split into a large number of islands, indexed by $i \in [0, 1]$. Each island is populated by a competitive firm and a competitive worker, who produce a differentiated, island-specific, intermediate good. The goods produced by different islands enter the production of a single, final, consumption good. This introduces strategic complementarity across islands: the optimal production on each island depends on other islands' production. Incomplete information is introduced by assuming the following: when the firm and the worker of any given island decide on the local employment and output, they are uncertain about the productivity, employment and output of other islands. Despite the incompleteness of information, incomplete risk-sharing is assumed away by letting workers pool their income at the end of each period: everybody

[bq] By "efficient" we mean the notion of constrained efficiency discussed in Section 9.

belongs to the same "big family," whose income and consumption is fully diversified against the idiosyncratic information and choices of the various family-members. Finally, it is assumed that the local productivity of each island is perfectly observed by the firm and the worker of the island,[br] which guarantees that any other information is relevant only insofar as it helps predict the production levels of other islands.

To facilitate an exact mapping to the class of beauty-contest games we studied in the previous section, information is assumed to be Gaussian and preferences and technologies are assumed to take a power-form specification. Without further loss of generality, let us impose a linear technology: $y_{it} = a_{it} + n_{it}$, where y_{it} is the (log)level of the output produced in island i, a_{it} is the (log)level of the exogenous local productivity, and n_{it} is the (log) level of local employment. Angeletos and La'O (2010) show that the general equilibrium of the model reduces to the solution of the following fixed-point relation:

$$y_{it} = (1-\alpha)\chi a_{i,t} + \alpha \mathbb{E}_{it} Y_t \tag{29}$$

where Y_i is the (log)level of aggregate output, and $\chi > 0$ and $\alpha < 1$ are constants that depend on the underlying preference and technology parameters. With the output levels obtained from the solution of (29), local and aggregate employment are given by, respectively, $n_{it} = y_{it} - a_{it}$ and $N_t = Y_t - A_t$.

Clearly, the fixed-point relation in (29) is mathematically equivalent to the best-response condition encountered in the previous section. It follows that the insights developed there are readily applicable to the present context. We now elaborate what this means for the empirical properties of the RBC framework.

Assume that local productivity is given by the sum of an aggregate and an idiosyncratic component: $a_{it} = A_t + \xi_{it}$, where A_t is the aggregate technology shock and ξ_{it} is an idiosyncratic one. The latter is i.i.d. across both i and t (for simplicity), whereas the former follows a random walk:

$$A_t = A_{t-1} + u_t,$$

where u_t is the period-t innovation.

When information is complete (equivalently, coordination is perfect), we have that $\mathbb{E}_{it} Y_t = Y_t$ for all i. Substituting this into the above fixed-point relation and aggregating across i yields the following:

Proposition 26 *Under complete information, aggregate output and employment are given by, respectively,*

$$Y_t = \chi A_t \quad \textit{and} \quad N_t = (\chi - 1) A_t.$$

It follows that equilibrium outcomes are pinned down by the technology shock; that χ and $\chi - 1$ identify the general-equilibrium elasticities of, respectively, aggregate output

[br] This is the analogue of the assumption we made earlier on in Proposition 16.

and aggregate employment to technology shocks, as predicted by the complete-information RBC model; and that, holding χ constant, the scalar α is irrelevant for macroeconomic outcomes.

When instead information is incomplete (equivalently, coordination is imperfect), equilibrium outcomes depend, in effect, on the entire hierarchy of beliefs about A_t. The scalar α then starts playing a crucial role for the observables of the model, because it determines the relative importance of higher-order beliefs.

Proposition 27 *Under incomplete information, aggregate output is given by*

$$Y_t = \chi \sum_{h=0}^{\infty} (1-\alpha)\alpha^h \bar{\mathbb{E}}_t^h [A_t] \tag{30}$$

How α depends on the underlying primitives is discussed in detail in Angeletos and La'O (2010). There are two opposing mechanisms: a "demand-side" effect that contributes towards strategic complementarity ($\alpha > 0$) and a "supply-side" effect contributing towards strategic substitutability ($\alpha < 0$).

Let us explain. When an island expects aggregate output to go up, the demand for the local good, its relative price, and the local real wage are all expected to go up as well. This effect motivates the local worker to work more and the local firm to produce more. This is the "demand-side" effect, which induces local output to increase with expectations of aggregate output. The opposing "supply-side" effect originates from an income effect: when an island expects aggregate output to go up, income is also expected to go up, which tends to discourage labor supply and production. Whether α is positive or negative depends on which of the aforementioned two effects dominates. For the remainder of our analysis, we impose $\alpha > 0$.

If we vary α holding χ constant,[bs] we vary the incomplete-information outcomes without varying their complete-information counterparts. We can thus think of α as a "sufficient statistic" of the primitives of the environment that regulate the macroeconomic effects of strategic uncertainty, and thereby the observable aggregate implications of the incomplete-information model, holding constant the observable aggregate implications of the standard, complete-information macroeconomic model.[bt]

This last observation seems particularly useful if we adopt a "relaxed" interpretation of the model at hand as a representative of a broader class of RBC models in which

[bs] By varying the underlying preference and technology parameters one can match any pair of values (χ, α), which explains why one can indeed vary α holding χ constant.

[bt] Note, however, that the combination of α and χ also matters for the observable implications of both models in the cross section: in the economy under consideration, the product $(1 - \alpha)\chi$ is identified by the micro-elasticity of the response of local output to island-specific productivity shocks. This is indicative of how the combination of micro and macro data could help discipline the mechanisms we study in this section, in a manner that complements the approach reviewed in Section 8.6.

complementarity may originate, not only in the aforementioned demand-side effect, but also in "financial multipliers" or other kinds of market interactions that make the fate of any given firm and consumer sensitive to aggregate economic activity. For the purposes of the subsequent discussion, we invite the reader to entertain such a flexible interpretation of the strategic complementarity and the associated coefficient α.

Let us now go back to the original motivation of this section, namely the negative employment response to technology shocks. As already noted, any empirically plausible calibration of the standard, complete-information, RBC model makes the opposite prediction. In the context of the present framework (which assumes away capital), this prediction is equivalent to imposing $\chi > 1$, but leaves α unrestricted. But once information is incomplete, the predicted employment response crucially depends on α and can turn negative irrespective of the value of χ. That is, we can reconcile the RBC framework with Gali's findings by removing common knowledge of the technology shock and letting α be large enough.

Angeletos and La'O (2010) demonstrate the above possibility with numerical examples that allow learning to be slow and the incompleteness of information to persist indefinitely. Here, we illustrate the key idea with an example that forces the incompleteness of information to be transient, lasting for only one period.

Assumption 9 In each period t, the previous-period aggregate technology shock, A_{t-1}, becomes commonly known. Furthermore, for every i, any information that island i has about the current-period shock, A_t, is summarized in a private signal of the form

$$x_{it} = A_t + \epsilon_{it},$$

where $\epsilon_{it} \sim \mathcal{N}(0, \sigma_\epsilon^2)$ is i.i.d. across (i, t) and independent of A_t for all t.[bu]

The first part of this assumption rules out noisy dynamic learning and guarantees that the economy reduces, in effect, to a repeated version of the static beauty-contest game studied in Section 7: in each period, it is as if the islands play a beauty-contest game in which the fundamental $\theta = A_t$ and the common prior about it is a Normal distribution with mean $\mu = A_{t-1}$. The second part of the assumption abstracts from public signals and any other form of correlated noise, thus isolating the mechanism we care about in this section, namely the role of strategic uncertainty in dampening the response to fundamentals. The alternative function of accommodating forces akin to animal spirits is the subject of Section 8.7.

Following an approach similar to that used in the proof of Proposition 18, we can establish the following.

[bu] Because local productivity is itself a private (local) signal of aggregate productivity, x_{it} is meant to be a sufficient statistic for both the information contained in local productivity and any other private information that island i has about A_t.

Proposition 28 *Under Assumption 9, equilibrium output is given by*

$$Y_t = \chi A_{t-1} + \phi u_t,$$

for some positive scalars ϕ that satisfy $0 < \phi < \chi$. Furthermore, for any given $\chi > 0$ and $\sigma_\epsilon > 0$, ϕ converges to 0 from above as α converges to 1 from below.

This result illustrates two properties that go beyond the specific information structure assumed above. The first property is that the *long-run* effect of a technology shock under incomplete information remains the same as the one under complete information (which is χ). The second property is that the short-run effect (given by ϕ) is smaller and can even be arbitrarily close to zero if α is large enough. The first property holds because the shock becomes common knowledge in the long run (where "long run" means "next periods" in the above example and "asymptotically" in the example studied below). The second property holds because, as long as the fundamental is not common knowledge, the following is true: as h goes to ∞, the hth order belief of A_t converges to the common prior, no matter what the current innovation u_t is; letting α be high enough therefore guarantees that the equilibrium belief of Y_t does not move much with u_t, and that actual output does not move much either.

To derive the aggregate employment response, recall that $N_t = Y_t - A_t$. It follows that the effect of the technology shock on aggregate employment is given by $\phi - 1$, which is negative for high enough α.

Corollary 3 *Suppose $\chi > 1$ and take for granted Gali's finding that the short-run response of employment to technology shocks is negative. This finding rejects the frictionless version of the RBC model, but does not reject its incomplete-information extension insofar as α is large enough.*

The above result has so far been established only under a narrow interpretation of what the "short run" is: the response of employment turns positive after a one-period lag. However, this last property is an artifact of the simplifying assumption that the technology shock becomes common knowledge after a lag of only one period: if we allow the lack of common knowledge to persist for more periods, then we can accommodate a negative employment response for more periods. See Angeletos and La'O (2010) for details.

Angeletos and La'O (2010) further show that the equilibrium response of the economy to technology shocks is constrained efficient in the sense that there is no allocation that can improve upon the equilibrium without violating either resource feasibility or the informational constraints of the economy.[bv] It follows that, unlike the New-Keynesian interpretation, the Gali fact is not more a symptom of suboptimality (or constraints) in monetary policy.

To recap, insofar as there is sufficient lack of common knowledge and sufficient strategic complementary, the RBC framework can be reconciled with the Gali fact. This, however, pegs the question of how strong the relevant strategic complementary is. In

[bv] See Section 9 for a definition and a discussion of this kind of efficiency concept.

Angeletos and La'O (2010), the only source of strategic complementarity is that induced by the Dixit-Stiglitz preference specification. For conventional parameterizations, this implies a rather low value for α, and therefore also a rather low role for higher-order uncertainty. Financial frictions and feedback effects as those in Kiyotaki and Moore (1997) can "boost" the degree of complementarity that is present in the RBC framework, while at the same time deliver different normative conclusions. A promising direction for future research is therefore to introduce incomplete information in the models of the growing literature on financial frictions that has been spurred by the recent crisis.

We conclude by discussing a few complementary papers which have used informational frictions to generate real rigidity in different contexts, most notably in the canonical consumption-saving problem. Sims (2003, 2006), Luo (2008), and Tutino (2013) show how rational inattention can induce inertia in the response of consumption to income shocks. Luo et al. (2015) show how slow learning can help generate excess smoothness in durable and nondurable consumption, bringing the model closer to the data. Alvarez et al. (2011) study the interaction of transaction and observation costs for liquidity and consumption. The results in all these papers have a similar flavor to those derived here. But there is a key difference. These papers feature no strategic, or general-equilibrium, interaction. As a result, the rigidity they document is a rigidity at the *micro* level: it dampens the response of individual outcomes to individual fundamentals. It also requires enough noise in the observation of such fundamentals; that is, first-order beliefs of fundamentals must themselves be rigid. By contrast, the rigidity we have documented obtains at the *macro* level; it rests on lack of common knowledge (ie, on higher-order beliefs being rigid) as opposed to individual uncertainty; and it can thus be consistent with considerable flexibility at the micro level.

8.2 General-Equilibrium Dampening and Rigidity vs Overshooting

Angeletos and Lian (2016b) push the aforementioned insights further, showing (i) that incomplete information is equivalent to a certain relaxation of the solution concept and (ii) that it can dampen the general-equilibrium effects of macroeconomic models, while holding constant the underlying micro elasticities. This helps reduce the disconnect between recent empirical works such as Mian et al. (2013) and Mian and Sufi (2014), which identify the cross-sectional effects of regional shocks, and the key questions of interest, namely the macroeconomic effects of aggregate shocks.

The results in Angeletos and Lian (2016b) also clarify that the same mechanism—the dampening of general-equilibrium effects—could mean either rigidity or overshooting. If the general-equilibrium effect works in the same direction as the corresponding partial-equilibrium effect, meaning that the macro elasticity is higher than the micro one under complete information, then the introduction of incomplete information contributes to rigidity. If, instead, the general-equilibrium works in the opposite direction, meaning that the macro elasticity is smaller than the micro one under complete information, then the introduction of incomplete information contributes to overshooting.

The first scenario corresponds to settings in which the general-equilibrium effect is akin to strategic complementarity. The second scenario corresponds to settings in which the general-equilibrium effect is akin to strategic substitutability. The application by Angeletos and La'O (2010) that we discussed above and the monetary applications by Woodford (2003) and others that we review in the sequel are, in effect, examples of the first case. Angeletos and Lian (2016b) contain examples of the second case.

An interesting example of the second case is also Venkateswaran (2014). This paper considers an incomplete-information version of the Diamond–Mortesen–Pissarides model and shows that the incompleteness of information increases the volatility in aggregate unemployment, helping reconcile the model with the business-cycle data.

8.3 Nominal Rigidity and Monetary Shocks

In this section, we review Woodford (2003), an influential contribution that illustrated how incomplete information offers a potent substitute to more conventional formalizations of nominal rigidity.

Before reviewing Woodford's contribution, it is worth to recall some empirical evidence on the macroeconomic effects of monetary shocks. Christiano et al. (1999) and Christiano et al. (2005) use a structural VAR method to identify the impulse responses of macroeconomic variables to monetary shocks. Two of their key findings are the following: (i) Output, consumption, and investment respond in a hump-shaped fashion, peaking after about one to one-and-a-half years and returning to preshock levels after about three years; and (ii) inflation responds also in a hump-shaped fashion, peaking after about two years.

These findings are illustrated in Fig. 6, which is borrowed from fig. 1 of Christiano et al. (2005). The figure shows the estimated responses of output and inflation to an identified monetary shock.[bw] These responses provide support for the New-Keynesian framework insofar as they indicate that monetary shocks have large and persistent real effects. However, they also raise a challenge, which we turn to next.

The baseline version of New-Keynesian Philips Curve, which is at the core of the New-Keynesian model, takes the following form:

$$\pi_t = \kappa y_t + \beta \mathbb{E}_t \pi_{t+1},$$

[bw] The estimated responses of consumption and investment are omitted because we focus on a simple model without capital and consider only the response of output and inflation. Units on the horizontal axis are quarters; on the vertical, it is deviation from the unshocked path (annualized percentage points for inflation, percentages for output). Grey areas indicate 95% confidence intervals.

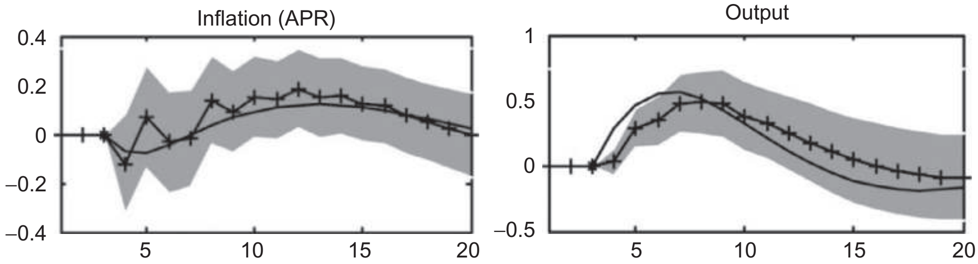

Fig. 6 Impulse responses of inflation and output to monetary shocks. Solid lines with plus signs are VAR-based impulse responses. Grey areas are 95% confidence intervals around the VAR-based estimates. Units on the horizontal axis are quarters. An asterisk indicates the period of the policy shock. The vertical axis units are deviations from the unshocked path. In the case of inflation, the unit is in annualized percentage points (APR). In the case of output, the unit is in percentage. Solid lines are the impulse responses generated by medium-scale new-Keynesian DSGE model (Christiano et al., 2005).

where π_t denotes inflation and y_t the output gap, κ is a function of the Calvo probability of resetting prices (along with preference and technology parameters), and β is the discount factor.[bx] Iterating the above condition gives current inflation as the best forecast of the present value of output gaps:

$$\pi_t = \kappa \mathbb{E}_t \left[\sum_{h=0}^{\infty} \beta^h y_{t+h} \right].$$

This implies that inflation must lead (or predict) output in response to monetary shocks: if the response of output to a monetary shock is hump-shaped as in the right panel of Fig. 6, then the peak in inflation has to come *before* the peak in output. But this is the opposite of what seen in the left panel of Fig. 6.

To overcome this failure, quantitative DSGE models have augmented the baseline New-Keynesian model with a number of ad hoc features, such as price indexation and certain kinds of adjustment costs, whose micro-foundations and immunity to the Lucas critique remain debatable. By contrast, Woodford (2003) shows that incomplete information, couple with strategic complementarity in price-setting decisions, can, not only substitute for the Calvo friction as a source of nominal rigidity, but also naturally produce the empirical pattern seen in Fig. 6.

Let us elaborate. Woodford (2003) considers a monetary economy similar to the one we sketched in Section 2.2. Unlike the New-Keynesian model, there is no Calvo

[bx] Strictly speaking, y_t measures the log deviation of the price-to-cost markup that obtains under sticky prices from the one that would have obtained if prices had been flexible. It is an open question what is the best empirical counterpart of this theoretical object. For simplicity, in the present discussion we interpret y_t as the output gap.

friction: firms are free to reset their prices period by period. Instead, nominal rigidity originates from the incompleteness of information about the underlying monetary shock. In particular, the (log) price set by the typical firm in period t is given by

$$p_{it} = \mathbb{E}_{it}[(1-\alpha)\theta_t + \alpha P_t], \tag{31}$$

where θ_t denotes (log) Nominal GDP, P_t denotes the (log) price level, and α is the degree of strategic complementarity in the firms' price-setting decisions. Nominal GDP is treated as an exogenous process. In line with the data, its growth rate is assumed to follow an AR(1) process:

$$\Delta\theta_t = \rho\Delta\theta_{t-1} + \nu_t,$$

where $\Delta\theta_t \equiv \theta_t - \theta_{t-1}$ is the growth of Nominal GDP, $\rho \in [0, 1)$ is the persistence, and ν_t is the innovation. Finally, the information received by the firm in any given period t is assumed to be a private signal x_{it} of the form

$$x_{it} = \theta_t + \epsilon_{it},$$

where $\epsilon_{it} \sim N\left(0, \sigma_\epsilon^2\right)$ is noise, i.i.d. across (i, t), and independent of θ_τ for all τ.

Woodford (2003) motivates the above information structure on the basis of rational inattention as in Sims (2003): the noise ϵ_{it} is interpreted as the byproduct of a cognitive friction. This helps bypass one of the critiques of the first generation of models that sought to attribute monetary nonneutrality to informational frictions (Lucas, 1972, 1973; Barro, 1976, 1977; Barro, 1978). That earlier literature was based on the assumption that there was no readily available information about the current monetary policy and the current aggregate price level. At face value, this assumption seems unrealistic. However, if agents face cognitive constraints in their ability to attend to and digest the available information, they may well act *as if* that information were unavailable: rational inattention is akin to adding noise in the observation of the underlying shocks.

In the absence of strategic complementarity, the above point would have provided merely a new rationale for the type of informational frictions that were assumed by Lucas and Barro. The hallmark of Woodford's contribution, however, is the interaction between the informational friction and the strategic complementarity in pricing decisions, and the associated role of higher-order beliefs.

As we show in the next section, the setting studied in Lucas (1972) is akin to imposing the restriction $\alpha = 0$ (no strategic complementarity) and thereby shutting down the role of higher-order beliefs. In a nutshell, the theoretical mechanism in Lucas (1972) had to do only with the response of first-order beliefs—which is also why Barro went after measuring "unanticipated changes" in monetary policy.

By contrast, Woodford (2003) shifts the focus to strategic complementarity and higher-order beliefs. As explained in the previous section, the response of higher-order beliefs to innovations in fundamentals is both weaker and more sluggish than that of lower-order beliefs. It follows that, holding constant the precision of the available information and the speed of learning, a stronger complementarity translates into a more muted and more sluggish response of equilibrium prices to the underlying monetary shock—and hence also to larger and more persistent real effects.

Putting the above observations together, Woodford's first contribution is to explain why there can be significant nominal rigidity at the aggregate level even if (i) there is a lot of readily available information about the underlying monetary shocks; and (ii) each firm alone is only modestly unaware of, or confused about, the underlying monetary shocks. The cognitive friction explains why each firm may be confused in the first place; the strategic complementarity explains why there can be significant inertia at the aggregate level even if the aforementioned confusion is modest.

This kind of amplification effect distinguishes Woodford's contribution, not only from the earlier literature by Lucas and Barro, but also from some more recent literature that has proposed "observation costs" as a source of nominal rigidity but has abstracted from strategic interactions. Consider, in particular, Alvarez and Lippi (2014) and Alvarez et al. (2015). These papers use models in which firms update their information sets infrequently because they have to pay a fixed cost whenever they do so. Because the updating is asynchronized, this implies that at any given point of time, firms are differentially informed about the underlying shocks, opening the door to higher-order uncertainty. However, these papers abstract from strategic complementarity in pricing decisions, thus ultimately shutting down the effects of higher-order beliefs.[by] It follows that the macro-level nominal rigidity that is formalized and quantified in those papers is tied to micro-level rigidity. By contrast, Woodford's work highlights that the nominal rigidity can be large at the aggregate, even if the underlying micro-level rigidity is modest. An important open question for future research is how this elementary insight matters for the mapping between micro-level data and macro-level responses developed in Alvarez and Lippi (2014) and Alvarez et al. (2015), and the quantitative conclusions that are drawn with the help of those mappings.

Let us now return to the motivating evidence reviewed in the beginning of this section. How does incomplete information help the model match this evidence? And does it offer a superior structural interpretation of the evidence than that offered by the Calvo friction?

[by] Another difference is that these papers impose that an agent learns *perfectly* the entire state of nature once she updates her information. This implies that, an given date t, an agent who updated her information at $t-j$ ($j \geq 0$) does not face any uncertainty about the beliefs of the set of agents who updated their information prior to $t-j$; she only faces uncertainty about the beliefs of the set of agents who updated their information after she did (which is an empty set if $j=0$). The same point applies to Mankiw and Reis (2002), which we discuss in the sequel.

Woodford (2003) addresses these questions with the help of Fig. 7 (which copies figs. 3 and 4 from the original paper). These figures illustrate the impulse response of inflation and real output to a positive innovation in θ_t, under four alternative parameterizations of ρ, the autocorrelation of the growth rate of Nominal GDP. The right column corresponds to the incomplete-information model studied here; the left column gives, for comparison purposes, the impulse response of a New-Keynesian variant, which replaces the informational friction with standard, Calvo-like, sticky prices.[bz]

For the reasons already explained, incomplete information generates inertia in the response of the price level, P_t, to the underlying shocks. However, the evidence requires that the model delivers two stronger properties: first, we need inertia in the response of *inflation*, not just in that of the price level; second, we need the inertia of inflation to be more pronounced that that of real output.

As is evident in the top panel of Fig. 7, both the incomplete-information and the Calvo model fail to deliver the required empirical properties when $\rho = 0$, ie, when θ_t follows a random walk: in this case, both inflation and output peak on impact (at the moment that the innovation occurs). What is more, Woodford (2003) shows that the two models are isomorphic with regard to the response of inflation and output:

Proposition 29 *Suppose $\rho = 0$. For any parameterization of the Calvo model, there is a parameterization of the incomplete-information model that delivers identical impulse responses for output and inflation, and vice versa.*

This result complements the intuitions we developed in Section 6. Not only can the Calvo friction be thought of as a friction in coordination, we now have a concrete example in which the Calvo friction is observationally equivalent to an information-driven friction in coordination.

That said, this equivalence is exact *only* when $\rho = 0$. When instead $\rho > 0$, this equivalence breaks, indeed in a manner that helps incomplete information outperform the Calvo friction vis-a-vis the data.

Proposition 30 *Suppose that the output response is hump-shaped. For any parameterization, the Calvo model predicts that inflation peaks before output. By contrast, for some parameterizations, the incomplete-information model predicts that inflation peaks after output.*

The first part of the proposition follows directly from the property noted earlier that the New-Keynesian Philips Curve requires that inflation is the best predictor of the present value of future output gaps: insofar as a monetary (or any other) shock causes the output gap to follow a hump-shaped response like the one seen in the data, the NK model predicts that inflation has to peak before output.

[bz] See Woodford (2003) for how the two models are calibrated. The calibration of the Calvo model is based on standard criteria; the calibration of the incomplete-information model is more ad hoc. See, however, Melosi (2014) for an estimated version of Woodford's model, which delivers similar lessons.

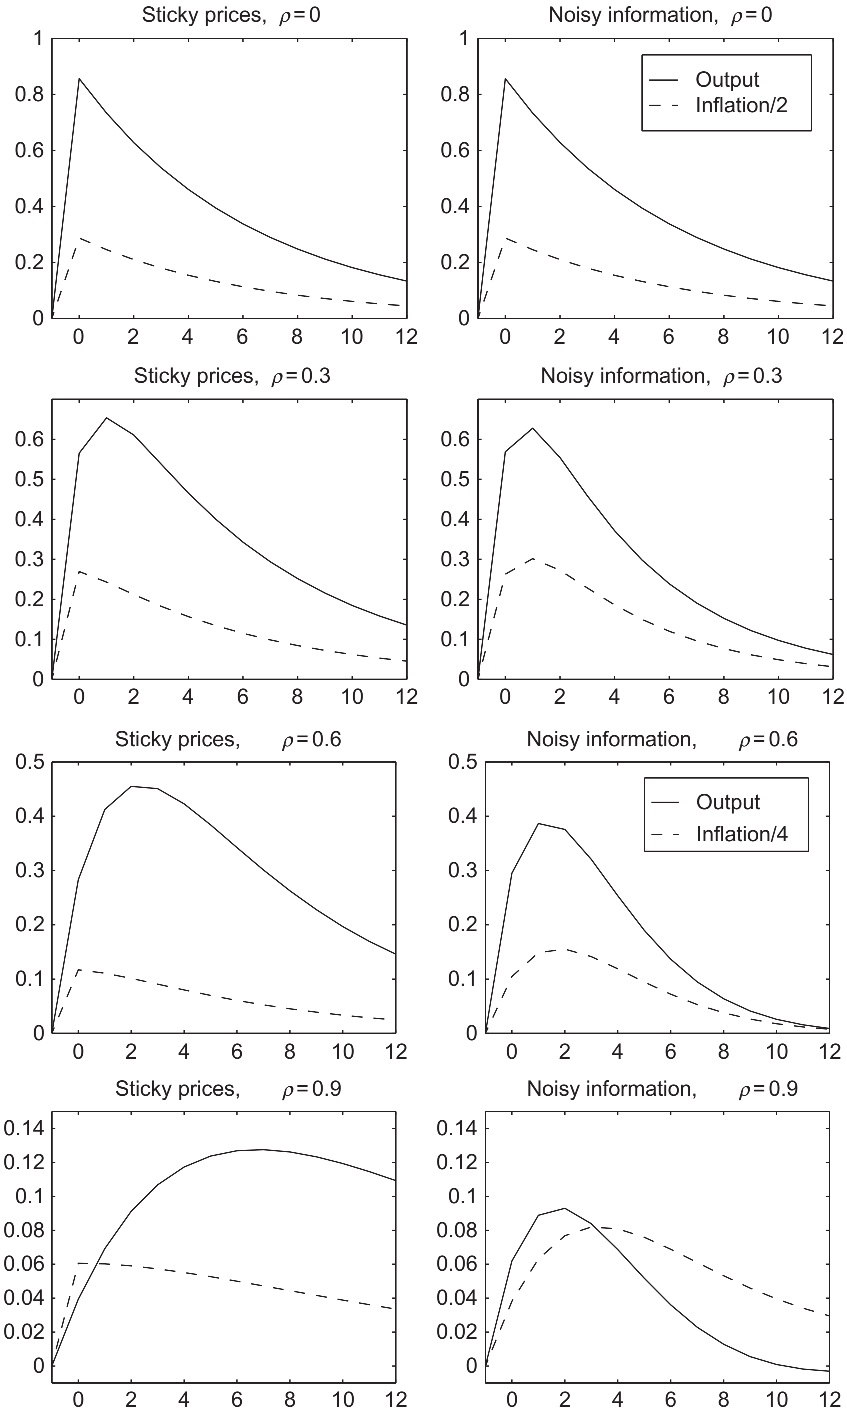

Fig. 7 Comparison of impulse response functions predicted by the textbook new-Keynesian model and by the incomplete-information model of Woodford (2003), for different values of ρ.

The second part follows from the numerical examples presented in Woodford (2003) and repeated in the lower panels of Fig. 7 here: once ρ is sufficiently high (such as $\rho = .6$ or $\rho = .9$ in the figure), the incomplete-information model delivers, not only a hump-shaped response for both inflation and output, but also a peak for inflation that comes later than the peak in output.

Let us explain why. A positive innovation v_t triggers a *gradual* increase in θ_t, from its initial level to a higher long-run level. This means that firms would find it optimal to increase their prices only gradually *even if* they become immediately aware of the shock and could perfectly coordinate their pricing decisions. The fact that each firm becomes only slowly aware about the shock causes each firm alone to delay its response. The fact that each firm expects other firms to do so adds further delay. This delay, however, is necessarily bounded. As time passes, not only first-order but also higher-order beliefs get closer to the true θ_t, which itself converges to its higher-long run level. It follows that the adjustment of prices accelerates after some point. Putting these observations together, we have that inflation is low early on and accelerates later on. By contrast, the growth rate of θ_t is, by assumption, high early on and slows down later on. It follows the difference between the two, which is the growth rate of output, can be high early on, exactly when inflation is still low. This explains why output can peak before inflation in the incomplete-information setting.

To recap, Woodford (2003) highlights how the inertia of higher-order beliefs can help rationalize nominal rigidity at the aggregate level in a manner that is empirically distinct from, and potentially superior to, the conventional Calvo-like formalization. Complementary subsequent work includes Nimark (2008) and Angeletos and La'O (2009), who study the interaction of the two frictions and find they tend to reinforce each other; Melosi (2014), who estimates Woodford's model on the basis of output and inflation data and finds that the model can match the data with a modest level of informational friction; and Hellwig (2005), who elaborates on the micro-foundations and the welfare implications of the model; and Angeletos and Lian (2016c), who study how lack of common knowledge can resolve the forward guidance puzzle. In what follows, we leave aside these extensions and instead relate Woodford's contribution to two other approaches: "sticky information" as in Mankiw and Reis (2002); and "rational inattention" as in Sims (2003) and Maćkowiak and Wiederholt (2009). But before doing this, we make an important parenthesis: we review a simplified version of Lucas (1972) and use this to clarify the novelty of the mechanism we have discussed in this section.

8.4 Parenthesis: Lucas (1972)

Consider the following simplified version of Lucas (1972). The economy consists of overlapping generations. Each agent lives for two periods, working when she is young and consuming when she is old. There is a continuum of islands, $i \in [0,1]$. In each period t, each island has a continuum of young and old agents.

Fix a period t and an island i. Consider the young agents who are born in that period and work in that island. There is a measure one of such agents and they are all identical. Each of them supplies $N_{i,t}$ units of labor to produce

$$Y_{i,t} = N_{i,t} \tag{32}$$

units of the island's good. Let $P_{i,t}$ denote the nominal price of that good in period t.

In period $t + 1$, the aforementioned agents become old; they are randomly relocated to different islands, according to an assignment rule that will be described shortly; and they each receive a monetary transfer that is proportional to the nominal income they made when young. At the aggregate level, the monetary transfer is pinned down by the growth rate of money supply. The latter follows a random walk in logs:

$$M_{t+1} = M_t e^{\nu_{t+1}},$$

where $\nu_{t+1} \sim N\left(0, \sigma_\nu^2\right)$ is an aggregate shock. It follows that the cash-in-hand of an old agent, who was born in island i and is currently (ie, in period $t + 1$) located in island j, is given by

$$M_{i,t+1} = P_{i,t} N_{i,t} e^{\nu_{t+1}}.$$

Her budget constraint is given by

$$P_{j,t+1} C_{i,j,t+1} = M_{i,t+1},$$

where $C_{i,j,t+1}$ denotes her consumption, Finally, the her realized utility is given by

$$\mathcal{U}_{i,j,t} = C_{i,j,t+1} - \frac{1}{1+\kappa} N_{i,t}^{1+\kappa}.$$

We now elaborate on the assignment of old agents to different islands and the resulting demand for the local good of each island. In each period t, the old agents on any given island are a representative sample of all the agents who were born in the previous period and work on different islands. However, different islands receive samples of different sizes. In particular, the mass of old agents that island i receives in period t is given by $\bar{\xi} e^{\xi_{i,t}}$, where $\xi_{i,t} \sim N\left(0, \sigma_\xi^2\right)$ is i.i.d. across islands and across periods, as well as independent from ν_t. We set $\bar{\xi}$ so that $\mathbb{E}[\bar{\xi} e^{\xi_{i,t}}] = 1$, that is, the average mass is one. It follows that the nominal demand on island i during period t is given by

$$D_{i,t} = \bar{\xi} e^{\xi_{i,t}} M_t,$$

where M_t is the aggregate quantity of money. Market clearing then imposes

$$P_{i,t} N_{i,t} = D_{i,t}. \tag{33}$$

The modeling role of $\xi_{i,t}$ is therefore to induce island-specific demand shocks—or, equivalently, variation in relative prices.

The above assumptions guarantee a simple characterization of the optimal labor supply of the young agents. From the budget constraint, we have that the consumption of a young agent who works on island i in period t and consumes on island j in period $t+1$ is given by

$$C_{i,j,t+1} = \frac{M_{i,t+1}}{P_{j,t+1}} = \frac{P_{i,t} N_{it} e^{\nu_{t+1}}}{P_{j,t+1}} = \frac{P_{i,t}}{M_t} \cdot \frac{M_{t+1}}{P_{j,t+1}} \cdot N_{i,t}.$$

It follows that the optimal labor supply of that agent in period t is given by

$$N_{i,t} = arg \max_N \mathbb{E}_{i,t}\left[\frac{P_{i,t}}{M_t} \cdot \frac{M_{t+1}}{P_{j,t+1}} \cdot N - \frac{1}{1+\kappa} N_{i,t}^{1+\kappa}\right] = \left(\mathbb{E}_{i,t}\left[\frac{P_{i,t}}{M_t} \cdot \frac{M_{t+1}}{P_{j,t+1}}\right]\right)^{\frac{1}{\kappa}}. \tag{34}$$

What remains then is to specify the information structure.

As in Lucas (1972), we assume that *previous-period* money supply, M_{t-1}, is public information, but *current* aggregate money supply, M_t, is unknown; equivalently, the current monetary shock v_t is unknown. We also assume that each agent observes the current nominal price in her island, but not those in other islands. It follows that the information set that enters the expectation in condition (34) is the pair $(M_{t-1}, P_{i,t})$.[ca] Finally, we restrict attention to equilibria in which $P_{i,t}$ is log-normally distributed.

Let lower-case variables denote the logarithm of the corresponding upper-case variables, measured as deviations from steady state, and restrict attention to rational-expectations equilibria in which p_{it} is Normally distributed. There exists a unique equilibrium of this type and is characterized as follows.

Proposition 31 (Lucas 72) *Consider the version of Lucas (1972) described above. There exist scalars $\beta, \lambda \in (0, 1)$ such that the following properties hold:*

(i) *The nominal price level is given by*

$$p_t = (1-\beta) m_t + \beta \bar{\mathbb{E}}[m_t]. \tag{35}$$

(ii) *Real output is given by*

$$y_t = m_t - p_t = \beta\left\{m_t - \bar{\mathbb{E}}[m_t]\right\}. \tag{36}$$

(iii) *The average forecast error of* $\mathrm{m_t}$ *(also known as the "unanticipated" change in the supply of money) is given by*

$$m_t - \bar{\mathbb{E}}[m_t] = \lambda v_t. \tag{37}$$

The combination of parts (ii) and (iii) reveal that monetary shocks have real effects. The intuition is simple. Young agents do not directly observe the shock in money supply.

[ca] We could also allow the agents to observe the entire history of money supply and nominal prices in all past periods. Given the rest of the assumptions we have made and the equilibrium we construct in the sequel, this history provides no additional information.

Instead, they only observe the movement in the local price, which confounds the aggregate monetary shock ν_t with the island-specific demand shock ξ_{it}. As a result, they (rationally) confuse nominal price movements for relative price movements. This confusion then explains why it is optimal for young agents to exert more effort and produce more output in response to a monetary shock.

For our purposes, however, it is more useful to focus on part (i). Contrast condition (35) with condition (31), that is, the condition that pins down the price level in Woodford (2003).[cb] It then becomes clear that the price level in Lucas's model depends only on first-order beliefs of the monetary shock (the "fundamental"), whereas in Woodford's model it also depends on higher-order beliefs. By the same token, the degree of monetary nonneutrality obtained in Lucas's model can be large only insofar as agents are uninformed about the monetary shock, which in turn explains why Barro sought to test the theory by measuring unanticipated monetary shocks. By contrast, insofar as there is strong complementarity in price-setting decisions, the degree of monetary nonneutrality obtained by Woodford can be large even if agents are well informed about the monetary shock—for the key is now the lack of common knowledge, as opposed to the lack of individual knowledge.

Remark 28 There are two reasons why higher-order beliefs are absent in Lucas's work. The one is the absence of strategic complementarity, which is emphasized above. The other is the assumption that the previous-period fundamental (m_{t-1}) is commonly known at the begin of each period. If the last assumption is appropriately relaxed, and in particular if different agents within any given island have differential information about the past fundamentals, then higher-order beliefs become relevant through the signal-extraction problem: the interpretation of the local price signal by any young agent depends, in general, on her beliefs regarding the information and the beliefs of old agents, as well as that of other young agents. This kind of mechanism—the role of higher-order beliefs in the interpretation of signals of the activity of others—was the topic of Townsend (1983) and of the subsequent works by Hansen and Sargent (1991) and Kasa (2000). But just as Lucas (1972) abstracted from strategic complementarity in actions, so did these works.

8.5 Sticky Information and Rational Inattention

Having clarified the key difference between Lucas (1972) and Woodford (2003), we now briefly comment on the connection of the latter with two other important recent contributions: that of Mankiw and Reis (2002), and that of Maćkowiak and Wiederholt (2009, 2015).

In Mankiw and Reis (2002), firms are free to adjust their prices continuously over time, but may update their information sets only infrequently. In particular, it is assumed that, in each period, and regardless of its history up to that point, a firm gets to see the

[cb] Note that θ_t in the previous section is the same as m_t presently.

underlying state with probability $\lambda \in (0, 1)$, and it is otherwise stuck with its previous-period information set. By the same token, a fraction λ of firms are perfectly informed within any given period, whereas the rest must set prices on the basis of outdated information. This friction is taken as given in Mankiw and Reis (2002), but it is microfounded on the basis of a fixed cost for observing the state of nature in Reis (2006), and Alvarez et al. (2011, 2015).[cc]

In their paper, Mankiw and Reis focus on the comparison of their model to the standard Calvo model. In particular, they show that their model imposes the following restriction on the joint dynamics of inflation and output, which can be interpreted as the Philips curve of the model:

$$\pi_t = \left(\frac{(1-\alpha)\lambda}{1-\lambda}\right) y_t + \lambda \Sigma_{j=0}^{\infty} (1-\lambda)^j \mathbb{E}_{t-1-j}(\pi_t + (1-\alpha)\Delta y_t),$$

where α is the degree of strategic complementarity in pricing decisions and λ is the aforementioned probability of observing the state. The above result indicates a certain backward-looking aspect, unlike the forward-looking nature of the New-Keynesian Philips Curve: inflation today depends on past information, simply because that past information is relevant for the current pricing choices of firms that have not updated their information.

Notwithstanding the distinct applied contribution of Mankiw and Reis (2002), we now proceed to clarify the manner in which this approach is similar to that of Woodford (2003).

Because the best responses in the two models are the same, the equilibrium price level can be expressed as the *same* function of the hierarchy of beliefs in both models. It follows that the two models can deliver quantitatively different predictions for the dynamics of prices, inflation, and output only to the extent that they happen to feature sufficiently different dynamics in higher-order beliefs.

As with Woodford (2003), we assume that $\Delta\theta_t$ follows an AR(1) process with autocorrelation coefficient $\rho \in [0, 1)$. A clear benchmark emerges when $\rho = 0$, that is, when θ_t follows a random walk. For this case, we already studied the dynamics of higher-order beliefs implied by Woodford's specification of the information structure. Turning to the dynamics implied by Mankiw and Reis's specification, we prove the following.

Proposition 32 *When $\rho = 0$, the first- and higher-order forecasts of θ_t are given by the following:*

[cc] See also the review in Mankiw and Reis (2011).

$$\bar{E}_t^h[\theta_t] = \sum_{j=0}^{+\infty} \left\{ \left(1-(1-\lambda)^{j+1}\right)^h \nu_{t-j} \right\} \quad \forall h \geq 1,$$

where λ ∈ (0, 1) is the probability that a firm updates its information in any given period.

This result gives a closed-form solution for the IRFs of the entire hierarchy of forecasts: the effect of an innovation on the h −th order forecast after j periods is $\left(1-(1-\lambda)^{j+1}\right)^h$, which is clearly increasing in λ, increasing in j, and decreasing in h.

In Woodford's specification such a closed-form solution was not feasible (with the exception of first-order beliefs). Nevertheless, it should now be evident that the qualitative features of the two specifications are the same. In both specifications, higher-order beliefs exhibit a weaker and more sluggish response to fundamentals than lower-order beliefs. Furthermore, the effect that λ has in the above IRFs is essentially the same as the one that the reciprocal of σ_ϵ has in Woodford's model. This is because in both cases these scalars relate to the speed of learning.

We further illustrate these points in Fig. 8. This figure depicts the impulse responses of first- and higher-order beliefs in the sticky-information model, under the maintained assumption that θ_t follows a random walk. Comparing this figure to Fig. 4, we see that the qualitative dynamics of the belief hierarchy is nearly indistinguishable—and therefore so are the impulse response of inflation and output.

Moving beyond the random-walk case, Fig. 9 revisits the last exercise we conducted for Woodford's contribution: it draws the impulse responses of inflation and output to a

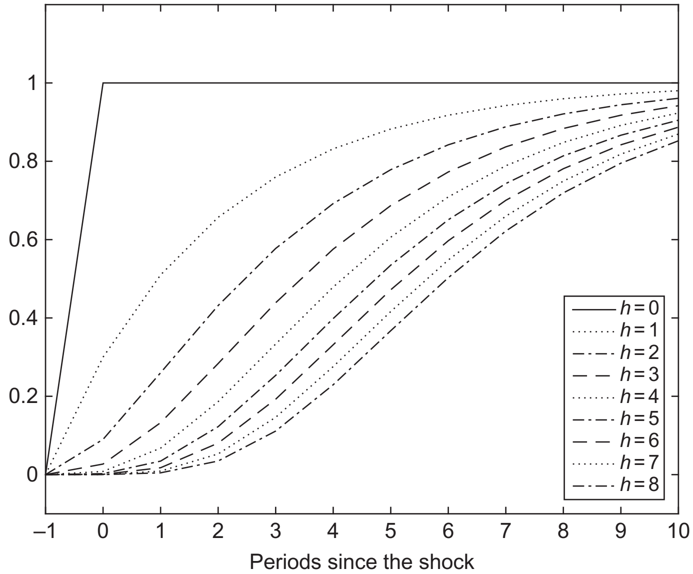

Fig. 8 Impulse response function of higher-order beliefs in sticky information model.

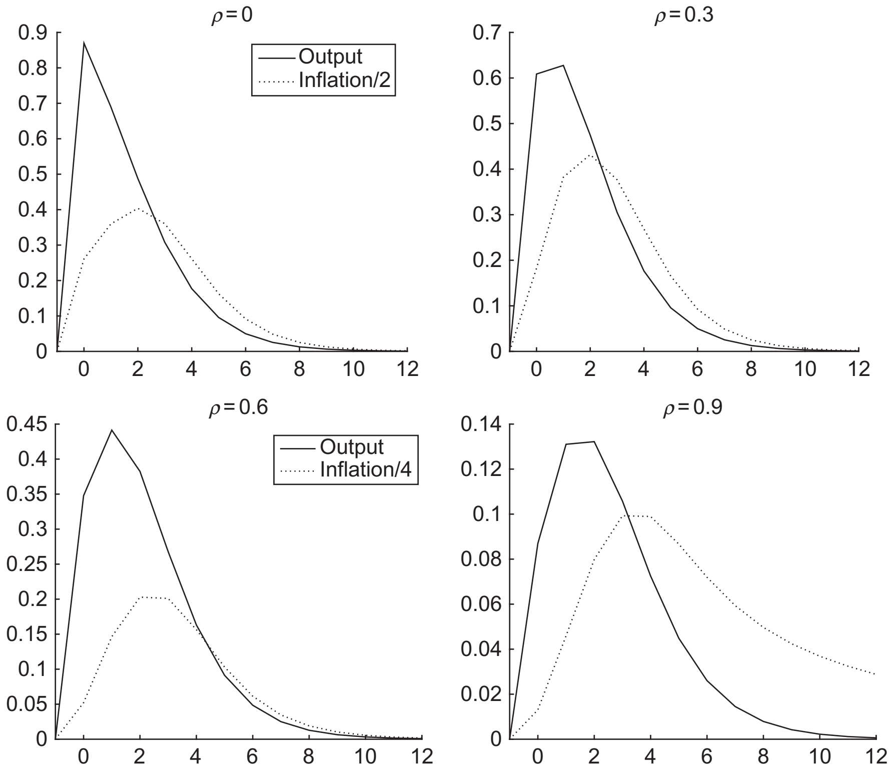

Fig. 9 Impulse response functions of inflation and output in sticky-information model.

positive monetary shock under different values for ρ. A comparison of this figure to Fig. 7 reveals that the predictions of the two models are closely related. The only noticeable difference is that, at least for the chosen parameterizations, the sticky-information model appears to have a relatively easier time in matching the fact that inflation peaks after output, even for low values of ρ.

To recap, Woodford (2003) and Mankiw and Reis (2002) appear to deliver similar dynamics for higher-order beliefs, and thereby also similar dynamics for inflation, output, and the average forecasts of any order. This, however, does not mean that the two models are observationally equivalent (or nearly equivalent) in *every* dimension or in every context. For instance, Woodford's specification implies that the cross-sectional dispersion of forecasts—whether of the exogenous shock or of inflation and all the other endogenous variables—is constant over time, whereas Mankiw and Reis's specification implies that the cross-sectional dispersion of forecasts *increases* following any innovation in the fundamentals.

Some authors have payed special attention to this last property.[cd] In our view, however, this property is not particularly interesting. We, economists, have little knowledge of the precise ways in which real-world people collect, exchange, and digest information. Accordingly, what we would like to retain as a lesson from *both*Woodford (2003) and Mankiw and Reis (2002) is their common predictions with regard to the inertia of higher-order beliefs and the consequent dynamics of inflation and output. These predictions are driven by the combination of strategic complementarity with private learning; they are therefore likely to be robust to other plausible specifications of the information structure.

Let us now consider yet another popular form of informational friction: the form of "rational inattention" proposed by Sims (2003). Because of space constraints, we will not review either the foundations of this approach or the extensive applied literature that followed Sims's original contribution.[ce] Instead, we limit our discussion to the relation of this approach to the central theme of this chapter.

Unlike the more ad hoc alternatives we have studied so far, Sims's formalization of rational inattention is grounded on the idea that, even if arbitrarily precise information is readily available, people may have limited capacity in processing all that information and they may therefore act *as if* their information were noisy. In short, noise is present, not because information is lacking, but rather because of a cognitive friction.

The basic idea is compelling. Applied to the context of monetary policy, it also allows us to avoid a critique of the earlier literature on imperfect information (Lucas, 1972), namely that information about monetary policy and the price level is readily available: even if this were true, rational inattention could explain why firms and consumers may act *as if* they did not have access to all the relevant data.

That said, we would also like to highlight that the foundations of rational inattention are decision theoretic. The issues that are central to this chapter—coordination, strategic or higher-order uncertainty, and solution concepts—were left completely out of the picture in Sims's original contribution.

Subsequent works, most notably those by Maćkowiak and Wiederholt (2009, 2015), applied Sims's approach to general-equilibrium models. The works impose information structures that rule out correlated noise: in the equilibria of those models, aggregate economic outcomes (such as prices and quantities) are pinned down by the aggregate

[cd] Mankiw et al. (2004) argue that this property helps explain certain time-varying patterns in the cross-sectional dispersion of inflation forecast. By contrast, Coibion and Gorodnichenko (2012) find no evidence of this property in the response of inflation forecasts to certain identified shocks (more on this in Section 8.6) and therefore conclude that the data is more in line with noisy information as in Woodford (2003) than with sticky information.

[ce] Important follow-up contributions include Luo (2008), Maćkowiak and Wiederholt (2009, 2015), Paciello and Wiederholt (2014), Matejka (2015a,b), Matejka and Sims (2011), Matejka and McKay (2015), Matejka et al. (2015), Sims (2006), Stevens (2015), Tutino (2013), and Woodford (2009). See also the review in Sims (2010).

fundamentals (such as monetary and productivity shocks). This assumes away the type of "animal spirits" identified earlier. Nevertheless, because agents act as if they observe the fundamentals with *idiosyncratic* noise, the following properties hold: first, information is incomplete (in the sense of Definition 10), not just imperfect (in the sense of Definition 9); second, as long as there is strategic complementarity, the mechanism we studied before regarding the inertia of higher-order beliefs is active.

In this respect, the approach taken in Maćkowiak and Wiederholt (2009, 2015) is closely related, and complementary, to Woodford (2003) and Mankiw and Reis (2002). Nevertheless, Mackowiak and Wiederholt's approach makes two distinct predictions, which are of independent interest.

The first distinct prediction is that the de-facto noise is likely to be much larger for aggregate shocks than for idiosyncratic shocks. This is because of the following. Empirically, idiosyncratic shocks are an order of magnitude more volatile than aggregate shocks. It follows that each individual agent finds it more worthwhile to allocate her attention (capacity) to idiosyncratic shocks rather than to aggregate shocks. What is more, strategic complementarity reinforces this decision-theoretic effect: when other firms pay less attention to aggregate shocks, the individual firm has an even small incentive to pay attention to such shocks.

The second distinct prediction has to do with comparative statics. In a setting where the signals are exogenously specified, one may find it natural to vary elements of the payoff structure—eg, the degree of strategic complementarity in pricing decision, or the specification of the policy rule followed by the monetary authority—keeping constant the precision of the available signals. In a rational-inattention setting, by contrast, the precision of the signals is tied to the underlying payoff characteristics. It follows that the two approaches may make different predictions about the effect of, say, a regime change in monetary policy, even if they deliver the same predictions about the effects of a monetary shock under a fixed policy regime.

Needless to say, the above point is not specific to rational inattention; it applies more generally to any model that endogenizes either the collection or the aggregation of information. Rational inattention imposes a particular structure on this kind of endogeneity. A plausible alternative is developed in Reis (2006) and Alvarez et al. (2015): this approach replaces rational-inattention with fixed costs in the observation of the underlying shocks, but shares the prediction that information is endogenous to policy.[cf]

[cf] This discussion pegs the question of how the endogeneity of information influences the nature of optimal monetary policy. For recent advances into answering this question, see Paciello and Wiederholt (2014) and Angeletos et al. (2016b).

8.6 Survey Evidence on Informational Frictions

In Section 7, we highlighted that complete-information and incomplete-information models have distinct predictions regarding the joint distribution of the aggregate action, the average expectation of the aggregate action, and the underlying fundamental. In the context of monetary models, these predictions regard, inter alia, the joint distribution of actual inflation, the average forecast of inflation, and the underlying shocks.

Consider the textbook New-Keynesian model, or any modern DSGE model that maintains the assumption of complete information. These models predict that firms face no uncertainty about the contemporaneous price level, or inflation, even if they face uncertainty about the underlying shock. It follows that, in these models, $\bar{\mathbb{E}}_t\pi_t$ coincides with π_t in all states of nature. Hence, the impulse response function of π_t to any shock coincides with that of $\bar{\mathbb{E}}_t\pi_t$. By contrast, incomplete-information models such as those in Woodford (2003), Mankiw and Reis (2002), and Maćkowiak and Wiederholt (2009) predict that the two IRFs are distinct, and in particular that $\bar{\mathbb{E}}_t\pi_t$ responds more sluggishly than π_t to innovations in the underlying fundamentals.

In an important recent paper, Coibion and Gorodnichenko (2012) provide evidence in favor of the latter prediction. This paper estimates the impulse response functions of actual inflation and of inflation forecasts to three distinct shocks recovered from the data: a technology shock identified as in Gali (1999); an oil shock identified as in Hamilton (1996); and a news shock identified as in Barsky and Sims (2011).[cg] Inflation forecasts are obtained from four sources: the Survey of Professional Forecasters (SPF); the University of Michigan Survey of Consumers; the Livingston Survey; and the FOMC blue book. For each of these sources, and for each of the aforementioned shocks, it is shown that the average inflation forecasts respond more sluggishly than actual inflation.

This finding is illustrated in Fig. 10, which is borrowed from Coibion and Gorodnichenko (2012). This figure depicts the IRFs of actual inflation, π_t, and of the average forecast error, $\bar{\mathbb{E}}\pi_t - \pi_t$, to each of the aforementioned shocks, using the SPF-based measure for $\bar{\mathbb{E}}\pi_t$. Note that the technology shock and news shock are found to be disinflationary, whereas the oil shock is found to be inflationary. These properties are consistent with previous empirical work, as well as with the predictions of standard macroeconomic models. More importantly for our purposes, note that the response of the average forecast error is found to be negative in the first two cases, positive in the last case, and always lower in absolute value than the actual inflation response. This means that, for all the three shocks, the average forecast $\bar{E}_t\pi_t$ moves in the same direction as

[cg] Given that Woodford (2003), Mankiw and Reis (2002), and Maćkowiak and Wiederholt (2009) were primarily interested in the response of prices to monetary shocks, it may seem peculiar that Coibion and Gorodnichenko (2012) do not study such shocks. Coibion and Gorodnichenko justify this on the basis that identified monetary shocks only drive a relatively small fraction of the business-cycle variation in inflation and economic activity.

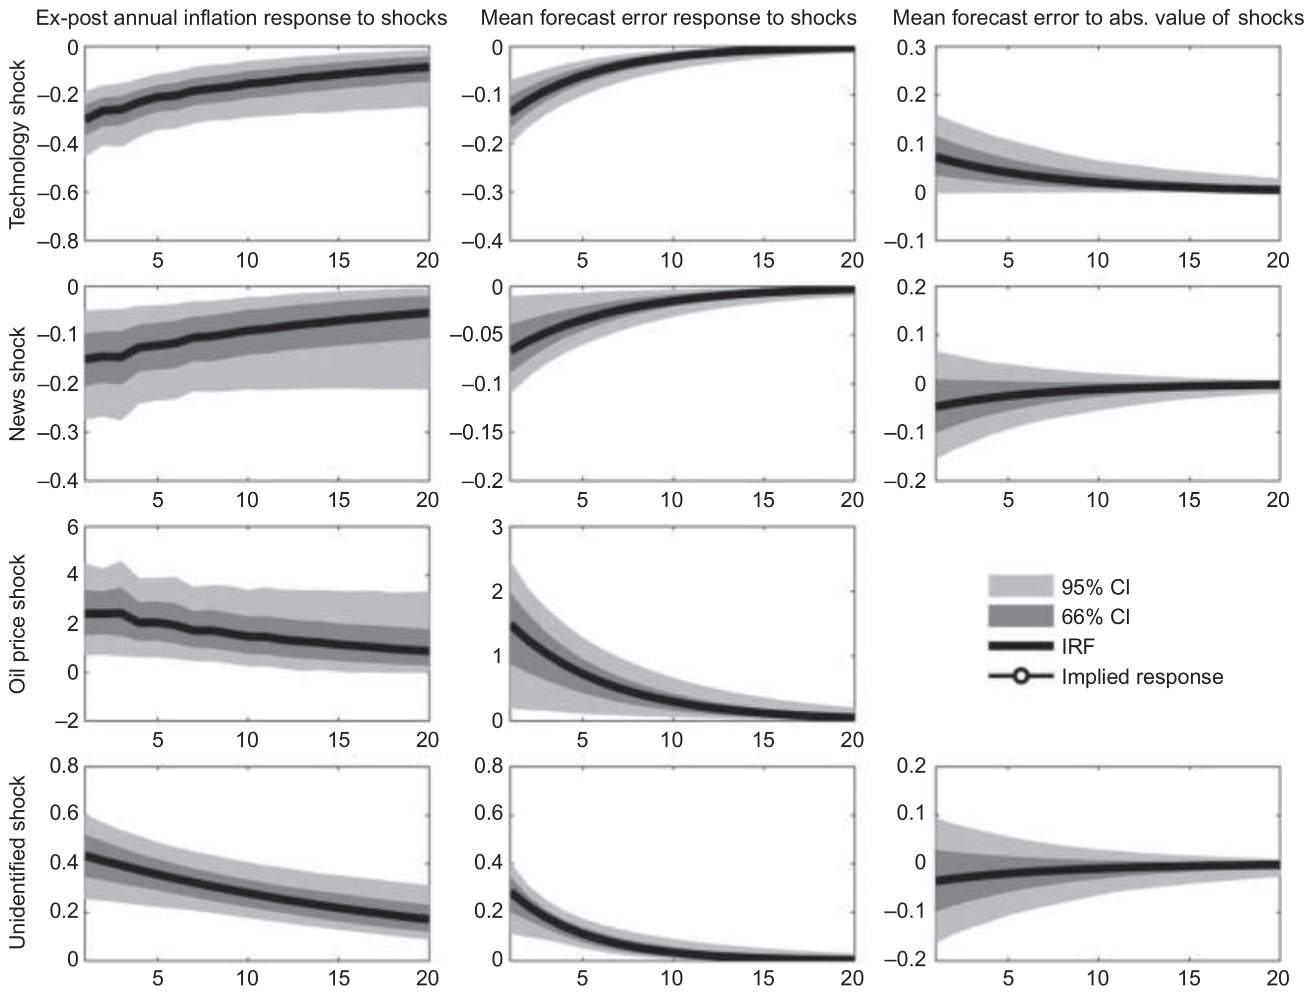

Fig. 10 Response of forecast errors to structural shocks in SPF.

actual inflation, π_t, but also in a more muted manner. Finally, note that the average forecast error vanishes with time.

Coibion and Gorodnichenko (2012) show that the same qualitative patterns hold if the SPF measure of inflation forecasts is replaced by forecasts measures from the University of Michigan Survey of Consumers the Livingston Survey, and the FOMC blue book. To the extent that these measures are good proxies for the average inflation forecast $\bar{\mathbb{E}}_t\pi_t$ in the theory, the above evidence provides prima-facie support against the standard framework and in favor of belief inertia like the one implied by incomplete information.

That said, there is an important disconnect between the empirical exercise and the theoretical models of interest. When Coibion and Gorodnichenko (2012) seek to map their evidence to the theory, they treat the observed inflation dynamics as exogenous to the observed forecast dynamics. By contrast, the models we have reviewed impose that the dynamics of inflation are endogenous to the dynamics of forecasts, indeed in a manner that is central to the predictions of the theory. To put it differently, Mankiw and Reis (2002), Woodford (2003), and others have use informational frictions, not just to explain why the agents' forecasts of inflation may adjust slowly to exogenous shocks, but also to explain why this kind of belief inertia may itself feed into inertia in actual inflation, which in turn may feed into further belief inertia, and so on.

To recap, Coibion and Gorodnichenko (2012) make a significant contribution by documenting salient comovement patterns in the joint responses of forecasts of inflation and of actual inflation to certain shocks. Nevertheless, the precise mapping from that evidence to the theory remains an open question: by treating inflation as an exogenous object, that paper has stopped short of quantifying the equilibrium mechanism that is at the core of the models we have reviewed.[ch]

We conclude by mentioning a few additional works that use survey data to information heterogeneity. Kumar et al. (2015) and Coibion et al. (2015) document widespread dispersion in firms' beliefs about macroeconomic conditions, especially inflation. Coibion and Gorodnichenko (2015) use the relationship between ex-post mean forecast errors and the ex-ante revisions in the average forecast to test the existence of information rigidities. Andrade and Le Bihan (2013), Branch (2007), Carvalho and Nechio (2014), Cavallo et al. (2015), and Sarte (2014) provide additional evidence in favor of information frictions. Combined, these papers provide ample motivations for studying the role of information frictions in the context of business cycles and monetary policy.

[ch] Relatedly, the finding in Coibion and Gorodnichenko (2012) that there is little evidence for strategic complementarity should not be misinterpreted. This finding refers to a rejection of the hypothesis that professional forecasters distort their reported forecasts in an attempt to conform to the forecasts of others. It has nothing to say about the role of strategic complementarity in price-setting behavior or, more generally, in business-cycle phenomena.

8.7 Demand-Driven Fluctuations

In Sections 8.3–8.6 we reviewed a literature that shows how informational frictions can offer a compelling micro-foundation for nominal rigidity. This literature complements the New-Keynesian paradigm, because nominal rigidity is central to this paradigm's ability to explain the observed business-cycles and to accommodate the notion of demand-driven fluctuations. We now turn attention to a different line of work, which goes against the New-Keynesian paradigm: we argue that informational frictions can achieve the aforementioned goals (ie, explain the business-cycle data and accommodate the demand-driven fluctuations) even in the absence of nominal rigidity.

There is a long tradition that formalizes demand-driven fluctuations as the product of "animal spirits" within multiple-equilibrium models. See, eg, Azariadis (1981), Benhabib and Farmer (1994), Cass and Shell (1983), Diamond (1982), Cooper and John (1988), and Guesnerie and Woodford (1993). This approach enjoys limited popularity in the modern business-cycle paradigm, in part because of debatable empirical foundations and in part because of the inconveniences that multiple-equilibrium models carry for estimation and policy evaluation. Nevertheless, what we find appealing with this tradition is that it disentangled the notion of demand-driven fluctuations from that of monetary non-neutrality. This contrasts with the New-Keynesian framework, which gives a central position to nominal rigidity and to monetary policies that fail to replicate flexible prices: in the absence of these features, the notion of demand-driven fluctuations evaporates, and so does the framework's ability to match salient features of the business-cycle data.

But now note that the modern business-cycle paradigm leaves no room for animal spirits, not only because it imposes a unique equilibrium, but also because it rules out imperfect coordination (in the sense we have defined in this chapter). This suggests that the introduction of incomplete information to otherwise canonical unique-equilibrium macroeconomic models may help accommodate a type of fluctuations in expectations and macroeconomic outcomes that resembles the sunspot fluctuations obtained in the older multiple-equilibrium literature, thus also providing a potent formalization of demand-driven fluctuations that does not rest on either nominal rigidity or "mistakes" in monetary policy.

This basic idea was pursued in Angeletos and La'O (2013). The authors consider a convex neoclassical economy in which agents are rational, markets are competitive, the equilibrium is unique, and there is no room for randomization devices. They also rule out aggregate shocks to preferences, technologies, or any other payoff-relevant fundamentals. This shuts down the type of higher-order uncertainty we have studied so far. And yet, the authors are able to obtain aggregate fluctuations, thanks to correlated higher-order beliefs about idiosyncratic trading opportunities.

Let us elaborate on the mechanics of that paper. The structure of the economy is similar to the one used in Section 8.1 to study real rigidity, except for two modifications:

islands are randomly matched in pairs; and in any given period, islands can trade and communicate only with their trading partners.

As in the model introduced in Section 8.1, each island specializes in the production of a specific good and consumes also the good produced by at least one other island. This gives rise to trade and, thereby, to a certain kind of strategic complementarity. Unlike the model of Section 8.1, however, trade is decentralized and takes place through random matching: in each period, each island meets and trades with only one other, randomly selected, island. This implies that game-theoretic representation of the general equilibrium of that model takes the following form:

$$y_{it} = (1-\alpha)\theta_i + \alpha\mathbb{E}_{it}[y_{m(i,t),t}], \tag{38}$$

where y_{it} is the output of island i in period t, θ_i is its exogenous and time-invariant productivity, $\alpha \in (0, 1)$ is the degree of strategic complementarity implied by the underlying preference and technology parameters, and $m(i, t)$ denotes the trading partner (or "match") of island i in period t. It follows that the output of an island depends, not only on its own productivity and the expected productivity of its likely trading partner, but also on what the later expects from its own trading partner, and so on. The authors then proceed to engineer aggregate fluctuations from this kind of higher-order uncertainty.

Formally, the fluctuations obtained in Angeletos and La'O (2013) are aggregate manifestations of exogenous correlated shifts in higher-order beliefs. As discussed before, however, these higher-order belief shifts need to be taken too literally. Rather, they can be interpreted as a device for accommodating nearly self-fulfilling fluctuations in expectations of "demand." This should be evident from equation (38): shifts in higher-order beliefs trigger shifts in actual output because, and only because, they rationalize shifts in the expectations (first-order beliefs) that each island forms about the demand for its product.[ci] What is more, even though the equilibrium is unique, the resulting fluctuations have a similar flavor as those sustained in multiple-equilibrium models: when an island expects more demand for its product, it produces more, which in turn raises the demand for other islands' products. Last but not least, these fluctuations are possible even if the aggregate fundamentals are constant, thus bypassing the limitation discussed in Proposition 21.

A related formalization of aggregate demand fluctuations appears in Benhabib et al. (2015b). As in Angeletos and La'O (2013), there are no aggregate shocks to fundamentals (preferences or technologies) and the equilibrium is unique when information is perfect. But unlike that paper, multiple equilibria obtain once a certain informational friction is introduced. What opens the door to multiplicity is the endogeneity of the information.

[ci] The higher an island's trading partner's output, $y_{m(i,t),t}$, the higher demand for the good produced by the island.

In the model, each firm observes an endogenous private signal about its demand, which in turn depends on the behavior of other firms. In one of the equilibria, which Benhabib et al. (2015b) argue is the most plausible one, aggregate activity is shown to vary with a sunspot. The sunspot is not publicly observable. Instead, the signal that each firm receives about its demand acts partly as an imperfect signal of an idiosyncratic demand shock and partly as an imperfect signal of the aggregate sunspot. What sustains the equilibrium is then the signal-extraction problem that firms face with regard to figuring out whether demand is driven by the one or the other shock.

Complementary are also the works of Gaballo (2015), Chahrour and Gaballo (2015), and Benhabib et al. (2015a, 2016). Gaballo (2015) studies an economy in which final producers are informed about aggregate conditions only through the equilibrium prices of their local inputs; shows that multiple equilibria can arise when idiosyncratic shocks to intermediate production are small; and documents the existence of an interesting equilibrium in which prices are rigid with respect to aggregate shock. Chahrour and Gaballo (2015) show that nontrivial aggregate fluctuations may originate with vanishingly small common shocks to either information or fundamentals. Benhabib et al. (2015a) introduce endogenous information acquisition in a model where firms face both idiosyncratic and aggregate demand shocks and show that endogenous information acquisition makes economic volatility time-varying and countercyclical. Benhabib et al. (2016) show that exuberant financial market sentiments can increase the price of capital, which signals strong fundamentals of the economy to the real side and consequently leads to an actual boom in real output and employment.

What all the aforementioned papers have in common with Angeletos and La'O (2013) is the central role played by incomplete information: if it were not for that feature, the models studied in all these papers would reduce to conventional, unique-equilibrium, neoclassical models, in which equilibrium outcomes would have been pinned down by fundamentals. What, however, distinguishes the aforementioned papers is the emphasis on the signal extraction problems that arise once information is incomplete and the additional volatility—including that in the form of multiple equilibria and sunspot fluctuations—which may obtain from such signal extraction problems.[cj]

Finally, Angeletos and Lian (2016a) study an environment that relates to the aforementioned papers in that it also rests on a signal-extraction problem between aggregate and idiosyncratic shocks, but shifts the emphasis away from multiple equilibria and sunspot fluctuations to a mechanism that helps formalize the notion of a Keynesian multiplier. In particular, a rational confusion between idiosyncratic and aggregate shocks—or at least the lack of common knowledge about aggregate shocks—is shown to explain why

[cj] At some abstract level, all these signal-extraction problems are similar to the one first formalized in Lucas (1972). However, not only are the applications very different, but also higher-order beliefs come into play.

a negative aggregate shock to consumer spending[ck] may lead firms to hire and produce less, which in turns leads consumers to spend less, and so on, ultimately leading to a recession. The same mechanism is then also shown to generate large fiscal multiplier: an exogenous increase in government spending may actually crowd in private consumption, leading to an increase in output that is higher than the exogenous increase in government spending, and helping undo the recession.

Combined, the papers we have discussed in this section indicate how incomplete information helps provide a set of complementary formalizations of the notion of demand-driven business cycles. Importantly, these formalizations do not require–but also do not preclude—either any form of nominal rigidity or any friction in monetary policy. Embracing these formalizations may thus affect, not only the structural interpretation of the available data, but also the policy implication one may wish to draw from the data. Indeed, if nominal rigidity is, by assumption, the only way one can make sense of demand-driven fluctuations, one is *forced* to think about frictions in monetary policy, such as the zero lower bound, as central to the observed phenomena. But if the key relevant mechanism is a friction in information and coordination, monetary policy could be a sideshow.[cl]

Angeletos et al. (2015) and Huo and Takayama (2015a) push this research agenda further by seeking to quantify the aforementioned kind of belief fluctuations. These papers share a similar objective, but take rather different approaches. The first one relaxes the assumption of a common prior in order to accommodate rich, higher-order belief dynamics in an arbitrary linear DSGE model and proceeds to conduct a wide range of horseraces between higher-order beliefs, nominal rigidity, and a variety of structural shocks commonly used in the literature. The second paper maintains the assumption of a common prior, thus disciplining the dynamics of higher-order beliefs, at the expense of a more limited range of quantitative explorations. Both papers nevertheless reach a similar conclusion: the kind of fluctuations in expectations and outcomes that are rationalized by shifts in higher-order beliefs can be quantitatively important and can offer a potent structural interpretation of salient features of the data.

An example of what this means is illustrated in Table 1, which is borrowed from Angeletos et al. (2015). This table compares the empirical performance of five alternative models. The first column in the table reports some key business-cycle moments of the US data; the other five columns report the corresponding moments of the five models. Let us explain what these models are.

[ck] Such shocks may reflect shifts in preferences or, more plausible, be proxies for shocks to consumer credit and/or consumer expectations.

[cl] To be clear, we do not question the empirical relevance of nominal rigidity; we only question whether nominal rigidities and Philips curves are central to understanding either the notion of demand-driven fluctuations or the key regularities of the business-cycle data.

Table 1 HOB shocks in the RBC model vs different kinds of demand shocks in the NK model

Boldface indicates significant difference between the model and the data.

The first model (column 2) is the authors' baseline model. This is a variant of the textbook RBC model that features only two sources of volatility: a persistent technology shock, A_t, which moves the production possibilities of the economy; and a transitory belief shock, ξ_t, which moves higher-order beliefs of A_t for given A_t. In the equilibrium of this model, variation in ξ_t manifests as waves of optimism and pessimism about the short-term economic outlook. The authors refer to ξ_t as a "confidence shock."

The remaining four models are versions of the New-Keynensian model. All four versions share the same RBC backbone as the baseline model of Angeletos et al. (2015). They differ from it only in two respects. First, they all add sticky prices a la Calvo and a Taylor rule for monetary policy, so as to accommodate the New-Keynesian transmission mechanism. Second, each one of them replaces the confidence shock with one of the following alternative structural shocks, which have been used in the literature as proxies for "demand shocks": an investment-specific shock; a consumption-specific, or discount-rate, shock; a news shock; and a monetary shock.

All five models are calibrated in a comparable manner: the technology and preference parameters, which are common to all models, are set at conventional values; and the stochastic properties of the shocks, which differ across models, are chosen so as to minimize the distance of the model's predicted volatilities for output, hours and investment from the corresponding volatilities in the US data. The models can then be judged in terms of how well they match these targeted moments and, most importantly, how well they match other salient features of the data.

As can be seen in the table, the belief-augmented RBC model does a good job in matching the US data. It also outperforms, in multiple fronts, the competing New-Keynesian models with either the investment shock, or the consumption shock, or

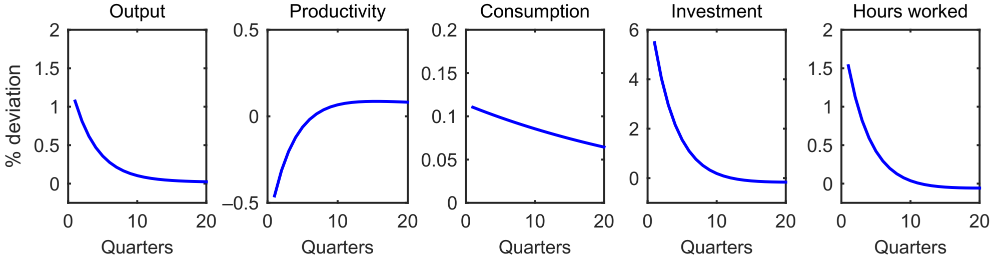

Fig. 11 IRFs to HOB shocks: A formalization of nonmonetary demand shocks.

the news shock. In this sense, the "confidence shock" is superior to these three conventional formalizations of "demand shocks."

The only New-Keynesian model that does as well as the RBC model with confidence shock is the one featuring monetary shock. The problem with that particular model is that its empirical fit rests on allowing for a size of monetary shocks that is an order of magnitude higher than standard estimates of monetary shocks.[cm] Nevertheless, the virtual tie between the two models is a measure of the ability of higher-order uncertainty to provide a potent substitute for the quintessential formalization of "demand shocks."

The reason for these findings can be found in Fig. 11. This figure shows the impulse response functions of the model's key endogenous outcomes to the exogenous shocks in higher-order beliefs. This shock triggers strong comovement in employment, output, consumption, and investment, without a strong comovement in either labor productivity (shown) or inflation (not shown). It is precisely these comovement patterns that are present in the data and that conventional structural shocks have difficulties in matching.

Angeletos et al. (2015) document that these lessons extend to an estimated medium-scale DSGE model that allows for richer propagation mechanisms (sticky prices, habit formation, and investment-adjustment costs) along with multiple structural shocks. In particular, the richer model includes both permanent and transitory TFP shocks, news shocks, investment shocks, consumption-specific shocks, and fiscal and monetary shocks. In the absence of the confidence shock, the estimated model delivers a similar picture as the one found in the extant DSGE literature. But once the confidence shock is included in the model, the picture changes dramatically: the confidence shock is estimated to account for more than half of the business-cycle volatility in output and other macroeconomic quantities.

Huo and Takayama (2015a) complement the above findings by studying a version of the RBC model that allows for a similar type of confidence shocks as in Angeletos and La'O (2013). Relative to Angeletos et al. (2015), the first key difference is the imposition

[cm] Relatedly, if we look at the model's predicted moments for inflation and the nominal interest rate, these moments are far away from their empirical counterparts.

of the common-prior assumption, which disciplines the magnitude and the persistence of the fluctuations in higher-order beliefs that can be entertained in the theory. The second key difference is the use of forecast data, which further discipline the aforementioned fluctuations. Despite these additional "constraints," Huo and Takayama (2015a) reach a similar bottom line as Angeletos et al. (2015): confidence shocks are shown to generate realistic business-cycle patterns and to account for a sizable component of the volatility in the data.

Whether one takes these quantitative findings at face value or not, they offer a very different message from Ramey (2016) in this *Handbook.*That chapter concludes: "we are much closer to understanding the shocks that drive economic fluctuations than we were twenty years ago." We contend that this conclusion hinges on structural interpretations of the data that rule out frictions in coordination and forces akin to market psychology and animal spirits. Once these elements are taken into account, both the interpretation of existing structural VAR evidence and the quantitative performance of existing DSGE models can be seriously upset. The state of our understanding is certainly *different* from what it was twenty years ago. But it is not necessarily closer to the "truth," at least not insofar as the "truth" assigns a prominent role to the type of frictions we have studied in this chapter.[cn]

Last but not least, the works we have reviewed in this section suggest that aggregate demand can be "deficient" during or in the aftermath of certain recessions, not only because of sticky prices and constraints on monetary policy such as the zero-lower bound, but also—and perhaps primarily—because of difficulties in the coordination of the decentralized choices of firms and consumers. How these ideas apply to the Great Recession is an important open question.

8.8 Financial Markets

In this section we discuss how incomplete information can help explain certain asset-pricing puzzles, such as the deviation of asset prices (or exchange rates) from fundamentals, or momentum. To this goal, we use a simple, forward-looking, asset-pricing model with incomplete information, which is the backbone of Futia (1981), Singleton (1987), Allen et al. (2006), Bacchetta and van Wincoop (2006), Kasa et al. (2007), Rondina and Walker (2014), and others. All these paper share the same key structural equation, namely condition (39) below, but make different assumptions about the information structure and the underlying stochastic processes.

[cn] Here is it important to clarify the following. Whenever macroeconomists talk about "shocks" and "propagation mechanisms," they do *not* talk directly about the data (the real world). Shocks and propagation mechanisms are theoretical objects, which are defined in specific models, or in associated structural VARs, and which are used to *interpret* the data.

There is a continuum of agents, or traders, who participate in a competitive market for a risky asset. The market operates for $T+1$ periods, where T can be either finite or infinite. In any period $t \leq T$, the demand for the asset of any given trader i is proportional to her expected excess return of the asset:

$$q_{it} = \mathbb{E}_{it} d_t + \beta \mathbb{E}_{it} p_{t+1} - p_t, \tag{39}$$

where q_{it} is the net position of trader i in period t, p_t is the price of the asset in period t, and d_t is the dividend the asset pays at the end of period t. In period $t = T+1$ (which is valid only if T is finite), we instead have $q_{iT+1} = \mathbb{E}_{iT+1} d_{T+1} - p_{T+1}$, because there is no further trading after that period. In what follows, we focus on what happens in $t \leq T$.

Condition (39), or a slight variation of it, is present in all the aforementioned papers. The papers differ only in the specification of the information structure and of the stochastic properties of d_t and s_t.

In what follows, we treat condition (39) as a primitive structural equation. It is worth noting, however, that this condition can be micro-founded in (at least) two ways.

First, suppose that the traders are risk neutral but need to pay a quadratic "holding" cost for any net position they hold in the risky asset. This means that the trader i's per-period payoff is given by

$$U_{it} = -p_t q_{it} - \frac{1}{2} q_{it}^2 + \left(d_t + \frac{p_{t+1}}{1+r} \right) q_{it}.$$

where r is the risk-free rate. It follows that the optimal demand is given by condition (39), with $\beta = \frac{1}{1+r}$.

Alternatively, suppose that the traders are myopic and have CARA preferences, meaning that their per-period payoff is given by

$$U_{it} = -\frac{1}{\gamma} \exp\left\{ -\gamma \left(-p_t q_{it} + \left(d_t + \frac{p_{t+1}}{1+r} \right) q_{it} \right) \right\},$$

where $\gamma > 0$ is the coefficient of absolute risk aversion. Suppose furthermore that the information structure is Gaussian and let us focus on equilibria in which the equilibrium price is itself a Gaussian signal of the dividend. Then, the optimal demand for the asset i is given by

$$q_{it} = \frac{\mathbb{E}_{it}[d_{it}(1+r) + p_{t+1}] - (1+r)p_t}{\gamma Var_{it}(d_{it}(1+r) + p_{t+1})},$$

where $V\,ar_{it}(X)$ denotes the variance of X conditional on the information of trader i in period t. Finally, suppose that all the underlying shocks have known time-invariant variances and let us focus on equilibria in which the conditional risk faced by the typical trader is also time-invariant. This means that $Var_{it}(d_{it}(1+r) + p_{t+1}) = V$, for some known constant V. The expression above then reduces to (39) if we let $\beta \equiv \frac{1}{1+r}$ and, without serious loss of generality, set $\gamma V = (1 + r)$.

We now put aside these micro-foundations and focus on how the equilibrium price dynamics are affected by the incompleteness of information. To start with, let us make the following basic, but important, observation. In any $t \leq T$, a trader faces two kinds of uncertainty in the return to her investment choice: one about the end-of-period dividend, d_t, and another about the next-period price, p_{t+1}. The first kind of uncertainty regards an exogenous variable; it therefore corresponds to what we have called fundamental uncertainty. The second kind of uncertainty has to do with the demand of future traders; it is therefore an example of strategic uncertainty.

Let s_t denote the exogenous supply of the asset, or equivalently the (negative of the) exogenous demand of any "noise traders." Market clearing requires $\int q_{it} di = s_t$. It follows that the equilibrium price satisfies

$$p_t = \beta \bar{\mathbb{E}}_t p_{t+1} + \bar{\mathbb{E}}_t d_t - s_t, \tag{40}$$

where $\bar{\mathbb{E}}_t$ denotes, as usual, the average expectation at t. Next, define the "fundamental" for this environment as $\theta_t \equiv \bar{\mathbb{E}}_t d_t - s_t$. This is somewhat at odds with the rest of our paper because θ_t now contains an average of first-order beliefs. If one finds this to be confusing, one can henceforth limit attention to the special case in which d_t is known, in which case one can also let $\theta_t \equiv d_t - s_t$. An additional advantage of this special case is that it isolates the role of strategic uncertainty: in the eyes of each trader, the only remaining uncertainty is the one about the behavior of future traders (as manifested in future prices).[co] Either way, condition (21) can be rewritten as

$$p_t = \beta \bar{\mathbb{E}}_t p_{t+1} + \theta_t, \tag{41}$$

which is essentially the same as the forward-looking condition we encountered in Section 7.8. This underscores that the type of strategic uncertainty that is relevant in the present context regards the *future* choices of other agents, as opposed to contemporaneous type of strategic interaction featured in either our abstract static framework or the business-cycles applications studied in Sections 8.1–8.5.

[co] The only minor caveat with this simplification is the following. If T is finite and the last-period dividend is known, the agents face no uncertainty in the last period of trading. Under the first of the two micro-foundations discussed above, the pricing condition $p_{T+1} = d_{T+1} - s_{T+1}$ is still valid. Under the second micro-foundation, however, the traders face no uncertainty and arbitrage now imposes $p_{T+1} = d_{T+1}$. For this case, we must therefore redefine the last-period fundamental as $\theta_{T+1} \equiv d_{T+1}$. (Note that we still have $\theta_t \equiv d_t - s_t$ for all $t \leq T$.)

As in Section 7.8, let

$$z_t^0 \equiv \theta_t, \qquad z_t^1 \equiv \bar{\mathbb{E}}_t z_{t+1}^0 = \bar{\mathbb{E}}_t \theta_{t+1},$$

and, for all $j \geq 2$,

$$z_t^j \equiv \bar{\mathbb{E}}_t z_{t+1}^{j-1} = \bar{\mathbb{E}}_t \{\bar{\mathbb{E}}_{t+1}\{\ldots\{\theta_{t+j}\}\ldots\}\},$$

Iterating (41) yields

$$p_t = \sum_{j=0}^{T+1} \beta^j z_t^j. \tag{42}$$

It follows that the equilibrium price in any given period depends, not only on today's fundamentals (z_t^0) and today's forecasts of tomorrow's fundamentals (z_t^1), but also on today's forecasts of tomorrow's forecasts of the fundamentals two periods ahead (z_t^2), and so on.

This result illustrates that higher-order beliefs of *future* fundamentals can be important determinants of asset prices. Importantly, this can be true even if the current fundamentals happen to be common knowledge: even if all traders are able to reach a common belief about θ_t in *every* period t, they may still fail to reach a common belief about the future demand-and-supply conditions, and can therefore disagree about future price movements. Finally, the relevant notion of the fundamentals now contains, not only the dividend, but also the supply of the asset or, equivalently, the residual demand of noise traders.

The related literature proceeds by making different special assumptions about the length of the horizon T, the stochastic process for the dividend and the supply, and the information that is available in each period. For example, Rondina and Walker (2014) assume that T is infinite, fix the dividend to a known constant (which can be normalized zero), and allow the supply shock to follow an autocorrelated process; they then focus on how higher-order uncertainty about the history of the underlying supply shock and therefore also about the future path of prices can persist even if the traders observe the entire history of past prices. By contrast, Allen et al. (2006) assume that T is finite, that the supply shock is i.i.d. over time, and that the asset pays out a dividend only in the last period; they then focus on the higher-order uncertainty the traders face with regard to the final-period dividend. In the rest of this section, we review some of the key findings of the latter paper as well as that of Bacchetta and van Wincoop (2006).

To nest Allen et al. (2006) in our setting we let the dividend be zero in all but the last period, namely $d_{T+1} = \vartheta \sim \mathcal{N}\left(\gamma, \sigma_\vartheta^2\right)$ and $d_t = 0 \forall 1 \leq t \leq T$; let the supply shock s_t be i.i.d. over time, drawn from $\mathcal{N}(0, \sigma_s^2)$; and finally assume that the traders receive no exogenous information about the supply shocks. The equilibrium price p_t always reveals some information about the current supply shock s_t. However, because the supply shock is i.i.d.

over time, and because the traders receive no exogenous information about future supply shocks, we have that $\bar{\mathbb{E}}_t s_{t+j} = 0$ for all t and all $j > 1$. As a result, condition (42) reduces to the following[cp]:

$$p_t = \beta^{T-t} \bar{\mathbb{E}}_t \bar{\mathbb{E}}_{t+1} \cdots \bar{\mathbb{E}}_{T+1}[\vartheta] - s_t.$$

In a nutshell, Allen et al. (2006) is a special case in which the higher-order uncertainty has a relatively small dimension: it regards only the last-period dividend, as opposed to the entire path of future dividends and supply shocks. Without any loss, we henceforth set $\beta = 1$.

Consider, as a benchmark, the scenario in which the supply is either fixed or commonly known. In equilibrium, the price p_t would perfectly reveal the value of $\bar{\mathbb{E}}_t \bar{\mathbb{E}}_{t+1} \cdots \bar{\mathbb{E}}_{T+1}[\vartheta]$. Under a common prior, the average belief of a random variable can be commonly known only if all the agents share a common belief about that variable. It follows that, in this benchmark scenario, the observation of the equilibrium price induces all traders to form the same belief about the underlying ϑ at all t, and therefore also the same belief about p_{t+1} at all $t < T$. By the same token, there is no speculative trading in this benchmark: all traders would choose the same position and would expect to make zero profits from their trades.

Consider then the alternative case in which the supply shock is present and unknown. In general, the equilibrium price is then only a noisy signal of the average belief $\bar{\mathbb{E}}_t \bar{\mathbb{E}}_{t+1} \cdots \bar{\mathbb{E}}_{T+1}[\vartheta]$. It follows that different traders may maintain different beliefs about this object in equilibrium, which in turn means that they can also maintain different beliefs about either the capital gain $p_{t+1} - p_t$ they can make at any $t < T$, or the final-period yield $\vartheta - p_t$ they can make at $t = T$. In other words, speculation obtains in equilibrium.

The above insights are general. To obtain sharper predictions, however, Allen et al. (2006) impose that all the information available to trader i in period t is given by the combination of the history of prices along with a private signal of the form $x_{it} = \vartheta + \epsilon_{it}$, with $\epsilon_{it} \sim \mathcal{N}(0, \sigma_\epsilon)$ for some $\epsilon > 0$. This in turn is justified by assuming that the traders are short-lived and do not observe any of the private signals of the earlier generations of traders, although they do observe the public history of prices.[cq]

With the assumed information structure, one can guess and verify the existence of an equilibrium in which the price in each period t conveys the same information as a Gaussian public signal of the form

[cp] Strictly speaking, the equilibrium in Allen et al. (2006) entails time-varying risk, which shows up in the demand for the asset (because of the assumption of CARA preferences) and thereby also in the equilibrium condition of the price. Here, we abstract from this nuisance.

[cq] For a discussion of this assumption and for the alternative of allowing long-term traders, see the original paper (Allen et al., 2006) and the references therein.

$$z_t = \vartheta - \chi_t s_t,$$

for some deterministic scalars $\chi = (\chi_t)_{t=0}^{T}$, which are themselves determined by the trading strategies of the agents. Together with the assumption that the private signal is also Gaussian, the above property guarantees a tractable dynamic structure for the posteriors of the traders—namely, a Kalman filter over the time-invariant variable ϑ. As it is standard in noisy rational-expectations settings, the scalars $\chi = (\chi_t)_{t=0}^{T}$ are then characterized by solving the fixed-point relation between (i) the forecasts that each trader forms on the basis of the available price signals and (ii) the price signal generated by the joint behavior of all the traders. The following two results emerge.

Proposition 33 *There exist weights* $\{\lambda_t\}$ *with* $0 < \lambda_T < \lambda_{T-1} < \cdots < \lambda_2 < \lambda_1 < 1$ *such that*

$$E_s(p_t) = \lambda_t \gamma + (1 - \lambda_t)\vartheta$$

where $E_s(.)$ denotes the average value over all the possible supply shocks (equivalently, the expectation conditional on γ and ϑ).

Proposition 34 *For all* $t < T$

$$E_s(|p_t - \vartheta|) > E_s(|\overline{E_t}(\theta) - \vartheta|).$$

Proposition 33 is reminiscent of the inertia effect we documented earlier: the equilibrium price is anchored to the initial prior γ and converges to the fundamental ϑ only sluggishly over time. By the same token, the price path exhibits "momentum": following certain innovations (namely, an innovation in ϑ), prices under-react in the short run relative to the long run; equivalently, they exhibit a drift reminiscent of the ones documented in empirical studies on momentum.[cr]

Proposition 33 complements the above lesson by establishing that the gap between the fundamental and the equilibrium price is more volatile than the gap between the fundamental and the average belief of it. This kind of "excess volatility" reflects the variation that obtains in higher-order beliefs for given first-order beliefs. Proposition 34 is therefore reminiscent of our earlier result regarding the role of incomplete information in sustaining animal spirits.

Combined, these results illustrate how incomplete information and higher-order uncertainty can help standard asset-pricing models accommodate momentum and other interesting volatility patterns in asset prices. In an insightful earlier contribution, Allen et al. (1993) show that higher-order uncertainty can also accommodate "bubbles": there can exist events in which the equilibrium price is higher, not only than the average expectation of the fundamental, but also than the expectation of *every* trader.

[cr] If we replace the private signals that the traders observe in each period t with a public signal of equal precision, then the weight λ_t remains positive but becomes smaller at each t. The dynamic effect documented above is therefore the product, not just of slow learning, but also of the heterogeneity of the information.

This particular possibility is ruled out in the present setting because the Gaussian specification implies that there always exists a trader whose private signal is arbitrarily high, and therefore whose forecast of ϑ is higher than the equilibrium price. Nevertheless, the excess volatility documented in Proposition 34 can be seen as a variant of the same possibility.

The paper by Allen et al. (1993) contains also an insightful discussion of the following issues: the appropriate definition of "fundamentals" in asset-pricing models; the close relation between incomplete-information common-prior settings like the one studied here and the kind of symmetric-information heterogeneous-prior settings studied in, inter alia, Harrison and Kreps (1978) and Scheinkman and Xiong (2003); and the potential richness of the relevant state space. The latter means that the revelation of information through prices can be quite limited in practice, or in sufficiently sophisticated models, even though it can be large in more simplistic models, therefore leaving significant room for higher-order uncertainty to drive asset prices. Complementary in this regard is also the message of Rondina and Walker (2014), although a quantitative evaluation of this insight is still missing.

Let us now shift attention to Bacchetta and van Wincoop (2006). This paper uses a version of the framework we have introduced in this section to argue that incomplete information may explain the disconnect of exchange rates from macroeconomic fundamentals at short to medium horizons. In their model, the asset price is the nominal exchange rate between two countries, which we denote by e_t.[cs] The key equilibrium condition is given by the following[ct]:

$$e_t = \beta \bar{\mathbb{E}}_t e_{t+1} + f_t - b_t,$$

where f_t is the observable difference in money supply between two countries—which is what the authors interpret as the macroeconomic fundamentals—and b_t is an unobserved hedging demand. It follows that Bacchetta and van Wincoop (2006) is nested in our setting simply by the following change in notation: $p_t = e_t$, $d_t = f_t$, and $s_t = b_t$.

The model is closed by assuming the following stochastic structure. The macroeconomic fundamental, f_t, follows a general MA process, $f_t = D(L)\epsilon_t^f$ where $D(L) = d_1 + d_2 L + \cdots$, L is the lag operator, and $\epsilon_t^f \sim N\left(0, \sigma_f^2\right)$. The hedging demand, b_t, follows an AR(1) process: $b_t = \rho_b b_{t-1} + \epsilon_t^b$, where $\epsilon_t^b \sim N\left(0, \sigma_b^2\right)$ and $\rho \in [0, 1)$. In each period, all traders observe the past and the current values of the fundamental and the exchange rate, but not of the hedging demand. In addition, each trader receives a private signal about the *future* fundamental. This is signal is given by $x_t^i = f_{t+\Delta} + \epsilon_t^{xi}$, where

[cs] In Bacchetta and van Wincoop (2006), the exchange rate is denoted by s_t; we use the alternative notation, e_t, in order to avoid any confusion with our earlier notation, which lets s_t denote the supply of the asset.

[ct] As in our discussion of Allen et al. (2006), we omit some potential time-varying coefficients on f_t and b_t.

$\epsilon_t^{xi} \sim \mathcal{N}(0, \sigma_x^2)$ is independent from f_τ for all τ, as well as of the noises in other agents' signals, and $\Delta \geq 1$.

The model's predictions are illustrated in Fig. 12, which we borrow from fig. 2 in Bacchetta and van Wincoop (2006).[cu] Panel A shows that the exchange rate responds sluggishly to innovations in the fundamental, a recurring theme of this chapter. At the same time, the exchange rate responds nontrivially to shocks in hedging demand, and more so than in the complete-information variant of the model. Both effects originate in rational confusion at the individual level, but get amplified by our familiar beauty-contest mechanism.

The amplification effect of hedging demand is evident in Panel C, which reports the contribution of the hedging demands to the variance of the exchange-rate change $e_{t+k} - e_t$ at different horizons $k \geq 1$. Although hedging shocks contribute to short-run volatility in both the incomplete-information and common-knowledge versions of the model, their contribution is far greater in the former case. The mirror-image of this result is Panel D, which reports the R^2 of the regression of $e_{t+k} - e_t$ on the realization of the fundamentals up to $t + k$. In the short run, the R^2 is far lower in the incomplete-information version of model than in its common-knowledge counterpart. In the long run, R^2 converges to 1 in both models, reflecting the fact that both first- and higher-order beliefs converge to the realized fundamental as time passes and more and more information is accumulated. However, the convergence is slower in the incomplete-information version, due to the fact that higher-order beliefs converge more slowly than first-order beliefs. These properties are consistent with empirical findings that macroeconomic fundamentals have weak explanatory power for exchange rates in the short to medium run (Meese and Rogoff, 1983), but play a much more important role over longer horizons.

Complementary to the above works are Biais and Bossaerts (1998), Kasa et al. (2007), Makarov and Rytchkov (2012), and Rondina and Walker (2014). The first paper is an early contribution that also touches on the beauty-contest aspect of asset markets and explores on the distinct positive implications of incomplete information and heterogeneous priors in a finite-horizon model with a finite number of agents. The other three papers use frequency-domain techniques to solve infinite-horizon models, where there are recurring shocks to fundamentals and the traders' beliefs remain perpetually heterogeneous. Combined, these papers show how higher-order belief dynamics can explain apparent violations of variance bounds and other cross-equation restrictions that guide the empirical test of representative-agent models; how they can accommodate momentum; and how can also generate endogenous boom-and-bust cycles.

Two other important contributions are Cespa and Vives (2012, 2015). These papers revisit the question of whether asset prices are closer or further away from the underlying fundamentals than the consensus (average) forecast of fundamentals. Whereas the aforementioned works by Allen et al. (2006), Bacchetta and van Wincoop (2006), and others answer this question always in the affirmative, Cespa and Vives (2012, 2015) show that

[cu] Panel B is omitted because it is not useful for our discussion.

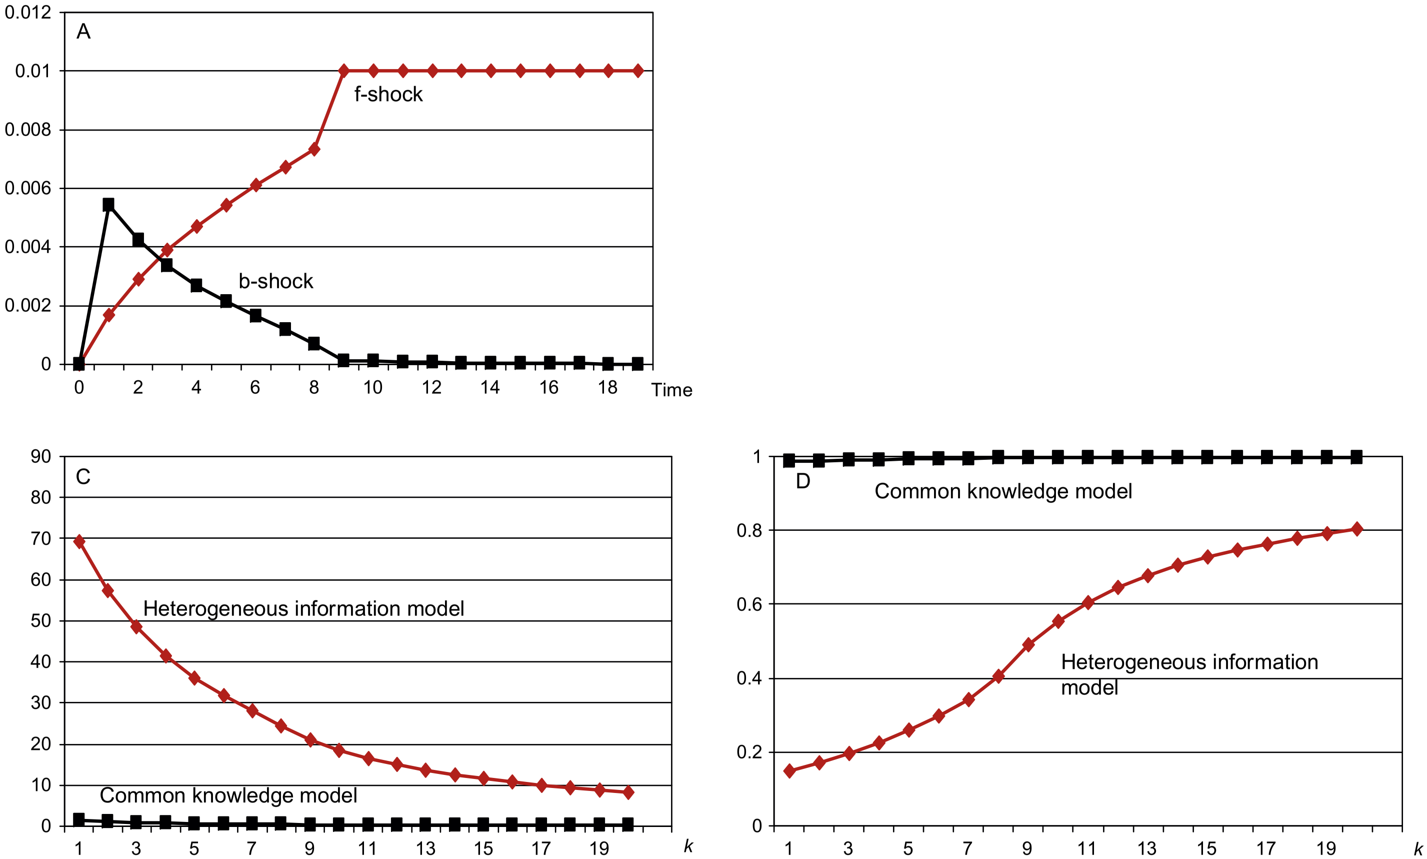

Fig. 12 Exchange rate disconnect in the short and long run. (A) Impulse response functions in heterogeneous information model. (C) Percent contribution b-shocks to $var(s_{t+k} - s_t)$. (D) Connection between exchange rate and observed fundamentals: R^2 of regression of $(s_{t+k} - s_t)$ on observed fundamentals.

the answer depends critically on the persistence of the shocks to liquidity (noise) trades, which is typically assumed to be zero in the literature.

More specifically, Cespa and Vives (2012) studies a model similar to that in Allen et al. (2006), except for two modifications: the informed, rational traders are long-lived; and the unobserved shocks to liquidity (noise) trades are allowed to be persistent. When this persistence is sufficiently low, equilibrium prices are systematically farther away from fundamentals than the average expectation, a pattern consistent with Allen et al. (2006) and Bacchetta and van Wincoop (2006). But when liquidity trades are sufficiently persistent, the opposite pattern emerges: rational traders chase long-term returns rather that short-term speculative gains, causing prices to be systematically closer to fundamentals than average expectations. Cespa and Vives (2015) provide a complementary result in a model where rational traders are short-lived. It nevertheless remains true that incomplete information can generate interesting time-series patterns, such as momentum.[cv]

All in all, the works we have reviewed in this section illustrate how higher-order uncertainty can offer a parsimonious explanation to various puzzles in asset pricing and international finance. These works are part of a broader literature that uses informational frictions—although not always higher-order uncertainty—in asset-pricing contexts. Grossman and Stiglitz (1980), Hellwig (1980), and Kyle (1985) are classics, which emphasize the aggregation of information through equilibrium prices. More recently, Albagli et al. (2014, 2015) develop an extension that accommodates more general specifications of the joint distribution of the dividend and the private signals. This helps shed light on the differential effect that the heterogeneity of information can have on different claims on the same underlying asset, such as the bonds and the stocks of the same firm. Hassan and Mertens (2014a), on the other hand, develop a framework for augmenting DSGE models with a noisy rational-expectations asset market, and use that to study the macroeconomic effects of the news contained in asset prices about future fundamentals. Notwithstanding the contributions of these papers, it is useful to note that none of them study the beauty-contest effects that are the core of the papers we reviewed above, for they study setting in which either the fundamentals become common knowledge at the end of each period (Hassan and Mertens, 2014a) or trading takes place only once (all the other papers mentioned in this paragraph).[cw]

More closely related to the papers we have reviewed above are, instead, Angeletos et al. (2010) and Hassan and Mertens (2011, 2014b). Angeletos et al. (2010) show that

[cv] What is more, Cespa and Vives (2015) show that the combination of incomplete information with short-term horizons may open the door to multiple equilibria, which are ranked both in terms of their informational efficiency and in terms of the strength of the momentum effect.

[cw] This statement should not be misinterpreted as a claim that that higher-order beliefs are entirely irrelevant. Because the agents extract a signal from prices, and because this signal is endogenous to the trades of other agents, higher-order beliefs matter in all the mentioned papers for essentially the same reason as the one suggested by Townsend (1983). But this mechanism, which has to do with the interpretation of endogenous signals, is different from the mechanism we discussed above, which has to do with speculation.

the information spillover between the real and the financial sector induces beauty-contest features in IPO activity and real investment, leading to excessive waves of optimism and pessimism in investment and asset prices. Hassan and Mertens (2011, 2014b) show how financial trading may amplify small correlated biases in traders' beliefs, while also reducing the individual incentive to correct one's beliefs from such biases, and how this mechanism can ultimately distort real investment. In these papers, strategic complementarity emerges endogenously and is key to the obtained results.

Finally, there is a growing strand of the asset-pricing literature that shifts the focus to the acquisition of information or the attention allocation (eg, Veldkamp, 2006; Van Nieuwerburgh and Veldkamp, 2009, 2010; Abel et al., 2007, 2013), but is beyond the scope of this chapter. For more thorough discussions of the broader asset-pricing literature on informational frictions, we refer the reader to Vives (1993) and Veldkamp (2011). A similar point applies to Goldstein et al. (2011), which focuses on trading frenzies; and to Goldstein et al. (2013), which focuses on the signal-extraction problem of a central bank in the context of self-fulfilling financial crises.

We conclude by mentioning a line of work that touches on similar mechanisms, albeit with different modeling techniques. This is the asset-pricing literature on heterogeneous beliefs and speculation, such as Harrison and Kreps (1978) and Scheinkman and Xiong (2003). What is common between this literature and the works we reviewed above is that equilibrium trades and asset prices are driven by higher-order beliefs. What is different is that variation in the relevant higher-order beliefs is engineered with the combination of heterogeneous priors and the arrival of public information over time, as opposed to dispersed private information. This means a great deal of tractability, the absence of which could have impeded the discovery of important results. But it also comes with three potential costs. First, this approach permits the theorist to choose higher-order beliefs at will, a freedom that must be exercised with great moderation. Second, this approach shuts down the role of the price mechanism in aggregating information and coordinating beliefs, a mechanism that is of interest on its own right. Last but not least, this approach invites tricky normative questions, such as which prior must be used to evaluate the welfare implications of different allocations.[cx] Whether one should use this approach or the more "conservative" one employed by the papers we reviewed in this section is ultimately a function of one's research objectives.[cy]

[cx] One possible answer to this last question is that the planner must evaluate the utility of each agent under the agent's *own* prior. This is effectively the assumption made in Debreu's classic proof of the two welfare theorems in economies with subjective probabilities. There are, however, other plausible, and potentially preferable, answers to the aforementioned question. See, for example, Brunnermeier et al. (2014) for a welfare criterion that instructs the planner to discard an allocation only if it is deemed inferior under multiple priors at once.

[cy] The discussion of this paragraph echoes our earlier discussion in Section 7.10 regarding solution methods and the heterogeneous-prior approach taken in Angeletos et al. (2015). Similar points apply to the recent literature on heterogeneous beliefs and leverage, such as Geanakoplos (2010) and Simsek (2013).

9. EFFICIENCY AND POLICY IMPLICATIONS

Although we often touched on policy implications in the preceding sections, we have not systematically studied either the normative content of the positive properties we have documented, or the implications of coordination frictions for the type of Ramsey policy problems that are commonly used in the study of optimal fiscal and monetary policy. In the RBC model considered in Section 8.1, we simply abstracted from policy altogether. In the monetary models studied in Section 8.3, nominal GDP was assumed to follow an exogenous stochastic process, bypassing the issue of what kind of monetary policies may or may not justify this assumption. Finally, in the applications of global games reviewed in Section 5, we restricted attention to specific policy instruments, such as a bailout from a lender of last resort in the context of bank runs and debt crises.

In this section, we take a different, and complementary, approach. We put aside any specific context and seek to identify a set of policy insights that may be robust across a variety of applications. In this regard, the approach taken in this section mirrors the one we have taken throughout this paper with regard to the study of the *positive* implications of frictions in information and coordination; the key difference is that we now shift attention to *normative* properties.

More specifically, we proceed as follows. First, we propose a notion of constrained efficiency, which suits our purposes, and discuss the ways in which the constrained efficient strategy may differ from either the first best or the equilibrium. Next, we compare the constrained efficient strategy to the equilibrium one within the class of beauty-contest games studied in Sections 7 and 8. This in turn paves the way to the last part of this section, where we consider a few applications. These applications regard the social value of information, the related argument in favor or against transparency in central bank communication, and the nature of optimal monetary policy in the presence of frictions in coordination.

Remark 29 Unlike the positive properties we have emphasized in this chapter, the normative properties of incomplete-information models are more sensitive to the underlying micro-foundations. This is naturally the case because the same strategic effects can be consistent with different externalities across the agents, and therefore the same positive properties can be consistent with different normative properties. A meaningful discussion of efficiency and policy therefore requires one to dig into the specifics of different applications, a task that is beyond the scope of this chapter with the exception of the few applications briefly considered in the last part of this section. What we nevertheless hope to accomplish in this section is to develop a useful way of posing the relevant normative questions.

9.1 Constrained Efficiency

The analysis follows Angeletos and Pavan (2007, 2009). The adopted efficiency concept corresponds to a benevolent planner who has the power to dictate to the agents how to act on the basis of their information, but can not collect information from one agent and send it to another. It therefore shares with Hayek (1945) and Radner (1962) the idea that information is dispersed and cannot be communicated to a "center." Similar efficiency concepts have been used to study the welfare properties of large Cournot games (Vives, 1988) and of business-cycle models with informational frictions (Angeletos and La'O, 2010; Lorenzoni, 2010).

To be concrete, consider the abstract framework introduced in Section 2 and, without serious loss of generality, restrict attention to settings in which the payoff of an agent depends on the actions of others only through the average actions. Next, for any strategy $k(\cdot): D_\omega \rightarrow D_k$, let[cz]

$$W(k(\cdot)) \equiv \mathbb{E}[U(k(\omega_i), K(\boldsymbol{\Omega}), \theta_i)]$$

denote the ex-ante utility attained by this strategy, with the understanding (i) that $K(\boldsymbol{\Omega}) \equiv \int k(\omega) d\boldsymbol{\Omega}(\omega)$ is the average action induced by the particular strategy when the distribution of information is $\boldsymbol{\Omega}$ and (ii) that the expectation is taken over the joint realizations of $s_i = (\omega_i, \theta_i)$ and $\mathbf{S}$. We can then define our efficiency benchmark as follows.[da]

Definition 16 A (constrained) efficient strategy is a strategy $k^*(\cdot)$ that maximizes $W(k(\cdot))$.

This concept lets the planner internalize how the action of each agent affects the payoff of other agents, which of course does not happen in equilibrium. Similarly to equilibrium, however, the action of any given agent is restricted to depend only on the information that Nature reveals to that particular agent, which means that the planner is precluded from transferring information from one agent to another.

If the planner were able to transfer information from one agent to another, then he would also be able to condition the action k_i of any agent i, not only on the agent's own ω_i, but also on $\boldsymbol{\Omega}$. And if that were true, the planner could instruct the agents to play the first-best actions. But as long as the planner is restricted from transferring information across agents, the first-best actions are generally not attainable. This explains the precise sense in which the notion of efficiency defined above is "constrained": the constraint is the measurability constraint that the action of each agent can not depend on the private information of other agents.

[cz] To avoid the confusion of strategies and realized actions, we henceforth denote strategies with $k(\cdot)$. That is, whereas k is an object in D_k, $k(\cdot)$ is an object in the space of functions that map D_ω to D_k.

[da] Note that Definition 16 imposes symmetry: the planner must choose the same strategy for all agents. This is without serious loss given the symmetry of the environment and the purposes of the exercises we conduct in the rest of this section, but it could matter in general. Relatedly, we envision a planner that maximizes ex-ante utility "behind the veil of ignorance," as opposed to a planner that favors any particular group of agents.

Although the planner is precluded from eliminating the heterogeneity in information, he can regulate the degree of strategic uncertainty by controlling the degree to which agents respond to their private information. For instance, the planner could eliminate strategic uncertainty altogether by instructing all agents to condition their actions only on publicly available information. Doing so, however, would mean that the agents completely disregard their private information, which is generally socially undesirable.

Studying the constrained efficient strategy therefore allows one to answer the following types of questions: What is the degree of coordination that is socially optimal given the underlying friction in communication? Should the planner use taxes, or other instruments that manipulate incentives, in an attempt to regulate the equilibrium use of information and the resulting strategic uncertainty? Do "animal spirits" justify policy intervention, and if yes of what kind?

A first step towards answering these questions is contained in the following proposition.

Proposition 35 (Efficiency) *Suppose that* $\mathrm{k}^*(\cdot)$ *is an efficient strategy, that* $k^*(\omega)$ *is in the interior of* D_k *for all* ω*, and that that* U *is differentiable. Then,*

$$\mathbb{E}[U_k(k^*(\omega),K^*(\Omega),\theta)+\Lambda^*(\Omega)|\omega]=0 \quad \forall\omega, \tag{43}$$

with

$$\Lambda^*(\Omega)\equiv\int U_K(k^*(\omega),K^*(\Omega),\theta)d\Omega(\omega) \quad \textit{and} \quad K^*(\Omega)=\int k^*(\omega)d\Omega(\omega) \quad \forall\Omega.$$

Condition (43) is simply the first-order condition of the planner's problem. The equilibrium counterpart is the best-response condition of the individual agent, which (assuming again an interior solution) is simply given by the following:

$$\mathbb{E}[U_k(k(\omega),K(\Omega),\theta)|\omega]=0 \quad \forall\omega.$$

The only essential difference between the two conditions is therefore the presence of Λ^* (Ω). This term captures the *average* externality that agents impose on one another when the cross-sectional distribution of information is $\mathbf{\Omega}$ and when all the agents follow the strategy k^*. In this regard, condition (43) is similar to the condition that characterizes the first best. What is different is that agents need not share a common belief about $\Lambda^*(\Omega)$, due to the incompleteness of the information.[db] We conclude that the efficient strategy is similar to the first best in the sense that the agents are instructed to internalize the externalities they impose on one another (if any), but departs from the first best in the sense that the agents hold different beliefs about the value of these externalities (because, and only because, they are unable to communicate with one another).

[db] Note that, as long as information is complete, $\Lambda(\Omega)$ remains commonly known even if information is *imperfect*: as with equilibrium, what matters is higher-order uncertainty, not first-order uncertainty.

A complementary interpretation of Proposition is the following. Note that we can represent the efficient strategy as the equilibrium of a fictitious game, in which the information structure remains the same as in the original game but the payoffs are appropriately modified, so that the best-response conditions of the fictitious game coincide with the first-order conditions of the planner's problem in the original game.[dc] Under this representation, condition (43) describes the socially optimal response of each agent to her beliefs of the actions of others. In this sense, the efficient strategy helps identify the degree of coordination that is socially optimal given the underlying friction in communication.

We develop below more concrete translations of these elementary insights by restricting attention to the class of beauty-contest games studied in Section 7 and to some of the related applications studied in Section 8. This focus is partly motivated by the fact that the efficiency concept defined above has not been sufficiently explored within the global-games literature.

A notable exemption to the last statement is Schaal and Taschereau-Dumouchel (2015), which characterizes, inter alia, the constrained efficient allocation within the global-games adaptation of an RBC model that we discussed in Section 5.6. See also Sakovics and Steiner (2012) and Frankel (2016), who study optimal subsidies within coordination games akin to the adoption of a network technology.

We conclude with two remarks regarding the applicability of the efficiency concept we have introduced.

First, it is straightforward to adapt this concept and the results developed in Section 9.2 to micro-founded macroeconomic models, at least insofar as one makes appropriate modeling choices. In particular, Angeletos and La'O (2010), Lorenzoni (2010), and Schaal and Taschereau-Dumouchel (2015) study business-cycle models in which the incompleteness of information introduces strategic uncertainty, without however introducing incomplete-risk sharing in consumption. This property is achieved by assuming that all relevant agents (firms, workers, etc.) belong to a "big family" whose income and consumption is fully diversified against the idiosyncratic noise in the information of different agents. All in all, one can find a direct mapping between the abstract analysis of this section and the specific results of those papers, a point that we revisit below.

Second, it is also possible to extend the notion of efficiency to accommodate certain forms of endogeneity in the information structure, whether this means endogenous *aggregation* of information or endogenous *collection* of information. For examples of the first type, we refer the reader to Amador and Weill (2012), Angeletos and Pavan (2009), Laffont (1985), Messner and Vives (2005), and Vives (2016); for example of the second type, see Angeletos et al. (2016a), Colombo et al. (2014), Llosa and Venkateswaran (2015), and Pavan (2015).

[dc] That is, the payoffs of the fictitious game are given by $\tilde{U}(k,K,\theta,\Omega) \equiv \mathbb{E}[U(k,K,\theta) + \Lambda^*(\Omega)k]$.

9.2 Efficient Coordination in Beauty Contests

We now turn to the study of constrained efficiency within the class of beauty-contests settings introduced in Section 7.1. To guarantee the existence and uniqueness of the efficient strategy, we complement Assumption 4 with the following additional restriction on the payoff structure.

Assumption 10 $U_{kk} + 2U_{kK} + U_{KK} < 0$.

We reach the following characterization of the efficient strategy.

Proposition 36 (Efficient Coordination) *There exist scalars* $(\kappa_0^*, \kappa_1^*, \kappa_2^*, \alpha^*)$*, pinned down by U, such that the following is true:*

(i) *Whenever information is complete, the efficient action is given by*

$$k_i = \kappa^*\left(\mathbb{E}_i\theta_i, \mathbb{E}_i\overline{\theta}\right) \equiv \kappa_0^* + \kappa_1^*\mathbb{E}_i\theta_i + \kappa_2^*\mathbb{E}_i\overline{\theta}. \tag{44}$$

(ii) *Whenever information is incomplete, the efficient strategy solves the following fixed-point relation:*

$$k_i = \mathbb{E}_i\left[\kappa^*\left(\theta_i, \overline{\theta}\right)\right] + \alpha^* \cdot \mathbb{E}_i\left[K - \kappa^*\left(\overline{\theta}, \overline{\theta}\right)\right]. \tag{45}$$

Parts (i) and (ii) are the normative counterparts of, respectively, Propositions 14 and 15. These propositions characterized the equilibrium under, respectively, complete and incomplete information.

By assuming that information is complete, part (i) identifies in effect the first-best action. The possibility that the scalars $(\kappa_0^*, \kappa_1^*, \kappa_2^*)$ differ from their equilibrium counterparts reflects the familiar reasons why equilibrium and first-best allocations can differ in complete-information models. But as with the equilibrium, the key observation here is that only first-order beliefs matter when information is complete.

Part (ii) then shows how the constrained efficient action differs from the first-best one when information becomes incomplete. As with equilibrium, the planner wants each agent to align her action with her forecast of the average deviation in the population. By direct implication, higher-order beliefs matter. But unlike equilibrium, the extent of the desired alignment in actions and the associated role on higher-order beliefs is parameterized by the new scalar α^*, as opposed to the scalar α we encountered before. This new scalar encapsulates the social value of coordination.

Angeletos and Pavan (2007, 2009) analyze how this value can be understood in terms of two more familiar concepts: the welfare cost of inefficiency volatility in the aggregate outcome K; and the welfare cost of inefficient dispersion in individual actions. In a business-cycle context, these objects map to the volatility of the "output gap" and the inefficient component of the cross-sectional dispersion in relative prices; see Angeletos et al. (2016b). To understand the general logic, note that if the planner induces the agents to coordinate more, then he also induces them to rely more on correlated sources of information, which in turn means more aggregate "mistakes" in actions (ie, more volatile gaps between the equilibrium and the first-best level of aggregate activity) but also fewer idiosyncratic mistakes (ie, less inefficient dispersion in the cross section). It follows that varying the level of coordination entails a trade-off between volatility and dispersion. The higher the social cost of the latter relative to the former, the higher the socially optimal degree of coordination (ie, the higher α^*).

9.3 Policy Implications

What does the result above imply for policy? If α and α^* happen to coincide, then the equilibrium and the efficient allocation exhibit the same sensitivity to higher-order beliefs. Therefore, although the equilibrium inertia and the animal spirits that we repeatedly encountered in Sections 7 and 8 are necessarily a symptom of departure from the first best, neither of them is necessarily a call for policy stabilization, at least insofar as the policy maker is unable to eliminate the incompleteness of information.

Now contrast this observation with conventional wisdom. In standard, complete-information models, animal spirits are tied to multiple, and often Pareto-ranked, equilibria. This has lead to the view that animal spirits are prima-facia rationale for policy intervention. For instance, the Keynesian tradition dictates that, if the business cycle is driven by animal spirits, then monetary and fiscal policy should be used to stabilize the economy. But if animal spirits are the product of incomplete information, and if α happens to coincide with α^*, then the aforementioned policy prescription is misguided.

Angeletos and La'O (2010) prove, in essence, that $\alpha = \alpha^*$ applies in the RBC model we studied in Section 8.1. In other words, the "aggregate demand externality" introduced by product differentiation gives rise to a private value for coordination that is perfectly aligned with its social counterpart.

Angeletos and La'O (2012) and Angeletos et al. (2016b) consider a richer framework that allows, inter alia, the type of real rigidity studied in Section 8.1 to coexist with the type of nominal rigidity studied in Section 8.3 and featured in Woodford (2003), Mankiw and Reis (2002), and Maćkowiak and Wiederholt (2009). Within that framework, it is shown that $\alpha = \alpha^*$ applies when monetary policy replicates flexible prices, as well as that such a policy is optimal when the business cycle is driven either by technology shocks or by shocks to the belief hierarchy about technology. The coincidence of the equilibrium and the efficient degrees of coordination is therefore an important benchmark for business-cycle analysis.

Angeletos and La'O (2012) further show that, similarly to the baseline New-Keynesian framework, the optimal monetary policy replicates flexible-price allocations as long as monetary policy does not have to substitute for missing tax instruments. But unlike that framework, replicating flexible-price allocations does not mean targeting price stability any more. Instead, because efficiency requires that both the quantity and the price of each firm move with its private information about the state of the economy, efficiency also requires that the aggregate price level moves with the average "sentiment" in the economy. This gives another concrete example of how accommodating realistic frictions in coordination can upset existing policy lessons.

Paciello and Wiederholt (2014) discuss additional implications in a variant setting in which firms are rationally inattentive. Monetary policy must substitute for missing tax instruments—there are markup shocks and no subsidies to correct them. For this kind of situation, the standard New-Keynesian model predicts that monetary policy should give up on price stability in order to mimic the missing counter-cyclical subsidy that would have offset the markup shocks. Paciello and Wiederholt (2014) instead show that the optimal policy may now target price stability in order to reduce the incentives of the firms to acquire information about the underlying markup shocks. Once again, existing policy lessons are upset.

A thorough analysis of the policy implications of higher-order uncertainty is beyond the scope of this chapter. Furthermore, the relevant literature is still relatively immature. For instance, all the aforementioned papers study settings in which firms are informationally constrained, but consumers are not; they also rule out the type of asset- and labor-market frictions that seem to be important in understanding business cycles. With the aforementioned examples we therefore only wish to indicate the significance of further investigations of the policy implications of incomplete information within the context of business cycles and monetary policy.

9.4 Welfare Effects of Public Information (and Central-Bank Transparency)

We conclude this section with a brief discussion of another topic, the welfare effects of the public information provided by policy makers, the media, or other sources.

As noted before, public signals can have a disproportionate effect on equilibrium outcomes in the presence of strategic uncertainty, because they become focal points and serve a role akin to coordination devices. In an influential article, Morris and Shin (2002b) relied on this observation to show that the provision of public information can contribute to more volatility and thereby also to lower welfare. They then argued that this raises questions about the social value of the information disseminated by the financial media, as well as that it justifies "constructive ambiguity" in central bank communications.

Subsequent work has questioned the applicability of Morris and Shin's welfare result to a macroeconomic context. Angeletos and Pavan (2004) document the opposite result in an investment game with production spillovers, illustrating how the welfare effects of information depend on the form of externalities, not just the form of complementarity. Angeletos and Pavan (2007) define and characterize the socially optimal degree of coordination in a flexible-class of linear-quadratic games and use this to show that Morris and Shin's welfare result hinges on assuming that coordination motives are socially unwarranted—a property that need not hold in workhorse macroeconomic models. Finally, starting with Hellwig (2005), a number of more applied works have studied the welfare effects of different types of information in micro-founded monetary models in which nominal rigidity originates from incomplete information; see, eg, Roca (2005), Walsh (2007), Baeriswyl and Cornand (2010a,b), and Lorenzoni (2010). This has lead to a variety of welfare lessons, some pro and some against central-bank transparency.

In a more recent paper, Angeletos et al. (2016b) develop a taxonomy of the welfare effects of information within a micro-founded business-cycle framework that encompasses the aforementioned applied works and disentangles the separate roles played by informational frictions and monetary policy. Importantly, the framework allows the incompleteness of information to be a source of *both* real and nominal rigidity, as in, respectively, Sections 8.1 and 8.3. Accordingly, the welfare effects of either public or private information can be decomposed into two channels: one working through the real rigidity, and another working through the nominal rigidity.

The first channel is present regardless of the conduct of monetary policy. It also contains a particularly sharp answer to the question of interest: through this channel, more information unambiguously contributes to higher welfare when the business cycle is driven by efficient forces such as technology shocks, and to lower welfare when the business cycle is driven by distortionary forces such as markup shocks.

The second channel hinges on the conduct of monetary policy. As in the baseline New-Keynesian framework, there is a policy that neutralizes the nominal rigidity; this is the same as replicating flexible-price allocations, recast in the context of models where the nominal rigidity originates from an informational friction as opposed to a Calvo-like friction. At this benchmark, the welfare effects of information are shaped solely by the real-rigidity channel. Away from it, they hinge on whether the provision of more information dampens or amplifies the deviation from the flexible-price benchmark and on whether that deviation was desirable to begin with.

When the business cycle is driven by technology shocks, the policy that replicates flexible prices is optimal. When, instead, the business cycle is driven by markup shocks, a deviation from this policy benchmark is desirable. In the latter case, more information in the hands of private agents can decrease welfare, not only because it exacerbates the inefficiency of the underlying flexible-price fluctuations, but also because it curtails the monetary authority's ability to combat these fluctuations.

These findings indicate that the welfare effects of information in baseline RBC and New-Keynesian models are closely connected to more familiar normative properties of RBC and New-Keynesian models, and have little, if anything, to do with the mechanism in Morris and Shin (2002b). That said, Morris and Shin's result may well apply to asset-markets applications insofar as speculative trading is a zero-sum game. If this is true, it would upset the conventional wisdom that the informational role of financial markets is welfare improving. It is also unclear—and therefore interesting to explore—whether the result applies to macroeconomic models that give a central role to financial markets, such as those discussed by Brunnermeier and Sannikov (2016), Gertler et al. (2016), and Guerrieri and Uhlig (2016) in this *Handbook*.

Amador and Weill (2010) identify a different reason for why the provision of public information can reduce welfare: the endogeneity of the information role of the price system. More specifically, they study the welfare effects of releasing public information about productivity and/or monetary shocks in a micro-founded model in which agents learn from the distribution of nominal prices. The release of such information induces private agents to rely less on their private sources of information. As this happens, the informational efficiency of the price system is reduced. The release of public information therefore has two competing effects: a beneficial direct one, and an adverse indirect one through the informativeness of the price system. Under certain conditions, the second effect dominates, yielding a negative overall welfare effect.

Vives (1993, 1997) and Amador and Weill (2012) develop related results within the context of a class of dynamic games with social learning. A key result is that, as long as some of the learning is private, the release of public information at some point may increase the overall level of information in the short run at the expense of lowering information in the long run. When agents are patient enough, this opens again the door to the possibility that public information is welfare deteriorating.

Whereas the above papers focus on the *aggregation* of information,[dd] Burguet and Vives (2000) focus on the *acquisition* of information. They study a model in which agents can collect private information at a cost and show that the release of public information may reduce the incentives to do so. This finding is reminiscent of a key observation made by Grossman and Stiglitz (1980), namely that the information revealed by asset prices may reduce the incentives for individual traders to collect valuable private information.

Notwithstanding the potential relevance of this last set of results, it is worth noting two facts. First, these results require that private and public information are *substitutes* for one another, which is not necessarily the case; if instead they are complements, the provision of public information can raise both the acquisition and the aggregation of private information.[de] Second, these results operate even in settings in which the payoff of each agent is independent of the actions of other agents; it is an open question whether there is sufficiently interesting interaction between these results and the mechanisms our chapter is preoccupied with.

[dd] Closely related is also the literature on herds and information cascades (Banerjee, 1992; Bikhchandani et al., 1992; Chamley, 2004). The results described above can indeed be seen as a smooth variant of a key lesson from that literature, namely the possibility that agents can *completely* cease to react to their private information after the revelation of sufficient information about the choices of other agents.

[de] This relates to the issue of whether there is strategic substitutability or complementarity in the acquisition of *private* information with the asset-market context; see Barlevy and Veronesi (2000, 2007), Veldkamp (2006), and the discussion in chapter 4 in Vives (2010).

Last but not least, Baeriswyl and Cornand (2010b) identify a potential trade off between the stabilization and the signaling roles of monetary policy. Suppose that the business cycle is driven by inefficient forces such as markup shocks. Suppose further that the monetary authority has some private information about these shocks and/or the level of economic activity.[df] To be more concrete, think of the monetary authority knowing something about either the sources or the severity of an inefficient recession. In such a situation, it is desirable for the monetary authority to withhold its information from the public, because disclosing it would only exacerbate the inefficient fluctuations. Clearly, it is also desirable to act on the basis of such information, by lowering interest rates or, perhaps, by engaging in unconventional policy measures. But note that acting means disclosing: the public will be able to extract a signal from the observed policy action about the state of the economy. It follows that the attempt to stabilize could backfire, which explains why there is a trade off between stabilization and signaling. Baeriswyl and Cornand (2010b) proceed to characterize the optimal resolution of this trade off under the assumption that the policy maker can commit on a state-contingent policy rule prior to the arrival of any information. An interesting open question is how this trade off plays out in shaping the optimal policy in the absence of such commitment.[dg]

We conclude with an obvious disclaimer. Although many of the papers we have reviewed here touch upon the topic of central-bank communication and transparency, there is a vast literature on the topic that is simply beyond the scope of our chapter. Important early contributions include Cukierman and Meltzer (1986) and Stein (1989); see also the review in Geraats (2002).

10. CONCLUSION

Since the publication of the first volume of the *Handbook of Macroeconomics*, a growing literature has emerged on the macroeconomic effects of various forms of informational frictions. In this chapter, we have tried to present and synthesize the results of this literature as it relates to coordination, strategic uncertainty, and higher-order beliefs. In the light of this synthesis, we invite the reader to consider two complementary

[df] This does not require the monetary authority's information to be more precise than that of any private agent; it only requires that the monetary authority's information is not a priori publicly available to the private agents.

[dg] Note here a certain parallel to the policy-traps setting of Angeletos et al. (2006), which we reviewed in Section 5.8. In both papers, there is a trade off between manipulating the incentives of the private agents and disclosing information to them. Apart from the apparent difference in the setting, what distinguishes the two papers is the assumption about commitment: in Angeletos et al. (2006), policy is determined in the interim state, after the policy maker has received her information.

interpretations of the particular departure from standard macroeconomic models undertaken in this chapter:

1. Insofar as signals represent "hard information," the theoretical advances we have reviewed in this chapter help understand the positive and normative implications of different kinds of information frictions within a variety of contexts, including financial crises and business cycles.
2. Insofar as signals represent "states of mind," incomplete information is more broadly a vehicle for operationalizing the notion that coordination is imperfect and for developing a more flexible framework of how agents form expectations about endogenous economic outcomes.

The mechanisms we have reviewed apply regardless of the interpretation. The interpretation, however, matters for the mapping of the theory to the real world. For certain issues, such as those that have to do with the aggregation of information or the welfare effects of public information, the first interpretation seems most appropriate. For other issues, such as interpreting the observed variation in expectations and economic outcomes, we would favor the second interpretation.

Underlying the mechanisms we have reviewed in this chapter is the difference between the strategic and the decision-theoretic aspects of informational frictions, a theme that we repeatedly visited in this chapter. We have argued that strategic uncertainty helps formalize frictions in coordination and have explored its distinct positive implications.

Throughout this chapter, we maintained the standard solution concept of rational-expectations equilibrium. While this is a standard practice, it is not necessarily the best one. We are sympathetic to other approaches that investigate plausible deviations from this practice. In fact, we are open to re-interpreting the departure considered in this chapter as a proxy for relaxing the equilibrium concept.

All in all, the following lesson emerges. Workhorse macroeconomic models, especially those used in the study of business cycles, abstract from the type of frictions in the coordination of expectations and behavior that we have studied in this chapter. As we have shown, this abstraction plays a central role in existing structural interpretations of the data and in the associated policy debate that is based on such structural interpretations. Once realistic frictions in coordination and expectations have been taken into account, our structural interpretation of the data, our view of the real world, and our prescriptions for policy can be significantly altered.

In this chapter we presented various applications of these ideas. We did not, however, offer a detailed empirical and quantitative assessment. This is because the relevant literature is still young and often confounds the decision-theoretic and the strategic aspects of informational frictions. By elucidating this distinction and the mechanisms that operate in a variety of applications, we hope to have offered, not only a sharper understanding and a certain synthesis of the literature, but also some guidance to future empirical and quantitative work.

APPENDIX. PROOFS

Proof of Propositions 1, 2, and 3 See the main text.

Proof of Proposition 4 The continuity of G together with the compactness of D_k guarantees that there always exists a solution to $K = G(K, \mathbf{B})$.

If the economy features either strategic substitutability or weak complementarity, G_K is uniformly bounded from above by 1, which guarantees that the solution is unique for all $\mathbf{B}$. With K thus determined, the optimal action of any agent i is pinned down by $k_i = g(K, b_i)$. It follows that there exists a unique equilibrium strategy, that is, a unique mapping from the realizations of b_i to those of k_i. By the same token, there is also a unique mapping from the realizations of the cross-sectional distribution of fundamentals, $\mathbf{B}$, to those of the cross-sectional distribution of actions, $\mathbf{K}$.

If instead the economy features strong complementarity, let K^* denote the solution of fixed point problem in the definition of strong complementarity. In a small neighborhood to the left of K^*, we have that $G(K,\mathbf{B}) < K$ due to the fact that the derivative $G_K(K, \mathbf{B})$ is locally higher than one. Let k_{low} be the lower bound of D_k. At $K = k_{low}$, we necessarily have that $G(K,\mathbf{B}) \geq K$. By the continuity of G, there must then exist another fixed point to G. In either case, once K is determined as a solution to $K = G(K, \mathbf{B})$, the optimal action of any agent i is given by $k_i = g(K, b_i)$. It follows that there exists multiple equilibrium strategies, each one associated with a different mapping from $\mathbf{B}$ to $\mathbf{K}$.

Proof of Proposition 5 See the main text.

Proof of Proposition 6 See Section 4.5.

Proof of Proposition 7 We start by studying the set of *monotone* or *threshold* equilibria, that is, equilibria in which the strategy of an agent satisfies the following property: for any realization of z, there is a threshold $x^*(z)$ such that an agent attacks if and only if $x \leq x^*(z)$.

When the agents follow such monotone strategies, the aggregate size of the attack is decreasing in θ, so that there is also a threshold $\theta^*(z)$ such that the status quo is abandoned if and only if $\theta \leq \theta^*(z)$. A monotone equilibrium is identified by thus identified by threshold functions $x^*$and θ^*.

The proof then proceeds in four steps. In step 1, we characterize the equilibrium θ^* for given x^*. In step 2, we characterize the equilibrium x^* for given θ^*. In step 3, we combine the two conditions to establish existence and to study the determinacy of monotone equilibria. In step 4, we conclude the proof by noting that, whenever the monotone equilibrium is unique, this gives also the unique rationalizable strategy.

Step 1. For given realizations of θ and z, the aggregate size of the attack is given by the mass of agents who receive signals $x \leq x^*(z)$. That is, letting $K(\theta, z)$ denote the size of attack when the fundamental is θ and the signal is z, we have

$$K(\theta,z) = Prob(x \leq x^*(z)|\theta) = \Phi(\sqrt{\alpha_\epsilon}(x^*(z) - \theta)),$$

where $\alpha_\epsilon = \sigma_\epsilon^{-2}$ and $\alpha_\zeta = \sigma_\zeta^{-2}$ denote, respectively, the precision of private and public information and Φ denotes the c.d.f. of the standardized Normal distribution.

Note that $K(\theta, z)$ is decreasing in θ, so that regime change occurs if and only if $\theta \leq \theta^*(z)$, where $\theta^*(z)$ is the unique solution to

$$K(\theta^*(z), z) = \theta^*(z).$$

Rearranging the above gives following relation between the thresholds x^* and θ^*:

$$x^*(z) = \theta^*(z) + \frac{1}{\sqrt{\alpha_\epsilon}}\Phi^{-1}(\theta^*(z)). \tag{A.1}$$

Step 2. Given that regime change occurs if and only if $\theta \leq \theta^*(z)$, the payoff of an agent is

$$\mathbb{E}[U(k, K(\theta, z), \theta)|x, z] = k(b\Pr[\theta \leq \theta^*(z)|x, z] - c).$$

The posterior of the agent is a Normal distribution with mean $\delta x + (1 - \delta)z$ and precision α, namely

$$\theta \ |x, z \sim \mathcal{N}\left(\delta x + (1-\delta)z, \ \ \alpha^{-1}\right),$$

where $\delta \equiv \alpha_\epsilon/(\alpha_\epsilon + \alpha_\zeta)$ captures the relative precision of private information and $\alpha \equiv \alpha_\epsilon + \alpha_\zeta$ captures the overall precision of information. Hence, the posterior probability of regime change is

$$\Pr[\theta \leq \theta^*(z)|x, z] = 1 - \Phi\left(\sqrt{\alpha}(\delta x + (1-\delta)z - \theta^*(z))\right),$$

which is monotonic in x. It follows that the agent attacks if and only if $x \leq x^*(z)$, where $x^*(z)$ solves the indifference condition

$$b\Pr[\theta \leq \theta^*(z)|x^*(z), z] = c.$$

Substituting the expression for the posterior and the definition of δ and α, we obtain:

$$\Phi\left(\sqrt{\alpha_\epsilon + \alpha_\zeta}\left(\frac{\alpha_\epsilon}{\alpha_\epsilon + \alpha_\zeta}x^*(z) + \frac{\alpha_\zeta}{\alpha_\epsilon + \alpha_\zeta}z - \theta^*(z)\right)\right) = \frac{b-c}{b}. \tag{A.2}$$

Step 3. Combining (A.1) and (A.2), we conclude that $\theta^*(z)$ can be sustained in equilibrium if and only if it solves

$$G(\theta^*(z)) = g(z), \tag{A.3}$$

where

$$G(\theta) \equiv -\frac{\alpha_\zeta}{\sqrt{\alpha_\epsilon}}\theta + \Phi^{-1}(\theta) \quad \text{and} \quad g(z) \equiv \sqrt{1 + \frac{\alpha_\zeta}{\alpha_\epsilon}}\Phi^{-1}\left(1 - \frac{c}{b}\right) - \frac{\alpha_\zeta}{\sqrt{\alpha_\epsilon}}z.$$

With $\theta^*(z)$ given by (A.3), $x^*(z)$ is then given by (A.1).

We are now in a position to establish existence and determinacy of the equilibrium by considering the properties of the function G.

Note that $G(\theta)$ is continuous in θ, with $G(\underline{\theta}) = -\infty$ and $G(\overline{\theta}) = \infty$, which implies that there necessarily exists a solution and any solution satisfies $\theta^*(z) \in (\underline{\theta}, \overline{\theta})$. This establishes existence; we now turn to uniqueness.

Next, note that

$$\frac{\partial G(\theta)}{\partial \theta} = \frac{1}{\phi(\Phi^{-1}(\theta))} - \frac{\alpha_\zeta}{\sqrt{\alpha_\epsilon}}.$$

Since $\max_{w \in \mathbb{R}} \phi(w) = 1/\sqrt{2\pi}$, the following properties are true. If $\alpha_\zeta/\sqrt{\alpha_\epsilon} \leq \sqrt{2\pi}$, we have that G is strictly increasing in θ, which implies a unique solution to (A.3) for *all* values of z. If, instead. $\alpha_\zeta/\sqrt{\alpha_\epsilon} > \sqrt{2\pi}$, then G is nonmonotonic in θ and there is an interval $(\underline{z}, \bar{z})$ such that (A.1) admits multiple solutions $\theta^*(z)$ whenever $z \in (\underline{z}, \bar{z})$ and a unique solution otherwise.

We conclude that the monotone equilibrium is unique if and only if $\alpha_\zeta/\sqrt{\alpha_\epsilon} \leq \sqrt{2\pi}$, or equivalently $\sigma_\epsilon \leq \sqrt{2\pi}\sigma_\zeta^2$.

Step 4. To complete the proof, we need to establish that, when the monotone equilibrium is unique, there is no other (nonmonotone) equilibrium. This follows from a similar argument as in the proof of Proposition 6 in the main text.

To see this, let $h(x, z)$ denote the threshold that an agent finds it optimal to follow when all other agents follow a threshold x and the public signal is z; this is the same as the function h used in the proof of Proposition 6, modulo the presence of the public signal. Next, note that there is a one-to-one mapping between the thresholds θ^* that solve the equation $G(\theta) = g(z)$ and the fixed points of h: the monotone equilibria are defined by the fixed points of h. Finally, fix an arbitrary z and re-consider the type of sequences we constructed in the proof of Proposition 6. One can always show that the sequence "from below" converges to the lowest fixed point of h, whereas the sequence "from above" converges to the higher fixed point of h. When h admits a unique fixed point, corresponding to a unique monotone equilibrium, then the same kind of argument as that in the proof of Proposition 6 implies that the unique monotone equilibrium is also the unique rationalizable outcome. And when h admits multiple fixed points, the same argument implies that the set of rationalizable outcomes is contained within the two extreme monotone equilibria.

Proof of Propositions 8 and 9 See Morris and Shin (2003).

Proof of Proposition 10 See Angeletos and Werning (2006).

Proof of Proposition 11 Similar to the proof of Proposition 5.

Proof of Proposition 12 See the argument in the main text and theorem 1 in Frankel and Pauzner (2000).

Proof of Proposition 13 Part (i) follows from theorem 3 in Frankel and Pauzner (2000) along with the following fact: that the limit considered in Frankel–Pauzner and the limit considered in Morris–Shin coincide with the risk-dominance criterion of Harsanyi and Selten (1988).

Part (ii) follows from the fact that, in the limit as $\lambda \to 0$, the drift in K_t explodes to plus infinity whenever (θ_t, K_t) is on the left of κ^* and to minus infinity on the right of it.

Proof of Proposition 14 First, consider the case of perfect information, which means that the agent knows $(\theta_i, \overline{\theta})$ and, in equilibrium, also knows K. His best response is pinned down by the following first-order condition:

$$U_k(k_i, K, \theta_i) = 0.$$

Using the fact that U is quadratic, we have:

$$U_k(0,0,0) + U_{kk}k_i + U_{kK}K + U_{k\theta}\theta_i = 0. \tag{A.4}$$

Aggregating gives

$$U_k(0,0,0) + (U_{kk} + U_{kK})K + U_{k\theta}\overline{\theta} = 0. \tag{A.5}$$

which proves that the equilibrium value of K is a linear function of $\overline{\theta}$:

$$K = -\frac{U_k(0,0,0)}{U_{kk} + U_{kK}} - \frac{U_{k\theta}}{U_{kk} + U_{kK}}\overline{\theta}.$$

Substituting this back into condition (A.4) gives the equilibrium value of k_i as a linear function of θ_i and $\overline{\theta}$:

$$k_i = \kappa\left(\theta_i, \overline{\theta}\right) \equiv \kappa_0 + \kappa_1\theta_i + \kappa_2\overline{\theta},$$

and by implication $K = \kappa(\overline{\theta}, \overline{\theta})$, where

$$\kappa_0 \equiv -\frac{U_k(0,0,0)}{U_{kk} + U_{kK}}, \quad \kappa_1 \equiv -\frac{U_{k\theta}}{U_{kk}}, \quad \kappa_2 \equiv \frac{U_{k\theta}U_{kK}}{U_{kk}(U_{kk} + U_{kK})}. \tag{A.6}$$

Next, consider the case that information is complete but not necessarily perfect. Relative to the previous case, θ_i and $\overline{\theta}$ are not necessarily known any more, yet K remains known in equilibrium. The preceding proof therefore continues to work if we simply replace θ_i with $\mathbb{E}_i[\theta_i]$ and we accordingly replace $\overline{\theta}$ with the cross-sectional average of these first-order forecasts. That is, we can now express the equilibrium action as

$$k_i = \kappa(\mathbb{E}_i[\theta_i], \vartheta^1),$$

where $\vartheta^1 \equiv \int \mathbb{E}_j[\theta_j]dj$. Because complete information means that every agent knows $\mathbf{\Omega}$, and because $\mathbf{\Omega}$ is a sufficient statistic for $\overline{\theta}$ with respect to $(\omega_i, \mathbf{\Omega})$, the following is true:

$$\mathbb{E}_i\left[\overline{\theta}\right] = \mathbb{E}\left[\overline{\theta}|\Omega\right] = \mathbb{E}\left[\theta_j|\Omega\right] = \mathbb{E}\left[\mathbb{E}_j\left[\theta_j|\omega_j, \Omega\right]|\Omega\right] = \mathbb{E}\left[\mathbb{E}_j\left[\theta_j|\omega_j\right]|\Omega\right] = \int \mathbb{E}_j\left[\theta_j\right]dj = \vartheta^1 \forall i. \tag{A.7}$$

It follows that we can express the equilibrium action as:

$$k_i = \kappa(\mathbb{E}_i[\theta_i], \mathbb{E}_i[\overline{\theta}]) = \mathbb{E}_i[\kappa(\theta_i, \overline{\theta})],$$

which proves the proposition.

Proof of Proposition 15 Let us start with a preliminary observation. From the definition of $\kappa(\cdot)$, the following is trivially true for all θ_i and $\overline{\theta}$:

$$U_k(0,0,0)+U_{kk}\kappa\left(\theta_i,\overline{\theta}\right)+U_{kK}\kappa\left(\overline{\theta},\overline{\theta}\right)+U_{k\theta}\theta_i=0.$$

Taking the expectation of both sides, we have the following is also true, no matter the information of the agent:

$$U_k(0,0,0)+U_{kk}\mathbb{E}_i\left[\kappa\left(\theta_i,\overline{\theta}\right)\right]+U_{kK}\mathbb{E}_i\left[\kappa\left(\overline{\theta},\overline{\theta}\right)\right]+U_{k\theta}\mathbb{E}_i[\theta_i]=0. \tag{A.8}$$

Turning now the agent's optimal choice of k_i under incomplete information, note that this is characterized by the following first-order condition:

$$\mathbb{E}_i[U_k(k_i,K,\theta_i)]=0.$$

Using the fact that U is quadratic, the above equation can be rewritten as follows:

$$U_k(0,0,0)+U_{kk}k_i+U_{kK}\mathbb{E}_i[K]+U_{k\theta}\mathbb{E}_i[\theta_i]=0 \tag{A.9}$$

Subtracting equation (A.8) from (A.9), we get:

$$U_{kk}\mathbb{E}_i\left[k_i-\kappa\left(\theta_i,\overline{\theta}\right)\right]+U_{kK}\mathbb{E}_i\left[K-\kappa\left(\overline{\theta},\overline{\theta}\right)\right]=0.$$

We thus arrive at equation (15) in Proposition (15), namely,

$$k_i=\mathbb{E}_i\left[\kappa\left(\theta_i,\overline{\theta}\right)\right]+\alpha\cdot\mathbb{E}_i\left[K-\kappa\left(\overline{\theta},\overline{\theta}\right)\right],$$

with

$$\alpha\equiv-\frac{U_{kK}}{U_{kk}}=\frac{\kappa_2}{\kappa_1+\kappa_2}. \tag{A.10}$$

Proof of Proposition 16 Substituting equation (14) and (A.10) into equation (15), we can write an agent's optimal action k_i under incomplete information as

$$k_i=\kappa_0(1-\alpha)+\kappa_1\theta_i+\alpha\mathbb{E}_i[K]+(\kappa_2-\alpha(\kappa_1+\kappa_2))\mathbb{E}_i\left[\overline{\theta}\right]=\kappa_0(1-\alpha)+\kappa_1\theta_i+\alpha\mathbb{E}_i[K]. \tag{A.11}$$

Aggregating over i, we have:

$$K=\kappa_0(1-\alpha)+\kappa_1\overline{\theta}+\alpha\overline{\mathbb{E}}[K].$$

Iterating, we have:

$$K=\kappa_0+\kappa_1\left\{\sum_{h=0}^{\infty}\alpha^h\overline{\mathbb{E}}^h\left[\overline{\theta}\right]\right\}.$$

where $\overline{\mathbb{E}}^0\left[\overline{\theta}\right]=\overline{\theta}$. Substituting the above into (A.11) gives:

$$k_i = \kappa_0 + \kappa_1\theta_i + \alpha\mathbb{E}_i\left[\kappa_1\left\{\sum_{h=0}^{\infty}\alpha^h\bar{\mathbb{E}}^h[\bar{\theta}]\right\}\right]. \tag{A.12}$$

From the definition of α in condition (A.10), we have $\alpha\kappa_1 = (1-\alpha)\kappa_2$. Substituting this into (A.12), we arrive at condition (16), namely:

$$k_i = \kappa_0 + \kappa_1\theta_i + \kappa_2\mathbb{E}_i\left\{\sum_{h=0}^{\infty}(1-\alpha)\alpha^h\bar{\mathbb{E}}^h[\bar{\theta}]\right\}.$$

Proof of Proposition 17 The posterior for θ conditional only on the public signal z is given by

$$\theta|z \sim N\left(\mu_{\theta|z}, \sigma^2_{\theta|z}\right), \tag{A.13}$$

where $\mu_{\theta|z} \equiv \eta_z z \equiv \dfrac{\sigma_\zeta^{-2}}{\sigma_\theta^{-2} + \sigma_\zeta^{-2}} z$ and $\sigma^{-2}_{\theta|z} \equiv \sigma_\theta^{-2} + \sigma_\zeta^{-2}$. Then we can derive the posterior for θ given both agent i's private signal x_i and public signal z as follows:

$$\theta|x_i, z \sim N\left(\lambda_x x_i + \lambda_\mu \mu_{\theta|z}, \sigma^2_{\theta|x,z}\right), \tag{A.14}$$

where $\lambda_x \equiv \dfrac{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\sigma^{-2}_{\theta|z} + \left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}} = \dfrac{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\sigma^{-2}_{\theta|x,z}} > 0$, $\lambda_\mu \equiv \dfrac{\sigma^{-2}_{\theta|z}}{\sigma^{-2}_{\theta|z} + \left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}} = \dfrac{\sigma_\theta^{-2} + \sigma_\zeta^{-2}}{\sigma^{-2}_{\theta|x,z}} > 0$ and $\sigma^{-2}_{\theta|x,z} \equiv \left(\sigma^2_{\theta|z}\right)^{-1} + \left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}$.

We can also derive the posterior for the correlated error in private signals u given both agent i's private signal x_i and public signal z, distributing as:

$$u|x_i, z \sim N\left(\Lambda\left(x_i - \mu_{\theta|z}\right), \sigma^2_{u|x,z}\right), \tag{A.15}$$

where $\Lambda \equiv \dfrac{\left(\sigma^2_{\theta|z} + \sigma_\epsilon^2\right)^{-1}}{\sigma_u^{-2} + \left(\sigma^2_{\theta|z} + \sigma_\epsilon^2\right)^{-1}} = \dfrac{\left(\left(\sigma_\theta^{-2} + \sigma_\zeta^{-2}\right)^{-1} + \sigma_\epsilon^2\right)^{-1}}{\sigma_u^{-2} + \left(\left(\sigma_\theta^{-2} + \sigma_\zeta^{-2}\right)^{-1} + \sigma_\epsilon^2\right)^{-1}} = \dfrac{\left(\sigma_\theta^{-2} + \sigma_\zeta^{-2}\right)\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\sigma_u^{-2}\left(\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1} + \sigma_\theta^{-2} + \sigma_\zeta^{-2}\right)}$ > 0 and $\sigma^{-2}_{u|x,z} \equiv \sigma_u^{-2} + \left(\sigma^2_{\theta|z} + \sigma_\epsilon^2\right)^{-1}$.

We now state two useful properties about λ_x, λ_μ, and Λ, which will be used later:

$$\lambda_x + \Lambda = \frac{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1} + \sigma_\theta^{-2} + \sigma_\zeta^{-2}}\left(\frac{\sigma_u^{-2} + \sigma_\theta^{-2} + \sigma_\zeta^{-2}}{\sigma_u^{-2}}\right) < 1, \tag{A.16}$$

$$\lambda_\mu - \Lambda = \frac{\sigma_\theta^{-2} + \sigma_\zeta^{-2}}{\sigma_\theta^{-2} + \sigma_\zeta^{-2} + \left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}} \left(1 - \frac{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\sigma_u^{-2}}\right) > 0. \tag{A.17}$$

To express in closed form the best response of the agent given her information, we calculate each term in equation (16). From condition (A.14), we know

$$\mathbb{E}_i[\theta] = \lambda_x x_i + \lambda_\mu \mu_{\theta|z}.$$

Aggregating over i gives

$$\bar{\mathbb{E}}[\theta] = \lambda_x(\theta + u) + \lambda_\mu \mu_{\theta|z}.$$

From condition (A.14) and condition (A.15), we have:

$$\mathbb{E}_i[\bar{\mathbb{E}}[\theta]] = \lambda_x\left(\lambda_x x_i + \lambda_\mu \mu_{\theta|z} + \Lambda\left(x_i - \mu_{\theta|z}\right)\right) + \lambda_\mu \mu_{\theta|z}.$$

Aggregating over i, we have:

$$\bar{\mathbb{E}}[\bar{\mathbb{E}}[\theta]] = \lambda_x(\lambda_x + \Lambda)(\theta + u) + \left(\lambda_x\left(\lambda_\mu - \Lambda\right) + \lambda_\mu\right)\mu_{\theta|z}.$$

Similarly, for any $h \geq 0$, we have:

$$\begin{aligned} \mathbb{E}_i[\bar{\mathbb{E}}^h[\theta]] &= \lambda_x(\lambda_x + \Lambda)^h x_i + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\left(1 + (\lambda_x + \Lambda)^1 + \cdots + (\lambda_x + \Lambda)^{h-1}\right) + \lambda_\mu\right)\mu_{\theta|z} \\ &= \lambda_x(\lambda_x + \Lambda)^h x_i + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1 - (\lambda_x + \Lambda)^h}{1 - (\lambda_x + \Lambda)} + \lambda_\mu\right)\mu_{\theta|z}, \end{aligned} \tag{A.18}$$

and

$$\begin{aligned} \bar{\mathbb{E}}^{h+1}[\theta] &= \bar{\mathbb{E}}[\bar{\mathbb{E}}^h[\theta]] = \lambda(\mathbb{E}_i[\theta] + \mathbb{E}_i[u]) \\ &= \lambda_x(\lambda_x + \Lambda)^h(\theta + u) + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1 - (\lambda_x + \Lambda)^h}{1 - (\lambda_x + \Lambda)} + \lambda_\mu\right)\mu_{\theta|z}. \end{aligned} \tag{A.19}$$

As a result, for any $h \geq 1$, we have:

$$\omega_u^h = \lambda_x(\lambda_x + \Lambda)^{h-1},$$

$$\omega_\zeta^h = \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1 - (\lambda_x + \Lambda)^{h-1}}{1 - (\lambda_x + \Lambda)} + \lambda_\mu\right)\eta_z,$$

$$\omega_\theta^h = \lambda_x(\lambda_x + \Lambda)^{h-1} + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1 - (\lambda_x + \Lambda)^{h-1}}{1 - (\lambda_x + \Lambda)} + \lambda_\mu\right)\eta_z = \omega_u^h + \omega_\zeta^h.$$

It is then straightforward to check that

$$0 < \omega_u^h < 1, \quad \omega_\zeta^h > 0, \quad \textit{and} \;\; \omega_\theta^h = \omega_u^h + \omega_\zeta^h > 0.$$

Now we use the fact that $\lambda_x + \lambda_\mu = 1$ to prove a useful property about the coefficients on u and ζ:

$$\omega_u^h + \frac{\omega_\zeta^h}{\eta_z} = 1 \tag{A.20}$$

This comes from

$$\begin{aligned}\omega_u^h + \frac{\omega_\zeta^h}{\eta_z} &= \lambda_x(\lambda_x + \Lambda)^{h-1} + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1-(\lambda_x+\Lambda)^{h-1}}{1-(\lambda_x+\Lambda)} + \lambda_\mu\right)\\ &= \frac{\lambda_x\left((\lambda_x+\Lambda)^{h-1} - (\lambda_x+\Lambda)^h + (1-(\lambda_x+\Lambda))\left(1-(\lambda_x+\Lambda)^{h-1}\right)\right)}{1-(\lambda_x+\Lambda)} + \lambda_\mu\\ &= \frac{\lambda_x(1-(\lambda_x+\Lambda))}{1-(\lambda_x+\Lambda)} + \lambda_\mu = 1.\end{aligned}$$

Together with the fact that $0 < \omega_u^h < 1$ and $0 < \eta_z < 1$, we have:

$$\omega_\theta^h = \eta_z\omega_u^h + \omega_\zeta^h + (1-\eta_z)\omega_u^h = \eta_z + (1-\eta_z)\omega_u^h < 1. \tag{A.21}$$

To prove

$$\omega_\theta^h > \omega_\theta^{h+1},$$

note that for any $h \geq 1$, we have:

$$\omega_u^h = \lambda_x(\lambda_x+\Lambda)^{h-1} > \lambda_x(\lambda_x+\Lambda)^h = \omega_u^{h+1}.$$

Together with equation (A.21) and the fact that $0 < \eta_z < 1$, we then have that $\omega_\theta^h > \omega_\theta^{h+1}, \;\; \forall h \geq 1$.

To prove

$$0 < \frac{Var\left(\bar{\mathbb{E}}^h[\theta]\middle|\theta\right)}{Var\left(\bar{\mathbb{E}}^h[\theta]\right)} < \frac{Var\left(\bar{\mathbb{E}}^{h+1}[\theta]\middle|\theta\right)}{Var\left(\bar{\mathbb{E}}^{h+1}[\theta]\right)} < 1,$$

note that

$$\frac{Var\left(\bar{\mathbb{E}}^h[\theta]\middle|\theta\right)}{Var\left(\bar{\mathbb{E}}^h[\theta]\right)} = \frac{\left(\omega_\zeta^h\right)^2\sigma_\zeta^2 + \left(\omega_u^h\right)^2\sigma_u^2}{\left(\omega_\zeta^h\right)^2\sigma_\zeta^2 + \left(\omega_u^h\right)^2\sigma_u^2 + \left(\omega_\theta^h\right)^2\sigma_\theta^2},$$

we obviously have

$$0 < \frac{Var\left(\bar{\mathbb{E}}^h[\theta]\middle|\theta\right)}{Var(\bar{\mathbb{E}}^h[\theta])} < 1.$$

We thus only need to prove

$$\frac{\left(\omega_\zeta^h\right)^2 \sigma_\zeta^2 + \left(\omega_u^h\right)^2 \sigma_u^2}{\left(\omega_\theta^h\right)^2 \sigma_\theta^2} < \frac{\left(\omega_\zeta^{h+1}\right)^2 \sigma_\zeta^2 + \left(\omega_u^{h+1}\right)^2 \sigma_u^2}{\left(\omega_\theta^{h+1}\right)^2 \sigma_\theta^2} \quad \forall h \geq 1.$$

Define $t(\omega) = \dfrac{\omega}{1-\omega} > 0, \quad \forall \omega \in (0,1)$, and use equation (A.20) and (A.21), we have:

$$\frac{\left(\omega_\zeta^h\right)^2 \sigma_\zeta^2 + \left(\omega_u^h\right)^2 \sigma_u^2}{\left(\omega_\theta^h\right)^2 \sigma_\theta^2} = \frac{t\left(\omega_u^h\right)^2 \sigma_u^2 + \eta_z^2 \sigma_\zeta^2}{\left(t\left(\omega_u^h\right) + \eta_z\right)^2 \sigma_\theta^2}.$$

Next, note that $1 > \omega_u^h > \omega_u^{h+1} > 0$ and $t(x)$ increases with $x \in (0,1)$, we have:

$$t\left(\omega_u^{h+1}\right) < t\left(\omega_u^h\right) \leq t\left(\omega_u^1\right) = \frac{\lambda_x}{1-\lambda_x} = \frac{\left(\sigma_u^2 + \sigma_\epsilon^2\right)^{-1}}{\sigma_\theta^{-2} + \sigma_\zeta^{-2}} < \frac{\sigma_u^{-2}}{\sigma_\theta^{-2} + \sigma_\zeta^{-2}}.$$

As a result, for $t \in \left(0, t\left(\omega_u^1\right)\right]$, we have:

$$t\sigma_u^2 - \eta_z \sigma_\zeta^2 = t\sigma_u^2 - \frac{1}{\sigma_\theta^{-2} + \sigma_\zeta^{-2}} < 0; \tag{A.22}$$

$$\frac{\partial \left[\frac{t^2 \sigma_u^2 + \eta_z^2 \sigma_\zeta^2}{(t+\eta_z)^2 \sigma_\theta^2}\right]}{\partial t} = \left(\frac{2t\sigma_u^2}{(t+\eta_z)^2 \sigma_\theta^2} - \frac{2\left(t^2 \sigma_u^2 + \eta_z^2 \sigma_\zeta^2\right)}{(t+\eta_z)^3 \sigma_\theta^2}\right) = 2\eta_z \left(\frac{t\sigma_u^2 - \eta_z \sigma_\zeta^2}{(t+\eta_z)^3 \sigma_\theta^2}\right) < 0. \tag{A.23}$$

Together with the fact that $t\left(\omega_u^{h+1}\right) < t\left(\omega_u^h\right)$, we have

$$\frac{t\left(\omega_u^h\right)^2 \sigma_u^2 + \eta_z^2 \sigma_\zeta^2}{\left(t\left(\omega_u^h\right) + \eta_z\right)^2 \sigma_\theta^2} < \frac{t\left(\omega_u^{h+1}\right)^2 \sigma_u^2 + \eta_z^2 \sigma_\zeta^2}{\left(t\left(\omega_u^{h+1}\right) + \eta_z\right)^2 \sigma_\theta^2}, \quad \forall h \geq 1,$$

and therefore

$$\frac{Var\left(\bar{\mathbb{E}}^h[\theta]\middle|\theta\right)}{Var(\bar{\mathbb{E}}^h[\theta])} < \frac{Var\left(\bar{\mathbb{E}}^{h+1}[\theta]\middle|\theta\right)}{Var(\bar{\mathbb{E}}^{h+1}[\theta])}, \quad \forall h \geq 1.$$

Proof of Proposition 18 From equation (17), we know that the individual's optimal action is given by:

$$k_i = \mathbb{E}_i\left\{\sum_{h=0}^{\infty}(1-\alpha)\alpha^h \bar{\mathbb{E}}^h[\bar{\theta}]\right\}.$$

Substituting $\mathbb{E}_i[\bar{\mathbb{E}}^h[\theta]]$ from equation (A.18), we obtain

$$\begin{aligned}
k_i &= (1-\alpha)\sum_{h=0}^{+\infty}\alpha^h\left(\lambda_x(\lambda_x+\Lambda)^h x_i + \left(\lambda_x\left(\lambda_\mu - \Lambda\right)\frac{1-(\lambda_x+\Lambda)^h}{1-(\lambda_x+\Lambda)} + \lambda_\mu\right)\mu_{\theta|z}\right)\\
&= \frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}x_i + (1-\alpha)\left(\frac{\lambda_\mu}{1-\alpha} + \frac{\lambda_x\left(\lambda_\mu-\Lambda\right)}{1-(\lambda_x+\Lambda)}\left(\frac{1}{1-\alpha} - \frac{1}{1-\alpha(\lambda_x+\Lambda)}\right)\right)\mu_{\theta|z}\\
&= \frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}x_i + \left(\lambda_\mu + \frac{\alpha\lambda_x\left(\lambda_\mu-\Lambda\right)}{1-\alpha(\lambda_x+\Lambda)}\right)\mu_{\theta|z}.
\end{aligned}$$

Aggregating over i, we get

$$K = \frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}(\theta+u) + \left(\lambda_\mu + \frac{\alpha\lambda_x\left(\lambda_\mu-\Lambda\right)}{(1-\alpha(\lambda_x+\Lambda))}\right)\mu_{\theta|z}.$$

As a result,

$$\phi_u = \frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}, \tag{A.24}$$

$$\phi_\zeta = \left(\lambda_\mu + \frac{\alpha\lambda_x\left(\lambda_\mu-\Lambda\right)}{(1-\alpha(\lambda_x+\Lambda))}\right)\eta_z, \tag{A.25}$$

$$\phi_\theta = \phi_u + \phi_\zeta. \tag{A.26}$$

Similarly to the proof of condition (A.20), using the fact that $\lambda_x + \lambda_\mu = 1$, we can prove:

$$\phi_u + \frac{\phi_\zeta}{\eta_z} = 1. \tag{A.27}$$

Together with the fact that $\lambda_x + \Lambda < 1$,$\lambda_\mu - \Lambda > 0$, and $0 < \eta_z < 1$, we have:

$$\begin{gathered}
0 < \phi_u, \phi_\zeta < 1\\
0 < \phi_\theta = \eta_z + (1-\eta_z)\phi_u < 1
\end{gathered} \tag{A.28}$$

We can also express the agents' average expectation of K as follows:

$$\begin{aligned}\bar{\mathbb{E}}[K] &= \frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}(\bar{\mathbb{E}}[\theta]+\bar{\mathbb{E}}[u]) + \left(\lambda_\mu + \frac{\alpha\lambda_x(\lambda_\mu-\Lambda)}{(1-\alpha(\lambda_x+\Lambda))}\right)\mu_{\theta|z} \\ &= \frac{\lambda_x(1-\alpha)(\lambda_x+\Lambda)}{1-\alpha(\lambda_x+\Lambda)}(\theta+u) + \left(\lambda_\mu + \frac{\lambda_x(\lambda_\mu-\Lambda)}{1-\alpha(\lambda_x+\Lambda)}\right)\mu_{\theta|z}.\end{aligned}$$

As a result,

$$\psi_u = \frac{\lambda_x(1-\alpha)(\lambda_x+\Lambda)}{1-\alpha(\lambda_x+\Lambda)}, \tag{A.29}$$

$$\psi_\zeta = \left(\lambda_\mu + \frac{\lambda_x(\lambda_\mu-\Lambda)}{1-\alpha(\lambda_x+\Lambda)}\right)\eta_z, \tag{A.30}$$

$$\psi_\theta = \psi_u + \psi_\zeta. \tag{A.31}$$

Similarly to the proof of equation (A.20) and (A.27), using the fact that $\lambda_x + \lambda_\mu = 1$, we can prove the following:

$$\psi_u + \frac{\psi_\zeta}{\eta_z} = 1. \tag{A.32}$$

Together with the fact that $\lambda_x + \Lambda < 1, \lambda_\mu - \Lambda > 0$, and $\eta_z > 0$, we have:

$$\begin{gathered} 0 < \psi_u < \phi_u < 1, \\ 0 < \phi_\zeta < \psi_\zeta < 1, \\ 0 < \psi_\theta = \eta_z + (1-\eta_z)\psi_u < \phi_\theta < 1. \end{gathered}$$

To prove

$$0 < \frac{Var(K|\theta)}{Var(K)} < \frac{Var\left(\bar{\mathbb{E}}[K]\middle|\theta\right)}{Var(\bar{\mathbb{E}}[K])} < 1,$$

we proceed in the same way as the proof of Proposition 17. First, note that

$$\frac{Var(K|\theta)}{Var(K)} = \frac{\phi_u^2\sigma_u^2 + \phi_\zeta^2\sigma_\zeta^2}{\phi_u^2\sigma_u^2 + \phi_\zeta^2\sigma_\zeta^2 + \phi_\theta^2\sigma_\theta^2} \quad \text{and} \quad \frac{Var\left(\bar{\mathbb{E}}[K]\middle|\theta\right)}{Var(\bar{\mathbb{E}}[K])} = \frac{\psi_u^2\sigma_u^2 + \psi_\zeta^2\sigma_\zeta^2}{\psi_u^2\sigma_u^2 + \psi_\zeta^2\sigma_\zeta^2 + \psi_\theta^2\sigma_\theta^2}.$$

We thus have

$$0 < \frac{Var(K|\theta)}{Var(K)}, \frac{Var\left(\bar{\mathbb{E}}[K]\middle|\theta\right)}{Var(\bar{\mathbb{E}}[K])} < 1.$$

We only need to prove

$$\frac{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2}{\phi_\theta^2\sigma_\theta^2}<\frac{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2}{\psi_\theta^2\sigma_\theta^2}.$$

Defining again $t(x)=\dfrac{x}{1-x}>0,\ \ \forall x\in(0,1)$, we have

$$\frac{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2}{\phi_\theta^2\sigma_\theta^2}=\frac{t(\phi_u)^2\sigma_u^2+\eta_z^2\sigma_\zeta^2}{(t(\phi_u)+\eta_z)^2\sigma_\theta^2},$$

$$\frac{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2}{\psi_\theta^2\sigma_\theta^2}=\frac{t(\psi_u)^2\sigma_u^2+\eta_z^2\sigma_\zeta^2}{(t(\psi_u)+\eta_z)^2\sigma_\theta^2}.$$

$$\frac{\sigma_u^{-2}}{\sigma_\theta^{-2}+\sigma_\zeta^{-2}}>\frac{\left(\sigma_u^2+\sigma_\epsilon^2\right)^{-1}}{\sigma_\theta^{-2}+\sigma_\zeta^{-2}}=t(\lambda_x)>t(\phi_u)>t(\psi_u)>0,$$

where we use the fact that $\phi_u=\dfrac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}<\lambda_x$, which comes from $\lambda_x+\Lambda<1$, to prove $t(\lambda_x)>t(\phi_u)$. Similar as the proof of Proposition 17, for $t\in(0,t(\lambda_x)]$, we have equations (A.22) and (A.23) hold. As a result,

$$\frac{t(\phi_u)^2\sigma_u^2+\eta_z^2\sigma_\zeta^2}{(t(\phi_u)+\eta_z)^2\sigma_\theta^2}<\frac{t(\psi_u)^2\sigma_u^2+\eta_z^2\sigma_\zeta^2}{(t(\psi_u)+\eta_z)^2\sigma_\theta^2},$$

and therefore

$$\frac{Var(K|\theta)}{Var(K)}<\frac{Var\left(\bar{\mathbb{E}}[K]\middle|\theta\right)}{Var(\bar{\mathbb{E}}[K])}.$$

Proof of Proposition 19 Let $w\equiv\lambda_x u+(1-\lambda_x)\eta_z\zeta$ be the residual of projecting $\bar{\mathbb{E}}[\theta]$ on θ. Next, let $R\equiv-(1-\lambda_x)\eta_z\sigma_\zeta^2u+\lambda_x\sigma_u^2\zeta$. Clearly, we have both $w\perp\theta$ and $R\perp\theta$. Furthermore, we have $R\perp w$. To see this, note that $cov(R,w)=-(1-\lambda_x)\lambda_x\eta_z\sigma_\zeta^2\sigma_u^2+(1-\lambda_x)\lambda_x\eta_z\sigma_\zeta^2\sigma_u^2=0$, and both R and w are distributed Normally. It follows that θ, w, and R are an orthogonal basis of the space spanned by random variable θ, ζ and u.

Using the above, we can express u and ζ as linear transformations of w and R. Replacing them in to $K=\phi_\theta\theta+\phi_u u+\phi_\zeta\zeta$, we can then express K as a linear combination of θ, w, and R:

$$K=\phi_\theta\theta+\frac{\phi_u\lambda_x\sigma_u^2+(1-\phi_u)(1-\lambda_x)\eta_z^2\sigma_\zeta^2}{\lambda_x^2\sigma_u^2+(1-\lambda_x)^2\eta_z^2\sigma_\zeta^2}w+\frac{(\lambda_x-\phi_u)\eta_z}{\lambda_x^2\sigma_u^2+(1-\lambda_x)^2\eta_z^2\sigma_\zeta^2}R.\qquad\text{(A.33)}$$

Similarly, we can express $\bar{\mathbb{E}}[K]=\psi_\theta\theta+\psi_u u+\psi_\zeta\zeta$ as a linear combination of θ, w, and R:

$$\bar{\mathbb{E}}[K] = \phi_\theta \theta + \frac{\psi_u \lambda_x \sigma_u^2 + (1-\psi_u)(1-\lambda_x)\eta_z^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} w + \frac{(\lambda_x - \psi_u)\eta_z}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} R. \tag{A.34}$$

From the above, we then have

$$\begin{aligned} Var(K|\theta, \bar{\mathbb{E}}\theta) = Var(K|\theta, w) &= \left[\frac{(\lambda_x - \phi_u)\eta_z}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2}\right]^2 Var(R) \\ &= \frac{(\lambda_x - \phi_u)^2 \eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} \\ &= \left[\frac{\alpha(1-(\lambda_x + \Lambda))}{1-\alpha(\lambda_x + \Lambda)}\right]^2 \frac{\lambda_x^2 \eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} > 0, \end{aligned} \tag{A.35}$$

$$\begin{aligned} Var\left(\bar{\mathbb{E}}K\middle|\theta, \bar{\mathbb{E}}\theta\right) = Var\left(\bar{\mathbb{E}}K\middle|\theta, w\right) &= \left[\frac{(\lambda_x - \psi_u)\eta_z}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2}\right]^2 Var(R) \\ &= \frac{(\lambda_x - \psi_u)^2 \eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} \\ &= \left[\frac{1-(\lambda_x + \Lambda)}{1-\alpha(\lambda_x + \Lambda)}\right]^2 \frac{\lambda_x^2 \eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} > 0, \end{aligned} \tag{A.36}$$

and finally

$$\begin{aligned} Cov\left(K, \bar{\mathbb{E}}K\middle|\theta, \bar{\mathbb{E}}\theta\right) = Cov\left(K, \bar{\mathbb{E}}K\middle|\theta, w\right) &= \frac{(\lambda_x - \phi_u)(\lambda_x - \psi_u)\eta_z^2}{\left[\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2\right]^2} Var(R) \\ &= \frac{(\lambda_x - \phi_u)(\lambda_x - \psi_u)\eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} \\ &= \alpha \left[\frac{1-(\lambda_x + \Lambda)}{1-\alpha(\lambda_x + \Lambda)}\right]^2 \frac{\lambda_x^2 \eta_z^2 \sigma_u^2 \sigma_\zeta^2}{\lambda_x^2 \sigma_u^2 + (1-\lambda_x)^2 \eta_z^2 \sigma_\zeta^2} > 0, \end{aligned} \tag{A.37}$$

where we have used the facts that

$$\lambda_x - \phi_u = \lambda_x \left[1 - \frac{1-\alpha}{1-\alpha(\lambda_x + \Lambda)}\right] = \lambda_x \left[\frac{1-\alpha(\lambda_x + \Lambda) - (1-\alpha)}{1-\alpha(\lambda_x + \Lambda)}\right] = \lambda_x \left[\frac{\alpha(1-(\lambda_x + \Lambda))}{1-\alpha(\lambda_x + \Lambda)}\right]$$

and

$$\lambda_x - \psi_u = \lambda_x \left[1 - \frac{(1-\alpha)(\lambda_x + \Lambda)}{1-\alpha(\lambda_x+\Lambda)}\right] = \frac{\lambda_x(1-(\lambda_x+\Lambda))}{1-\alpha(\lambda_x+\Lambda)}.$$

Proof of Proposition 20 Using the fact that $\lambda_x + \Lambda < 1$, shown in condition (A.16), we have:

$$\begin{aligned}\frac{\partial\phi_u}{\partial\alpha} &= \frac{-\lambda_x}{1-\alpha(\lambda_x+\Lambda)} + \frac{\lambda_x(1-\alpha)(\lambda_x+\Lambda)}{(1-\alpha(\lambda_x+\Lambda))^2}\\ &= \frac{\lambda_x}{1-\alpha(\lambda_x+\Lambda)}\left(\frac{\lambda_x+\Lambda-1}{1-\alpha(\lambda_x+\Lambda)}\right) < 0.\end{aligned}$$

From condition (A.28), we have

$$\frac{\partial\phi_\theta}{\partial\alpha} = (1-\eta_z)\frac{\partial\phi_u}{\partial\alpha} < 0.$$

Similarly,

$$\begin{aligned}\frac{\partial\psi_u}{\partial\alpha} &= (\lambda_x+\Lambda)\left(\frac{-\lambda_x}{1-\alpha(\lambda_x+\Lambda)} + \frac{\lambda_x(1-\alpha)(\lambda_x+\Lambda)}{(1-\alpha(\lambda_x+\Lambda))^2}\right)\\ &= \frac{\lambda_x(\lambda_x+\Lambda)}{1-\alpha(\lambda_x+\Lambda)}\left(\frac{\lambda_x+\Lambda-1}{1-\alpha(\lambda_x+\Lambda)}\right) < 0\end{aligned}$$

and therefore also

$$\frac{\partial\psi_\theta}{\partial\alpha} = (1-\eta_z)\frac{\partial\psi_u}{\partial\alpha} < 0.$$

Note that

$$Cov(K,\theta) = \phi_\theta\sigma_\theta^2 \quad\text{and}\quad Cov(\bar{\mathbb{E}}K,\theta) = \psi_\theta\sigma_\theta^2.$$

It follows that

$$\frac{\partial Cov(K,\theta)}{\partial\alpha} < 0 \quad\text{and}\quad \frac{\partial Cov(\bar{\mathbb{E}}K,\theta)}{\partial\alpha} < 0.$$

To prove

$$\frac{\partial}{\partial\alpha}\left(\frac{Var(K|\theta)}{Var(K)}\right) > 0 \quad\text{and}\quad \frac{\partial}{\partial\alpha}\left(\frac{Var(\bar{\mathbb{E}}K|\theta)}{Var(\bar{\mathbb{E}}K)}\right) > 0,$$

note that

$$0<\frac{Var(K|\theta)}{Var(K)}=\frac{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2}{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2+\phi_\theta^2\sigma_\theta^2}<1 \text{ and } 0<\frac{Var(\bar{\mathbb{E}}[K]|\theta)}{Var(\bar{\mathbb{E}}[K])}=\frac{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2}{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2+\psi_\theta^2\sigma_\theta^2}<1,$$

To get the desired result, we therefore only need to prove

$$\frac{\partial}{\partial\alpha}\left(\frac{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2}{\phi_\theta^2\sigma_\theta^2}\right)>0 \quad\text{and}\quad \frac{\partial}{\partial\alpha}\left(\frac{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2}{\psi_\theta^2\sigma_\theta^2}\right)>0.$$

Defining again $t(x)=\frac{x}{1-x}>0,\quad \forall x\in(0,1)$ we have

$$\frac{\phi_u^2\sigma_u^2+\phi_\zeta^2\sigma_\zeta^2}{\phi_\theta^2\sigma_\theta^2}=\frac{t(\phi_u)^2\sigma_u^2+\sigma_\zeta^2}{(t(\phi_u)+\eta_z)^2\sigma_\theta^2},$$

$$\frac{\psi_u^2\sigma_u^2+\psi_\zeta^2\sigma_\zeta^2}{\psi_\theta^2\sigma_\theta^2}=\frac{t(\psi_u)^2\sigma_u^2+\sigma_\zeta^2}{(t(\psi_u)+\eta_z)^2\sigma_\theta^2},$$

$$\frac{\sigma_u^{-2}}{\sigma_\theta^{-2}+\sigma_\zeta^{-2}}>\frac{(\sigma_u^2+\sigma_\epsilon^2)^{-1}}{\sigma_\theta^{-2}+\sigma_\zeta^{-2}}=t(\lambda_x)>t(\phi_u)>t(\psi_u)>0,$$

where we used the fact that $\phi_u=\frac{\lambda_x(1-\alpha)}{1-\alpha(\lambda_x+\Lambda)}<\lambda_x$, which comes from $\lambda_x+\Lambda<1$, to prove $t(\lambda_x)>t(\phi_u)$. Because $\frac{\partial\phi_u}{\partial\alpha}<0$ and $\frac{\partial\psi_u}{\partial\alpha}<0$, we also have

$$\frac{\partial}{\partial\alpha}(t(\phi_u))<0 \quad \mathit{and} \quad \frac{\partial}{\partial\alpha}(t(\psi_u))<0.$$

Similar as the proof of Proposition 17 and 18, for $t\in(0,t(\lambda_x)]$, we have equations (A.22) and (A.23) hold. As a result,

$$\frac{\partial}{\partial\alpha}\left(\frac{Var(K|\theta)}{Var(K)}\right)>0 \quad\text{and}\quad \frac{\partial}{\partial\alpha}\left(\frac{Var(\bar{\mathbb{E}}K|\theta)}{Var(\bar{\mathbb{E}}K)}\right)>0,$$

We finally prove

$$\frac{\partial Var(K|\theta,\bar{\mathbb{E}}\theta)}{\partial\alpha}>0,\quad \frac{\partial Var(K|\theta,\bar{\mathbb{E}}\theta)}{\partial\alpha}>0 \quad\text{and}\quad \frac{\partial\left(Cov\left(K,\bar{\mathbb{E}}K|\theta,\bar{\mathbb{E}}\theta\right)\right)}{\partial\alpha}>0.$$

From conditions (A.35), (A.36), and (A.37), we have

$$Var(K|\theta,\bar{\mathbb{E}}\theta) = \left[\frac{\alpha(1-(\lambda_x+\Lambda))}{1-\alpha(\lambda_x+\Lambda)}\right]^2 \frac{\lambda_x^2\eta_\gamma^2\sigma_u^2\sigma_\zeta^2}{\lambda_x^2\sigma_u^2+(1-\lambda_x)^2\eta_\gamma^2\sigma_\zeta^2},$$

$$Var\left(\mathbb{E}K\middle|\theta,\bar{\mathbb{E}}\theta\right) = \left[\frac{1-(\lambda_x+\Lambda)}{1-\alpha(\lambda_x+\Lambda)}\right]^2 \frac{\lambda_x^2\eta_\gamma^2\sigma_u^2\sigma_\zeta^2}{\lambda_x^2\sigma_u^2+(1-\lambda_x)^2\eta_\gamma^2\sigma_\zeta^2},$$

$$Cov\left(K,\bar{\mathbb{E}}K\middle|\theta,\bar{\mathbb{E}}\theta\right) = \alpha\left[\frac{1-(\lambda_x+\Lambda)}{1-\alpha(\lambda_x+\Lambda)}\right]^2 \frac{\lambda_x^2\eta_\gamma^2\sigma_u^2\sigma_\zeta^2}{\lambda_x^2\sigma_u^2+(1-\lambda_x)^2\eta_\gamma^2\sigma_\zeta^2}.$$

Note that

$$\frac{\partial}{\partial\alpha}\left\{\frac{[1-(\lambda_x+\Lambda)]}{1-\alpha(\lambda_x+\Lambda)}\right\}>0 \quad\text{and}\quad \frac{\partial}{\partial\alpha}\left\{\frac{\alpha[1-(\lambda_x+\Lambda)]}{1-\alpha(\lambda_x+\Lambda)}\right\}>0.$$

The result then follows.

Proof of Proposition 21 Note that for any random variable X, and any information set I, according to law of total variance, we have:

$$Var(\mathbb{E}[X|I]) \le Var(X).$$

As a result, we have:

$$Var(\bar{\mathbb{E}}[\theta]) = Var(\mathbb{E}[\mathbb{E}[\theta|\omega]|\Omega]) \le Var(\mathbb{E}[\theta|\omega]) \le Var(\theta).$$

Similarly, for any $h \ge 2$, we have:

$$Var\left(\bar{\mathbb{E}}^h[\theta]\right) \le Var\left(\mathbb{E}\left[\mathbb{E}\left[\bar{\mathbb{E}}^{h-1}[\theta]|\omega\right]|\Omega\right]\right) \le Var\left(\mathbb{E}\left[\bar{\mathbb{E}}^{h-1}[\theta]|\omega\right]\right) \le Var\left(\bar{\mathbb{E}}^{h-1}[\theta]\right).$$

It follows that $Var\left(\bar{\mathbb{E}}^h[\theta]\right) \le Var(\theta)\forall h\ge 1$, and therefore

$$Var(K) = Var\left(\sum_{h=1}^{\infty}(1-\alpha)\alpha^{h-1}\bar{\mathbb{E}}^h[\theta]\right) \le \left(\sum_{h=1}^{\infty}(1-\alpha)\alpha^{h-1}\sqrt{Var(\theta)}\right)^2 = Var(\theta).$$

For the last result, we used the fact that, for any random variable X, Y and scalars a, $b \ge 0$, the following inequality is true:

$$\begin{aligned} Var(aX+bY) &= a^2 Var(X) + 2abCov(X,Y) + b^2 Var(Y) \\ &\le a^2 Var(X) + 2ab\sqrt{Var(X)Var(Y)} + b^2 Var(Y) \\ &= \left(a\sqrt{Var(X)} + b\sqrt{Var(Y)}\right)^2. \end{aligned}$$

Proof of Proposition 22 See the main text.

Proof of Proposition 23 The result follows essentially from Woodford (2003); see Angeletos and La'O (2010) for the particular version stated in Proposition 23. The exact characterization of the scalars $(\gamma_K, \gamma_\theta, \gamma_v)$ cannot be found in these earlier works, but can be obtained with the method developed in Huo and Takayama (2015a,b).

Proof of Proposition 24 See proposition 2 in Myatt and Wallace (2012), and proposition 1 and corollary 1 in Pavan (2015).

Proof of Proposition 25 See proposition 4 in Myatt and Wallace (2012).

Proof of Proposition 26 Under complete information, $\mathbb{E}_{it} Y_t = Y_t$ for all i. As a result, optimal output level in island i in equation (29) can be written as:

$$y_{it} = (1-\alpha)\chi a_{i,t} + \alpha Y_t.$$

Aggregating the above equation, we have $Y_t = \chi A_t$, and thus $N_t = (\chi - 1)A_t$, which completes the proof.

Proof of Proposition 27 Aggregating equation (29), we have:

$$Y_t = (1-\alpha)\chi A_t + \alpha \bar{\mathbb{E}}_t Y_t.$$

Iterating, we have:

$$Y_t = \chi \sum_{h=0}^{\infty} (1-\alpha)\alpha^h \bar{\mathbb{E}}_t^h [A_t].$$

Proof of Proposition 28 Given the information structure introduced in Assumption 9, we have:

$$\bar{\mathbb{E}}_t^h [A_t] = \left(\frac{\sigma_\epsilon^{-2}}{\sigma_u^{-2} + \sigma_\epsilon^{-2}} \right)^h u_t + A_{t-1} \quad \forall h \in \mathbb{N}.$$

Substituting it into equation (30) gives

$$Y_t = \chi A_{t-1} + \chi \frac{(1-\alpha)\left(\sigma_u^{-2} + \sigma_\epsilon^{-2}\right)}{\sigma_u^{-2} + (1-\alpha)\sigma_\epsilon^{-2}} u_t \equiv \chi A_{t-1} + \phi u_t,$$

where

$$\phi \equiv \chi \frac{(1-\alpha)\left(\sigma_u^{-2} + \sigma_\epsilon^{-2}\right)}{\sigma_u^{-2} + (1-\alpha)\sigma_\epsilon^{-2}}$$

measures the response of aggregate output to a innovation in the current fundamental. Note that $\lim_{\alpha \to 1^-} \phi = 0$. This means that, no matter how precise the information is, we can always make the aforementioned response to be arbitrarily small by boosting enough the degree of strategic complementarity.

Proof of Proposition 29 See section 4 in Woodford (2003).

Proof of Proposition 30 For the first property, see argument in Section 8.3. For the second property, see Fig. 7.

Proof of Proposition 31 Because m_{t-1} is common knowledge in the beginning of period t, it has no real effect in that period, which means that p_{it} must move one-to-one with m_{t-1}. Because local demand varies only with the sum $v_t + \xi_{it}$ and young agents have no information about the individual components of this sum, the variation in p_{it} conditional on m_{t-1} must be spanned by the variation in that sum. Along with the assumption that p_{it} is Normal, this means that $p_{it} - m_{t-1}$ is linear in the sum $v_t + \xi_{it}$. In what follows, we thus guess and verify the existence of an equilibrium in which

$$p_{it} = m_{t-1} + \phi(v_t + \xi_{it}), \tag{A.38}$$

for some scalar ϕ (which remains to be determined).

Taking the first-order condition of the problem of a young agent, we obtain the optimal labor supply, up to a constant, as follows:

$$n_{it} = \frac{1}{\kappa}\left(\mathbb{E}_{it}[p_{it} - m_t] - \mathbb{E}_{it}\left[p_{j,t+1} - m_{t+1}\right]\right). \tag{A.39}$$

Because $\mathbb{E}_{it}[m_{t+1}] = \mathbb{E}_{it}[m_t]$, we can rewrite the above as

$$n_{it} = \frac{1}{\kappa}\left(p_{it} - \mathbb{E}_{it}[p_{j,t+1}]\right).$$

Intuitively, labor supply depends on the perceived *relative* price. Using (A.38), we get that $\mathbb{E}_{it}\left[p_{j,t+1}\right] = \mathbb{E}_{it}[m_t + \phi(v_{t+1} + \xi_{it+1})] = \mathbb{E}_{it}[m_t]$, simply because no agent in period t has any information about the next-period shocks v_{t+1} and $\xi_{i,t+1}$. We conclude that the optimal labor supply can be express as follows:

$$n_{it} = \frac{1}{\kappa}(p_{it} - \mathbb{E}_{it}[m_t]).$$

Note next that the local demand is given by

$$d_{it} = m_t + \xi_{it} = m_{t-1} + v_t + \xi_{it},$$

and that market clearing imposes

$$p_{it} + n_{it} = d_{it}.$$

Combining the above we get

$$y_{it} = n_{it} = \frac{1}{\kappa + 1}\left(\xi_{i,t} + v_t - \mathbb{E}_{it}[v_t]\right),$$

and

$$p_{it} = v_t + \xi_{it} - \frac{1}{\kappa+1}\left(\xi_{i,t} + v_t - \mathbb{E}_{it}[v_t]\right) = m_{t-1} + \frac{\kappa}{\kappa+1}\left(\xi_{i,t} + v_t\right) + \frac{1}{\kappa+1}\mathbb{E}_{it}[v_t].$$

Aggregating the last equation, and letting $\bar{\mathbb{E}}_t$ denotes the average expectation of young agents in the cross section of islands, we reach the following result for the aggregate price level:

$$p_t = m_{t-1} + \frac{\kappa}{\kappa+1}v_t + \frac{1}{\kappa+1}\bar{\mathbb{E}}[v_t] = \frac{\kappa}{\kappa+1}m_t + \frac{1}{\kappa+1}\bar{\mathbb{E}}[m_t].$$

Using the fact that $m_t = m_{t-1} + v_t$ and that m_{t-1} is commonly known, we can rewrite the above as

$$p_t = (1-\beta)m_t + \beta\bar{\mathbb{E}}[m_t],$$

where $\beta \equiv \frac{1}{\kappa+1}$. This gives part (i) in the proposition.

Real output can then be expressed as

$$y_t = m_t - p_t = \beta\left\{m_t - \bar{\mathbb{E}}[m_t]\right\},$$

which gives part (ii) of the proposition. The above condition simply means that real output is pinned down by the average forecast error of the underlying money supply (also known as the "unanticipated" component of money growth).

Part (iii) follows from solving the signal-extraction problem of the young agents. In particular, condition (A.38) implies that the observation of p_{it} contains the same information as the observation of the signal

$$x_{it} \equiv \frac{1}{\phi}(p_{it} - m_{t-1}) = \frac{1}{\phi}(v_t + \xi_{it}),$$

which in turn means that $\mathbb{E}_{it}[m_t] = m_{t-1} + \delta x_{it}$ and therefore $\bar{\mathbb{E}}_t[m_t] = m_{t-1} + \delta v_t$, where $\delta \equiv \frac{\sigma_v^2}{\sigma_v^2 + \sigma_\xi^2} \in (0,1)$. By implication, we can write the price level as $p_t = m_{t-1} + (1 - \beta + \beta\delta)v_t$, which in turn verifies our initial guess in (A.38) with $\phi = 1 - \beta + \beta\delta \in (0, 1)$. This completes the characterization of the equilibrium; it also proves condition (37) with $\lambda \equiv 1 - \delta = \frac{\sigma_\xi^2}{\sigma_v^2 + \sigma_\xi^2}$.

Proof of Proposition 32 The average first-order belief of θ_t is a simple weighted average of beliefs of the firms that updated their information at different lags:

$$\bar{\mathbb{E}}_t[\theta_t] = \lambda\Sigma_{j=0}^{\infty}(1-\lambda)^j\mathbb{E}_{t-j}[\theta_t],$$

where $\mathbb{E}_{t-j}[\theta_t]$ is the expectation conditional on all the information that is available at $t-j$. This proves that the following condition holds for $h = 1$:

$$\bar{\mathbb{E}}_t^h[\theta_t] = \sum_{j=0}^{+\infty}\left[\left(1-(1-\lambda)^{j+1}\right)^h - \left(1-(1-\lambda)^j\right)^h\right]\mathbb{E}_{t-j}[\theta_t]. \tag{A.40}$$

We then prove that the condition holds for all $h \geq 1$ by induction.

Thus suppose that (A.40) holds for some arbitrary h. It follows that

$$\begin{aligned}\mathbb{E}_{t-j}\left[\bar{\mathbb{E}}_t^h[\theta_t]\right] &= \left(1-(1-\lambda)^{j+1}\right)^h \mathbb{E}_{t-j}[\theta_t] \\ &\quad + \Sigma_{l=j+1}^{\infty}\left[\left(1-(1-\lambda)^{l+1}\right)^h - \left(1-(1-\lambda)^l\right)^h\right]\mathbb{E}_{t-l}[\theta_t].\end{aligned}$$

Then it also follows that

$$\begin{aligned}\bar{E}_t^{h+1}[\theta_t] &= \sum_{j=0}^{+\infty}\left[\lambda(1-\lambda)^j\left(1-(1-\lambda)^{j+1}\right)^h + \Sigma_{l=0}^{j-1}\lambda(1-\lambda)^l\left[\left(1-(1-\lambda)^{j+1}\right)^h - \left(1-(1-\lambda)^j\right)^h\right]\right]\mathbb{E}_{t-j}[\theta_t] \\ &= \sum_{j=0}^{+\infty}\left[\lambda(1-\lambda)^j\left(1-(1-\lambda)^{j+1}\right)^h + \left[1-(1-\lambda)^j\right]\left[\left(1-(1-\lambda)^{j+1}\right)^h - \left(1-(1-\lambda)^j\right)^h\right]\right]\mathbb{E}_{t-j}[\theta_t] \\ &= \sum_{j=0}^{+\infty}\left[\left(1-(1-\lambda)^{j+1}\right)^{h+1} - \left(1-(1-\lambda)^j\right)^{h+1}\right]\mathbb{E}_{t-j}[\theta_t],\end{aligned}$$

which means that condition (A.40) holds for $h + 1$ and proves the claim.

Now let us focus in the case in which $\rho = 0$, that is, $\theta_t = \theta_{t-1} + \nu_t$. As a result,

$$\mathbb{E}_{t-j}[\theta_t] - \mathbb{E}_{t-j-1}[\theta_t] = \nu_{t-j}, \quad \forall j \geq 0.$$

Then condition (A.40) can be written as

$$\bar{\mathbb{E}}_t^h[\theta_t] = \sum_{j=0}^{+\infty}\left\{\left(1-(1-\lambda)^{j+1}\right)^h\left(\mathbb{E}_{t-j}[\theta_t] - \mathbb{E}_{t-j-1}[\theta_t]\right)\right\} = \sum_{j=0}^{+\infty}\left\{\left(1-(1-\lambda)^{j+1}\right)^h \nu_{t-j}\right\}.$$

Proof of Propositions 33 and 34 See, respectively, propositions 2 and 1 in Allen et al. (2006).
Proof of Proposition 35 This follows from the same argument as in step 1 in the proof of propositions 1 and 2 in Angeletos and Pavan (2009). The only nonessential differences are (i) that Angeletos and Pavan (2009) uses a different notation and (ii) that their framework allows for externalities to obtain, not only from the mean action, but also from the dispersion of actions.
Proof of Proposition 36 See propositions 1 and 2 in Angeletos and Pavan (2009).

Abstract

The global financial crisis and the ensuing criticism of macroeconomics have inspired researchers to explore new modeling approaches. There are many new models that deliver improved estimates of the transmission of macroeconomic policies and aim to better integrate the financial sector in business cycle analysis. Policy making institutions need to compare available models of policy transmission and evaluate the impact and interaction of policy instruments in order to design effective policy strategies. This chapter reviews the literature on model comparison and presents a new approach for comparative analysis. Its computational implementation enables individual researchers to conduct systematic model comparisons and policy evaluations easily and at low cost. This approach also contributes to improving reproducibility of computational research in macroeconomic modeling. Several applications serve to illustrate the usefulness of model comparison and the new tools in the area of monetary and fiscal policy. They include an analysis of the impact of parameter shifts on the effects of fiscal policy, a comparison of monetary policy transmission across model generations and a cross-country comparison of the impact of changes in central bank rates in the United States and the euro area. Furthermore, the chapter includes a large-scale comparison of the dynamics and policy implications of different macro-financial models. The models considered account for financial accelerator effects in investment financing, credit and house price booms and a role for bank capital. A final exercise illustrates how these models can be used to assess the benefits of leaning against credit growth in monetary policy.

1. INTRODUCTION

The global financial crisis and the ensuing criticism of macroeconomics have inspired researchers to develop new modeling approaches. There are many new models that aim to better integrate the financial sector in business cycle analysis. In these models, financial disturbances can have major macroeconomic consequences and the financial sector can amplify disturbances emanating from other sectors. They have potentially important implications concerning the effects of monetary and fiscal policy and the role of macroprudential and regulatory policy instruments. Thus, it is essential to be able to compare model implications for business cycle and policy analysis, and inform policy makers about policy strategies that are robust to model uncertainty. In fact, macroeconomic model comparison has a long tradition in the fields of monetary and fiscal policy. Central banks and international organizations have made much use of academic research on macroeconomic modeling, and they have invested staff resources in practical policy applications and sometimes large-scale comparison exercises.

In this chapter, we report on new developments and new techniques for comparative analysis in macroeconomic modeling. It illustrates the usefulness of model comparison with practical applications concerning the effects of fiscal measures and the transmission of monetary policy. Furthermore, it gives an overview of recent macro-financial models and compares new propagation mechanisms that arise from different financial frictions.

The chapter is meant to provide researchers, graduate students, economists at policy institutions, as well as business cycle analysts with access to a variety of macroeconomic models that reflect different theoretical paradigms, and to new hands-on tools for comparative analysis of policy and business cycle implications. A new online macroeconomic model archive together with a computational platform for model comparison takes center stage. It builds on and extends recent work on model comparison by Taylor and Wieland (2012), Wieland et al. (2012), and Schmidt and Wieland (2013). The computational platform for model comparison, the Macroeconomic Model Data Base (MMB), enables individual researchers to conduct systematic model comparisons and policy evaluations easily and at low cost.[a] Furthermore, it is straightforward to include new models and compare their empirical and policy implications to a large number of established benchmark models from academia and policy-making institutions.

Thus, the chapter and associated tools should help users to investigate questions such as: What are key features of well-known macroeconomic models? How do they influence the implications these models have for policy making and business cycle analysis? To what extent have these implications changed over time, as new models have been developed? How can I easily replicate models other researchers have developed, so as to apply them to new policy questions, or to extend them with new theoretical insights? How can I include my model in a comparison with other models in order to show what is new about it and where it improves upon earlier work? Which policy prescriptions would perform well across a range of models and economies?

Next, we review some key contributions to the literature on model comparison and highlight a recent example concerning fiscal stimulus in the Great Recession. Section 3 briefly describes a formal approach for making sure that comparisons across different models focus on comparable objects. Section 4 deals with practical issues in conducting comparisons including reproducibility and user-friendliness. Illustrative applications and extensions of earlier comparisons are presented in section 5. The in-depth comparison of financial propagation mechanisms is discussed in section 6. Section 7 gives an example of how to evaluate policy robustness and section 8 concludes.

2. LITERATURE ON MODEL COMPARISON AND POLICY ROBUSTNESS

2.1 How Model Comparison Has Been Done So Far

Model comparison has a long tradition in the fields of monetary economics and macroeconomic modeling. Typically, comparisons were not undertaken by individual researchers or small teams. Rather, comparative studies brought together several teams of researchers multiple times to obtain results. In such a setting, each team usually just works with the model they have developed.

Interest in medium- to large-scale comparisons has invariably been supported by central banks and international organizations which have been building and using macro models for decades. Decision makers at central banks and finance ministries typically rely on their staff economists to inform them about likely macroeconomic consequences of various policy actions. Furthermore, they have a strong interest in projections conditional on different policy measures. Macroeconomic models are central to fulfilling this task. And, since policy makers are interested in many scenarios and want to know about effects on different markets and sectors of the economy, the staff of their institutions are often

[a] The model archive and software are available for download at www.macromodelbase.com.

asked to build a fairly large model of the economy, or to maintain a suite of models that are useful for addressing different questions.

In the following, we review some of the contributions to this literature, the questions that were investigated, the methodological problems that presented themselves, results obtained as well as some currently hot topics.

2.1.1 1980s to Early 1990s: Standardizing Experiments and Comparing Policy Multipliers

Between 1984 and 1993, a number of large-scale comparisons were undertaken, several of them coordinated by the Brookings Institution in Washington, DC. Results were made available in the form of books with chapters being contributed by many well-known researchers in the field. These include Bryant et al. (1988, 1989), Klein (1991), and Bryant et al. (1993).

Bryant et al. (1988) aimed at improving the empirical understanding of cross-border macroeconomic and policy interactions. The study focused on the effects of monetary and fiscal policy and compared policy multipliers. To this end, participants developed and implemented a set of standardized exercises within 12 multicountry econometric models. These included models from the International Monetary Fund (IMF), the Organization for Economic Cooperation and Development (OECD), the Federal Reserve and other policy institutions as well as models developed by leading academic macroeconomists. As emphasized by Hughes-Hallett (1989), this was a very impressive undertaking at the time. The objective was to investigate to what extent the different models produce different and potentially conflicting policy implications.

A key focus was to implement common policy experiments that are comparable across models. To this end, common baseline paths of variables and common shocks were constructed across the models. Furthermore, methods were proposed to derive standardized comparison objects, such as estimates of policy multipliers. Interestingly, the study proposed computational procedures to recover estimates of the coefficients of policy variables in "final-form" equations, to cast models to IS-LM relations, and to summarize model performances in simple analytic constructs (slopes of IS-LM curves, inflation–output-tradeoffs, partial policy multipliers). The study helped identifying many challenges for standardized model comparisons and addressed some of them. It also revealed substantial differences in dynamic policy multipliers across models. Frankel and Rockett (1988) used the results from the Brookings model comparison project to explore how important uncertainty about the *true* model is for policy.

The follow-up study by Bryant et al. (1989) investigated the effects of changes in U.S. government spending and U.S. monetary policy. The majority of models participating in the exercises featured adaptive expectations. The authors computed averages and standard deviations of domestic and cross-border effects of U.S. policies across 20 global econometric models. Predicted effects from individual models, however, varied considerably. This study raised the question whether such model averages could be used as guideline for robust policy design. Another lesson of this comparison was the need to understand and evaluate the effects of policies on more variables, eg, by decomposing the effects on output into its components rather than concentrating on this variable alone.

Another round of model comparisons was documented by Klein (1991). The study focused on dynamic multipliers of fiscal spending increases, monetary expansion, and supply shocks. Similarly to earlier studies, the authors found significant variation in the behavior of models, resulting in very different policy multipliers. They aimed to put forth a common policy experiment and to apply common methods to understand the sources of variability in the multipliers. Yet, the study also made clear the difficulties in achieving comparability. The participating model teams admitted that "*it required more than a year of repeated meetings to agree on a set of inputs to be used in all models and to be sure that each model operator made the appropriate arithmetic calculations*" (Chapter 1, page 8).

Bryant et al. (1993) continued the Brookings comparison project that began in 1984. This study aimed at evaluating alternative regimes for the conduct of national monetary policies and understanding the stabilization properties of alternative operating regimes. Policy regimes were represented by simple policy rules. Taylor (1993a) credits the comparative exercise of Bryant et al. (1993) as the testing grounds for what would later become known as the Taylor rule. In contrast with previous comparative studies that focused on policy multipliers alone, Bryant et al. (1993) was the first large-scale project to compare stabilization properties of monetary policy regimes across models. The editors concluded: "*A principal conclusion of the book is that some simplified regimes for monetary policy are markedly less promising than others for achieving the stabilization objectives customarily sought by policy makers. Most notably, for a wide variety of circumstances, neither money targeting nor exchange rate targeting performs as well as a regime that targets either nominal GNP or the sum of real GNP and the inflation rate.*"

Of course, all these comparison exercises were performed at a time when simulation techniques were much less developed than today. This made the comparisons such a challenging task. In particular, shocks and exogenous processes were very different across models, which made it difficult to disentangle the effects of different patterns of stochastic shocks from different model structure and different policy regimes. In many cases, it was not possible to use a common structure of stochastic disturbances, common transition paths, and terminal conditions. Different techniques in stochastic simulation were used to perform policy experiments, which again affected the comparability of results. Furthermore, quarterly and annual models were not fully comparable. Annual models would identify monetary policy very differently by construction. Therefore, one of the lessons from this wave of comparative studies concerned the need for more standardization in methodology. Also, they highlighted the importance of expectations formation with models assuming either adaptive or rational expectations. Importantly, these comparison exercises typically concluded with an urgent call for improving empirical model validation and estimation techniques.

2.1.2 Late 1990s and Early 2000s: New Models, Policy Rules, and Robustness

Large-scale model comparison resumed with Taylor (1999). First, there was a new generation of New Keynesian models with a microfoundation built around a representative agent framework in which a household maximizes utility over time. Yet, these models were still fairly small such as the models of Rotemberg and Woodford (1997) and McCallum and Nelson (1999). They were being compared to models from the earlier generation of New Keynesian models that also featured nominal rigidities and rational expectations but a microeconomic foundation that consisted of separate decision rules for a household's consumption or a firm's investment and production problems, rather than a consistent representative agent framework. These included Fuhrer (1997), one model from Bank of England staff economists, and four models developed by staff at the Federal Reserve Board (FRB). Also, there were some models with adaptive expectations such as Rudebusch and Svensson (1999) and Ball (1999).

In terms of modeling and numerical solution techniques, there had been much progress since the earlier studies. As pointed out in the introduction of the volume, participating models had certain common features that made it easier to compute key statistics such as the variances of inflation and output under different monetary policy rules. For example, it was possible to derive linear systems determining the endogenous variables as functions of lags of themselves, the policy rate, and exogenous shocks.

A central objective was to present econometric evidence on which type of monetary policy rule is likely to be both efficient and robust when used as a guideline for the conduct of monetary policy in the United States. The stabilization performance of selected interest rate rules was evaluated across nine models. Exploiting the improvements in modeling solution techniques, Levin et al. (1999) were able to optimize over classes of policy rules using four different models, including the large-scale FRB-US model that was heavily used to inform policy makers at the Fed. Taylor (1999) concluded that simple policy rules worked well, their performance was surprisingly close to that of fully optimal policies. Furthermore, simple rules turned out to be more robust than complex rules across a variety of models.

There was disagreement about whether the central bank should react to the exchange rate and whether policy should respond to the lagged interest rate (interest rate smoothing). Furthermore, there was disagreement whether the interest rate should respond solely to a measure of expected future inflation. Follow-up work by Levin et al. (2003) found that rules that respond to forecasts with a horizon of more than one year are less robust and more prone to generating equilibrium indeterminacy than rules that respond to current observations or near-term forecasts.

With the creation of the euro area many new models were built to inform policy makers at the European Central Bank (ECB) and other European and international institutions. A special issue of *Economic Modeling* was put together by Hughes-Hallett and Wallis (2004) to present and compare models for the euro area. It was preceded by conferences bringing together modelers from central banks, international institutions, and academia to discuss estimates from different models. The paper by Wallis (2004) presents comparative results from four models, the ECB's area-wide model, and three established multicountry models (IMF's MULTIMOD model, NIGEM from the National Institute of Economic and Social Research in London, and the QUEST model from the European Commission). He found the principal source of differences across the four models to be the different degree of forward-looking behavior incorporated in the treatment of consumption and investment decisions and the setting of wages and prices. Of course, at that point models for the euro area had to be estimated on pre-EMU macroeconomic data. Hence substantial uncertainty remained about the stability of established empirical regularities.

2.1.3 Building a Model Archive to Provide Easy Access to Model Comparison

The last 15 years have experienced a massive surge in macroeconomic model building. A new generation of medium-size New Keynesian Dynamic Stochastic General Equilibrium (DSGE) models emerged following the contribution by Christiano et al. (2005), which was first circulated as a working paper in 2001. These models extended the microfoundations of the representative agent framework with additional rigidities, adjustment costs, and behavioral economics features such as habit formation. Smets and Wouters (2003) estimated a version of such a medium-size model for the euro area and helped popularize the use of Bayesian estimation methods. Widely used solution and estimation techniques were implemented in the DYNARE software package developed by Juillard (2001) (see also Adjemian et al., 2011).

These advances in model building, model solution, model estimation, and software implementations prepared the ground for more easy access to model comparison and the analysis of policy robustness by small teams of researchers. Taylor and Wieland (2012) extended the earlier model comparisons with U.S. models to the new medium-size DSGE models. They compare three such models built and estimated for the U.S. economy with the earlier-generation multicountry model of Taylor (1993b). Somewhat surprisingly, despite all the differences in structural assumptions, estimation techniques and data sample, all four models considered produce strikingly similar output responses to monetary policy shocks. Here, we extend this analysis further in Section 5.2.

Kuester and Wieland (2010) and Orphanides and Wieland (2013) studied the robustness of simple monetary policy rules, the latter study using 11 new models estimated on euro area data. Orphanides and Wieland (2013) find that rules optimized for just one model are not robust, as they often result in substantially worse performance in other models. Yet, they show that a simple (not optimized) difference rule reacting to current inflation and output growth performs quite well across models.

Wieland et al. (2012) brought together models from these and earlier comparative studies to build an archive of macroeconomic models for easy simulation and comparison. This archive together with a new platform for performing standardized comparative exercises will be presented and used in subsequent sections of this chapter.

2.1.4 Hot Topics: Fiscal Policy, Macro-Financial Modeling, and Macroprudential Policy

Following the global financial crisis and Great Recession, there is high demand for new and improved models. Issues of great interest include the impact of fiscal stimulus and consolidation, the effects of unconventional monetary policy measures, and the interaction of the real and financial sectors of the economy. Furthermore, there are new policy instruments to evaluate in banking regulation and macroprudential policy making. As a result, many new macro-financial models are being developed.

There have been several model comparison studies regarding fiscal policy, among them Cogan et al. (2010), Cwik and Wieland (2011), Cogan et al. (2013), and two large-scale comparisons of fiscal multipliers across models and countries by Coenen et al. (2012) and Kilponen et al. (2015). Section 2.2 reviews results from this debate concerning the likely effects of fiscal policy near zero interest rates.

Of course, policy makers and modelers alike have been preoccupied with the role of the financial sector as a source of disruptions and as an amplifier of other economic disturbances for some time. There are many new modeling approaches. Thus, comparative research can generate useful insights. As a first step, Gerke et al. (2013) have considered five models of the European economies that are based on theoretical contributions from the precrisis period and are currently employed by central banks in the Eurosystem. They compare open-economy models featuring the financial accelerator mechanism as in Bernanke et al. (1999) and/or collateral constraints in the spirit of Iacoviello (2005). The focus of the study is on qualitative comparison of impulse responses of macroeconomic and financial variables to a range of common shocks (eg, monetary policy shocks, net worth shocks, loan-to-value shocks). The study concludes that models display qualitatively similar features, reflecting a common understanding of macro-financial linkages preceding the financial crisis and the Great Recession. The authors, however, emphasize the need for a new generation of macro-financial models.

Guerrieri et al. (2015) is one of the first comparative studies of models that explicitly consider risks emanating from the banking system itself. Five groups of modelers from the Federal Reserve Board participated in the study. The authors compare macroeconomic spillovers from a (standardized) shortfall in bank capital across five DSGE models. The shortfall in bank capital is modeled as a gradually decaying pure transfer from the banking sector to the household sector.

The models under consideration exhibit many differences. There are nominal and real models, models solved with linear and nonlinear techniques, models featuring complementary approaches to modeling financial intermediation. The financial shock is carefully standardized. Responses of macroeconomic and financial variables vary substantially. Noteworthy, the range of model-based outcomes is contained in the confidence bands of a bivariate vector autoregression (VAR), suggesting a similar degree of uncertainty in response to the financial shocks in the models as in the VAR. The authors identify several sources of differences in responses across models. For instance, modeling of different sources of bank funding (eg, inside vs. outside equity) and interactions between alternative sectors, which can provide credit in the economy, are found to be particularly relevant for the results.

Section 6 provides an overview of different approaches for modeling macro-financial interactions. It also presents a range of examples and new findings from model comparisons. The model archive to be presented allows individual researchers to conduct such comparisons fairly easily themselves, and to include their own model so as to identify its contributions relative to more established benchmarks.

2.2 A Recent Example: Comparing Effects of the 2009–10 Fiscal Stimulus

The ongoing debate about the benefits and drawbacks of discretionary fiscal stimulus provides an excellent example of the need for model comparisons. The Great Recession of 2008 and 2009 has triggered substantial interest in assessing the likely impact of fiscal measures. In response to the financial market meltdown and the sharp contraction of real GDP, central banks in advanced economies have first slashed interest rates for central bank liquidity and then resorted to quantitative easing in order to further expand their balance sheets as policy rates remained near zero percent. At the same time, governments have launched large-scale fiscal stimulus packages.

In the United States, for example, the American Recovery and Reinvestment Act (ARRA) of February 2009 comprised US$ 787 billion of additional government purchases, transfers, and tax reductions. The lion's share was planned to be spent over a period of five years reaching a peak in 2010. The European Union initiated the European Economic Recovery Plan (EERP) and euro area member states launched fiscal stimulus packages on the scale of €175 billion to be spent in the years 2009 and 2010. Clearly, when deciding on such large programs, policy makers should be informed of the likely quantitative impact.

2.2.1 Determinants of Keynesian Multiplier Effects

Advocates of fiscal stimulus refer to the Keynesian multiplier effect and emphasize that it would increase in strength with constant interest rates. The multiplier effect arises in the textbook IS-LM model due to the static nature of the Keynesian consumption function, which assumes a positive relationship between consumption and current household income. Additional government spending results in more aggregate demand, more production and more income, which in turn feeds additional household consumption and hence yet another increase in income and so on. This multiplication suggests that an increase in government spending would induce a greater than one-for-one increase in overall GDP.

However, there are several countervailing forces. An increase in government borrowing to finance spending puts upward pressure on interest rates and exchange rates, which tends to reduce domestic consumption and investment as well as foreign demand for domestic goods. Future tax increases needed to pay off the debt act to reduce current and future consumption of households that consider their life-time income. Thus, the increase in government demand tends to crowd out private sector demand. Yet, if central banks keep interest rates unchanged, there is less crowding out and more room for multiplication.

Whether GDP ultimately goes up and by how much is a quantitative question. Answering it requires an empirically estimated macroeconomic model, which accounts for key structural features of the economy that impact on the relative magnitudes of the multiplier and crowding-out effects. Furthermore, the particular timing and path of government spending and taxes, the reaction of monetary policy, and the expectations of households and firms regarding the paths of fiscal and monetary measures exert influence on the ultimate effects of fiscal stimulus.

2.2.2 Controversy About Model-Based Evaluations of ARRA and the Zero Bound

Several studies employed macroeconomic model comparisons in order to provide policy makers with quantitative estimates of the likely impact of the above-mentioned stimulus measures. In January 2009, Christina Romer, then Chair of the President's Council of Economic Advisers, and Jared Bernstein, Chief Economist of the Office of the Vice-President, estimated that a lasting increase in government purchases of 1% of GDP would lead to a rapid increase in GDP of 1.6% persisting for at least five years. This multiplier effect was obtained by averaging the effects in two macroeconomic models—a model from an unnamed private sector forecasting firm and a model from the staff of the Federal Reserve Board—while assuming constant interest rates for the full simulation period. On this basis, Romer and Bernstein (2009) anticipated that the ARRA would raise GDP by 3.6% by the fourth quarter of 2010 and employment by 3.5 million. Their report served as important quantitative policy advice for U.S. President Obama and the Members of U.S. Congress.

In a study first circulated in March 2009, Cogan et al. (2010) questioned the validity of the Romer–Bernstein estimate and reported much smaller GDP effects for simulations with the multicountry model of Taylor (1993b) and the model of the U.S. economy by Smets and Wouters (2007). The Smets–Wouters model is representative of current thinking in macroeconomics. It is largely based on another empirically estimated and widely-known medium-size New Keynesian model developed by Christiano et al. (2005). On this basis, Cogan et al. (2010) conclude that the likely impact of the ARRA on U.S. GDP would only be around 1/6 of the Romer–Bernstein estimate.

Crowding-out effects are more important in these models because they take into account the forward-looking behavior of households and firms. Regarding fiscal policy, the path for government purchases is anticipated based on the information published with the ARRA. Regarding monetary policy, the simulations assume that the interest peg lasts between one and two years, which is more consistent with market expectations at the time than the Romer–Bernstein assumption. Afterwards, the policy rate responds again to economic conditions as in the simple policy rule of Taylor (1993a). The period of constant interest rates is motivated by the lower bound on interest rates. Due to availability of cash, a zero interest rate asset, savers need not accept negative rates on bank deposits. Thus, in a situation where the central bank reaction function calls for a negative policy rate, the rate would be constrained near zero. As a result, fiscal stimulus that raises GDP would not be followed right away by tighter monetary policy as in normal times.

Cogan et al. (2010) account for the negative effect of increased future (lump sum) taxes on household income and current consumption, but not for the negative effect of distortionary taxation on potential growth (see Drautzburg and Uhlig, 2015). Furthermore, they extend the Smets–Wouters model by including "rule-of-thumb" households. Such households consume their current income as prescribed by the Keynesian consumption function. The empirically estimated share of Keynesian consumers is about 27%. The presence of rule-of-thumb consumers and the anticipation that interest rates remain constrained at zero for two years raise the GDP impact to about 1/4 of the Romer–Bernstein estimate.

In contrast to these findings, Christiano et al. (2011) suggest that under certain conditions Keynesian multiplier effects can be much larger than one, even in modern New Keynesian models, when the zero-bound constraint on monetary policy rates binds. They present simulations of particular shocks in a small New Keynesian model and in a version of the medium-size model of Christiano et al. (2005). Thus, there appears to be stark disagreement between Cogan et al. (2010) and Christiano et al. (2011) even though both studies rely on fairly similar modern New Keynesian macroeconomic models estimated on U.S. macro data and both try to account for implications of the zero lower bound.

2.2.3 A Large-Scale Comparison Study

To illustrate how additional model comparisons can help improve policy advice in light of such disagreements, it is instructive to take a peak at a large comparison exercise that was organized by the IMF. This exercise involved several teams of researchers from central banks and international institutions which met at an IMF conference to compare a set of standardized simulations of fiscal stimulus that each team implemented in its

Table 1 Models participating in the comparison of Coenen et al. (2012)

Notation	Description
CEE	Christiano et al. (2011) model
CCTW	Cogan et al. (2010) extension of Smets and Wouters (2007) model with rule-of-thumb households
IMF-GIMF	The IMF's Global Integrated Monetary and Fiscal Policy model
FRB-US	The Federal Reserve Board's U.S. model
SIGMA	The Federal Reserve Board's two-country DSGE model
BoC-GEM	The Bank of Canada's Global Economy Model
EC-QUEST	The European Commission's QUEST model
ECB-NAWM	The European Central Bank's New Area-Wide Model
OECD	The OECD's macroeconomic model

institution's model. Key findings were summarized in the journal article by Coenen et al. (2012). The article involves 17 authors and nine different macroeconomic models. The authors are staff members of six different institutions: the International Monetary Fund, the Federal Reserve Board, the Bank of Canada, the European Central Bank, the Organization for Economic Cooperation and Development, and the European Commission. Seven models were developed and used by staff members from these institutions, while the other two models are from Cogan et al. (2010) and Christiano et al. (2011) (see Table 1).

Here, we review just one particular set of simulations from Coenen et al. (2012). In this comparison, all participating models are simulated with the same fiscal stimulus. The stimulus corresponds to the increase in government purchases as planned according to the ARRA and previously studied by Cogan et al. (2010). Technically, the spending path is simulated as an anticipated sequence of discretionary shocks. Regarding monetary policy, three different scenarios are considered that differ according to the importance of the zero bound.

The findings are presented in Fig. 1. This figure is identical to Fig. 7 of Coenen et al. (2012). The bars shown in each panel are identical and show the time profile for government purchases planned under the ARRA. The simulations assume that market participants anticipate the execution of the announced purchases over the coming years according to this plan. The different lines shown in the panels indicate the estimated impact of these government purchases on GDP in different macroeconomic models. Models estimated with euro area data are reported in the right column of panels, labeled "Europe," whereas the left column displays results for the models of the U.S. economy.

Regarding monetary policy, three different scenarios are considered. The first row of panels in Fig. 1 displays results for the case of no monetary accommodation, ie, nominal interest rates in each model are set according to a model-specific interest rate rule.

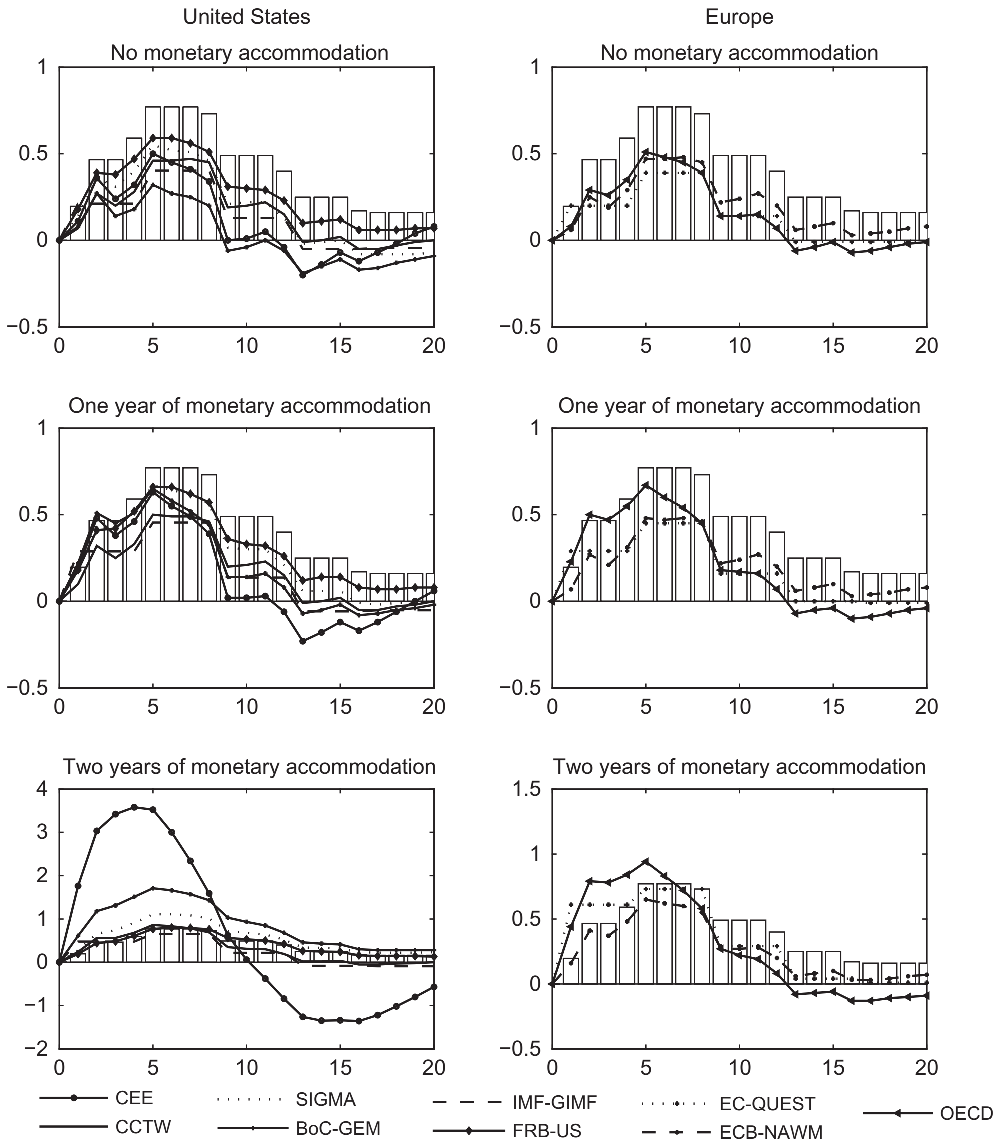

Fig. 1 Estimated GDP effects of planned ARRA spending. *Notes*: Horizontal axis represents time horizon in quarters. Units of the vertical axis are the percentage of GDP. Shown are estimated GDP effects of government purchases in the February 2009 U.S. stimulus legislation for nine macroeconomic models. The bars shown in each panel are identical and indicate the time profile of the planned ARRA government spending. CEE is the model of Christiano et al. (2011); CCTW is the model of Cogan et al. (2010); IMF-GIMF is the IMF's Global Integrated Monetary and Fiscal Policy model; FRB-US is the Federal Reserve's U.S. model; SIGMA is the Federal Reserve's two-country model; BoC-GEM is the Bank of Canada's Global Economy Model; EC-QUEST is the European Commission's QUEST model; ECB-NAWM is the European Central Bank's New Area-Wide Model; and OECD refers to the OECD's macroeconomic model.

Thus, interest rates rise along with the increase in GDP and inflation and dampen the stimulative effects of government spending. In this scenario, all models under consideration deliver an increase in GDP over the first 2.5 years of the stimulus. However, the increase in GDP remains well below the associated increase in government spending, as private demand is being crowded out by government demand. Some of the models even predict an overall negative effect on GDP in the fourth year of the stimulus. The simulation outcome of the CCTW model lies in between the other outcomes displayed in the left panel of Fig. 1. This finding provides further support for the CCTW results, in particular, since several of the other models incorporate a more detailed fiscal sector.

For the simulations shown in the second row of panels, nominal interest rates are held constant for one year and follow a model-specific rule thereafter. For the results shown in the third row, nominal interest rates are held constant for two years. These simulations illustrate the role of the degree of monetary accommodation in the effectiveness of fiscal stimulus. If nominal interest rates are initially held constant, fiscal multipliers increase. With one year of anticipated monetary accommodation, multipliers still remain below one in all of the models. With two years of monetary accommodation, the increase in GDP exceeds the increase in government spending a little bit in some of the models, due to crowding-in of private demand. There is one outlier. The CEE model exhibits a very large effect for two years, followed by a recession. As suggested in Christiano et al. (2011), government spending multipliers may be large in this model. Yet, all the other models considered by Coenen et al. (2012) imply much smaller effects on GDP. Thus, the larger multiplier effect in the CEE model is not just due to the monetary accommodation resulting from the presence of the zero bound. There are other features of the CEE model that lead to greater effectiveness of fiscal stimulus in this scenario. Coenen et al. (2012) suggest that the CEE model is an outlier, because it exhibits a much lower degree of price rigidity.

In sum, the large-scale comparison exercise confirms the cautionary assessment of the likely impact of ARRA provided by Cogan et al. (2010) and helps identify outliers. It would certainly have been useful to have such a large-scale comparison available in 2009 in order to provide policy advice to the Obama Administration and the members of U.S. Congress. Thus, it is of great interest to explore how model comparisons can be implemented more easily and more frequently whenever such analysis can help inform policy makers in real time.

3. A SYSTEMATIC APPROACH TO MODEL COMPARISON

One important goal of model comparison exercises is to identify policy implications that are due to different structural features of the respective models. Yet, quantitative simulation results may also differ because the economic concepts and variables to be compared are not defined consistently across models. Furthermore, different outcomes may be due to different assumptions about policy rather than different structures of the economy.

This section briefly describes how macroeconomic models can be augmented systematically with a few equations to produce comparable objects concerning policy implications for key macroeconomic aggregates, while keeping the total number of modifications quite small. This formal approach is elaborated on in Wieland et al. (2012).

3.1 Notation for a General Nonlinear Model

The following notation is used to define a general nonlinear model of the economy. The superscript $m=(1,2,3,\ldots,M)$ denotes the equations, variables, parameters, and shocks of a specific model m that is to be included in the comparison. These model-specific objects need not be comparable across models. They are listed in Table 2. In the computational implementation, m corresponds to an abbreviated model name rather than simply a number.

Two types of model equations are distinguished. Policy rules are denoted by $g_m(.)$ while all other equations and identities are denoted by $f_m(.)$. Together, they determine the endogenous variables denoted by the vector x_t^m. These variables are functions of each other, of model-specific shocks, $[\epsilon_t^m \quad \eta_t^m]$, and of model-specific parameters $[\beta^m \quad \gamma^m]$. A particular model m is then defined by:

$$E_t[g_m(x_t^m, x_{t+1}^m, x_{t-1}^m, \eta_t^m, \gamma^m)] = 0 \tag{1}$$

$$E_t[f_m(x_t^m, x_{t+1}^m, x_{t-1}^m, \epsilon_t^m, \beta^m)] = 0 \tag{2}$$

The superscript m refers to the version of the respective model originally presented by its authors. The model may include current values, lags, and the expectation of leads of endogenous variables. In Eqs. (1) and (2), the lead and lag lengths are set to unity for notational convenience. Additional leads and lags can be accommodated with auxiliary variables. Even so, our software implementation does not restrict the lead and lag lengths of participating models.

The model may also include innovations that are random variables with zero mean and covariance matrix, Σ^m:

Table 2 Model-specific variables, parameters, shocks, and equations

Notation	Description
x_t^m	Endogenous variables in model m
$x_t^{m,g}$	Policy variables in model m (also included in x_t^m)
η_t^m	Policy shocks in model m
ϵ_t^m	Other economic shocks in model m
$g_m(.)$	Policy rules in model m
$f_m(.)$	Other model equations in model m
γ^m	Policy rule parameters in model m
β^m	Other economic parameters in model m
Σ^m	Covariance matrix of shocks in model m

$$E([\eta_t^m \ \epsilon_t^m]') = 0 \tag{3}$$

$$E([\eta_t^{m\prime} \ \epsilon_t^{m\prime}]'[\eta_t^{m\prime} \ \epsilon_t^{m\prime}]) = \Sigma^m = \begin{pmatrix} \Sigma_\eta^m & \Sigma_{\eta\epsilon}^m \\ \Sigma_{\eta\epsilon}^m & \Sigma_\epsilon^m \end{pmatrix} \tag{4}$$

We refer to innovations interchangeably as shocks. Some models include serially correlated economic shocks that are themselves functions of random innovations. In our notation, such serially correlated economic shocks would appear as elements of the vector of endogenous variables x_t^m, only the innovations would appear as shocks. Eq. (4) distinguishes the covariance matrices of policy shocks and other economic shocks as Σ_η^m and Σ_ϵ^m. The correlation of policy shocks and other shocks is typically assumed to be zero, $\Sigma_{\eta\epsilon}^m = 0$.

3.2 Introducing Common Variables, Parameters, Equations, and Shocks

In order to compare policy implications from different models, it is necessary to define a set of comparable variables, shocks, and parameters. They are common to all models considered. Policies can then be expressed in terms of such common parameters, variables and policy shocks, and their consequences can be calculated for a set of common endogenous variables. Our notation for comparable endogenous variables, policy instruments, policy shocks, policy rules, and parameters is given in Table 3.

Every model to be included in the comparison has to be augmented with common variables, parameters, and shocks. Augmenting the model requires adding some equations. These additional equations serve to define the common variables in terms of model-specific variables. We denote these definitional equations or identities by $h_m(.)$. They are necessarily model-specific. Additionally, the original model-specific policy rules need to be replaced with common policy rules. Of course, these common rules could be defined generally enough such that they nest many of the model-specific policy rules. Furthermore, there are many interesting questions that would require comparing model implications for common variables of interest when policy follows the respective model-specific rule. An example is provided in Section 5.3.

All the other equations, variables, parameters, and shocks may be preserved in the original notation of the model's authors. Consequently, the augmented model consists

Table 3 Comparable common variables, parameters, shocks, and equations

Notation	Description
z_t	Common variables in all models
z_t^g	Common policy variables in all models (also included in z_t)
η_t	Common policy shocks in all models
$g(.)$	Common policy rules
γ	Common policy rule parameters

of three components: (i) the common policy rules, $g(.)$, expressed in terms of common variables, z_t, policy shocks, η_t, and policy parameters, γ; (ii) the model-specific definitions of common variables in terms of original model-specific endogenous variables, $h_m(.)$, with parameters θ^m; (iii) the original set of model-specific equations $f_m(.)$ that determine the endogenous variables. It corresponds to:

$$E_t[g(z_t, z_{t+1}, z_{t-1}, \eta_t, \gamma)] = 0 \tag{5}$$

$$E_t[h_m(z_t, x_t^m, x_{t+1}^m, x_{t-1}^m, \theta^m)] = 0 \tag{6}$$

$$E_t[f_m(x_t^m, x_{t+1}^m, x_{t-1}^m, \epsilon_t^m, \beta^m)] = 0 \tag{7}$$

Models augmented accordingly are ready for comparing policy implications. For example, it is then straightforward to compare the consequences of a particular policy rule for the dynamic behavior of consistently defined endogenous variables across models. This approach requires only a limited number of common elements. The rest of each model remains unchanged in the authors' original notation. This includes the variable names and definitions of endogenous variables, x_t^m, the other economic shocks ϵ_t^m, the equations $f_m(.)$ with model parameters β^m and the covariance matrix of shocks Σ_ϵ^m. The covariance matrix of policy shocks Σ_η may be treated as an element of the vector of policy parameters or set to zero.

Wieland et al. (2012) provide some concrete examples for the model augmentation step, which includes setting up the additional definitional equations, $h_m(.)$, and determining their parameters, θ^m. The subsequent steps in comparing policy implications consist of solving the augmented models, constructing appropriate objects for comparison and computing a metric that quantifies the differences of interest.

3.3 Computing Comparable Policy Implications

Solving the augmented nonlinear structural model defined by Eqs. (5)–(7) involves expressing the expectations of future variables in terms of currently available information. To this end, one needs to define how expectations are formed. Our computational implementation and model archive, Macroeconomic Model Data Base, includes models using several different assumptions. While most of the models are solved under the assumption of rational model-consistent expectations, several models can also be solved under the assumption of adaptive learning in expectations as in Slobodyan and Wouters (2012). Other assumptions regarding expectations formation include the sticky-information model of Mankiw and Reis (2007) with staggered information sets of otherwise rational expectations and VAR-based expectations used in Orphanides (2003) and in a version of the Federal Reserve's FRB-US model.

Here, we proceed under the assumption of rational expectations. The solution step involves checking for existence and uniqueness of equilibrium. For linear models one can use the Blanchard–Kahn conditions. For nonlinear models one may have to rely on search by numerical methods. The solution of the structural model is given by a set of reduced-form equations:

$$z_t = k_z(z_{t-1}, x^m_{t-1}, \eta_t, \epsilon^m_t, \kappa_z) \tag{8}$$

$$x^m_t = k_x(z_{t-1}, x^m_{t-1}, \eta_t, \epsilon^m_t, \kappa_x) \tag{9}$$

If the structural model is nonlinear, the reduced-form equations will also be nonlinear. (κ_z, κ_x) denote the reduced-form parameters. They are complicated functions of the structural parameters, β^m, the policy parameters, γ, and the covariance matrix, Σ^m. Nonlinear models may be solved approximately by means of numerical methods, for example, perturbation-based, projection-based, or two-point-boundary-value algorithms (see Judd, 1998; Fair and Taylor, 1983; Collard and Juillard, 2001). When the model is first linearized around a deterministic steady state, either analytically or numerically, a range of methods are available for computing the solution to the linear system of expectational equations. These methods include the generalized eigenvalue–eigenvector method (see Uhlig, 1995), generalized Schur decomposition (see Klein, 2000), QZ decomposition (see Sims, 2001), the undetermined coefficients method (see Christiano, 2002), or the Anderson–Moore algorithm for solving linear saddle point models (see Anderson and Moore, 1985).

The reduced form solution of the augmented nonlinear model can then be used to obtain particular objects for comparison defined in terms of comparable variables. With regard to policy implications, one object of interest could be the impact of a policy shock and its transmission to key macroeconomic aggregates. This object corresponds to the dynamic response of a particular common variable (an element of z) to a policy shock η_t, conditional on a certain common policy rule, $g(z_t, z_{t+1}, z_{t-1}, \eta_t, \gamma)$. Such impulse response functions describe the isolated effect of a single shock on the dynamic system holding everything else constant. Other objects of interest for comparing policy implications would be the unconditional variances and serial correlation functions. Finally, one may compute suitable metrics for measuring the distance between two or more models. Such metrics could be the absolute difference of the unconditional variances or the absolute difference of the impact effects of policy shocks under different models.

4. PRACTICAL PROBLEMS AND A NEW PLATFORM

Large-scale macroeconomic model comparison exercises have been relatively rare. These exercises are costly because they typically involve multiple meetings of several teams of model developers, with each team analyzing the policy scenarios in its own model. At the same time, the number of policy scenarios studied in these exercises has been limited. In this section, we review some practical problems that have hampered easy and frequent use of model comparison. We also report on the experience with strategies employed in the construction of the Macroeconomic Model Data Base to overcome these problems. At this point, there are 66 models available for easy use by individual researchers and students. It is straightforward to include new models and compare their policy implications to existing benchmarks.

4.1 Replication, Computational Implementation, and Model Archiving

4.1.1 Replication

The first practical problem that arises if a researcher wishes to compare her macroeconomic model to those of others is how to obtain sufficient information about their models to conduct her own analysis. Replicability is a basic scientific principle. The web-course "*Understanding science 101*" at UC Berkeley describes this principle as follows:

> *"Scientists aim for their studies' findings to be replicable - so that, for example, an experiment testing ideas about the attraction between electrons and protons should yield the same results when repeated in different labs. Similarly, two different researchers studying the same dinosaur bone in the same way should come to the same conclusions regarding its measurements and composition. This goal of replicability makes sense. After all, science aims to reconstruct the unchanging rules by which the universe operates, and those same rules apply, 24 hours a day, seven days a week, from Sweden to Saturn, regardless of who is studying them. If a finding can't be replicated, it suggests that our current understanding of the study system or our methods of testing are insufficient."*

Unfortunately, however, there is no general practice guaranteeing replicability of macroeconomic models that are solved and simulated by means of computational methods. This state of the field is somewhat surprising compared to other fields of economics. In economic theory, it is standard that articles in scientific economic journals provide sufficient detail on mathematical derivations and proofs such that academics and advanced students can replicate the analysis. In econometrics, new methods and estimators are fairly quickly implemented in software packages such as EViews, RATS, SAS, GAUSS, and others. Thus, new econometric tools are not only spread to academic researchers and students but widely used by practitioners in many fields of applied economic analysis. In the last two decades, macroeconomic modeling has benefited from a similar development with regard to numerical techniques for solving and estimating models with rational expectations. Initially, individual researchers have made particular toolkits available that have been adopted by many others in their work. Over the years, the software package DYNARE developed by Michel Juillard and collaborators has gained more and more users and contributors such that it has become a widely used tool for macroeconomic model solution and estimation (see Juillard, 2001 and Adjemian et al., 2011). While new techniques for model solution and estimation can now be easily employed by academics, students, and practitioners almost as "black box" systems, this is not true for most of the many new macroeconomic models.

The following problems can arise when one attempts to replicate macroeconomic models presented in economic journals:

1. The published article does not contain all the equations needed to write the model code for replicating the analysis presented in the article. Typically, journals are not willing to devote space to present all the information that is needed. Also, the models are quite complex. Thus, errors may occur in transcribing model equations that were successfully implemented in computer code to the text file for the article.
2. The published article does not contain all the parameter values or steady-state values needed to replicate the model simulations reported in the article.
3. The code for replicating the model is not available from the journal's website. While many journals provide options for online archiving of supplementary materials, only a few have the capacity to insist in every case that authors provide a reliable version of their code.
4. The code is not available from the authors' website and authors are not replying to requests for the code.
5. The code is available but the software needed to simulate is unavailable to individual researchers because its price is high and it is only used at large institutions. An example is the TROLL software used at some policy-making institutions.
6. The code is available but the simulation results it delivers differ from the results published in the article. Such inconsistencies may simply be due to differences in the date of the version used for preparing the results shown in the article and the version made available for replication.
7. The code that is available does not contain sufficient description and explanations such that it is easily understood by users.
8. The software platform for which the code has been written has been updated such that the code cannot be executed successfully anymore on this platform.
9. The researcher attempting replication makes errors in his implementation of the model.
10. The published model cannot be replicated correctly because the derivation of the equations or their implementation in computer code contain errors. Given the complex nature of computational implementation of medium- and large-scale macroeconomic models, such errors are to be expected and can happen to the most meticulous scholars. It is useful to recognize and correct them so as to make it easier for other researchers to build on this work.

These difficulties are not unique to macroeconomic modeling. Replication in reference to computations is more commonly known as *reproducible research* and forms the subject of an expanding literature in computer science, statistics, and related fields of application (see for example Fomel and Claerbout, 2009; Donoho, 2010; Freire et al., 2012; and Sandve et al., 2013). Stanford statistician Donoho (2010) characterizes the central problem in these words:

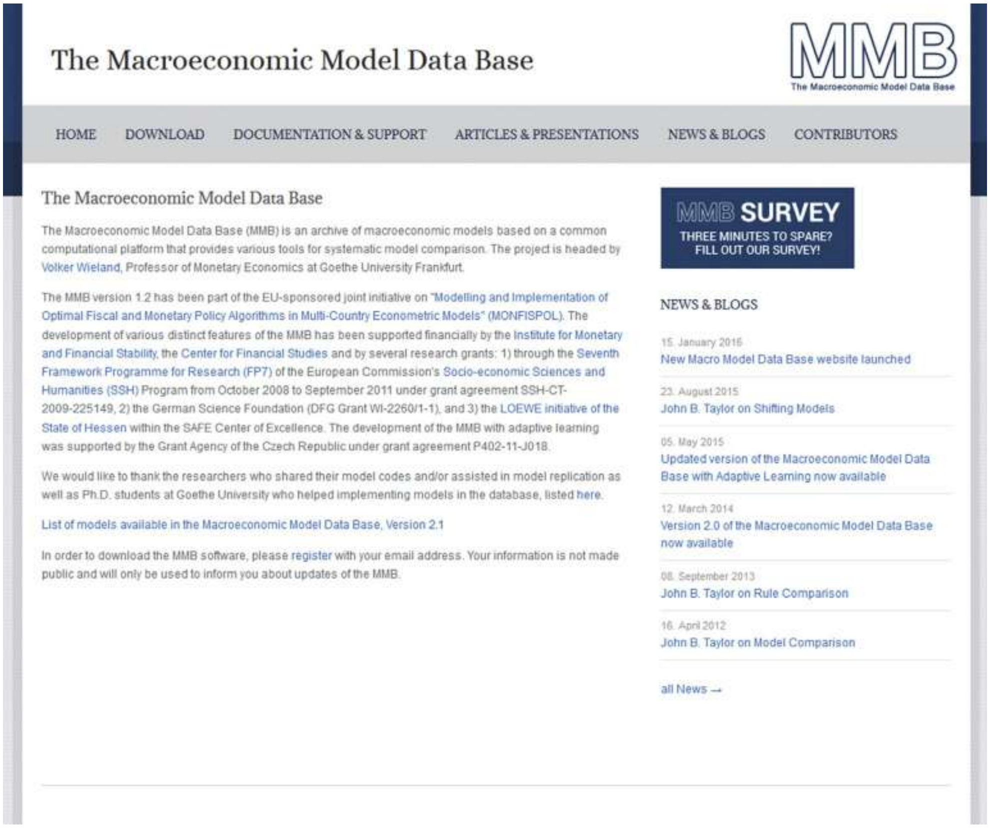
> "an article about computation result is advertising, not scholarship. The actual scholarship is the full software environment, code and data, that produced the result."[b]

We have pursued the following strategies for replicating models to be included in our model comparison software:

1. The ideal case is that authors or other users of the model provide the code describing the model and integrate it themselves in MMB. Generally, authors can expect wider dissemination, use and citation of their work by other researchers if they make their code available in an easy-to-use format. We have also found that policy-making institutions such as central banks and international organizations have become very open toward making their models available, at least those versions that economists from these institutions have circulated in working papers or used for publications in scientific journals.
2. The next best scenario is when model authors provide the complete code that replicates the findings reported in their article and remain available for answering questions of research assistants in Frankfurt who integrate the model in MMB.
3. Research assistants in the Frankfurt MMB team have replicated a number of models using software made available on journal or author websites.
4. We teach advanced Ph.D. courses that focus on a particular area of new model development. A team of two or three students receives the task of presenting a paper from the literature, replicating the model and integrating the model in MMB. This approach has proved quite successful in terms of training Ph.D. students in model building and getting them to the research frontier, where they can work on extending existing models for new applications. Whether they succeed in replicating the model often depends on whether they receive feedback from model authors on problems or missing items. Students give presentations on the original paper and the technical replication and they also prepare a replication report.
5. Once a model has been replicated, we make the files documenting the replication available for download on the MMB website (http://www.macromodelbase.com) as shown in Fig. 2. The replication package is offered separately from the comparison software itself. It is not augmented for model comparison and remains as close as possible to the authors' original code or article. A readme file and graphics files make reference to the specific original research findings and provide information on how close we came to matching the authors' work.

In total, MMB 2.1 makes available 66 models. Taking into account that some of them are simple variants of one model, MMB 2.1 includes 57 quite distinct models. Out of 57 models, about 12 models were made ready for integration by their respective authors or other researchers, 31 models were implemented by the MMB team in Frankfurt in

[b] Noteworthy, this quote is inspired by Claerbout (1994). Very similar ideas are expressed much earlier by A. Williams (see White, 1978).



The Macroeconomic Model Data Base

The Macroeconomic Model Data Base

The Macroeconomic Model Data Base (MMB) is an archive of macroeconomic models based on a common computational platform that provides various tools for systematic model comparison. The project is headed by Volker Wieland, Professor of Monetary Economics at Goethe University Frankfurt.

The MMB version 1.2 has been part of the EU-sponsored joint initiative on "Modelling and Implementation of Optimal Fiscal and Monetary Policy Algorithms in Multi-Country Econometric Models" (MONFISPOL). The development of various distinct features of the MMB has been supported financially by the Institute for Monetary and Financial Stability, the Center for Financial Studies and by several research grants: 1) through the Seventh Framework Programme for Research (FP7) of the European Commission's Socio-economic Sciences and Humanities (SSH) Program from October 2008 to September 2011 under grant agreement SSH-CT-2009-225149, 2) the German Science Foundation (DFG Grant WI-2260/1-1), and 3) the LOEWE initiative of the State of Hessen within the SAFE Center of Excellence. The development of the MMB with adaptive learning was supported by the Grant Agency of the Czech Republic under grant agreement P402-11-J018.

We would like to thank the researchers who shared their model codes and/or assisted in model replication as well as Ph.D. students at Goethe University who helped implementing models in the database, listed here.

List of models available in the Macroeconomic Model Data Base, Version 2.1

In order to download the MMB software, please register with your email address. Your information is not made public and will only be used to inform you about updates of the MMB.

cooperation with the authors, and the remainder were integrated on the basis of course work by Ph.D. students.

4.1.2 Computational Implementation

In terms of implementing the model comparison approach outlined in the previous section computationally, there are choices to be made regarding computer language as well as model solution and simulation methods. Furthermore, problems to be dealt with concern the compatibility with earlier or subsequent versions of the respective software solutions and operating systems.

Most academic researchers in the area of macroeconomic model building have adopted MATLAB as their preferred high-level programming language. This choice concerns specifically the recent development of DSGE models in the real business cycle and New Keynesian literatures. MATLAB—the name is derived from MATrix LABoratory—is a commercial software product of MATHWORKS Inc. It is fairly widely used in engineering, physics, economics, and other fields applying computational methods. This software product is expensive but there are discounts for student licences. Also, there exists a freeware software GNU OCTAVE that is largely compatible with the proprietary MATLAB software. Thus, executables that run on MATLAB can presumably be executed on OCTAVE without needing major modifications. Competing software packages such as GAUSS or MATHEMATICA are not as popular in macroeconomic modeling but offer advantages in econometric or symbolic methods, respectively.

Developers of numerical solution methods for macroeconomic models with rational expectations have written routines that are MATLAB executables for a long time. Over recent years, the free software package DYNARE has been adopted by many researchers in academia, central banks, and international organizations that are working in the field of macroeconomic modeling (see www.dynare.org). DYNARE runs on MATLAB but can also be used with OCTAVE. There is a growing community of researchers that is contributing freely available routines for solution, estimation, and optimization to the DYNARE environment. Some central banks and international organizations also employ the software system TROLL for simulating models used in policy formulation. TROLL is a commercial software with features that make it easy to manage large data sets.

MMB has been developed as free software to be used with DYNARE and MATLAB. Models are defined in the syntax needed for DYNARE. It should also be possible to use the first version of MMB 1.2 and DYNARE with the free software OCTAVE. Yet, so far we have not had the resources to ensure that MMB 2.0 and 2.1 are OCTAVE compatible. MMB 2.0 has been extended with graphical user interfaces (GUI) to improve user friendliness. At this point, GUI facilities are apparently not yet available on OCTAVE, thus restricting MMB 2.0 to MATLAB environments. A Mac OS compatible version of MMB 1.2 is available for download thanks to the contribution of Raymond Hawkins from the University of Arizona.

4.2 User Friendliness and a MATLAB-Based Platform for Comparative Analysis

4.2.1 User Friendliness

The first version of MMB 1.2 was intended for researchers that work on building macroeconomic models. MMB 2.0 and updates are meant to be accessible to a wider group of interested professional economists in the public and private sector and to students of macroeconomics. Thus, we have built graphical user interfaces that make it easier to simulate a wide variety of scenarios with any of the models included in the archive.

First, the user can choose among different applications, such as the comparison of different models under a common policy rule (*One policy rule, many models*) or an in-depth analysis of one specific model under different policy rules (*One model, many policy rules*).

Then she is offered a menu of choices concerning models, policy rules, simulation scenarios, and output formats.

For example, the menu for *One policy rule, many models* is shown in Fig. 3. This menu offers options to conduct comparisons across models under the assumption that the central bank in each model implements the same interest rate rule. It gives access to a software implementation of the mathematical representation of model comparison in Section 3.

On the left-side of the menu the user can choose multiple models by checking the respective boxes. Models are grouped under different categories, such as calibrated New Keynesian models, estimated models of the U.S. economy, estimated models of the euro area economy, models of other economies such as Canada, Chile, Brazil, or Hong Kong and finally several multicountry models. A button on the bottom right of the menu titled "Models description" leads to a PDF file with further information on the models included in the archive. On the top right side, there is a section for choosing a common policy rule from a list of rules. Alternatively, the user can enter coefficients for the common rule in a submenu popping up after choosing "User-specified rule". Furthermore, there are various options for generating simulation output such as unconditional variances, autocorrelation functions, and impulse response functions to monetary and fiscal policy shocks.

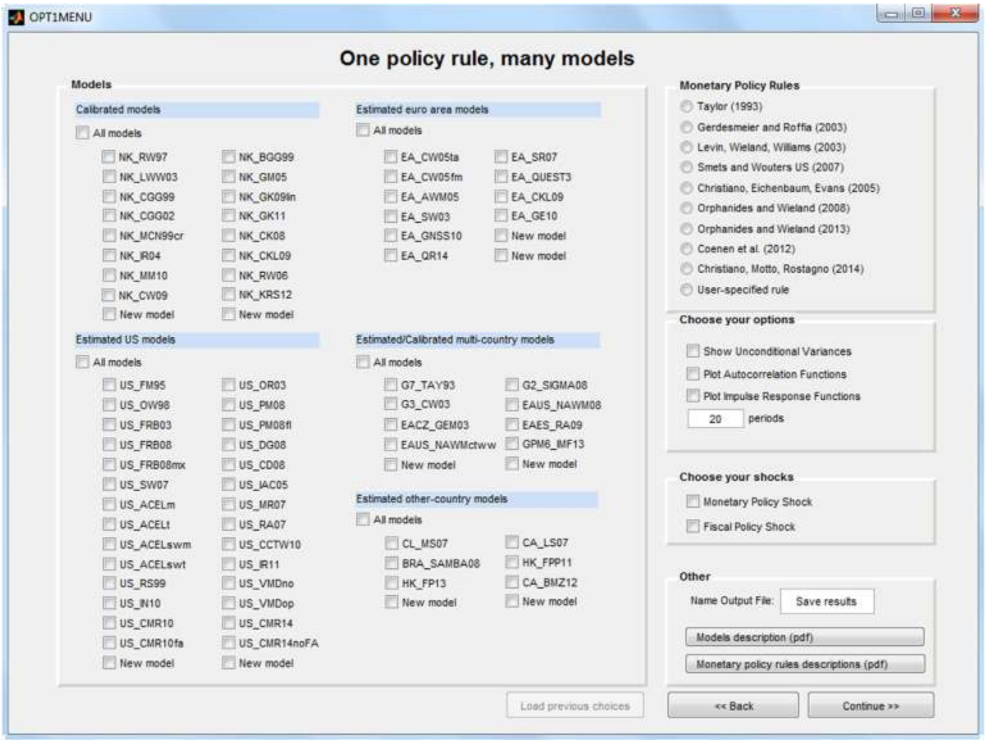

Fig. 3 Modelbase menu: One policy rule, many models.

4.2.2 Common and Model-Specific Policy Rules

The comparison using a common policy rule makes it possible to identify differences in policy implications that are due to differences in model structure and parameter estimates. Yet, there are other interesting questions one might want to ask. For example, it may be of interest to explore the dynamics of one particular model under a variety of different policy rules in more detail. And there are questions that would require simulating each model under the original policy rule estimated or calibrated by the model authors. For example, one would use the model-specific rules if one wants to compare the fit of each model to the data, if one wants to identify the typical empirical response to a particular model-specific shock, or if one wants to compare forecasts obtained from different models.

The application *One model, many policy rules*, for which the menu is shown in Fig. 4, allows a thorough investigation of the properties of a single model and can be used to compare the implications of a variety of policy rules in this model. The user can only

choose one model at a time, but multiple policy rules. It is possible to list the structural shocks in each model and simulate impulse responses for some or all of them under the different rules. In addition to the list of rules and the user-specified rule, the rules menu also includes the model-specific rule estimated or calibrated by the original model's authors as long as the model-specific rule can be written in terms of MMB common variables.

4.2.3 How to Include Your Own Model in MMB

It is fairly straightforward to include additional models in the archive. A detailed description of the necessary steps is provided in the MMB User Guide that can be downloaded along with the MMB software. Thus users can easily integrate their own model for comparison with the models in the archive. The new model can be assigned a button in the graphical user interface. If users send their model file to the model base team in Frankfurt, it can also be included in the publicly available archive.

The complete process of augmenting a model has been described formally in Section 3. If modelers have already simulated their model using DYNARE, they only need to make a few adjustments and additions to the DYNARE model in order to integrate their model in the MMB software. To illustrate this process, Figs. 5 and 6 present the central elements of the DYNARE model file with the New Keynesian model by Rotemberg and Woodford (1997) (NK_RW97) in MMB. A typical model file is comprised of the preamble block, in which variables and parameters are initialized, and the model block.[c]

With regard to the preamble of their model file, contributors simply need to copy and paste in the common variables, common policy shocks, and common policy parameters from another MMB model file. The lines of code that need to be pasted in are shown between starred lines in the preamble section in Fig. 5. They are the same for all MMB model files.

The augmented model block consists of three parts: (i) the common policy rules ($g(.)$ in Eq. (5)); (ii) the definitional equations ($h_m(.)$ in Eq. (6)); (iii) the original model equations ($f_m(.)$ in Eq. (7)). Including the common policy rules is simply another "copy and paste" operation (see lines 63–75 in Fig. 6). Of course, the model-specific monetary policy rule then needs to be commented out (see line 87). The only step that requires more knowledge of the original model concerns adding the definitions of the common variables in terms of model-specific variables to the code. Table 4 describes the relevant common variables. The resulting definitional equations in the case of the NK_RW97 model can be found in lines 54–59 of Fig. 6.

[c] For more detailed explanations, please refer to section 1.4 in the MMB User Guide available online at www.macromodelbase.com.

5. COMPARING FISCAL AND MONETARY POLICY TRANSMISSION USING THE NEW PLATFORM

The Macroeconomic Model Data Base offers individual users many options for comparing model structures and policy implications and for exploring a particular model in great detail. There is no need for bringing together teams of model builders each analyzing its own model. In the following, we present three exercises that are easy to carry out and serve to showcase the potential usefulness of the MMB technology to economists in academia and at policy institutions.

The first exercise shows how researchers can use it to evaluate the sensitivity of policy implications to key model parameters. Specifically, it reviews the importance of Keynesian consumers and monetary policy accommodation for fiscal stimulus effects in one of the models participating in the Coenen et al. (2012) comparison study. The second exercise extends the study of Taylor and Wieland (2012) on monetary policy transmission across earlier and more recent generations of structural macro models by including the medium-size New Keynesian model with financial frictions and risk shocks that Christiano et al. (2014) have recently estimated for the U.S. economy. Finally, the third exercise shows how to conduct cross-country comparisons and illustrates the use of model-specific rules in order to measure model uncertainty about policy effects.

5.1 Effects of Fiscal Stimulus: Sensitivity to Structural Parameters

The large-scale comparison study of Coenen et al. (2012) has highlighted the importance of monetary policy accommodation for Keynesian fiscal multiplier effects (see Section 2.2). Furthermore, the models participating in this study differed in terms of a relevant structural feature in this regard, namely the relative importance of Keynesian consumers that make decisions based on current income and Friedman–Modigliani permanent-income consumers that make forward-looking decisions based on lifetime income. Here, we show how MMB users can evaluate the sensitivity of fiscal policy effects to the parameters governing household consumption choices and central bank reactions. To this end, we consider one of the models participating in the Coenen et al. (2012) study: the US_CCTW10 model of Cogan et al. (2010).

In terms of fiscal shock, we look at the effects of a surprise increase in government purchases that fades out gradually according to an autoregressive process. The shock is implemented as a common policy shock in MMB, that is, an element of the common shock vector η_t introduced in Section 3.[d] As a consequence, government purchases increase on impact by 1% of GDP and then return slowly toward the original level.

5.1.1 Parameter Sensitivity Analysis: Share of Rule-of-Thumb Consumers

The US_CCTW10 model extends the Smets and Wouters (2007) model with Keynesian-style rule-of-thumb households. These households simply consume all current disposable income. Using the same data as Smets and Wouters (2007), Cogan et al. (2010) estimate the share of Keynesian rule-of-thumb consumers in the population jointly with the other structural parameters of the model. For the Bayesian estimation, the prior mean is assumed to be 50%. The resulting posterior mean is 27% with a standard deviation of 6%. Meanwhile, the other models used in Coenen et al. (2012) calibrate or estimate the population share of financially constrained households to values between 20% and 50%.

Fig. 7 reports on the effects of the fiscal policy shock for three different values of the share of rule-of-thumb consumers that is denoted by ω in the US_CCTW10 model. There are six panels displaying simulation outcomes for GDP, inflation, the nominal interest rate, consumption, investment, and government purchases. Each panel contains three lines indicating outcomes with a share of rule-of-thumb households of 0% ($\omega = 0$), 26.5% ($\omega = 0.265$, US_CCTW10), and 50% ($\omega = 0.5$).[e] For each simulation, the other parameters are kept unchanged at the posterior means estimated by Cogan et al. (2010). Noteworthy, setting $\omega = 0$ or $\omega = 0.5$ implies a deviation from the point estimate delivering the optimal fit of the model to the data. The simulation outcomes are best understood as a sensitivity exercise with respect to the single parameter ω.

With $\omega = 0$ there are no rule-of-thumb households. All consumers are forward-looking and base their decision on expected lifetime income as in Smets and Wouters (2007). By contrast, the value of 50% can be considered an upper limit of estimates for the share of rule-of-thumb consumers found in the literature on the U.S. economy. In all three simulations, government spending increases on impact by 1% of GDP and gradually returns to the steady-state ratio of government spending to output (lower right panel).

[d] At this point, the autoregressive parameter remains model-specific as an element of the parameter vector β_m. Yet, in other exercises we show how to consider common autoregressive parameters.

[e] Technically, users can easily change this structural parameter by editing the model file *US_CCTW10.mod* in the subdirectory */MODELS/US_CCTW10* of the archive. The parameter is found under "*// fixed parameters*" and denoted by "*omega = 0.2651; // share of rule-of-thumb consumers*" as in the published article. Then, the user simply needs to run the fiscal shock simulation in the menu "*One model, many policy rules*," repeating it every time he has edited the model file. Three sets of results can be saved in Excel files and then displayed in graphs.

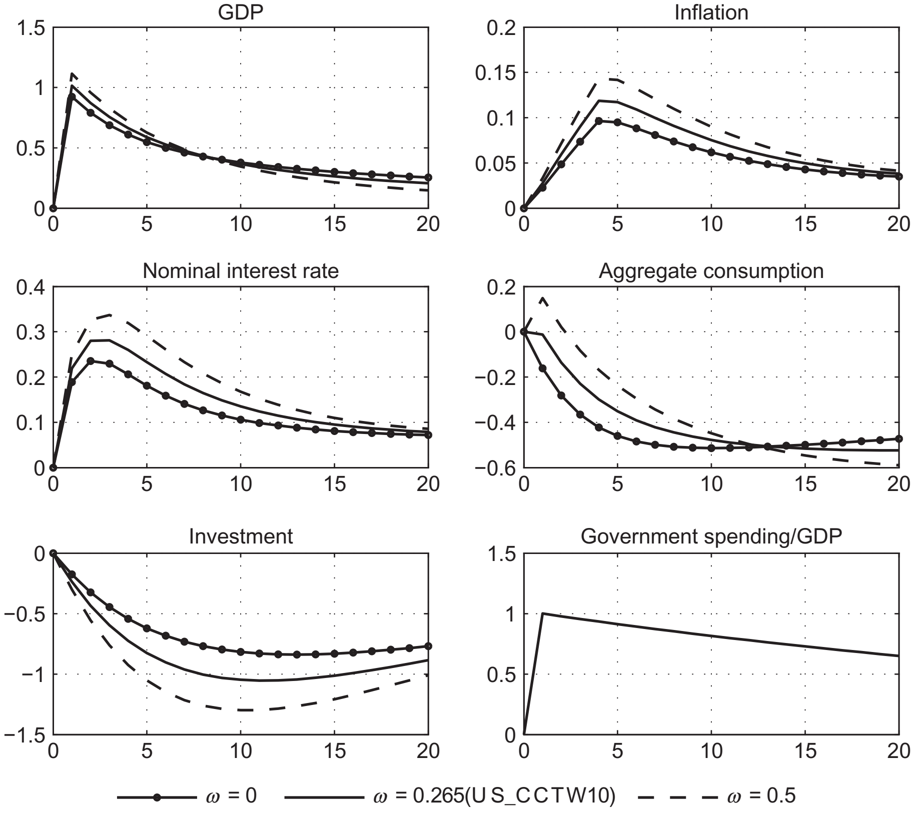

Fig. 7 Impulse responses to an expansionary fiscal policy shock in the US_CCTW10 model for alternative shares of the rule-of-thumb households. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values except government spending. Government spending is expressed as a share of GDP in percentage point deviations from the respective steady-state ratio. Inflation is the rate of inflation over the previous four quarters. The nominal interest rate is annualized. Other variables are expressed in quarterly terms. ω refers to the population share of rule-of-thumb households. The value of $\omega = 0.265$ (US_CCTW10) corresponds to the posterior mean estimate of Cogan et al. (2010). The simulation is carried out under the monetary policy rule of Cogan et al. (2010).

The effect on GDP increases with the population share of rule-of-thumb consumers. Yet, the quantitative differences in the GDP impact of the fiscal shock are not very large. The reason is that a crowding-out effect becomes more pronounced with a larger share of rule-of-thumb consumers. On the one side, aggregate consumption is higher with higher values of ω. With 50% of rule-of-thumb consumers, aggregate consumption even increases a bit in the first quarter consistent with the Keynesian multiplier effect. However, in response to higher GDP and higher inflation, the central bank raises the nominal interest rate. As prices adjust sluggishly due to nominal rigidities, the real interest rate (not shown) rises as well and by a larger amount for higher values of ω. Higher real rates reduce demand for investment purposes and incentivize forward-looking households to postpone consumption. Thus, the expansion in government spending crowds out private spending on investment and consumption. The model with rule-of-thumb consumers also accounts for the dynamics of government debt and taxes. First, government debt increases, then lump-sum taxes respond so as to return debt to the initial debt-to-GDP ratio. While rule-of-thumb consumers ignore the reduction of future disposable income, forward-looking consumers respond by reducing current consumption.

5.1.2 Parameter Sensitivity Analysis: Central Bank Reaction Function

Next, the effect of monetary accommodation is easily evaluated by changing the response coefficients in the monetary policy rule. This can either be accomplished by picking different preset rules under the *One model, many policy rules* menu or by entering different coefficients in the submenu for the *User-specified rule*. We compare the outcomes under the model-specific estimated rule from Cogan et al. (2010) (CCTW10 rule) with the model-specific rule from Bernanke et al. (1999) (BGG99 rule). The latter rule will also be used in Section 6 when we compare the small New Keynesian model of Bernanke et al. (1999) (NK_BGG99 model) to more recent macro-financial models. Here, the BGG99 rule is of interest because it responds only to lagged values for inflation and the interest rate and does not react to GDP (see Eq. (12)).[f] Thus, it should be much more accommodative than the CCTW10 rule.

Fig. 8 presents the implications of the government spending shock for inflation, nominal interest rate and output under the two different policy rules. The panels in the right column report selected results from the previous exercise with the CCTW10 rule (compare Fig. 7). Again, we consider the same three values for ω. The panels in the left column display the outcomes simulated under the BGG99 rule.

The increase in government purchases induces much stronger effects on aggregate GDP under the BGG99 rule. Even in the absence of rule-of-thumb consumers ($\omega = 0$), the GDP impact exceeds unity in the first four quarters. The much more accommodative monetary policy regime exhibited by the BGG99 rule allows for a Keynesian multiplier effect. Private consumption rises due to higher government consumption. This crowding-in effect outweighs the negative wealth effect coming from higher anticipated future taxes. The comparison emphasizes the importance of fiscal-monetary interactions for the effects of discretionary fiscal policy.

[f] This rule can be specified using the *User-specified rule* tab in the panel *Monetary Policy Rules* in the MMB graphical user interface. More specifically, the user needs to assign '0.9' for the entry for *interest (t-1)* and '0.11' for the entry for *inflationq (t-1)*.

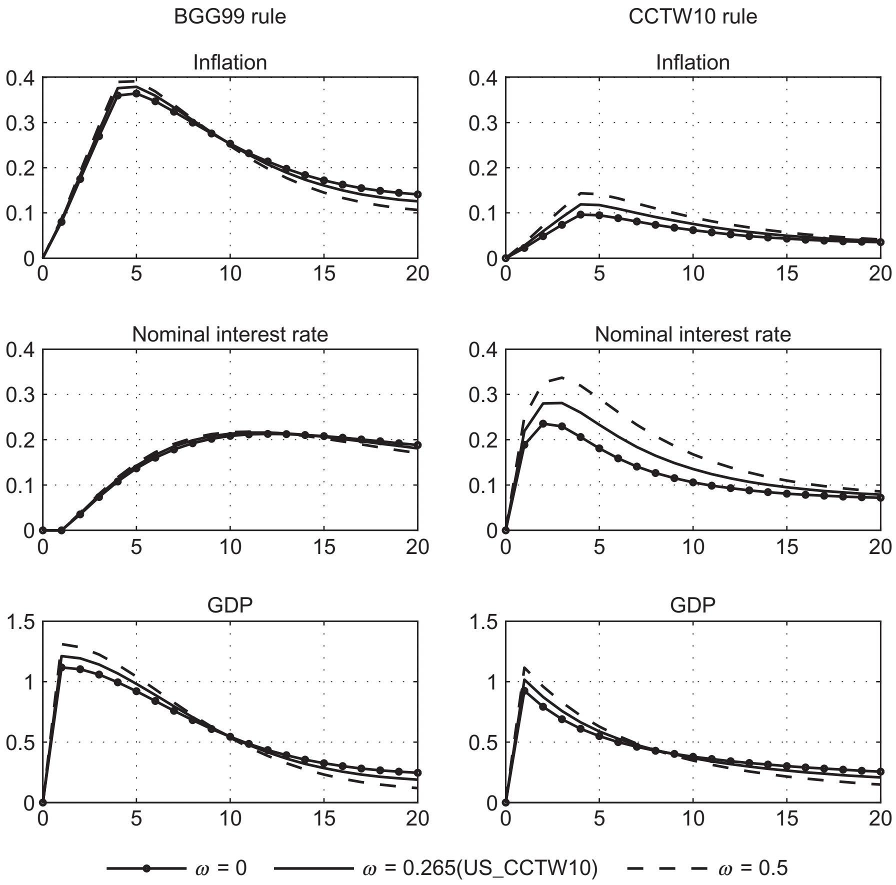

Fig. 8 Impulse responses to an expansionary fiscal policy shock in the US_CCTW10 model with alternative monetary policy rules. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. GDP is expressed in quarterly terms. BGG99 rule refers to the monetary policy rule of the NK_BGG99 model by Bernanke et al. (1999). CCTW10 rule refers to the estimated rule of the US_CCTW10 model by Cogan et al. (2010).

5.2 Monetary Policy Transmission: Comparing Generations of Models

The Macroeconomic Model Data Base serves as an archive of models and contains models developed at different times and based on different theories about how the economy functions. Thus, it offers the possibility to compare different generations of models and their policy implications. One would expect that policy implications change substantially over time, either because new theories offer new insights in macroeconomic interdependencies or because new estimation methods and new data induce different estimates of key parameters. But there may also be surprising similarities.

Table 5 Three model generations

Notation	Description
G7_TAY93	Taylor (1993b): 1st generation New Keynesian model with rational expectations, wage, and price rigidities
US_ACELm	Christiano et al. (2005): 2nd generation New Keynesian medium-size Dynamic Stochastic General Equilibrium model
US_SW07	Smets and Wouters (2007): 2nd generation NK-DSGE model
US_DG08	De Graeve (2008): 3rd generation NK-DSGE model with financial frictions
US_CMR14	Christiano et al. (2014): 3rd generation NK-DSGE model, financial frictions

For example, Taylor and Wieland (2012) compare four different models of the U.S. economy that were developed and estimated at different times with different data, and find very similar estimates of the transmission of a monetary shock to GDP. This holds at least when a common central bank reaction function is used. Here, we extend this comparison to a fifth model that was estimated very recently. The models are listed in Table 5. MMB users can easily replicate and extend this comparison further with the MMB graphical user interface *One policy rule, many models*.

5.2.1 The Models

The G7_TAY93 model, which is a multicountry model of the G7 economies built more than 20 years ago, has been used extensively in the model comparison projects of the late 1980s and 1990s (see Section 2.1). It has New Keynesian properties such as nominal wage and price rigidities, rational expectations, and policy rules. However, it does not yet incorporate the complete set of microeconomic foundations developed in the real and monetary business cycle literature. We refer to it as a first-generation New Keynesian model.

US_ACELm[g] and US_SW07 are the best-known representatives of the second generation of empirically estimated New Keynesian models with additional microeconomic foundations, often referred to as New Keynesian DSGE models. Although they differ from G7_TAY93 also in terms of the estimation approach, data, and sample span, they exhibit almost identical GDP effects of an unexpected change in the federal funds rate. Following the global financial crisis, New Keynesian DSGE models have been fitted out with more detailed financial sectors and financial frictions that serve to amplify financial and economic shocks. Taylor and Wieland (2012) showed that one of these third-generation New Keynesian models, the US_DG08 model, also indicated similar monetary policy effects.

Here, we extend the comparison exercise by bringing one more model with financial frictions into the picture. Noteworthy, the US_CMR14 model is the only one among

[g] The impulse response functions for the monetary policy shock in Altig et al. (2005) are almost identical to those of Christiano et al. (2005). Altig et al. (2005), however, incorporate two additional shocks (a neutral and investment-specific technology shock). The Macroeconomic Model Data Base thus includes the model of Altig et al. (2005).

these five models estimated on data that covers the Great Recession (the sample spans 1985: Q1–2010:Q2) and includes financial time series such as credit to nonfinancial firms, the slope of the term structure, credit spreads on corporate bonds, and an index of stock prices.

> ***US_CMR14 Model Description***: *Christiano et al. (2014) introduce the financial accelerator mechanism of Bernanke et al. (1999) into an otherwise standard New Keynesian model, such as the model of Christiano et al. (2005). This mechanism is described in more detail in Section 6. In contrast to earlier models with financial frictions (see, e.g., Christensen and Dib, 2008; De Graeve, 2008), the authors introduce a shock to the variance of idiosyncratic productivity that influences individual entrepreneur's return to capital. It is referred to as a risk shock. With an agency problem between entrepreneurs and banks, a positive risk shock increases the required return on borrowing, that is, the external finance premium. As a consequence, entrepreneurs' borrowing is reduced and investment declines. As capital prices fall, entrepreneurial net worth decreases, which in turn raises the external finance premium further. These amplification effects are propagated to the real economy over time. Importantly, the authors' analysis suggests that the risk shock is a major driving force of the U.S. business cycle.*

5.2.2 Strikingly Similar Impulse Responses to a Monetary Policy Shock

Fig. 9 displays the effects of a one-percentage point unexpected increase in the federal funds rate on output, inflation, and the interest rate itself in all five models under two alternative monetary policy rules. The panels on the left side show the outcomes when the interest rate is set according to the monetary policy rule estimated in Smets and Wouters (2007) (SW rule), while the panels on the right side refer to the outcomes under the monetary policy rule estimated in Christiano et al. (2014) (CMR rule). The SW rule[h] and the CMR rule are given by Eqs. (10) and (11), respectively.

$$i_t^z = 0.81 i_{t-1}^z + 0.39 p_t^z + 0.97 q_t^z - 0.90 q_{t-1}^z + \eta_t^i. \tag{10}$$

$$i_t^z = 0.85 i_{t-1}^z + 0.36 p_t^z + 0.05 y_t^z - 0.05 y_{t-1}^z + \eta_t^i. \tag{11}$$

The superscript z refers to common variables, that are defined consistently and therefore allow quantitative comparisons. The monetary policy instrument is the annualized short-term federal funds rate in quarter t denoted by i_t^z. p_t^z refers to the annualized quarter-to-quarter rate of inflation, y_t^z is the deviation of quarterly real GDP from its long-run potential, while q_t^z refers to the output gap defined as the difference between actual GDP and the level of GDP that would be realized if prices and wages were flexible. All variables are expressed in percentage deviations from steady-state values. η_t^i refers to the common monetary policy shock.

Under the SW rule, US_SW07, US_ACELm, and G7_TAY93 indicate almost identical GDP responses and quite similar inflation responses to the interest rate shock. GDP declines by 25–30 basis points within 3–4 quarters and then returns to its steady-state level

[h] The monetary policy shock in the estimation of Smets and Wouters (2007) exhibits weak serial correlation with a correlation coefficient of 0.15. In MMB the policy shocks are iid.

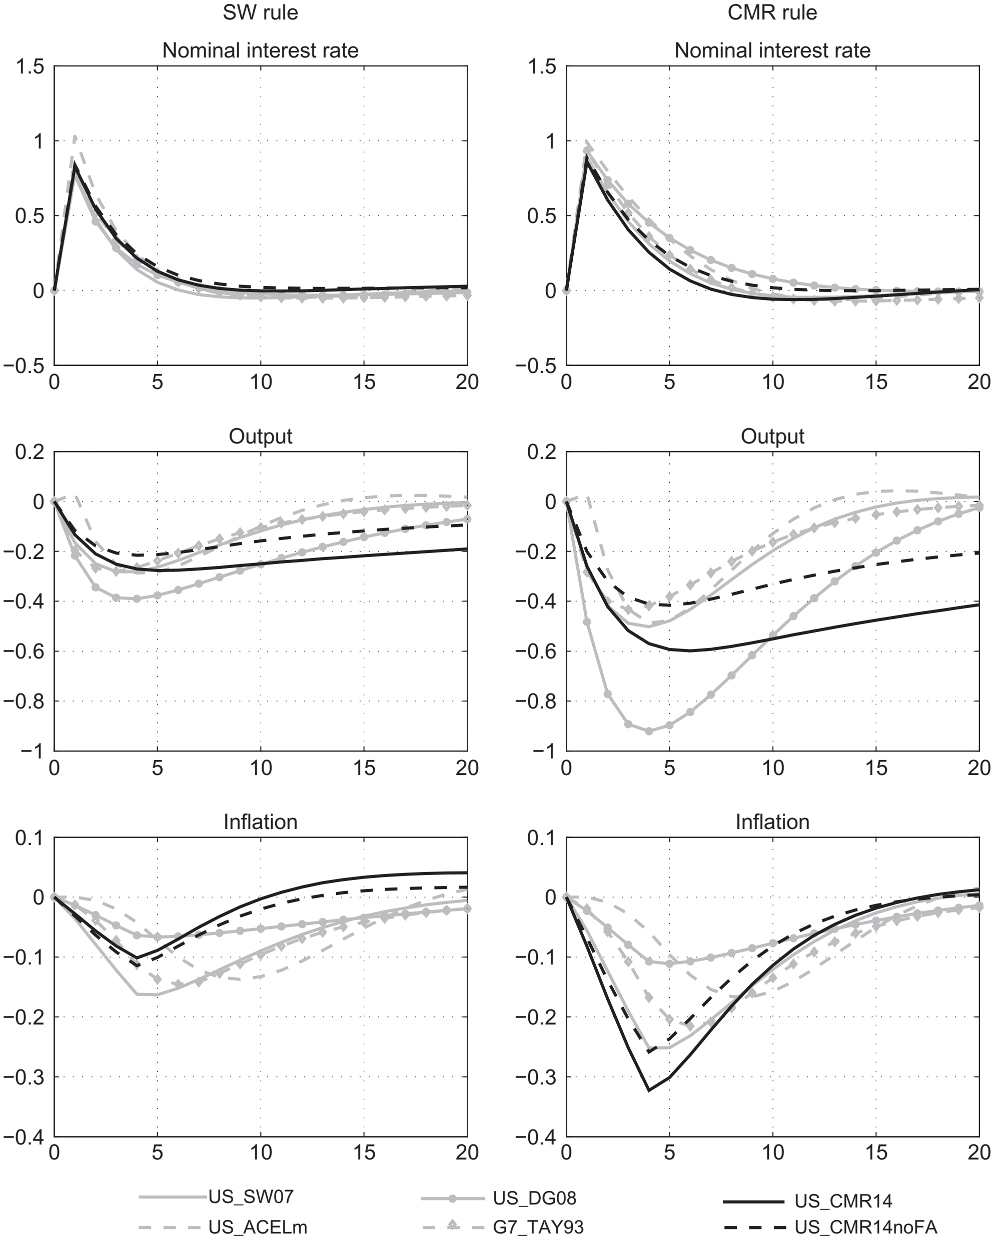

Fig. 9 Impulse responses to a contractionary monetary policy shock in selected models of the U.S. economy under alternative policy rules. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Output is expressed in quarterly terms. SW rule and CMR rule refer to the monetary policy rules estimated in Smets and Wouters (2007) and Christiano et al. (2014), respectively. US_SW07 is the model of Smets and Wouters (2007), US_ACELm replicates the model of Christiano et al. (2005); G7_TAY93 is the model of Taylor (1993b), US_CMR14 is the model of Christiano et al. (2014); and US_CMR14noFA is the modified version of US_CMR14 without the financial friction.

again. The effects are only slightly larger in the US_DG08 model that was also considered by Taylor and Wieland (2012).

Interestingly, the maximum GDP effect in the US_CMR14 model is again of the same magnitude, about 30 basis points within four quarters under the SW rule. Yet, it is much more persistent. GDP returns to steady state very slowly. It barely moves back over the first 20 quarters. It seems monetary policy has become more powerful in terms of inducing lasting consequences for the real side of the economy. Clearly, this finding requires further study.

When using the CMR rule, we obtain greater effects of the policy shock on GDP and inflation in all five models. The reason is that the CMR rule is more accommodative. Its reaction coefficients concerning real GDP are smaller. Yet again, US_SW07, US_ACELm, and G7_TAY93 imply very similar GDP effects, on the scale of a reduction of 45 to 50 basis points within three to four quarters. With this rule, the differences in the third generation of New Keynesian models with financial frictions come out more clearly. In US_DG08, the impact on GDP is quite a bit stronger reaching −90 basis points, while it is again much longer lasting in US_CMR14.

As a further check on the source of the stronger, more lasting effect of monetary policy on real GDP, we modify the US_CMR14 in order to shut down the financial accelerator mechanism. We label this modified version of the model US_CMR14noFA. All other parameters are kept at the values in the original model specification. Noteworthy, the US_CMR14noFA model is structurally very close to the US_ACELm model, the main difference being the presence of the cost channel in US_ACELm. We find that the GDP response is less pronounced in the version without the financial accelerator, yet it remains somewhat more persistent than in the other models.

5.2.3 Unusually Persistent Real Effects of Monetary Shocks in the Model of Christiano et al. (2014)

To investigate the possible origin of the unusually long-lasting real effects of monetary policy in the US_CMR14 model, we repeat the same exercise with four different versions of the model, and show impulse responses over 40 quarters after the shock. In doing so, we always use the model-specific rule, ie, the CMR rule. In addition to US_CMR14noFA, which shuts down the financial accelerator, we consider a version that shuts down nominal wage rigidities (US_CMR14noNW), and a version without both, wage rigidities and financial frictions (US_CMR14noFA&NW). Fig. 10 presents the resulting impulse responses.

The persistent response of GDP in the baseline model (US_CMR14) is reflected in both investment and consumption. Investment falls for eight quarters and then returns very slowly to the steady state. Consumption falls and stays far below the steady state for about thirty quarters and then starts returning to the steady state. Such a long-lasting effect of a monetary shock on household consumption in real terms appears rather unrealistic. In particular, as inflation, nominal and real interest rates return to steady state in ten quarters.

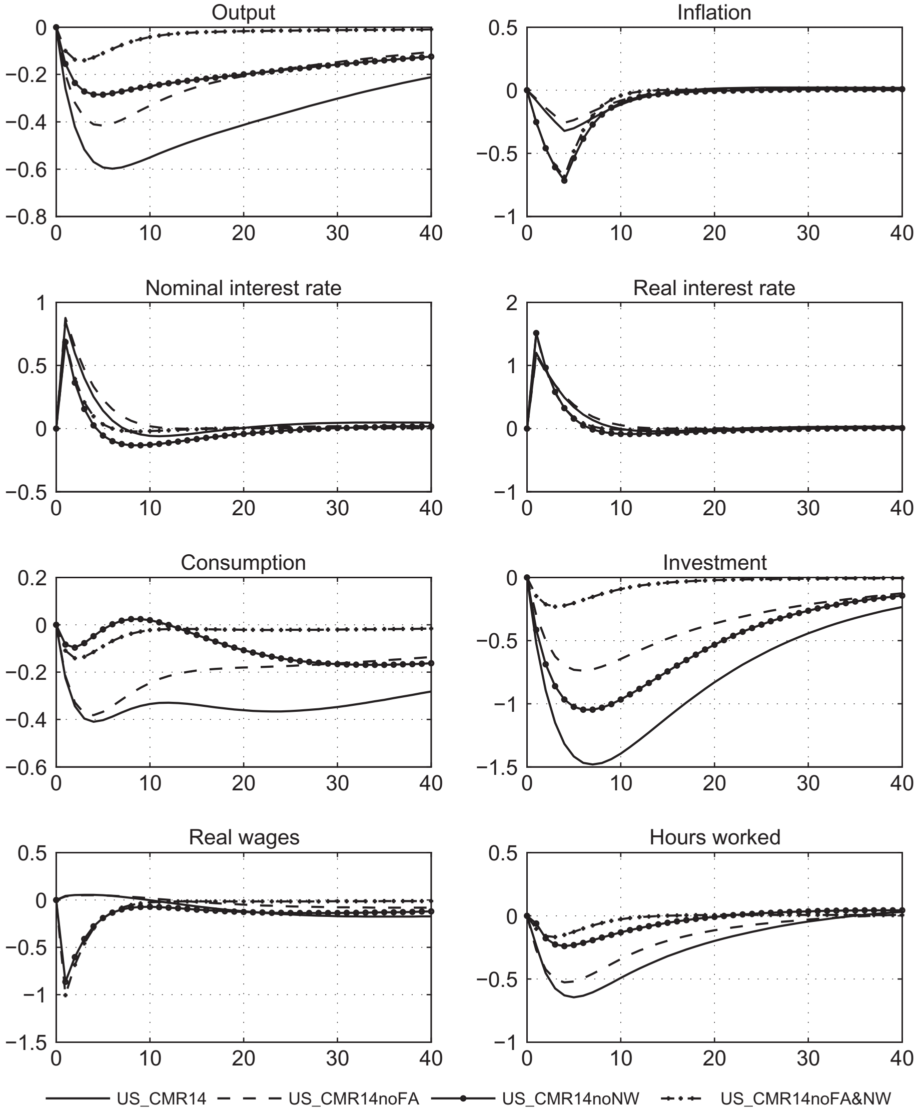

Fig. 10 Impulse responses to a contractionary monetary policy shock in modified versions of the Christiano et al. (2014) model with CMR Rule. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms. US_CMR14 is the model of Christiano et al. (2014); US_CMR14noFA is the version of US_CMR14 without the financial friction; US_CMR14noNW is the version of US_CMR14 without nominal wage rigidities; and US_CMR14noFA&NW is the version of US_CMR14 without both the financial friction and nominal wage rigidities.

While the magnitude of the effect is reduced in the model without the financial accelerator (US_CMR14noFA), consumption, and investment remain highly persistent. In the model without nominal wage rigidities (US_CMR14noNW), real wages fall sharply, while hours worked decline somewhat. The reason is that intermediate good producing firms respond to the contractionary policy shock by adjusting prices rather than quantities. It leads to smaller effects on output and larger effects on inflation. However, the dynamics of output, consumption, and investment are still very persistent. For instance, consumption first returns to the steady state ten quarters after the shock but then continues to decrease even more than during the initial ten quarters.

Finally, in the model without wage rigidities and financial friction (US_CMR14noFA&NW), the real effects of a policy shock are much reduced. The magnitude of the maximum output effect is about one-third of that in the baseline model. More importantly, the strikingly persistent dynamic responses of real variables disappear. Output, investment, consumption, and hours worked return close to steady state in 10 to 15 quarters.

Our comparative exercise shows that the US_CMR14 model implies highly persistent output effects of monetary policy shocks relative to other estimated models of the U.S. economy. Given that the policy debate after the global financial crisis and the Great Recession has been dominated by the fear that monetary policy has become less effective, this result is surprising. The comparisons with modified versions of the model suggests that this feature of the US_CMR14 model is rooted in the parameter estimates that govern the importance of wage rigidities and of the financial accelerator. Yet, it would be important to explore further whether this effect depends on unusual combinations of parameter estimates and whether the extreme persistence disappears if the model is estimated over part of the data sample.

5.3 Predicted Effects of Identified Policy Shocks: United States vs Euro Area

5.3.1 When a Model Comparison Should Make Use of Model-Specific Policy Rules

In the preceding exercise, we have considered the consequences of monetary policy shock across models when the central bank in each model applies the same common policy rule. The idea of these simulations is to examine model differences stemming from model structure, while eliminating the differences stemming from model-specific monetary policy rules. They correspond exactly to the approach laid out in Section 3. Assuming a common rule serves its purpose in making a clean comparison of the policy implications of different model structures.

However, there are other questions that can be answered with model comparisons that employ model-specific rules. For example, if one wants to compare the forecasting performance of different models, the model should be used as fitted to the data. Using a different policy rule would reduce the fit of the model to the data it was estimated on, and its forecasting performance would presumably deteriorate. Thus, for such a comparison each model should be used with the model-specific policy rules that were estimated along with the rest of the model.

Hence any question that involves comparing model fit would make use of model-specific rules. The question to be considered here concerns the empirical degree of model uncertainty about the consequences of identified monetary policy shocks in the United States vs the euro area. Specifically, we aim to assess the range of predicted effects across models. Conditional on the structural assumptions of a model and the sample the model was estimated on, the impulse response under the model-specific rule represents the most likely data-driven reaction of the economy to the monetary policy shock. The comparison exercise then provides a measure of the degree of model uncertainty about monetary policy transmission.

5.3.2 Models with Different Structural Features Estimated with United States and Euro Area Data

Specifically, we choose models from the MMB archive for which all equations are jointly estimated and the model-specific monetary policy rule is formulated for the nominal short-term interest rate. This selection includes twelve U.S. models and eight euro area models (see Table 6). Although all models share certain New Keynesian features, there is a lot of heterogeneity in terms of structural assumptions, observables, and estimation techniques.[i]

All the U.S. models and most euro area models are closed economies. Exceptions include EA_SR07 and EA_QUEST3, which are small open economies, and the two-country models, EAES_RA09 and EA_QR14. Most models only consider forward-looking permanent-income households. EA_QUEST3 and US_CCTW10, however, also include rule-of-thumb households. Models with housing finance, such as US_IAC05, US_IN10, EA_GNSS10, and EA_QR14, feature two types of households that behave as borrowers and savers, respectively. The difference in decision making arises from differences in their discount factors. Savers are more patient than borrowers. Impatient agents face a borrowing constraint and use housing as collateral for borrowing.

Another financial friction that influences credit demand—the financial accelerator mechanism of Bernanke et al. (1999)—is incorporated in the US_CD08, US_DG08, US_CMR14, and EA_GE10 models. Frictions in credit supply are considered in the EA_GNSS10 model, which includes a more detailed banking sector. US_PM08fl, the IMF's small projection model for the U.S. economy, also includes a macro-financial linkage in form of a behavioral relation between bank lending conditions and the real

[i] A brief description of each model is included in the MMB software package and can be downloaded from the MMB website.

Table 6 Estimated models used in the comparison across economies

Estimated U.S. models		Estimated euro area models	
US_ACELm	Christiano et al. (2005)	EA_SW03	Smets and Wouters (2003)
US_IAC05	Iacoviello (2005)	EA_SR07	Adolfson et al. (2007)
US_MR07	Mankiw and Reis (2007)	EA_QUEST3	Ratto et al. (2009)
US_RA07	Rabanal (2007)	EAES_RA09	Rabanal (2009)
US_SW07	Smets and Wouters (2007)	EA_CKL09	Christoffel et al. (2009)
US_CD08	Christensen and Dib (2008)	EA_GE10	Gelain (2010)
US_DG08	De Graeve (2008)	EA_GNSS10	Gerali et al. (2010)
US_PM08fl	Carabenciov et al. (2008)	EA_QR14	Quint and Rabanal (2014)
US_IN10	Iacoviello and Neri (2010)		
US_CCTW10	Cogan et al. (2010)		
US_IR11	Ireland (2011)		
US_CMR14	Christiano et al. (2014)		

Note: The first and third columns contain the model name in the MMB for the respective paper.

economy. The propagation mechanisms generated by financial frictions are to be studied more thoroughly in Section 6.

The models considered in this exercise also incorporate different labor market structures. Some models (US_IAC05, US_CD08, US_IR11, EA_QR14) assume competitive labor markets, but a majority of the models accounts for monopolistic competition in labor supply and Calvo-style rigidity in nominal wages. EA_CKL09 additionally introduce Mortensen and Pissarides (1994) type of matching frictions in the labor market.

Furthermore, US_MR07 differs from all other models due to the assumption of sticky information. In this model, only a fraction of agents (consumers, workers, and firms) updates their information regularly when making decisions. The other agents are inattentive. This feature gives rise to sluggish macroeconomic adjustment.

With regard to model-specific interest rate rules, most models feature interest rate smoothing as well as a reaction to inflation and a real variable (typically, the output gap or output growth). The exceptions are US_CD08 and EA_SR07, where the monetary policy rule also includes reactions to money growth and the real exchange rate, respectively.

Finally, there are also important differences in terms of the time series employed in estimating the models. At a minimum, these include real GDP, inflation, and the short-term nominal interest rate. Most of the models, however, are estimated on a larger set of observables. For example, Smets and Wouters (2007), De Graeve (2008), Smets and Wouters (2003), and Gelain (2010) use seven macroeconomic time series: real GDP, inflation, consumption, investment, real wages, employment, and the short-term nominal interest rate. Adolfson et al. (2007) employ fifteen macroeconomic time series to estimate the euro area model of Sveriges Riksbank (EA_SR07). Iacoviello and Neri (2010) use ten observables, including measures of housing construction and prices. In terms of sample period, the U.S. models are typically estimated on longer samples than the euro area models. Most models are estimated with Bayesian techniques. However, US_CD08 and US_IR11 are estimated with maximum likelihood techniques, while US_ACELm and US_IAC05 are estimated by minimizing the distance between VAR-based and model-implied impulse responses.

5.3.3 Dynamic Responses of Output, Inflation, and Interest Rates: United States vs Euro Area

Fig. 11 reports the outcomes for a one-percentage point contractionary shock to the nominal interest rate under model-specific rules.[j] The panels in the left column display the results for twelve estimated models of the U.S. economy, while the panels in the right column show the results for eight euro area models.

In every case, the unexpected increase in the nominal interest rate leads to a decline in output and inflation. Due to sticky prices the real interest rate rises, which depresses aggregate demand. Lower demand curbs production. As a fraction of price setters adjust to lower demand, inflation falls.

At first glance, there appears to be considerable variation in the magnitude and dynamic patterns of effects. Yet, this impression results from a few outliers. Outliers with regard to output are US_IAC05, US_RA07 and EA_SW03, while US_MR07, US_RA07 and EA_SW03 are outliers with regard to inflation dynamics. Except for US_IAC05, the strong reactions to the policy shock are largely due to a coefficient near unity on the lagged interest rate in the policy rule.[k] The anticipation of a longer period of higher interest rates induces a larger and longer lasting effect on output and inflation, because households and firms take into account expectations of future interest rates in their decision making. In the case of US_IAC05, the lack of important real rigidities, such as habit formation in consumption and investment adjustment cost, coupled with the presence of collateral constraints gives rise to a large initial impact of the monetary policy shock on output.

5.3.4 A Few Summary Statistics

Table 7 provides some summary statistics. In the U.S. models, the trough of output following a contractionary policy shock is reached within one to six quarters, and on average

[j] We obtain simulation results in two ways. When a model-specific policy rule is nested in the generalized rule in MMB, it is available for simulation for the model in question using the options menu *One model, many policy rules*. If this is not the case, we use the replication files for the original models that are provided together with the MMB comparison software.

[k] The coefficients on the lagged interest rate in the policy rule of the models with the strongest responses are as follows: 0.94 for US_RA07, 0.92 for US_MR07, 0.96 for EA_SW03. Noteworthy, the model-specific policy rule of Mankiw and Reis (2007) does not explicitly include a lagged interest rate but the policy shock is modeled as an AR(1)-process with the persistence coefficient of 0.92.

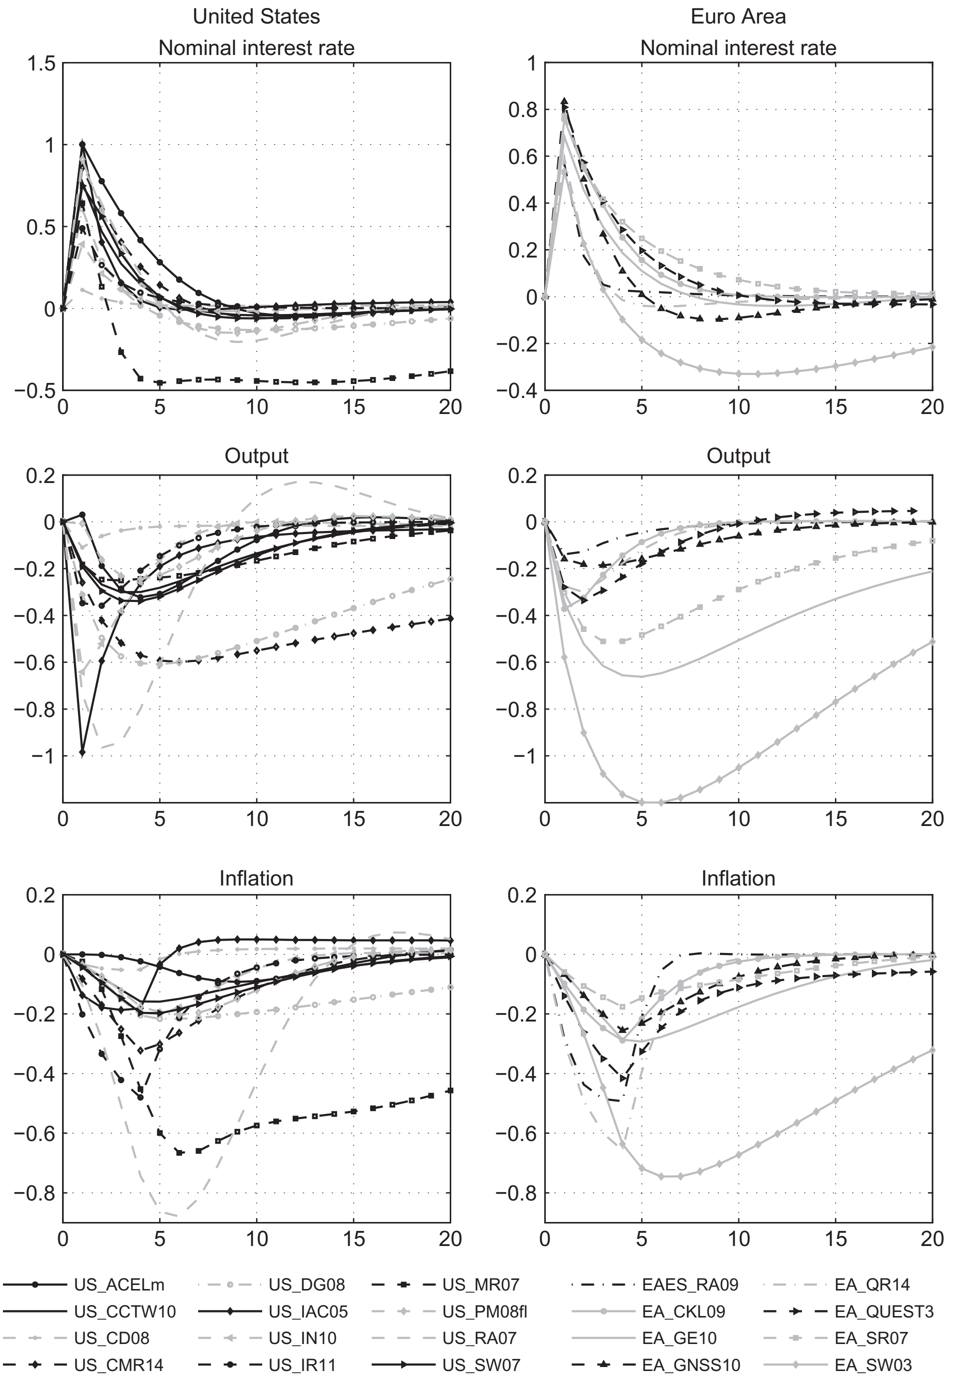

Fig. 11 Impulse responses to a contractionary monetary policy shock in various models with model-specific rules. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Nominal interest rate is annualized. Inflation is the rate of inflation over the previous four quarters. Output is expressed in quarterly terms.

Table 7 Effects of a one percentage point unexpected increase in the policy rate on output and inflation in the United States models and the Euro area models

	Output		Inflation	
	Timing	**Magnitude**	**Timing**	**Magnitude**
(a) Estimated U.S. models				
US_ACELm	4	−0.32%	9	−0.09%
US_IAC05	1	−0.98%	3	−0.19%
US_MR07	3	−0.25%	6	−0.67%
US_RA07	2	−0.96%	6	−0.88%
US_SW07	4	−0.34%	5	−0.20%
US_CD08	1	−0.11%	3	−0.05%
US_DG08	5	−0.61%	6	−0.22%
US_PM08fl	4	−0.25%	6	−0.20%
US_IN10	1	−0.64%	5	−0.20%
US_CCTW10	3	−0.30%	5	−0.16%
US_IR11	2	−0.36%	4	−0.48%
US_CMR14	6	−0.60%	4	−0.32%
Model averages	3.0	−0.48%	5.2	−0.30%
Standard deviations	1.7	0.28%p	1.6	0.25%p
(b) Estimated euro area models				
EA_SW03	6	−1.20%	6	−0.75%
EA_SR07	3	−0.51%	4	−0.18%
EA_QUEST3	2	−0.34%	4	−0.42%
EAES_RA09	1	−0.14%	4	−0.49%
EA_CKL09	1	−0.37%	4	−0.29%
EA_GE10	5	−0.66%	5	−0.29%
EA_GNSS10	3	−0.19%	4	−0.26%
EA_QR14	2	−0.30%	4	−0.66%
Model averages	2.9	−0.46%	4.4	−0.42%
Standard deviations	1.8	0.34%p	0.7	0.20%p

Note: Timing refers to the quarter after the shock, when the trough or the deepest point in the response of the respective variable is reached.

in the third quarter. The average magnitude of the drop in output is 0.48% with a standard deviation of 0.28%p. Interestingly, the timing of the trough and the magnitude of the output drop in the euro area models is very similar. In the euro area, output also reaches the trough within 1–6 quarters, on average in the third quarter. The average output decline at the trough corresponds to −0.46%. Thus, it is very close to its U.S. counterpart, albeit the standard deviation of 0.34%p is a bit larger.

As for inflation, the U.S. models imply that the deepest point in the inflation response occurs within 3–9 quarters, on average, in the fifth quarter. In the euro area models, the span of this range is more narrow at 4–6 quarters, with an average of 4.4 quarters. The average decline in inflation at the trough corresponds to −0.30% for the U.S. models and −0.42% for the euro area models. The respective standard deviations are very similar: 0.25%p for the U.S. and 0.20%p for the euro area.

Thus, the above comparison exercise serves to show that model averages of the predicted impact of identified policy shocks on output and inflation are very similar for the United States and the euro area in terms of timing and magnitude of the resulting contraction.

6. COMPARING IMPLICATIONS OF NEW MACRO-FINANCIAL MODELS

6.1 Key Characteristics: Investment Finance, Housing Finance, and Banking Capital

The global financial crisis has drawn attention to the need for improving the characterization of the financial sector in macroeconomic models used for business cycle and policy analysis. Many new contributions have included financial market imperfections in New Keynesian DSGE models, in particular in three areas: the financing of new investment in firms' capital for production purposes, the financing of housing investment, and the role of banks and bank capital in financial intermediation. These financial frictions help explain how the consequences of economic shocks for macroeconomic aggregates can be amplified via the financial sector, and how financial sector stress and financial crises can spill over into the real economy.

6.1.1 Corporate Investment Financing and the Financial Accelerator

Fortunately, research on integrating financial frictions in macroeconomic models for policy analysis do not need to start from scratch. A prominent starting point is the so-called financial accelerator model of Bernanke et al. (1999) (BGG99). Here, the accelerator term refers to the amplification of economic fluctuations via the financial sector. Long before the global financial crisis, they already provided a tractable approach for including information asymmetries, which are central to the relationship between borrowers and lenders, in dynamic New Keynesian models.

Lending institutions and financial contracts aim to reduce the costs of collecting information and to mitigate principal-agent problems in credit markets. By contrast, economic shocks may increase the cost of extending credit and reduce the efficiency of matching borrowers and lenders. Hence, the credit market imperfections may amplify the effects of shocks from the financial sector as well as other sectors of the economy. BGG99 focus on the financing of investment in firms' capital for production purposes. Their model includes risk-averse households, risk-neutral entrepreneurs, and retailers. Entrepreneurs use capital and labor to produce wholesale goods. These are sold to the retailers. The retail market is characterized by monopolistic competition and price rigidities. Entrepreneurs borrow funds from households via a financial intermediary. These funds serve to pay for part of the new capital, which becomes productive in the next period. The agency problem arises because the return to capital is subject to idiosyncratic risk and can only be observed by the financial intermediary after paying some auditing cost. As a result, the entrepreneurs' net worth becomes a key factor determining their borrowing costs. Entrepreneurs with high net worth need less external funding for a given capital investment and pay lower premia. To the extent that net worth rises and falls with the business cycle, the premium to be paid for external borrowing varies counter-cyclically. Thus, it increases fluctuations in borrowing, investment, spending, and production.

A version of the BGG99 model is included in MMB. The implementation differs somewhat from the handbook article because it omits entrepreneurial consumption. Its short-hand reference in MMB is NK_BGG99. The model archive also contains several more recent contributions of empirically estimated models that extend the financial accelerator mechanism of BGG99. For example, Christensen and Dib (2008) (US_CD08) extend the dynamic New Keynesian model of Ireland (2003) (see US_IR04) with a financial accelerator and estimate the model on U.S. data. In their model, debt contracts are written in nominal terms in contrast to BGG99. De Graeve (2008) (US_DG08) includes the financial accelerator in the medium-scale New Keynesian model of Smets and Wouters (2007) (US_SW07) and estimates the extended model with Bayesian methods using U.S. data on the same nonfinancial macroeconomic time series as Smets and Wouters (2007). In addition, he documents a reasonably close match between the model-implied external finance premium and lower-grade corporate bond spreads. Similarly, Christiano et al. (2014) (US_CMR14) incorporate financial frictions à la BGG99 into the version of the model by Christiano et al. (2005) (US_ACEL). Unlike De Graeve (2008), they also employ financial data including the credit spread in the estimation. Furthermore, they allow the volatility of idiosyncratic productivity to vary over time. Table 8 summarizes the key features of the financial accelerator models relative to the comparison benchmark, US_SW07.

6.1.2 Housing Finance

Real estate booms and busts have played a central role in triggering the global financial crisis. These include not only the subprime mortgage boom and bust in the United States but also the credit-driven housing booms in a number of European countries such as Spain and Ireland. Thus, models with a more detailed housing sector that recognize the relevant financing constraints are of great interest to policy makers.

The underlying rationale of housing finance is the limited enforceability of debt contracts, as borrowers may choose to default. To overcome this limited commitment problem, lenders require collateral, typically housing and land, and provide funds only below the value of the collateral. Thus, the borrowing capacity, and hence the size of the loan is tied to the housing value. A starting point for modeling borrowing and lending under such a collateral constraint in macroeconomic models is to introduce an incentive for

economic agents to act as lenders or borrowers. Technically, it is assumed that the agents differ in their discount factors: some are more patient than others. In equilibrium, the more patient ones become savers while the impatient ones become borrowers.

The collateral constraint has the following consequences: suppose an aggregate shock shifts housing demand upwards such that house prices increase. As a result, borrowing capacity expands. On this basis, the impatient agents increase expenditure on nonhousing and housing goods, which in turn puts additional upward pressure on house prices. Thus, the effect of the initial shock is amplified over time due to the presence of the collateral constraint.

Kiyotaki and Moore (1997) develop a simple dynamic model with patient (and unproductive) entrepreneurs and impatient (and productive) entrepreneurs to show that the collateral channel can generate large and persistent business cycles. Iacoviello (2005) then incorporated such collateral constraints together with nominal debt in a dynamic New Keynesian model. In his model, impatient households and entrepreneurs face collateral constraints, when borrowing funds from patient households. Both household types obtain utility from housing services, while entrepreneurs use housing for the production of nonhousing (consumption) goods.[1] The model is estimated with U.S. data and referred to as US_IAC05 in the MMB model archive.

MMB includes two other U.S. models with housing finance. The model of Iacoviello and Neri (2010) (US_IN10) features a two-sector production structure with housing and nonhousing goods and imposes a collateral constraint only on impatient households. They consider various real and nominal rigidities similar to medium-scale New Keynesian models such as Christiano et al. (2005) and Smets and Wouters (2007). The US_IN10 model is estimated on U.S. macroeconomic and housing data. The model by Kannan et al. (2012) (NK_KRS12) is a simplified version of Iacoviello and Neri (2010). Key elements of the model are the presence of financial intermediaries and the determination of the spread between the lending rate and the deposit rate. The functional form for the determination of the spread is assumed rather than derived from a microfounded optimization problem. Financial intermediaries take deposits from patient households and lend to impatient households charging a spread that varies inversely with the net worth of borrowers. Thus, the financial accelerator mechanism operates in housing finance. Table 9 provides further information concerning key features of the three models with housing finance.

6.1.3 Financial Intermediation and Bank Capital

Banks' illiquidity, insolvency as well as counter-party risks played a prominent role during the global financial crisis, impairing credit supply by banks and thereby deepening the negative impact from excessive leverage of borrowers on the real economy. In contrast

[1] Aggregate housing supply is assumed to be fixed.

with financial accelerator and housing sector models, which focus on frictions stemming from the demand side of financial intermediation, banking sector models deal with frictions on the supply side. In these models, the balance sheet and decision processes of banks are treated explicitly. Thus, shocks originating in the banking sector can have significant spillover effects on the macroeconomy and standard nonfinancial shocks can operate via new transmission channels, when macro-financial linkages are taken into account. In what follows, we focus on three quantitative monetary DSGE models in which banking capital plays a key role.

In the model of Gertler and Karadi (2011) (NK_GK11), banks obtain short-term funds from households and lend them to nonfinancial firms by purchasing the firms' long-term securities. There is no financial friction between banks and nonfinancial firms. Instead, the possibility that the banker can divert part of the bank' assets creates a moral hazard problem between the bank and households. In order to induce households to provide funds, the bank has to satisfy an incentive constraint: the pecuniary benefit from diverting funds must be at least as small as the gain from staying in business. This condition serves as an endogenous constraint on the bank's leverage. Such financial intermediaries are imbedded into an otherwise standard medium-scale New Keynesian model such as Christiano et al. (2005).

Meh and Moran (2010) (NK_MM10) use the double moral hazard framework of Holmstrom and Tirole (1997) and introduce banking decisions via an optimal financial contract. The first moral hazard problem is between a representative household and a representative bank. As the bank's monitoring technology is not directly observed by the investor, the latter requires the bank to participate in the project with its own net worth to mitigate this information asymmetry. Therefore, the ability of the bank to attract loanable funds depends on its capital position. The second moral hazard problem is between the bank and the entrepreneur, because entrepreneurial effort is private information. The bank requires entrepreneurs to participate financially, ie, "to put some skin in the game." The double moral hazard problem is then incorporated within a standard New Keynesian framework.

In Gerali et al. (2010) (EA_GNSS10), banks channel funds from patient households to entrepreneurs and impatient households. Meanwhile, the bank faces a leverage constraint as a form of paying a pecuniary cost whenever its net worth to asset ratio moves away from an exogenously given target. The bank's optimal decision implies that credit supply depends positively on bank net worth. In addition, banks have monopolistic power to set deposit and loan rates. These rates exhibit stickiness due to adjustment costs. The banking sector is included in a model with collateral constraint à la Iacoviello (2005). While the preceding two models are calibrated, the EA_GNSS10 model is estimated on the euro area macroeconomic data. Table 10 summarizes the key features of the models with bank capital.

6.1.4 Exploring How the Financial Sector Propagates and Amplifies Disturbances

In the following, we use MMB to explore and compare the dynamics of the above-mentioned macro-finance models. For models with financial accelerator on corporate investment and models with housing finance, we compare impulse response functions to a monetary policy shock, a general technology shock, and shocks that are more akin to aggregate demand shocks. Here, we extend the model comparison approach outlined in Section 3 by utilizing some economic shocks as common shocks in the models considered. The Smets and Wouters (2007) model (US_SW07) serves as a benchmark for comparison. Furthermore, we use the monetary policy rule estimated by Smets and Wouters (2007) as the common policy rule for all models. In this manner, we can isolate differences due to structural assumptions of each model from differences due to different assumptions on monetary policy. The SW rule is given in Eq. (10). For models with a role of bank capital, we simulate the original model to investigate the effects of an unexpected reduction in bank capital.

6.2 Propagation Mechanisms: Investment Financing and the Financial Accelerator

6.2.1 Striking Differences in Amplification of the Effect of Monetary Policy

To begin, we compare the transmission of the monetary policy shock in the four models with financial accelerator effects due to information asymmetries in the financing of corporate investment, (NK_BGG99, US_CD08, US_DG08, and US_CMR14), relative to the benchmark (US_SW07). Fig. 12 displays the effects of an unanticipated increase in the nominal interest rate of one percentage point for the commonly defined macroeconomic aggregates. In all four models, the nominal interest rate increases while output and inflation decline. The standard channel of monetary transmission is reflected in higher real interest rates that lead households to reduce consumption today and firms to refrain from investment.

The financial accelerator mechanism is at work in all four models that contain financial frictions. As can be seen from Fig. 13, firms' net worth falls due to a reduction in the price and return of capital.[m] Borrowing needs and leverage[n] of entrepreneurs increase, and the external finance premium (EFP) rises, depressing investment. The US_CD08 model, where the financial contract is in nominal terms, also exhibits a debt-deflation mechanism.

Yet, the magnitude, timing, and dynamic pattern of responses differ substantially across the models. It is particularly striking that the smaller New Keynesian models NK_BGG99 and US_CD08 display much stronger responses of output and inflation

[m] Note that the financial variables have not been redefined as common variables. Thus, the differences can only be interpreted qualitatively. Yet, the impact on GDP is directly comparable.

[n] Leverage is defined as the ratio of the value of capital, Q_tK_t, to the entrepreneur's net worth.

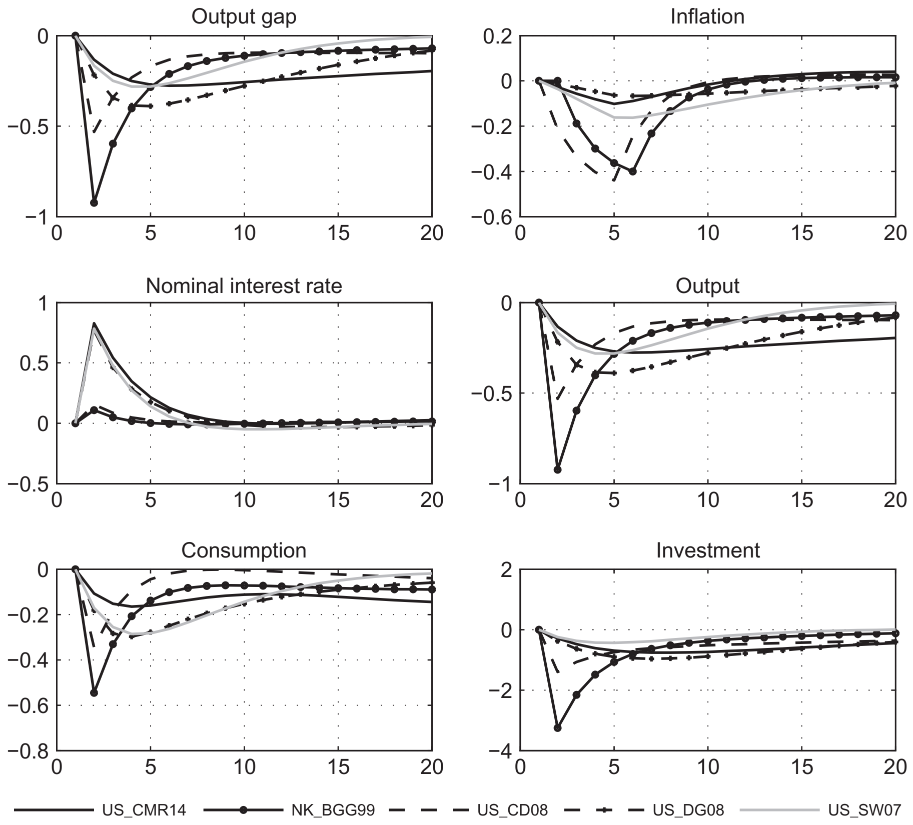

Fig. 12 Impulse responses to a contractionary monetary policy shock under SW rule: Macro variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

and a much smaller response of the nominal interest rate than the medium-size DSGE models US_SW07, US_DG08, and US_CMR14. This diversity of responses to a monetary policy shock stands in contrast to the findings of Taylor and Wieland (2012). The estimated medium-size DSGE models with financial accelerator US_DG08 and US_CMR14 still remain close to the other medium-size models, although the response of output in US_CMR14 is substantially more persistent as discussed in Section 5.2.

In US_DG08, investment responds more strongly to the unexpected policy tightening than in US_SW07 due to the financial accelerator effect.[o] The effect on consumption remains very similar. In sum, the impact on GDP is magnified a bit. GDP declines by about 40 basis points relative to 30 basis points in US_SW07. There is no similar

[o] Noteworthy, estimates of the curvature of the investment adjustment costs function are almost identical in US_SW07 and US_DG08.

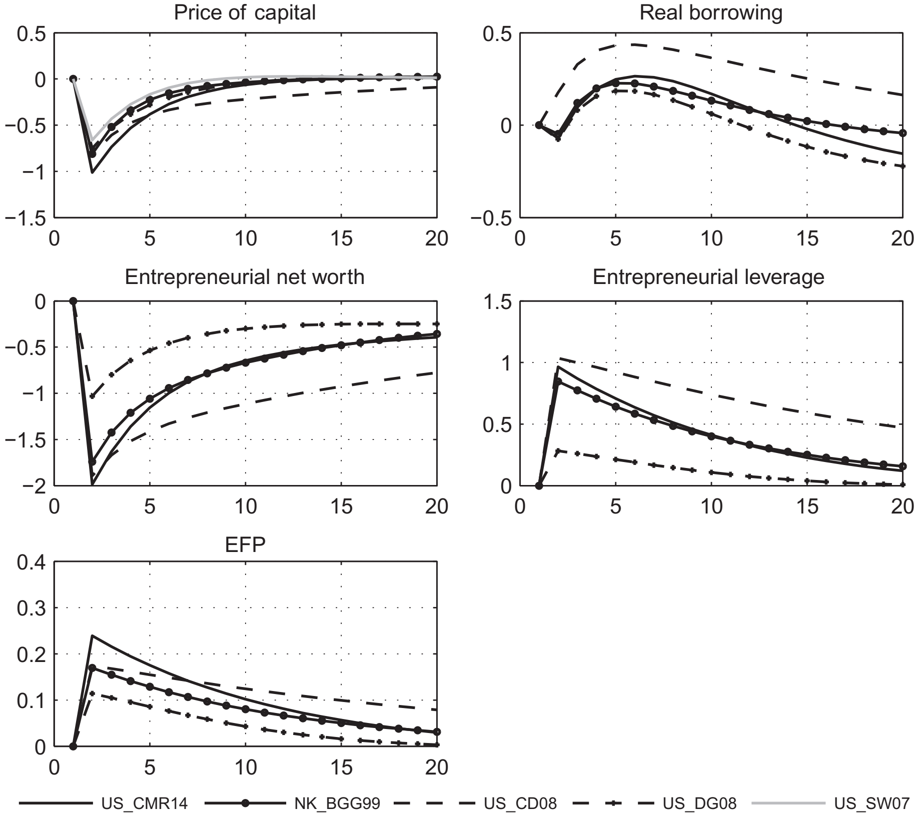

Fig. 13 Impulse responses to a contractionary monetary policy shock under SW rule: Financial variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. EFP (external finance premium) is annualized. Other variables are expressed in quarterly terms.

magnification effect, when output responses in US_SW07 and US_CMR14 are compared. The reasons are a somewhat smaller consumption response and a weaker financial accelerator effect to investment in US_CMR14. In particular, the response of investment in US_CMR14 is less pronounced than in US_DG08 due to a higher curvature of the investment adjustment cost function.

6.2.2 Investment Adjustment Costs Attenuate Sharp Responses of the External Finance Premium

Where does the big difference in GDP effects between medium-size DSGE models and smaller models with financial accelerator come from? The reason is the different working of the financial accelerator effect on investment in the two smaller models. The sharp increase in the external finance premium translates directly into a sharp reduction in investment in the two smaller financial accelerator models. In US_DG08 and

US_CMR14 instead the response of investment is hump-shaped and persistent, reaching a substantially lower peak effect than in NK_BGG99 and US_CD08. This is due to different specifications of adjustment costs across models: US_DG08 and US_CMR14 assume investment adjustment costs (as in Christiano et al., 2005), whereas NK_BGG99 and US_CD08 assume capital adjustment costs. As in US_DG08 and US_CMR14 it is costly to adjust the flow of investment, forward-looking agents adjust investment already today in expectation of an increase in the external finance premium. Accordingly, fluctuations in the premium have a smaller effect on the economy under investment adjustment costs than under capital adjustment costs ceteris paribus (see De Graeve, 2008). One might also ask why the largest impact on GDP occurs in NK_BGG99, rather than in US_CD08 where the financial accelerator is reinforced by a debt-deflation mechanism. This has to do with the calibration of capital adjustment costs. It is less costly to adjust capital in NK_BGG99 than in US_CD08.

Given the importance of the capital vs investment adjustment cost assumption and the striking differences it implies for output responses, one might ask which of the assumptions is supported by the data. We compare impulse responses of output from the models with the empirical impulse responses stemming from a VAR. To this end, we estimate a VAR, using the same observables and recursive identification as in Christiano et al. (2005) on the sample 1965Q3–2007Q3.[p] Fig. 14 presents impulse

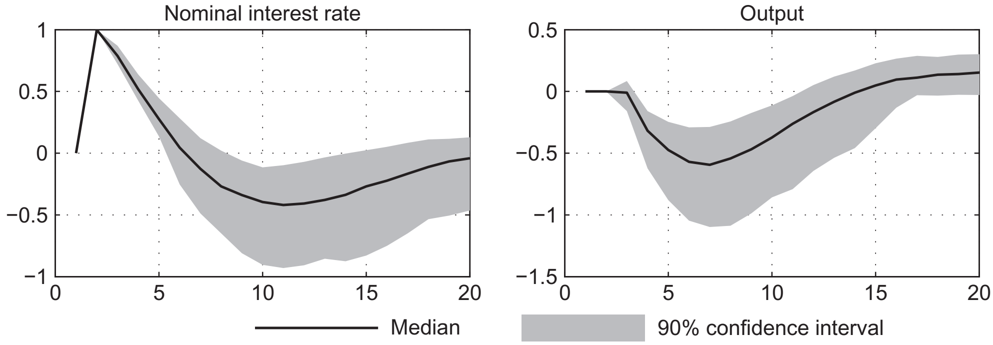

Fig. 14 Impulse responses to a one percentage point increase in the federal funds rate in a structural VAR. *Notes*: The variables and recursive identification are consistent with Christiano et al. (2005) on the sample of 1965Q3–2007Q3. The horizontal axis represents quarters after the shock. The solid lines refer to the median impulse responses. Shaded areas represent the 90% confidence intervals obtained by bootstrapping.

[p] The order of variables in the vector of observables is as follows: real GDP, real consumption, the GDP deflator, real investment, real wage, labor productivity, federal funds rate, the change in real money stock (M2), and real profits. The lag length is set to two quarters based on the Akaike Information Criterion. The VAR model also includes an intercept and a linear trend. The confidence bands are obtained by bootstrapping with 500 draws.

responses of the federal funds rate and real GDP to a one percentage point increase in the monetary policy rate. The federal funds rate increases on impact by one percentage point and then gradually declines. Real GDP exhibits a hump-shaped response, reaching a trough six quarters after the shock. This dynamic pattern of GDP response is consistent with investment adjustment costs assumption. Noteworthy, the VAR-based median response of output in the trough period is quantitatively close to the model-average of the trough output effect in the U.S. estimated models reported in Table 7.

6.2.3 Sharp GDP Responses Trigger Strong Contemporaneous Policy Feedback

Another difference between the medium-size models and the smaller models concerns the behavior of the nominal interest rate (see Fig. 12). In US_DG08, US_CMR14, and US_SW07 the nominal interest rate increases by about one percentage point in response to the policy shock as one might have expected. By contrast, the interest rate rises by less than 20 basis points in NK_BGG99 and US_CD08. In these two models, monetary policy has a strong contemporaneous effect on GDP growth that feeds back to the interest rate via the contemporaneous response to GDP growth in the SW rule. At first sight, this finding appears odd, particularly in light of the simulation of monetary policy shocks reported in Bernanke et al. (1999) which indicates a much stronger within-quarter effect of the policy shock on the interest rate. However, it turns out that the model dynamics are quite different under the original monetary policy rule. To illustrate this effect, we simulate all the other models under the original policy rule from Bernanke et al. (1999) (BGG99 rule).[q] The rule is given by:

$$i_t^z = 0.9 i_{t-1}^z + 0.11 p_{t-1}^z + \eta_t^i, \tag{12}$$

where i_t^z refers to the annualized short-term interest rate; p_t^z is the annualized quarter-to-quarter rate of inflation and η_t^i refers to the common monetary policy shock. As shown in Fig. 15, the strong contemporaneous feedback to the nominal interest rate disappears when simulating this rule with lagged inflation. Since this rule implies no reaction to the current state of the economy, the resulting impact of the policy shock on output and inflation is much greater.

The sensitivity of interest rate dynamics to the timing assumption of the policy rule in the two smaller models suggests that the specification of dynamics in these models is not rich enough to be used to assess the transmission of monetary policy in a quantitative manner for policy purposes. It indicates the usefulness of building and estimating medium-size DSGE models for this purpose. Interestingly, the five medium-size models considered here continue to indicate fairly similar GDP impact of policy shocks under the

[q] Simulations are carried out in the MMB menu *One policy rule, many models* by assigning the policy rule coefficients under the tab "User-specified rule."

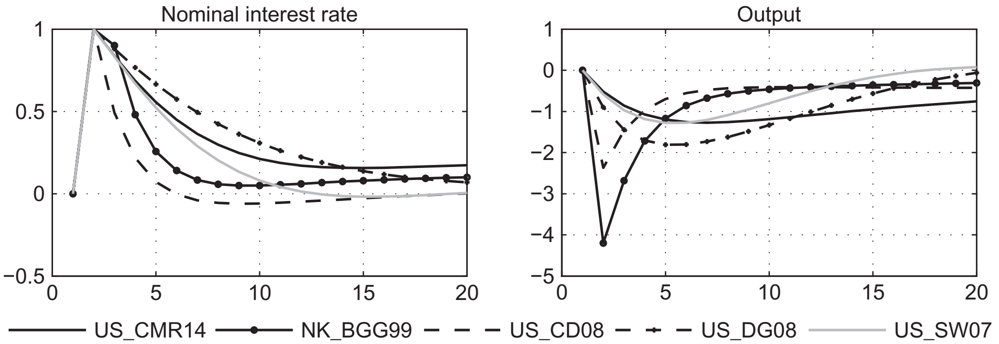

Fig. 15 Impulse responses to a contractionary monetary policy shock under BGG99 rule: Nominal interest rate and output. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Nominal interest rate is annualized. Output is expressed in quarterly terms.

rule from Bernanke et al. (1999) (BGG) (US_SW07, US_DG08, and US_CMR14 are shown in Fig. 15, but not G7_TAY93 and US_ACEL).

6.2.4 Financial Accelerator or Decelerator of Productivity Disturbances?

Figs. 16 and 17 report on the impact of a positive 1% technology shock.[r] The degree of exogenous persistence of this shock is assumed to be identical in the models considered. In particular, we set the common persistence parameter of the AR(1)-technology process to 0.9. Again, the common monetary policy rule corresponds to the estimated interest rate rule in US_SW07.

In all four models output increases in response to such technological progress. This increase is also visible in investment and consumption. Due to the rigidity of price adjustment, and in the case of the US_SW07 and US_DG08 models also nominal wage adjustment, actual output increases less than the output level that would be realized under flexible prices. For some time, a gap opens up between actual output and this measure of potential output.[s] The negative output gap leads to a decline in inflation. The SW rule then calls for monetary easing and the nominal interest rate declines.

With regard to the financial accelerator effect, the price of capital, firms' net worth and real borrowing increase in response to the technology shock. As leverage first declines and then rises, so does the external finance premium. Magnitudes and dynamic

[r] For comparison, the size of the shock in each model is scaled such that it would increase output on impact by 1% in the absence of endogenous responses of other variables.

[s] De Graeve (2008) defines potential output as the level of output under flexible prices and *in absence* of financial frictions. For direct comparability with the other financial accelerator models US_CD08 and NK_BGG99, we employ a common definition of potential output—under flexible prices and *in the presence* of financial frictions—also for US_DG08. The results are, however, not sensitive to the definition of potential output in this case.

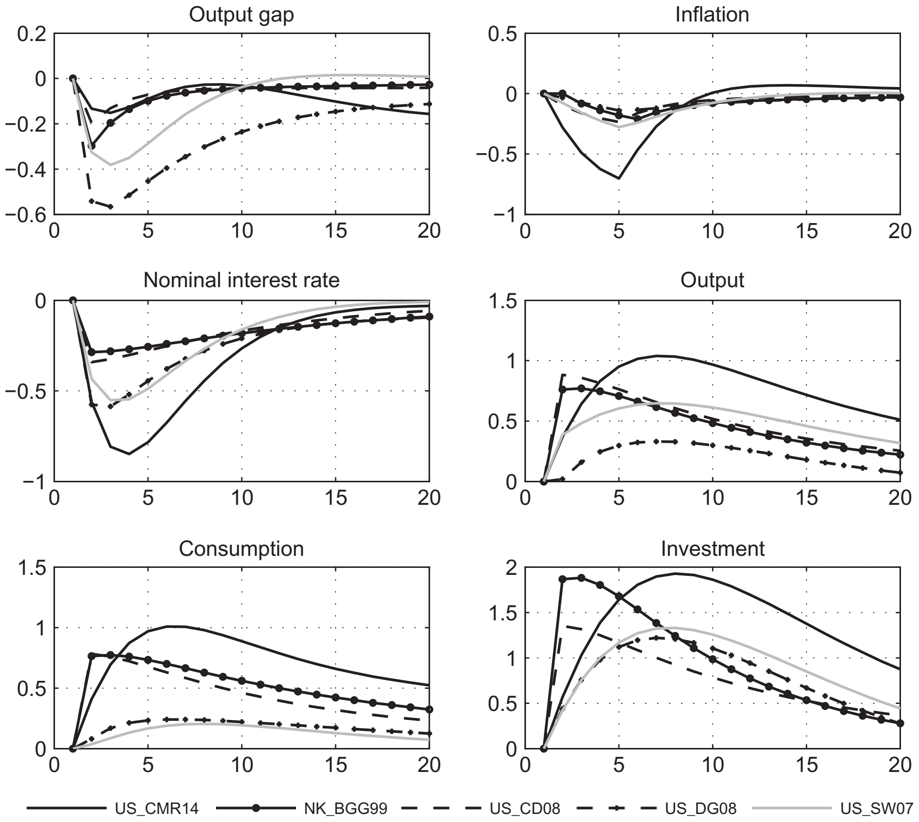

Fig. 16 Impulse responses to a positive technology shock under SW rule: Macro variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

patterns differ. Again, the NK_BGG99 and US_CD08 indicate a sharp positive impact of the change in financial variables on firms' investment. Investment and output dynamics in US_SW07, US_DG08, and US_CMR14 follow a hump-shaped pattern departing from and returning to steady state more slowly than in the other two models. The presence of investment adjustment costs in the medium-size models explains the more sluggish responses than in the NK_BGG99 and US_CD08 models that assume capital adjustment costs. Bernanke et al. (1999) showed that the financial accelerator amplified the effect of technology shocks on investment and GDP relative to the benchmark without the financial friction. The model of De Graeve (2008) delivers the opposite result. Relative to the model without the financial friction, the financial accelerator mechanism added by De Graeve (2008) actually dampens the investment and GDP response to a technology shock. As the demand for and price of capital increase, investment stays high for some

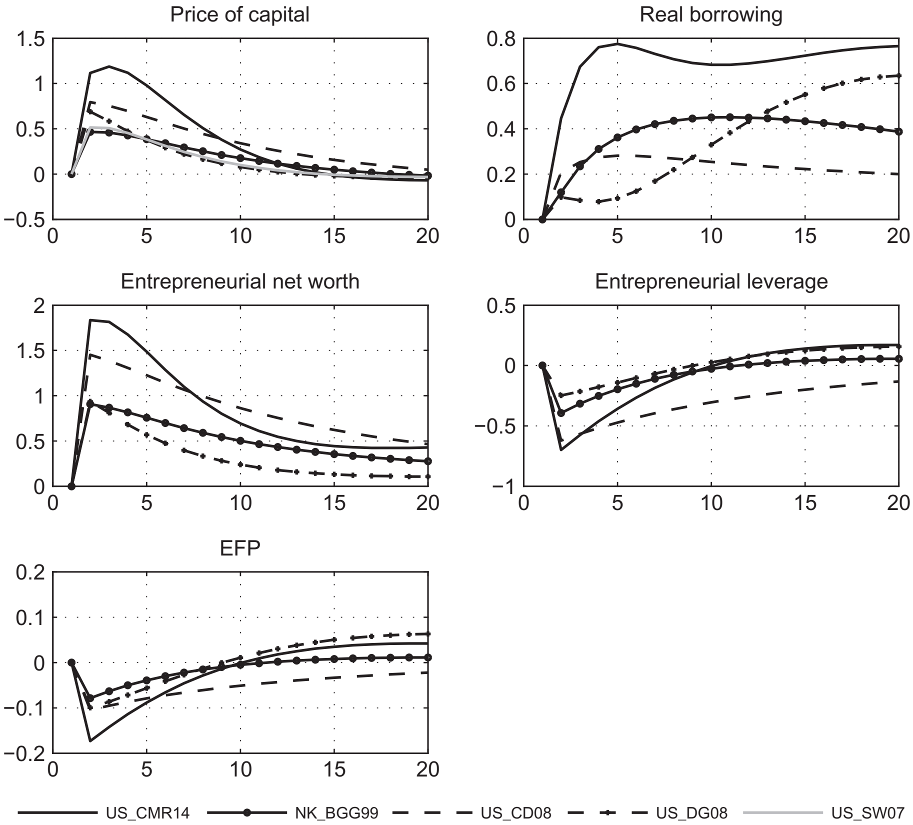

Fig. 17 Impulse responses to a positive technology shock under SW rule: Financial variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. EFP (external finance premium) is annualized. Other variables are expressed in quarterly terms.

time. The value of the capital stock then outgrows net worth and increases borrowing needs for quite some time. Accordingly, the external finance premium rises. As De Graeve (2008) notes, because long-lasting positive investment will be costly due to a high future premium for external finance, investment will be lower in all periods than otherwise. Indeed, the investment response in US_DG08 is smaller relative to US_SW07, which also features investment adjustment costs but no financial friction. However, this is not the case for US_CMR14, that is structurally very close to US_DG08 and yet exhibits larger responses of consumption, investment and hence output relative to US_SW07.

6.2.5 Estimated Parameters of Price Stickiness Make a Difference for the Accelerator Effect

A key parameter for investment dynamics is the curvature of the investment adjustment costs. In US_SW07 and US_DG08, this parameter is almost identical (5.76 and 5.77, respectively), whereas in US_CMR14 it is estimated to be substantially higher (10.78). Ceteris paribus, a higher curvature makes the adjustment process costlier, dampening the investment response. Yet, the investment response in US_CMR14 is stronger than in the other models.

Another important parameter is the degree of price stickiness. In US_DG08, the probability that firms will not be able to reset the price, is estimated at 0.92, whereas the corresponding estimate in US_SW07 is 0.65 and 0.74 in US_CMR14. In other words, prices are more flexible in US_SW07 and US_CMR14. The degree of price flexibility determines the strength of response of consumption and investment variables to a technology shock, because it determines the dynamics of the real interest rate. Conditional on the monetary policy rule, which is common for all models in this exercise, more flexible prices imply that inflation will ceteris paribus fall by more in response to a technology shock, causing the central bank to loosen the nominal rate by more. As a result, the real interest rate is lower for more flexible prices. Thus, consumption increases more for more flexible prices. Also investment rises more substantially. In a model without financial friction such as US_SW07, equilibrium requires the real rate to move together with the aggregate return on capital. Therefore, in an economy with more flexible prices, capital increases by more ceteris paribus, causing a higher investment response. With the financial accelerator, a lower real rate translates into a lower external finance premium, strengthening entrepreneurial net worth and thereby also supporting the investment boom.

To sum up, greater price stickiness dampens the responses of consumption and investment to technology shocks. This is a further reason why the responses in US_DG08 are smaller relative to the model without the financial friction—US_SW07. The other important reason is the presence of the 'decelerator' effect, as described in De Graeve (2008). The differences in price stickiness also explain why consumption and investment responses are stronger in US_CMR14 when compared to US_DG08.

With regard to the earlier findings of Bernanke et al. (1999) it is noteworthy to point out the sensitivity to the assumption for the monetary policy rule and the persistence of the technology process. They use a random walk process for technology. In this case, a shock has very large and persistent effects on output. Consequently, actual output exceeds potential output and inflation goes up.

6.2.6 Investment-Specific Shocks

We have also simulated and compared the impact of investment-specific shocks in the US_SW07, US_DG08, and US_CD08 models. De Graeve (2008) calls this shock an investment supply shock, since it causes investment to increase and the price of capital to decrease. Smets and Wouters (2007) group it under (aggregate) demand shocks because they lead to an increase in both output and inflation. In this context, it is of interest to note that such investment-specific shocks play an important role in explaining the Great Recession following the global financial crisis when the US_SW07 model is extended to cover this period (see Wieland and Wolters, 2013). Conditional on the model parameterization, the financial friction included in the US_DG08 and US_CD08 models dampens the impact of such investment shocks on investment and GDP.

6.3 Propagation Mechanisms: Housing Finance and Credit Booms

Next, we compare the effects of monetary and technology shocks in the three models with housing finance, US_IAC05, US_IN10, and NK_KRS12, relative to the US_SW07 model as benchmark.[t] In addition, we examine the impact of demand shocks originating in the housing sector on the broad economy.

6.3.1 Monetary Transmission via Housing Finance

Fig. 18 shows the consequences of a contractionary monetary policy shock on macro variables. Qualitatively, the three models with housing finance exhibit the same Keynesian-style features as the benchmark. Due to price rigidities, the contractionary monetary shock induces an increase in the real interest rate, output declines below its flexible price level,[u] and this gap causes lower inflation. Both, consumption and investment decrease. Quantitatively, the impact on real GDP is much sharper and more pronounced in the US_IAC05 and US_IN10 models. The NK_KRS12 model, however, is closer to the US_SW07 benchmark. The latter two models exhibit more muted and hump-shaped responses of GDP and its components, consumption and investment.

Fig. 19 displays the transmission of the monetary shock via housing finance. The collateral constraints on nominal borrowing in the US_IAC05 and US_IN10 models magnify the effect of unanticipated policy tightening. As inflation falls and real house prices decrease, the debt capacity of borrowers is reduced. In the US_IAC05 model impatient households and entrepreneurs are both borrowing constrained. Accordingly, the impatient households cut back further on consumption, while the entrepreneurs reduce nonresidential investment along with consumption. Likewise, in the US_IN10 model impatient households curtail consumption by more. Moreover, residential investment declines significantly, because sticky wages in combination with flexible house prices intensify the effect of a monetary shock on output in the residential sector. Meanwhile, output shows no hump-shaped responses in these two models. The reasons is that the

[t] The components of aggregate consumption and investment differ in the models with housing due to different assumptions on the production sector and housing market. In the US_IN10 and NK_KRS12 models, aggregate consumption consists of the consumption of patient and impatient households, and investment is defined as the sum of nonresidential and residential investment. Meanwhile, in the US_IAC05 model, aggregate consumption includes the consumption of entrepreneurs additionally to two types of households' consumption and investment comprises only nonresidential investment.

[u] In the NK_KRS12 model, the potential output is defined as the level of output that could be realized without nominal *and* financial frictions.

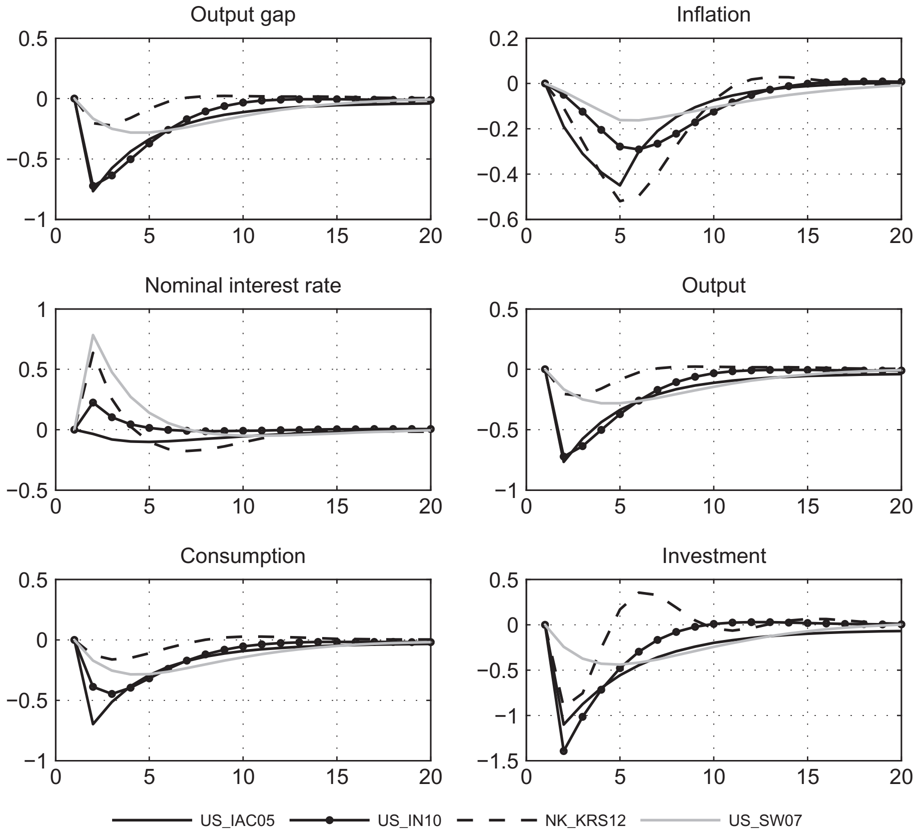

Fig. 18 Impulse responses to a contractionary monetary policy shock under SW rule: Macro variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

US_IAC05 model exhibits no habit formation in consumption and only small capital adjustment costs, while the US_IN10 model features no capital adjustment costs.

The NK_KRS12 model exhibits a more flexible collateral constraint. This generates less amplification than the standard collateral constraints used in the other models with housing. A higher loan-to-value ratio in this model is accompanied by a rise in lending rates. By contrast, the amount of borrowing is restricted to a certain fraction of collateral in case of the standard collateral constraint. Accordingly, a fall in the collateral value leads directly to the reduction of borrowing. In the NK_KRS12 model, impatient households still take out more loans even with higher interest rate in response to a contractionary monetary shock. This dampens the responses of consumption and residential investment. Furthermore, since there is no capital in this model, aggregate demand does not include nonresidential investment which is an interest-sensitive component of GDP. Overall, the

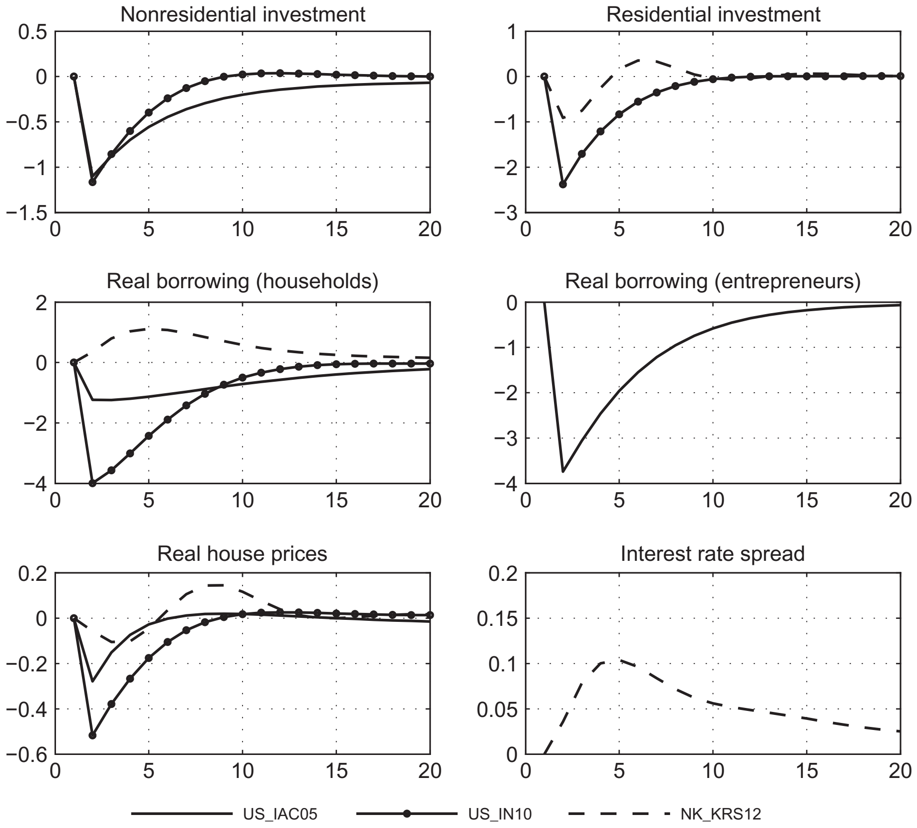

Fig. 19 Impulse responses to a contractionary monetary policy shock under SW rule: Investment & financial variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Interest rate spread is annualized. Other variables are expressed in quarterly terms.

impact of the monetary shock on output is smaller in the NK_KRS12 model than in the other models.

As in the case of the NK_BGG99 and US_CD08 models in Section 6.2.3, we find that due to insufficient real rigidities, the US_IAC05 and US_IN10 models exhibit a sharp contemporaneous response of output that strongly feeds back via the SW rule to the contemporaneous nominal interest rate. For the US_IAC05 model, the positive monetary policy shock implies a slight decline in the nominal interest rate. Similarly to the financial accelerator models analyzed earlier, this strong contemporaneous effect disappears when the models are simulated under the policy rule of Bernanke et al. (1999) (see Fig. 20).

The sensitivity of interest rate dynamics to the timing assumption of the policy rule suggests that the dynamics in these models are not rich enough to be used to assess the transmission of monetary policy in a quantitative manner as in the case of medium-size

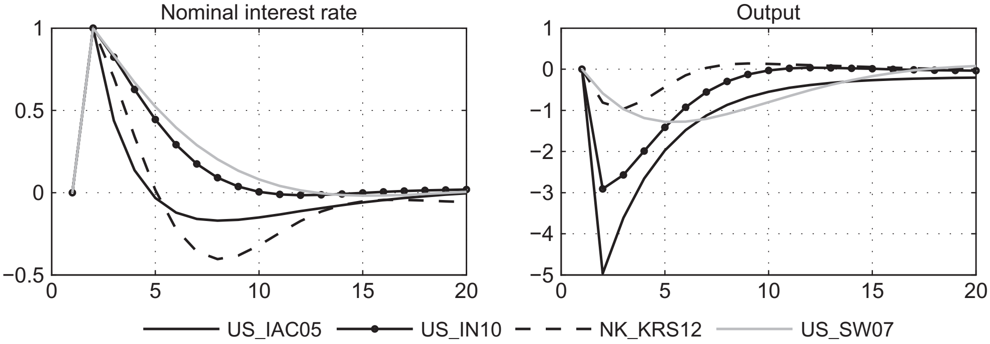

Fig. 20 Impulse responses to a contractionary monetary policy shock under BGG99 rule: Nominal interest rate and GDP. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Nominal interest rate is annualized. Output is expressed in quarterly terms.

DSGE models with more sources of endogenous persistence. Thus, the comparison of monetary transmission mechanisms in the two groups of macro-financial models supports including habit formation in consumption and investment adjustment costs in models for quantitative monetary policy analysis.

6.3.2 General Technological Progress and Housing Finance

We also examine effects of a common technology shock in the housing finance models. The shock has a common autocorrelation coefficient of 0.9. In the US_IN10 and NK_KRS12 models, which contain two production sectors, the shock increases the total factor productivity in the nonresidential (consumption goods) sector. Figs. 21 and 22 present the impact of a 1% increase in such a shock.

As in the US_SW07 model, GDP rises and inflation declines in response to a positive technology shock in the models with housing. It leads to a housing boom without inflation, which is amplified by collateral constraints.

The persistent but temporary increase of productivity in the nonresidential sector is followed by a lower real interest rate so that aggregate demand is equated to the expanded aggregate supply. The reduction of the real rate causes real house prices to rise, which in turn increases the borrowing capacity of collaterally constrained agents. This allows borrowers to obtain more funds, which are either consumed or invested. The amplifying effect of the collateral channel is most apparent in the responses of consumption. Consumption increases two or four times more in the housing finance models than in the US_SW07 model. Though the decline in inflation reduces collateral values, the collateral channel outweighs the debt deflation channel.

Surprisingly, the output gap in the US_IN10 model increases, whereas inflation declines. When house prices rise, the combination of flexible house prices and sticky wages in the residential sector increases new housing construction by more than in

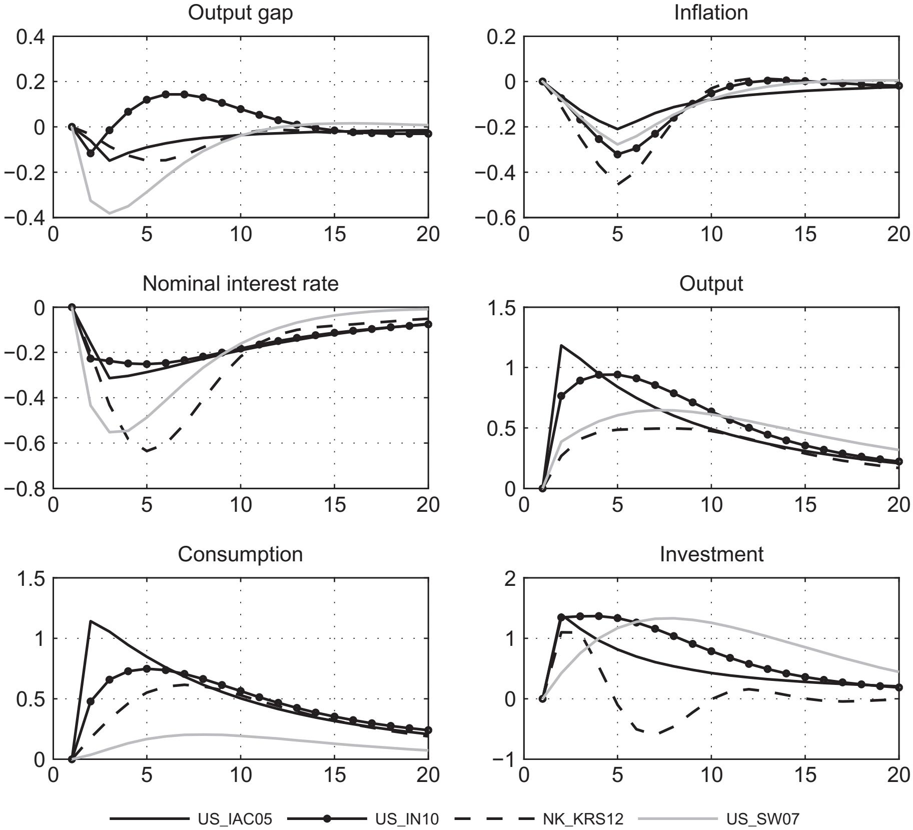

Fig. 21 Impulse responses to a positive technology shock under SW rule: Macro variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

the case of flexible wages. As a result, total output, the sum of the value added of the two sectors, increases beyond the level of output that would be realized if prices and wages were flexible. Yet, with the two-sector production structure, a positive output gap does not necessarily lead to an increase in inflation in the consumption sector. Though positive spillover effects from the residential to the nonresidential sector put upward pressure on inflation, the positive technology shock also lowers the marginal cost of intermediate goods. The latter effect dominates and inflation declines.

6.3.3 Housing Demand Shocks Driving a Housing Boom

The models with a housing sector include new types of shocks emanating from this sector that have potentially major macroeconomic consequences. In the following, we consider a housing demand shock. It could also be called a housing preference shock, since it is

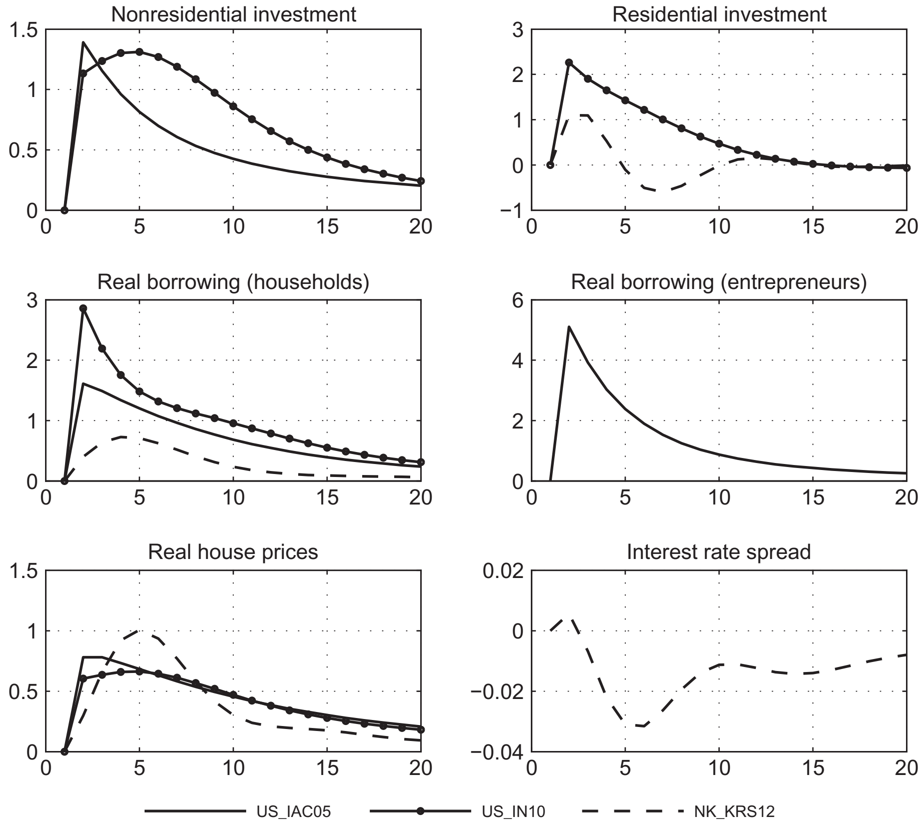

Fig. 22 Impulse responses to a positive technology shock under SW rule: Investment & financial variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Interest rate spread is annualized. Other variables are expressed in quarterly terms.

modeled as random disturbance to utility from housing services. For comparison, the size of the shock is adjusted across the models such that it increases the real house prices on impact by 1%. Yet, we ask a slightly different question than previously with the technology shock, namely, what the consequences of such a housing demand shock would be when the degree of exogenous persistence remains model-specific.[v] Under this scenario, GDP increases in all the models. The housing boom leads to an economic boom.

However, the responses of other macroeconomic and financial variables are quite different across the models as shown in Figs. 23 and 24. The heterogenous dynamics reflect the different model structure and assumptions with regard to the housing market.

[v] The AR(1) coefficients of a housing demand shock for each model are the following: 0.85 (US_IAC05), 0.96 (US_IN10), 0.95 (NK_KRS12)

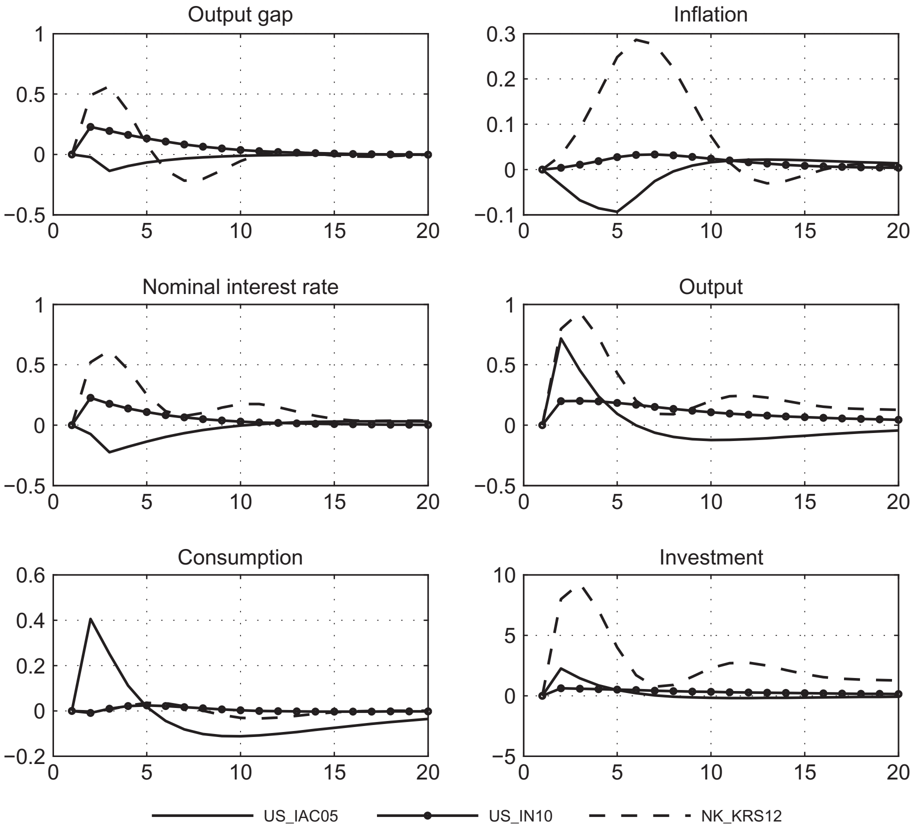

Fig. 23 Impulse responses to a positive housing demand shock under SW rule: Macro variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

Unlike the US_IAC05 and US_IN10 models, house prices are subject to Calvo-type nominal frictions in the NK_KRS12 model. Thus, house prices continue to rise for more than one year after the initial shock.[w] The effects of higher house prices on investment and GDP are amplified by the financial accelerator mechanism. As shown in Fig. 24, the surge in residential investment and housing prices dominates the increase in households' borrowing. As households' leverage decreases, financial intermediaries charge a lower spread of the lending rate over the deposit rate. The reduced spread results in a further increase of borrowers' housing demand, which in turn leads to another increase of house prices. Actual GDP rises more than it would under flexible prices, hence a gap opens up and inflation goes up.

[w] The Calvo pricing parameter in the housing sector is 0.75.

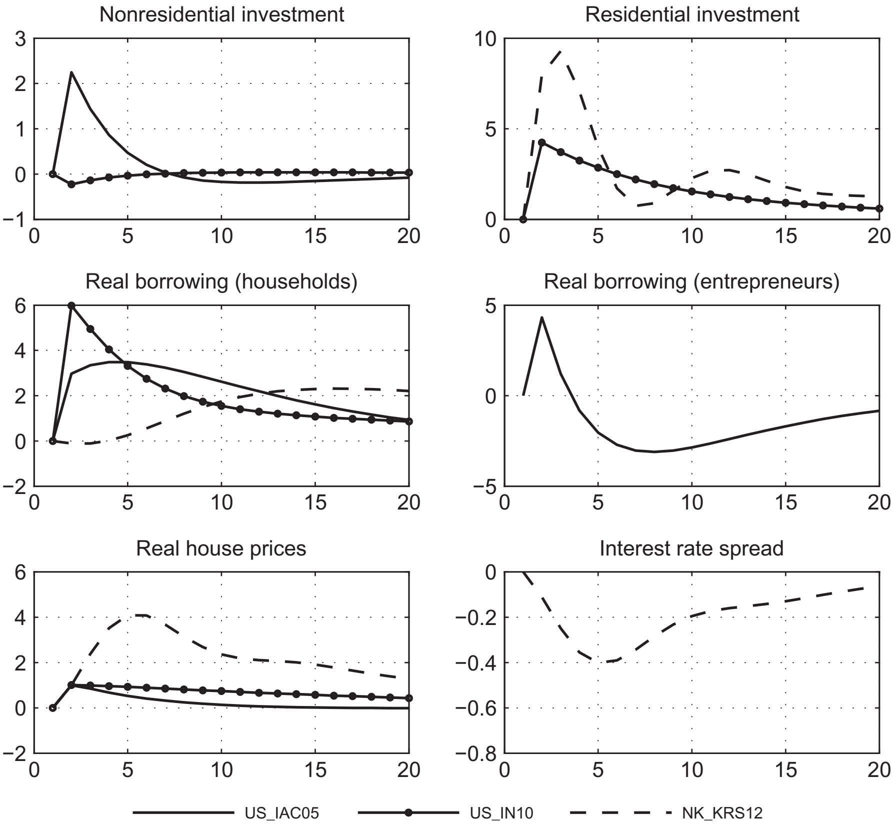

Fig. 24 Impulse responses to a positive housing demand shock under SW rule: Investment & financial variables. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Interest rate spread is annualized. Other variables are expressed in quarterly terms.

In the US_IAC05 model, the housing demand shock sharply pushes up consumption, investment, and GDP. The increase in households' demand for housing drives up house prices. As a consequence, the collateral value of borrowers rises and the borrowing capacity is expanded. It leads impatient households to increase consumption and entrepreneurs to invest more. The model does not exhibit hump-shaped dynamics since it assumes no habit formation in consumption and only a small adjustment cost in nonresidential investment. Contrary to the other two models, flexible price output rises more than actual output. Accordingly, inflation declines. The reason is that the increased physical capital and housing stock raise factor productivities, thereby shifting the aggregate supply curve outwards. With borrowing-constrained entrepreneurs, the housing preference shock acts like an aggregate supply shock, which causes output and inflation to move in opposite directions.

The response of output is smallest in the US_IN10 model. The housing demand shock expands the borrowing capacity of impatient households, so that they increase consumption and housing investment. The role of the collateral channel is illustrated by the responses of residential investment and real borrowing of the households. However, patient households decrease consumption and investment in response to the increase in interest rates. Overall, GDP increases less than in the other two models.

6.4 Propagation Mechanisms: Financial Intermediation and Bank Capital

Finally, we explore macroeconomic consequences of shocks emanating from the banking sector. To this end, we make use of the three macro-financial models with a detailed representation of the banking sector: the model of Gertler and Karadi (2011) (NK_GK11), the model of Meh and Moran (2010) (NK_MM10), and the model of Gerali et al. (2010) (EA_GNSS10). Specifically, we evaluate the impact of an unanticipated reduction in bank capital on macroeconomic and financial variables. This shock can be interpreted as a sudden reduction in bank capital due to bank loan losses and asset writedowns.

The technical definition of the shock, however, differs across the three models. In the NK_GK11 model, the shock is modeled as a one-time wealth transfer from banks to households, whereas in the NK_MM10 model the shock is defined as sudden accelerated depreciation of bank net worth. In the EA_GNSS10 model, the shock implies an unexpected deadweight loss to bank net worth. In the NK_MM10 and EA_GNSS10 models, the shock follows a first-order autoregressive process, whereas in NK_GK11 the shock is assumed to have no persistence at all.[x] The size of the shock is normalized such that bank capital declines by 5% on impact in all models.

The question to be answered with this comparison exercise differs from the previous comparative analysis. Rather than investigating the consequences of bank capital shocks under a common monetary policy and a common shock process, we ask what consequences would be predicted by the different models. Thus, the scenario assumes model-specific policy rules and model-specific bank capital shock processes.

Fig. 25 displays simulation outcomes of a shock that reduces bank net worth.[y] In all models, the decrease in bank net worth in the presence of a constraint on bank leverage leads to a decline in lending, which in turn reduces investment and output. However, in the NK_GK11 model, investment and output recover relatively quickly from the decrease, whereas in the EA_GNSS10 and NK_MM10 models, they decline for some time.

[x] The autocorrelation coefficients are as follows: 0.95 (EA_GNSS10), 0.9 (NK_MM10), and 0 (NK_GK11). Gerali et al. (2010) set the parameter to 0.95 for this simulation exercise, although the median of the posterior distribution for this parameter is 0.81.

[y] To perform these simulations, we use replication files for each model.

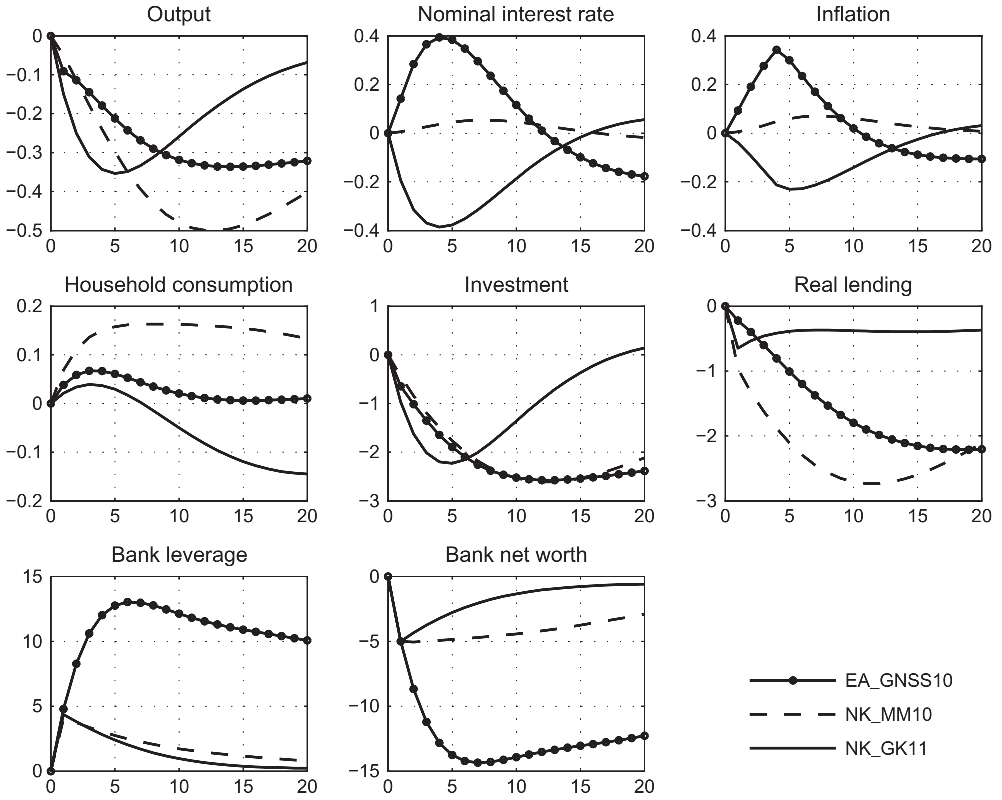

Fig. 25 Impulse responses to a negative shock to bank net worth. *Notes*: Horizontal axis represents quarters after the shock. Units of the vertical axis are percentage deviations from steady-state values. Inflation is the rate of inflation over the previous four quarters. Nominal interest rate is annualized. Other variables are expressed in quarterly terms.

The transmission and propagation channels differ across models. In NK_GK11, the financial accelerator mechanism applies to the bank. Since bank net worth declines, financing conditions get tighter. Correspondingly, bank lending goes down, external finance premia rise sharply, and aggregate investment declines. As to the speed of return to steady-state conditions, the main reason for a faster rebound of investment is the absence of serial correlation in the bank capital shock. Household consumption increases somewhat following the one-time redistribution from the bank but declines steadily afterwards.

In EA_GNSS10, banks reduce credit supply and increase the lending rates in order to repair their balance sheets after a shortfall in bank net worth. It also depresses demand for loans via the collateral channel. As a result, investment declines. Since bank interest rates adjust only in a sticky fashion, tight financing conditions persist for several periods, depressing investment further. The decline in bank net worth is persistent. This is due to the endogenous decline of bank retained earnings as well as the exogenous persistence of the shock process. Meanwhile, household consumption slightly increases mainly due to higher wages.

In NK_MM10, the financial contract imposes a solvency condition on banks that determines banks' ability to attract funds for lending. Therefore, in response to an unanticipated fall in bank net worth, banks' ability to attract funds deteriorates and they reduce lending. The decline in loan supply depresses investment, which lowers the retained earnings of banks and therefore bank net worth, reinforcing the initial shock endogenously. However, household consumption increases. The reason is that capital prices (not shown) increase in response to the shock, which in turn leads households to consume more as consumption goods become cheaper relative to capital goods.

With regard to output and inflation, the bank net worth shock appears to act as a negative demand shock in NK_GK11, where output and inflation decrease and call for monetary easing. By contrast, the shock acts as a negative supply shock in NK_MM10 and EA_GNSS10, where contraction in output is accompanied by modest inflationary pressures calling for some monetary tightening.

7. HOW TO ASSESS POLICY ROBUSTNESS: AN ILLUSTRATIVE EXAMPLE

Finally, we close the series of comparative exercises with an example of how one can evaluate the robustness of policy rules under model uncertainty. The idea is simple: A policy rule is more robust than another one, if it performs better, on average, across a range of models. The search for robustness has been a central objective for many contributions to the literature on model comparison (see Section 2). Here, we just illustrate how the MMB software can be employed to this end.

The global financial crisis has been preceded by a massive credit-driven real-estate boom in the United States and other economies. If central banks had responded earlier by raising interest rates, they might have been able to avoid excessive credit growth and housing price inflation. The Taylor rule, for example, would have recommended higher interest rates ahead of the crisis. The models with financial frictions include mechanisms that can explain such credit-driven booms. Thus, it is of interest to evaluate what rules perform better and whether it might be advantageous to "lean against the wind," that is, to include an explicit reaction to credit growth into the policy rule.

7.1 Participating Models and Rules

In this exercise, policy performance is evaluated across four different models with financial frictions that have been estimated for the U.S. economy and have appeared in the preceding sections: the US_DG08, US_CMR14, US_IAC05 and US_IN10 models. We consider eight simple monetary policy rules (see Table 11). These include the four model-specific rules that were estimated along with the respective macro-financial

Table 11 Eight interest rate rules

Model-specific rules	
DG08 rule	$i_t^z = 0.90 i_{t-1}^z + 0.23 p_t^z - 0.08 p_{t-1}^z + 1.14 q_t^z - 1.10 q_{t-1}^z$
IAC05 rule	$i_t^z = 0.73 i_{t-1}^z + 0.34 p_{t-1}^z + 0.14 y_{t-1}^z$
IN10 rule	$i_t^z = 0.60 i_{t-1}^z + 0.56 p_t^z + 0.82 y_t^z - 0.82 y_{t-1}^z$
CMR14 rule	$i_t^z = 0.85 i_{t-1}^z + 0.36 p_t^z + 0.05 y_t^z - 0.05 y_{t-1}^z$
Other simple rules	
Taylor rule	$i_t^z = 1.5 \pi_t^z + 0.50 q_t^z$
SW rule	$i_t^z = 0.81 i_{t-1}^z + 0.39 p_t^z + 0.97 q_t^z - 0.90 q_{t-1}^z$
OW08 rule	$i_t^z = 2.34 E_t \pi_{t+3}^z + 0.765 E_t q_{t+3}^z$
DIF rule	$i_t^z = i_{t-1}^z + 0.5 \pi_t^z + 0.5 (q_t^z - q_{t-4}^z)$

Note: The superscript z refers to common variables. i_t^z is the annualized short-term federal funds rate in quarter t. p_t^z refers to the annualized quarter-to-quarter rate of inflation, π_t^z is the year-on-year inflation rate, y_t^z is the deviation of quarterly real GDP from its long-run potential, while q_t^z refers to the output gap defined as the difference between actual GDP and the level of GDP that would be realized if prices and wages were flexible. All variables are expressed in percentage deviations from steady-state values.

model, that is, the DG08, CMR14, IAC05, and IN10 rules. They will be compared to four other simple rules: the well-known Taylor rule (see Taylor, 1993a); the SW rule; a forecast-based rule that was estimated to fit FOMC decisions in response to FOMC forecasts with real-time data by Orphanides and Wieland (2008) (OW08 rule); and a simple difference rule that performed very well in the studies of policy robustness by Levin et al. (2003) and Orphanides and Wieland (2013). The latter is referred to as the DIF rule.

7.1.1 Stabilization Performance and Robustness

A simple central bank loss function serves as a measure of performance. It is the sum of the unconditional variance of inflation deviations from the central bank's target and the unconditional variance of the output gap. Both variances are standard simulation output in MMB.

$$L = Var(\pi_t^z) + Var(q_t^z) \tag{13}$$

The resulting losses are reported in Table 12. The first row shows the losses under the model-specific rules in the respective models. The second row indicates the performance of one of them, the CMR14 rule, in all four models. Performance deteriorates in US_DG08 and US_IAC05 while it improves in US_IN10 relative to the model-specific estimated rule. The Taylor rule delivers much more stable outcomes than any of the rules estimated with the four macro-financial models. Average loss is much lower than under the CMR14 rule. The SW rule performs a little worse than Taylor's rule in US_DG08 but improves outcomes in the other three models even further.

Table 12 Stabilization performance and robustness

	US_DG08	US_CMR14	US_IAC05	US_IN10	Average loss
Model-specific rule	5.8	47.6	12.3	6.9	–
CMR14 rule	9.1	47.6	20.4	3.0	20.0
Taylor rule	5.3	34.5	6.2	4.3	12.5
SW rule	5.7	19.6	5.1	3.3	8.3
OW08 rule	4.6	29.3	∞	3.0	∞
DIF rule	2.7	5.5	3.3	2.6	3.6

Notes: The loss function is the sum of the unconditional variances of inflation and output gap. ∞ indicates indeterminacy.

The rule estimated on FOMC forecasts lacks robustness (OW08 rule). While it further improves performance in the US_DG08 model and US_IN10 model, losses in US_CMR14 deteriorate and it causes instability and multiple equilibria in US_IAC05. Finally, the DIF rule performs best in each of the four models and, thus, also on average.

7.1.2 Leaning Against Credit Growth

Next, we investigate whether it helps to add an explicit reaction to credit growth to the rules. The reaction coefficient on the quarterly growth rate of credit in real terms[z] takes on one of two values: 0.1 and 0.3.

Table 13 reports on the effectiveness of such a leaning-against-the-wind policy. Indeed, it helps adding a direct reaction to credit growth to the model-specific estimated rules in US_DG08, US_CMR14, US_IAC05. With a reaction coefficient of 0.1 they outperform the original model-specific rules. In US_IN10, however, leaning against credit growth does not improve the stabilization performance of the baseline rule. In US_CMR14 and US_IAC05, a stronger reaction to credit growth (0.3) further reduces loss, whereas in US_DG08 and US_IN10 the loss increases again.

For the SW rule, at least some leaning against credit growth is beneficial in the US_DG08, US_CMR14, and US_IN10 models, but not in US_IAC05. In case of the DIF rule, which is already very effective in stabilizing output and inflation in any of the four models, leaning against credit growth is destabilizing, except with the US_CMR14 model.

These results suggest that some degree of leaning against credit growth can help reduce output and inflation variability. Yet, the possibility of improvement depends on the baseline rule and the particular model. If the baseline rule without credit growth is already fairly robust, "leaning against the wind" is more likely to hurt performance.

As a next step, it would be of great interest to employ techniques for model-averaging and worst-case analysis to search for robust rules within a larger set of macro-financial

[z] As the model-specific rule in US_IAC05 reacts to lagged outcomes, a lagged credit growth rate is considered for this rule. In other cases, contemporaneous credit growth is used.

Table 13 Stabilization performance of policy rules with leaning-against-the-wind (credit growth)

	US_DG08	US_CMR14	US_IAC05	US_IN10
Model-specific rule				
Baseline	5.8	47.6	12.3	6.9
Leaning (0.1)	5.3	28.8	11.4	7.0
Leaning (0.3)	6.1	19.8	11.3	7.8
SW rule				
Baseline	5.7	19.4	5.1	3.3
Leaning (0.1)	4.9	13.1	5.3	3.1
Leaning (0.3)	4.7	8.4	6.7	3.7
DIF rule				
Baseline	2.7	5.5	3.3	2.6
Leaning (0.1)	2.8	4.7	3.9	2.7
Leaning (0.3)	3.5	5.2	5.0	3.3

Notes: the loss function includes the variance of inflation and the variance of the output gap.

models. Such a search could make use of optimization procedures from earlier work on policy robustness under model uncertainty (see Section 2).

8. CRITICAL ASSESSMENT AND OUTLOOK

While there is a limited set of macroeconomic time series and country experiences, there is a multitude of macroeconomic models, and their number is growing rapidly. This is as much due to economists' creativity as to the great challenges faced by policy makers, for which they need advice and guidance based on more adequate models. There are many urgent policy questions. For example, economists need to obtain a better understanding of the macroeconomic consequences and interactions of banking regulation, private and public debt, fiscal consolidation, macroprudential policies and structural reforms. Furthermore, globalization and growth have created a demand for economic modeling expertise in many countries around the world. While academic research in macroeconomics largely focuses on the United States, Europe, and Japan, central banks and government institutions in many other countries need models that are more appropriate for analyzing their economies.

At the same time, much effort is invested in building models that will never be used by anyone else. Rather than building directly on work by others, researchers usually start from scratch. Practices that would ensure easy reproducibility are not widespread. There is little systematic comparison of existing models.

This need not be the case. There has been tremendous progress with regard to model design, model solution techniques, econometric estimation procedures and software solutions. Many researchers are using those same techniques. While model comparison was extremely cumbersome in the past, a task reserved for meetings of teams of modelers from policy institutions, it can now be accomplished fairly easily by individual researchers. As this chapter aimed to show, comparative model analysis helps critically assessing available models, identifying similarities and differences as well as empirical inconsistencies that require more research.

The potential for comparative work has barely been tapped. Going forward, key areas for more methodological work that could rapidly bear fruit are the following: comparisons of the role of expectations formation, learning and heterogeneity; model validation and real-time estimation of competing macroeconomic models; combining statistical nowcasting techniques with model-based forecasting for the medium term; and implementation of nonlinear solution techniques for occasionally binding constraints.

Another important aspect concerns openness to competing modeling paradigms. Despite many critical assessments of the DSGE approach and its microeconomic foundations in the aftermath of the global financial crisis, DSGE modeling remains by far the most productive branch of macroeconomic modeling at this time. It takes on board elements from behavioral economics and other fields. Model comparison techniques help create standards that make it possible to compare models based on different paradigms. Thus, they support a more pluralistic yet rigorous approach to research in macroeconomics.

ACKNOWLEDGMENTS

The chapter has benefited from helpful discussions with and comments by Thorsten Drautzburg, Simon Gilchrist, Johannes Pfeifer, John B. Taylor, Harald Uhlig, as well as participants at the Handbook of Macroeconomics Conference in Chicago, the Macrofinancial Modeling Winter Meeting 2015 of the Becker Friedman Institute in New York, MACFINROBODS Annual Conference in Paris, the 10th Workshop on Macroeconomics and the Business Cycle at the Ifo Institute in Dresden, and AEA Meetings in San Francisco. Abstract

There has been considerable progress in developing macroeconomic models of banking crises. However, most of this literature focuses on the retail sector where banks obtain deposits from households. In fact, the recent financial crisis that triggered the Great Recession featured a disruption of wholesale funding markets, where banks lend to one another. Accordingly, to understand the financial crisis as well as to draw policy implications, it is essential to capture the role of wholesale banking. The objective of this chapter is to characterize a model that can be seen as a natural extension of the existing literature, but in which the analysis is focused on wholesale funding markets. The model accounts for both the buildup and collapse of wholesale banking and also sketches out the transmission of the crises to the real sector. We also draw out the implications of possible instability in the wholesale banking sector for lender-of-last resort policy as well as for macroprudential policy.

1. INTRODUCTION

One of the central challenges for contemporary macroeconomics is adapting the core models to account for why the recent financial crisis occurred and for why it then devolved into the worst recession of the postwar period. On the eve of the crisis, the basic workhorse quantitative models used in practice largely abstracted from financial market frictions. These models were thus largely silent on how the crisis broke out and how the vast array of unconventional policy interventions undertaken by the Federal Reserve and Treasury could have worked to mitigate the effects of the financial turmoil. Similarly, these models could not provide guidance for the regulatory adjustments needed to avoid another calamity.[a]

From the start of the crisis there has been an explosion of literature aimed at meeting this challenge. Much of the early wave of this literature builds on the financial accelerator and credit cycle framework developed in Bernanke and Gertler (1989) and Kiyotaki and Moore (1997). This approach stresses the role of balance sheets in constraining borrower spending in a setting with financial market frictions. Procyclical movement in balance sheet strength amplifies spending fluctuations and thus fluctuations in aggregate economic activity. A feedback loop emerges as conditions in the real economy affect the condition of balance sheets and vice-versa. Critical to this mechanism is the role of leverage: The exposure of balance sheets to systemic risk is increasing in the degree of borrower leverage.

[a] For a description of the causes leading to the recent financial crisis see Bernanke (2010).

The new vintage of macroeconomic models with financial frictions makes progress in two directions: First, it adapts the framework to account for the distinctive features of the current crisis. In particular, during the recent crisis, it was highly leveraged financial institutions along with highly leveraged households that were most immediately vulnerable to financial distress.[b] The conventional literature featured balance sheet constraints on nonfinancial firms. Accordingly, a number of recent macroeconomic models have introduced balance sheet constraints on banks, while others have done so for households.[c] The financial accelerator remains operative, but the classes of agents most directly affected by the financial market disruption differ from earlier work.

Another direction has involved improving the way financial crises are modeled. For example, financial crises are inherently nonlinear events, often featuring a simultaneous sudden collapse in asset prices and rise in credit spreads.[d] A sharp collapse in output typically ensues. Then recovery occurs only slowly, as it is impeded by a slow process of deleveraging. A number of papers have captured this nonlinearity by allowing for the possibility that the balance sheet constraints do not always bind.[e] Financial crises are then periods where the constraints bind, causing an abrupt contraction in economic activity. Another approach to handling the nonlinearity is to allow for bank runs.[f] Indeed, runs on the shadow banking system were a salient feature of the crisis, culminating with the collapse in September 2008 of Lehman Brothers, of some major money market funds and ultimately of the entire investment banking sector. Yet another literature captures the nonlinearity inherent in financial crises by modeling network interactions (see, eg, Garleanu et al., 2015).

One area the macroeconomics literature has yet to address adequately is the distinctive role of the wholesale banking sector in the breakdown of the financial system. Our notion of wholesale banks corresponds roughly, though not exactly, to the shadow banking sector on the eve of the 2007–09 financial crisis. Shadow banking includes all financial intermediaries that operated outside the Federal Reserve's regulatory framework. By wholesale banking, we mean the subset that (i) was highly leveraged, often with

[b] To be sure, the financial distress also directly affected the behavior of nonfinancial firms. See Giroud and Mueller (2015) for evidence of firm balance sheet effects on employment during the crisis.

[c] See Gertler and Karadi (2011), Gertler and Kiyotaki (2010), and Curdia and Woodford (2010) for papers that incorporate banking and Iacoviello (2005), Eggertsson and Krugman (2012), Guerrieri and Lorenzoni (2011), and Midrigan and Philippon (2011) for papers that included household debt.

[d] See He and Krishnamurthy (2014) for evidence in support of the nonlinearity of financial crises.

[e] See Brunnermeier and Sannikov (2014), He and Krishnamurthy (2013), He and Krishnamurthy (2014), and Mendoza (2010).

[f] For the seminal contribution on bank runs see Diamond and Dybvig (1983). Some recent examples of macroeconomic models that consider bank runs include Gertler and Kiyotaki (2015), Ferrante (2015a), Robatto (2014), Martin et al (2014), Angeloni and Faia (2013) and Ennis and Keister (2003). See Boissay, Collard, and Smets (2013) for an alternative way to model banking crises that does not involve runs per se. For other related literature see Allen and Gale (2007), Cooper and Ross (1998), Farmer (1999), Holmstrom and Tirole (2011) and the references within.

short-term debt and (ii) relied heavily on borrowing from other financial institutions in "wholesale" markets, as opposed to borrowing from households in "retail" markets for bank credit.

When the crisis hit, the epicenter featured malfunctioning of the wholesale banking sector. Indeed, retail markets remained relatively stable while wholesale funding markets experienced dry-ups and runs. By contrast, much of the macroeconomic modeling of banking features traditional retail banking. In this respect, it misses some important dimensions of both the run-up to the crisis and how exactly the crisis played out. In addition, by omitting wholesale banking, the literature may be missing some important considerations for regulatory design.

In this Handbook chapter, we present a simple canonical macroeconomic model of banking crises that (i) is representative of the existing literature and (ii) extends this literature to feature a role for wholesale banking. The model will provide some insight both into the growth of wholesale banking and into how this growth led to a build-up of financial vulnerabilities that ultimately led to a collapse. Because the model builds on existing literature, our exposition of the framework will permit us to review the progress that is made. However, by turning attention to wholesale banks and wholesale funding markets, we are able to chart a direction we believe the literature should take.

In particular, the model is an extension of the framework developed in Gertler and Kiyotaki (2011), which had a similar twofold objective: first, present a canonical framework to review progress that has been made and, second, chart a new direction. That paper characterized how existing financial accelerator models that featured firm level balance sheet constraints could be extended to banking relationships in order to capture the disruption of banking during the crisis. The model developed there considered only retail banks which funded loans mainly from household deposits. While it allowed for an interbank market for credit among retail banks, it did not feature banks that relied primarily on wholesale funding, as was the case with shadow banks.

For this Handbook chapter, we modify the Gertler and Kiyotaki framework to incorporate wholesale banking alongside retail banking, where the amount credit intermediated via wholesale funding markets arises endogenously. Another important difference is that we allow for the possibility of runs on wholesale banks. We argue that both these modifications improve the ability of macroeconomic models to capture how the crisis evolved. They also provide insight into how the financial vulnerabilities built up in the first place.

As way to motivate our emphasis on wholesale banking, Section 1 presents descriptive evidence on the growth of this sector and the collapse it experienced during the Great Recession. Section 3 presents the baseline macroeconomic model with banking, where a wholesale banking sector arises endogenously. Sector 4 conducts a set of numerical experiments. While the increased size of the wholesale banking improves the efficiency of financial intermediation, it also raises the vulnerability of this sector to runs. Section 5 considers the case where runs in the wholesale sector might be anticipated. It illustrates how the model can capture some of the key phases of the financial collapse, including the slow run period up to Lehman and the ultimate "fast run" collapse. In Section 6, we introduce a second asset in which retail banks have a comparative advantage in intermediating. We then show how a crisis in wholesale banking can spill over and affect retail banking, consistent with what happened during the crisis. Section 7 analyzes government policy to contain financial crises, including both ex-post lender of last resort activity and ex-ante macroprudential regulation. Finally, we conclude in Section 8 with some directions for future research.

2. THE GROWTH AND FRAGILITY OF WHOLESALE BANKING

In this section, we provide some background motivation for the canonical macroeconomic model with wholesale funding markets that we develop in the following section. We do so by presenting a brief description of the growth and ultimate collapse of wholesale funding markets during the Great Recession. We also describe informally how the disruption of these markets contributed to the contraction of the real economy.

Fig. 1 illustrates how we consider the different roles of retail and wholesale financial intermediaries, following the tradition of Gurley and Shaw (1960).[g] The arrows indicate

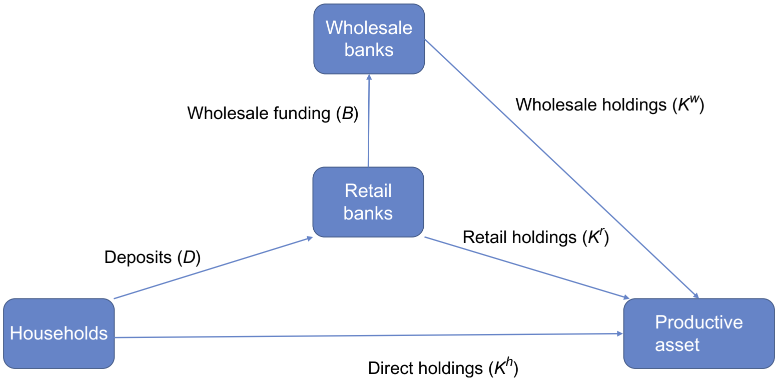

Fig. 1 Modes of financial intermediation.

[g] Gurley and Shaw (1960) consider that there are two ways to transfer funds from ultimate lenders (with surplus funds) to ultimate borrowers (who need external funds to finance expenditure): direct and indirect finance. In direct finance, ultimate borrowers sell their securities directly to ultimate lenders to raise funds. In indirect finance, financial intermediaries sell their own securities to raise funds from ultimate lenders in order to buy securities from ultimate borrowers. By doing so, financial intermediaries transform relatively risky, illiquid, and long maturity securities of ultimate borrowers into relatively safe, liquid, and short maturity securities of intermediaries. Here, we divide financial intermediaries into wholesale and retail financial intermediaries, while both involve asset transformation of risk, liquidity, and maturity. We refer to intermediaries as "banks" and to ultimate lenders as "households" for short.

the direction that credit is flowing. Funds can flow from households (ultimate lenders) to nonfinancial borrowers (ultimate borrowers) through three different paths: they can be lent directly from households to borrowers $\left(K^h\right)$; they can be intermediated by retail banks that raise deposits (D) from households and use them to make loans to nonfinancial borrowers $\left(K^r\right)$; alternatively, lenders' deposits can be further intermediated by specialized financial institutions that raise funds from retail banks in wholesale funding markets (B) and, in turn, make loans to ultimate borrowers $\left(K^w\right)$. In what follows we refer to these specialized financial institutions as wholesale banks. We think of wholesale banks as highly leveraged shadow banks that rely heavily on credit from other financial institutions, particularly short-term credit. We place in this category institutions that financed long-term assets, such as mortgaged back securities, with short-term money market instruments, including commercial paper and repurchase agreements. Examples of these kinds of financial institutions are investment banks, hedge funds, and conduits. We focus attention on institutions that relied heavily on short-term funding in wholesale markets to finance longer term assets because it was primarily these kinds of entities that experienced financial turmoil.

Our retail banking sector, in turn, includes financial institutions that rely mainly on household saving for external funding and provide a significant amount of short-term financing to the wholesale banks. Here, we have in mind commercial banks, money market funds, and mutual funds that raised funds mainly from households and on net provided financing to wholesale banks.

Fig. 1 treats wholesale banking as if it is homogenous. In order to understand how the crisis spread, it is useful to point out that there are different layers within the wholesale banking sector. While the intermediation process was rather complex, conceptually we can reduce the number of layers to three basic ones: (1) origination, (2) securitization, (3)

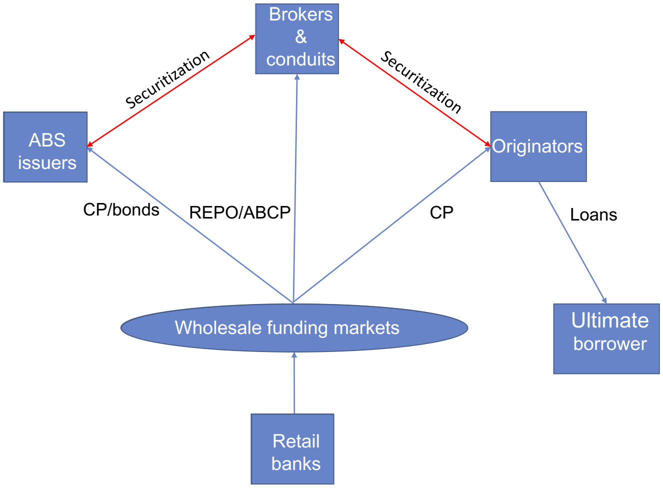

Fig. 2 Wholesale intermediation.

and funding. Fig. 2 illustrates the chain. First there are "loan originators," such as mortgage origination companies and finance companies, that made loans directly to nonfinancial borrowers. At the other end of the chain were shadow banks that held securitized pools of the loans made by originators. In between were brokers and conduits that assisted in the securitization process and provided market liquidity. Dominant in this group were the major investment banks (eg, Goldman Sachs, Morgan Stanley, and Lehman Brothers). Each of these layers relied on short-term funding, including commercial paper, asset-backed commercial paper and repurchase agreements. While there was considerable interbank lending among wholesale banks, retail banks (particularly money market funds) on net provided short-term credit in wholesale credit markets.

We next describe a set of facts about wholesale banking. We emphasize three sets of facts in particular: (1) wholesale banking grew in relative importance over the last four decades, (2) leading up to the crisis wholesale banks were highly exposed to systemic risk because they were highly leveraged and relied heavily on short-term debt, and (3) the subsequent disruption of wholesale funding markets raised credit costs and contracted credit flows, likely contributing in a major way to the Great Recession.

1. *Growth in Wholesale Banking*

We now present measures of the scale of wholesale banking relative to retail banking as well as to household's direct asset holdings. Table 1 describes how we construct measures of assets held by wholesale vs retail banks. In particular, it lists how we categorized the various types of financial intermediaries into wholesale vs retail banking.[h,i] As the table

Table 1 Wholesale and Retail sector in the Flow of Funds

Retail sector	Private depository institutions Money market mutual funds Mutual funds	
Wholesale sector	*Origination*	Finance companies Real estate investment trusts Government sponsored enterprises
	Securitization	Security brokers dealers ABS issuers
	Funding	GSE mortgage pools Funding corporations Holding companies

[h] Appendix D provides details about measurement of the time series shown in this section from Flow of Funds data.

[i] It is important to notice that the measures we report are broadly in line with analogous measures computed for shadow banking. See, eg, Adrian and Ashcraft (2012), for an alternative definition of shadow banking that yields very similar conclusions and Pozsar et al. (2013), for a detailed description of shadow banking.

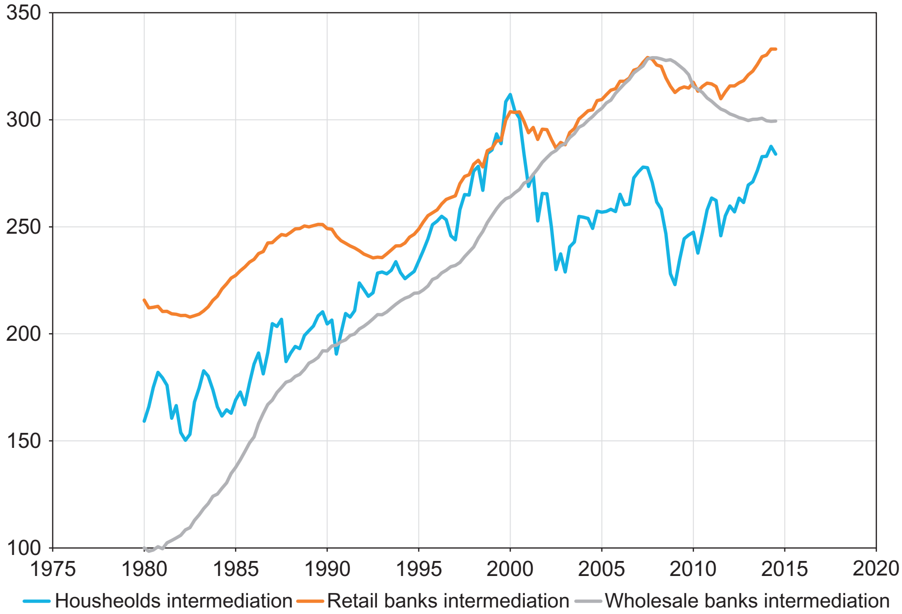

Fig. 3 Intermediation by sector. The graph shows the evolution of credit intermediated by the three different sectors. Nominal data from the Flow of Funds are deflated using the CPI and normalized so that the log of the normalized value of real wholesale intermediation in 1980 is equal to 1. The resulting time series are then multiplied by 100.

indicates, the wholesale banking sector aggregates financial institutions that originate loans, that help securitize them and that ultimately fund them. A common feature of all these institutions, though, is that they relied heavily on short-term credit in wholesale funding markets.

Fig. 3 portrays the log level of credit to nonfinancial sector provided by wholesale banks, by retail banks, and directly by households from the early 1980s until the present.[j] The figure shows the rapid increase in wholesale banking relative to the other means of credit supply to nonfinancial sector. Wholesale banks went from holding under 15% of total credit in the early 1980s to roughly 40% on the eve of the Great Recession, an amount on par with credit provided by retail banks.

Two factors were likely key to the growth of wholesale banking. The first is regulatory arbitrage. Increased capital requirements on commercial banks raised the incentive to transfer asset holding outside the commercial bank system. Second, financial innovation improved the liquidity of wholesale funding markets. The securitization process in particular improved the (perceived) safety of loans by diversifying idiosyncratic risks as

[j] The measure we present also include nonfinancial corporate equities. Excluding equities, households would become negligible but the relative size of wholesale and retail banks would evolve very similarly. See Appendix D for details on how we construct the measures reported.

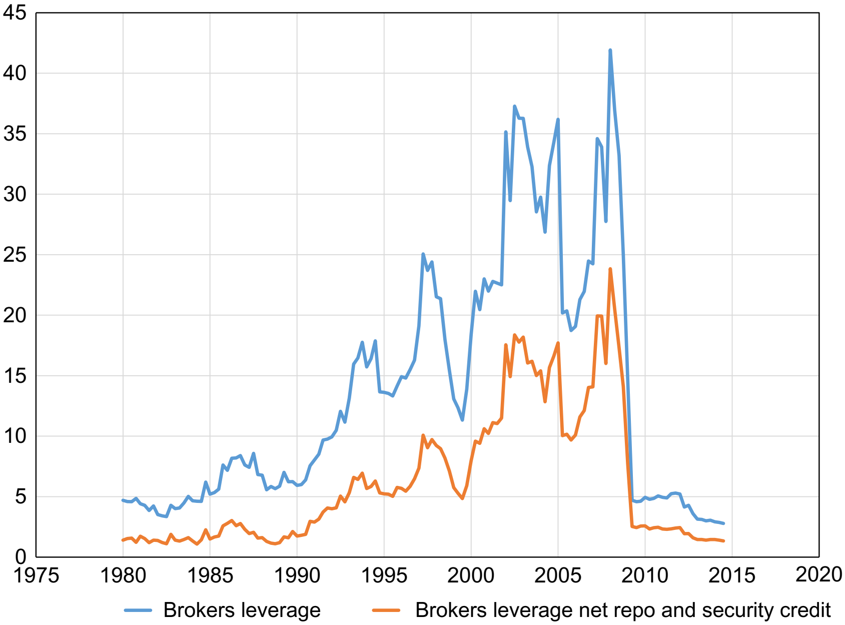

Fig. 4 Brokers leverage. Leverage is given by the ratio of total financial assets over equity. Equity is computed from the Flow of Funds by subtracting total financial liabilities from total financial assets. The net position leverage computes assets by netting out long and short positions in REPO and Security Credit. See the Appendices for details.

well as by enhancing the liquidity of secondary markets for bank assets. The net effect was to raise the borrowing capacity of the overall financial intermediary sector.

2. *Growth in Leverage and Short-Term Debt in Wholesale Banking*

Wholesale banking not only grew rapidly, it also became increasingly vulnerable to systemic disturbances. Fig. 4 presents evidence on the growth in leverage in the investment banking sector. Specifically it plots the aggregate leverage multiple for broker dealers (primarily investment banks) from 1980 to the present. We define the leverage multiple as the ratio of total assets held to equity.[k] The greater is the leverage multiple, the higher is the reliance on debt finance relative to equity. The key takeaway from Fig. 4 is that the leverage multiple grew from under five in the early 1980s to over forty at the beginning of the Great Recession, a nearly tenfold increase.

Arguably, the way securitization contributed to the overall growth of wholesale banking was by facilitating the use of leverage. By constructing assets that appeared safe and liquid, securitization permitted wholesale banks to fund these assets by issuing debt.

[k] The data is from the Flow of Funds and equity is measured by book value. We exclude nonfinancial assets from measurement as they are not reported in the Flow of Funds.

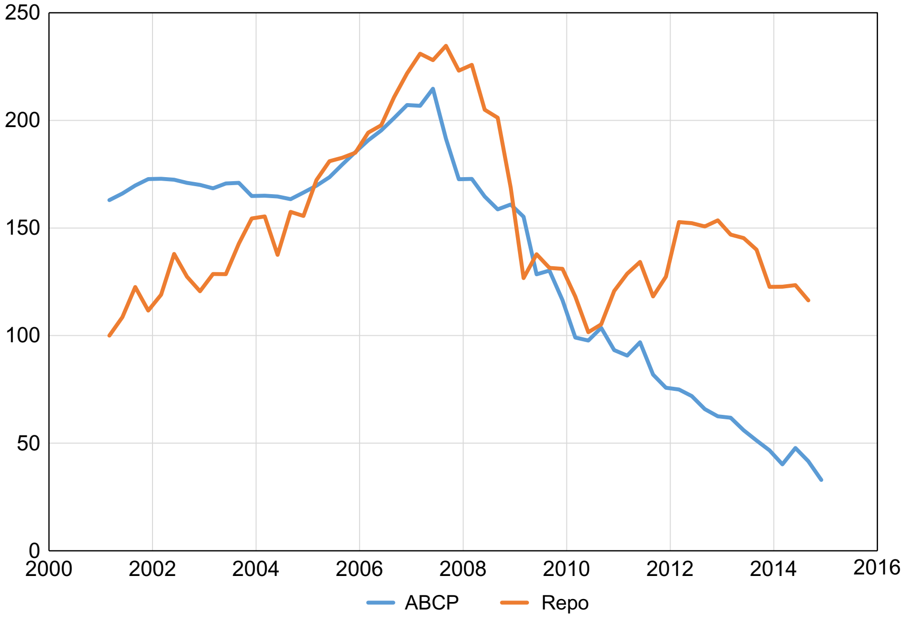

Fig. 5 Short-term wholesale funding. The graph shows the logarithm of the real value outstanding. Nominal values from Flow of Funds are deflated using the CPI.

At a minimum debt finance had the advantage of being cheaper due to the tax treatment. Debt financing was also cheaper to the extent the liabilities were liquid and thus offered a lower rate due to a liquidity premium.

Why were these assets funded in wholesale markets as opposed to retail markets? The sophistication of these assets required that creditors be highly informed to evaluate payoffs, especially given the absence of deposit insurance. The complicated asset payoff structure also suggests that having a close working relationship with borrowers is advantageous. It served to reduce the possibility of any kind of financial malfeasance. Given these considerations, it makes sense that wholesale banks obtain funding in interbank markets. In these markets lenders are sophisticated financial institutions as opposed to relatively unsophisticated households in the retail market.

Fig. 5 shows that much of the growth in leverage in wholesale banking involved short-term borrowing. The figure plots the levels of asset backed commercial paper (ABCP) and repurchase agreements (Repo). This growth reflected partly the growth in assets held by wholesale banks and partly innovation in loan securitization that made maturity transformation by wholesale banks more efficient. Also relevant, however, was a shift in retail investors demand from longer term security tranches towards short-term credit instruments as the initial fall in housing prices in 2006 raised concerns about the quality of existing securitized assets.[l,m] As we discuss next, the combination of high leverage and short-term debt is what made the wholesale banking system extremely fragile.

3. *The Crisis: The Unraveling of Wholesale Bank Funding Markets*

The losses suffered by mortgage originators due to falling housing prices in 2006 eventually created strains in wholesale funding markets. Short-term wholesale funding markets started experiencing severe turbulence in the summer of 2007. In July 2007 two Bear Sterns investment funds that had invested in subprime related products declared bankruptcy. Shortly after, BNP Paribas had to suspend withdrawals from investment funds with similar exposure. These two episodes led investors to reassess the risks associated with the collateral backing commercial paper offered by asset backed securities issuers. In August 2007 a steady contraction of Asset Backed Commercial Paper (ABCP) market began, something akin to a "slow run," in Bernanke's terminology.[n] The value of Asset Backed Commercial Paper outstanding went from a peak of 1.2 trillion dollars in July 2007 to 800 billion dollars in December of the same year and continued its descent to its current level of around 200 billion dollars.

The second significant wave of distress to hit wholesale funding markets featured the collapse of Lehman Brothers in September of 2008. Losses on short-term debt instruments issued by Lehman Brothers led the Reserve Primary Fund, a large Money Market Mutual Fund (MMMF), to "break the buck": the market value of assets fell below the value of its noncontingent liabilities. An incipient run on MMMFs was averted only by the extension of Deposit Insurance to these types of institutions. Wholesale investors,[o] however, reacted by pulling out of the Repo market, switching off the main source of funding for Security Broker Dealers. Fig. 5 shows the sharp collapse in repo financing around the time of the Lehman collapse. Indeed if the first wave of distress hitting the ABCP market had the features of a "slow run," the second, which led to the dissolution of the entire investment banking system had the features of a traditional "fast run." We emphasize that a distinctive feature of these two significant waves of financial distress is that they did not involve traditional banking institutions. In fact, the retail sector as a whole was shielded thanks to prompt government intervention that halted the run on

[l] See Brunnermeier and Oemke (2013) for a model in which investors prefer shorter maturities when release of information could lead them not to roll over debt.

[m] It is not easy to gather direct evidence on this from the aggregate composition of liabilities of wholesale banks since data from the Flow of Funds excludes the balance sheets of SIVs and CDOs from the ABS Issuers category. Our narrative is based on indirect evidence coming from ABX spreads as documented for example in Gorton (2009).

[n] Covitz et al. (2013) provide a detailed description of the run on ABCP programs in 2007. A very clear description of the role of commercial paper during the 2007–09 crisis is presented by Kacperczyk and Schnabl (2010).

[o] The poor quality of available data makes it difficult to exactly identify the identity of the investors running on Repo's. See Gorton and Metrick (2012) and Krishnamurthy et al. (2014).

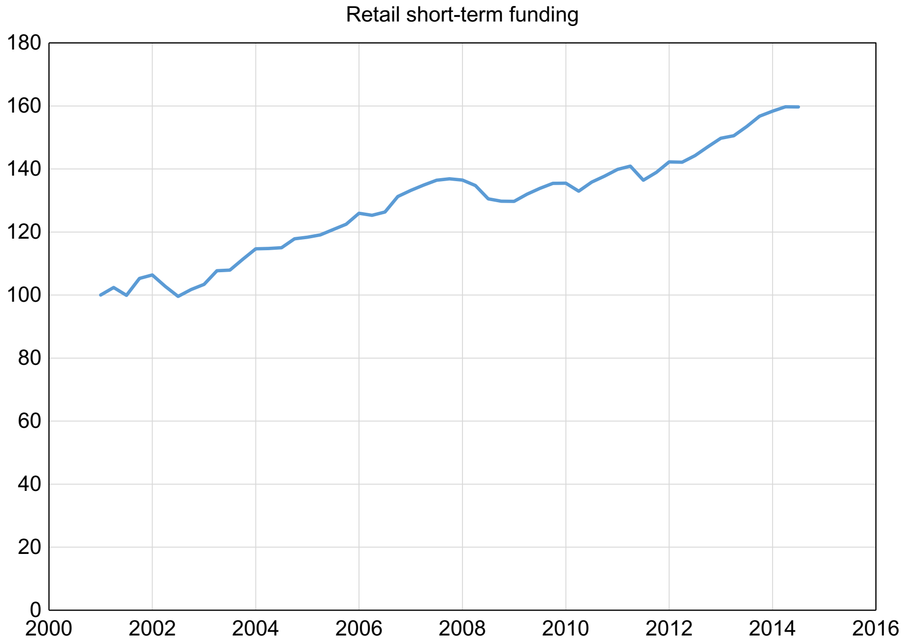

Fig. 6 Retail short-term funding. The graph shows the logarithm of the real value outstanding. Nominal values from Flow of Funds are deflated using the CPI and normalized so that the log of the normalized value of retail short-term funding in 2001 is equal to 100.

MMMFs in 2008 as well as the Troubled Asset Relief Program and other subsequent measures that supplemented the traditional safety net. In fact, total short-term liabilities of the retail sector were little affected overall (see Fig. 6). This allowed the retail banking sector to help absorb some of the intermediation previously performed by wholesale banks.

Despite the unprecedented nature and size of government intervention and the partial replacement of wholesale intermediation by retail bank lending, the distress in wholesale bank funding markets led to widespread deterioration in credit conditions. Fig. 7 plots the behavior of credit spreads and investment from 2004 to 2010. We focus on three representative credit spreads: (1) The spread between the 3 month ABCP rate and 3 month Treasury spread, (2) The financial company commercial paper spread, and (3) The Gilchrist and Zakrajsek (2012) excess bond premium. In each case, the spread is the difference between the respective rate on the private security and a similar maturity treasury security rate. The behavior of the spreads lines up with the waves of financial distress that we described. The ABCP spread jumps by 1.5% in August 2007, the beginning of the unraveling of this market. The increase in this spread implies a direct increase in credit costs for borrowing funded by ABCP including mortgages, car loans, and credit card

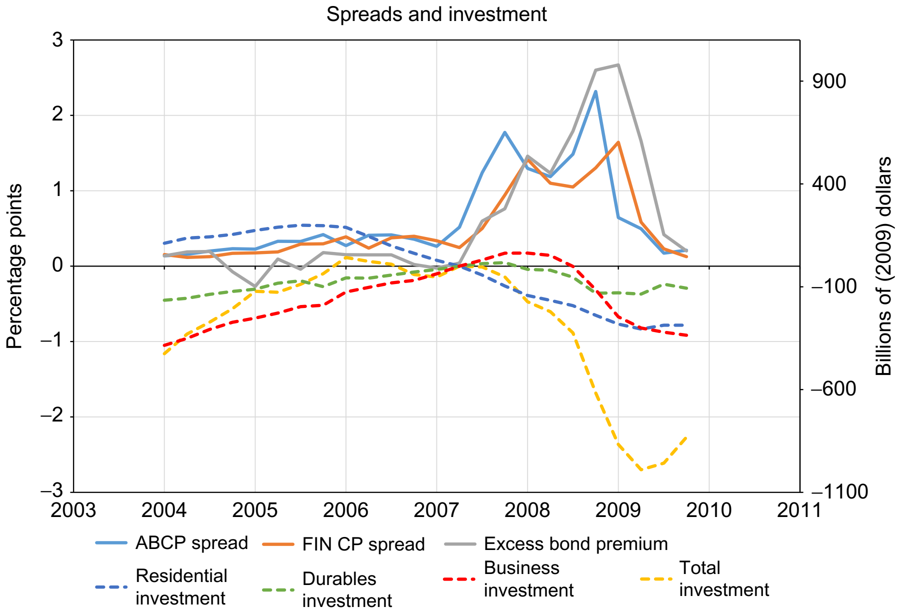

Fig. 7 Credit spreads and investment.

borrowing. As problems spread to broker dealers, the financial commercial paper spread increases reaching a peak at more than 1.5% at the time of the Lehman collapse. Increasing costs of credit for these intermediaries, in turn, helped fuel increasing borrowing costs for nonfinancial borrowers. The Gilchrist and Zakrajsek's corporate excess bond spread jumps more than 2.5% from early 2007 to the peak in late 2008.

It is reasonable to infer that the borrowing costs implied by the increased credit spreads contributed in an important way to the slowing of the economy at the onset of the recession in 2007:Q4, as well as to the sharp collapse following the Lehman failure. As shown in Fig. 7, the contraction in business investment, residential investment, durable consumption, and their sum-total investment, moves inversely with credit spreads.

In our view, there are three main conclusions to be drawn from the empirical evidence presented in this section. First, the wholesale banking sector grew into a very important component of financial intermediation by relying on securitization to reduce the risks of lending and expand the overall borrowing capacity of the financial system. Second, higher borrowing capacity came at the cost of increased fragility as high leverage made wholesale banks' net worth very sensitive to corrections in asset prices. Third, the disruptions in wholesale funding markets that took place in 2007 and 2008 seem to have played an important role in the unfolding of the Great Recession. These observations motivate our modeling approach below and our focus on interbank funding markets functioning and regulation.

3. BASIC MODEL

3.1 Key Features

Our starting point is the infinite horizon macroeconomic model with banking and bank runs developed in Gertler and Kiyotaki (2015). In order to study recent financial booms and crises, in this chapter we disaggregate banking into wholesale and retail banks. Wholesale banks make loans to the nonfinancial sector funded primarily by borrowing from retail banks. The latter use deposits from households to make loans both to the nonfinancial sector and to the wholesale financial sector. Further, the size of the wholesale banking market arises endogenously. It depends on two key factors: (1) the relative advantage wholesale banks have in managing assets over retail banks and (2) the relative advantage of retail banks over households in overcoming an agency friction that impedes lending to wholesale banks.[p]

In the previous section, we described the different layers of the wholesale sector, including origination, securitization, and funding. For tractability, in our model we consolidate these various functions into a single type of wholesale bank. Overall, our model permits capturing financial stress in wholesale funding markets which was a key feature of the recent financial crisis.

There are three classes of agents: households, retail banks, and wholesale banks. There are two goods, a nondurable good and a durable asset, "capital." Capital does not depreciate and the total supply of capital stock is fixed at $\bar{K}$. Wholesale and retail banks use borrowed funds and their own equity to finance the acquisition of capital. Households lend to banks and also hold capital directly. The sum of total holdings of capital by each type of agent equals the total supply which we normalize to unity:

$$K_t^w + K_t^r + K_t^h = \bar{K} = 1, \tag{1}$$

where K_t^w and K_t^r are the total capital held by wholesale and retail bankers and K_t^h is the amount held by households.

Agents of type j use capital and goods as inputs at t to produce output and capital at $t+1$, as follows:

$$\begin{array}{ccc} \textit{date } t & & \textit{date } t+1 \\ \left.\begin{array}{r} K_t^j \text{ capital} \\ F^j(K_t^j) \text{ goods} \end{array}\right\} & \rightarrow & \left\{\begin{array}{c} Z_{t+1}K_t^j \text{ output} \\ K_t^j \text{ capital} \end{array}\right. \end{array} \tag{2}$$

where type $j = w$, r, and h stands for wholesale banks, retail banks, and households, respectively. Expenditure in terms of goods at date t reflects the management cost of

[p] Our setup bears some resemblance to Holmstrom and Tirole (1997), which has nonfinancial firms that face costs in raising external funds from banks that in turn face costs in raising deposits from households. In our case, it is constrained wholesale banks that raise funds from constrained retail banks.

screening and monitoring investment projects. In the case of retail banks, the management costs might also reflect various regulatory constraints. We suppose this management cost is increasing and convex in the total amount of capital, as given by the following quadratic formulation:

$$F^j(K_t^j) = \frac{\alpha^j}{2}(K_t^j)^2. \tag{3}$$

In addition, we suppose the management cost is zero for wholesale banks and highest for households (holding constant the level of capital):

$$\alpha^w = 0 < \alpha^r < \alpha^h. \tag{Assumption 1}$$

This assumption implies that wholesale bankers have an advantage over the other agents in managing capital.[q] Retail banks in turn have a comparative advantage over households. Finally, the convex cost implies that it is increasingly costly at the margin for retail banks and households to absorb capital directly. As we will see, this cost formulation provides a simple way to limit agents with wealth but lack of expertise from purchasing assets during a firesale.

In our decentralization of the economy, a representative household provides capital management services both for itself and for retail banks. For the latter, the household charges retail banks a competitive price f_t^r per unit of capital managed, where f_t^r corresponds to the marginal cost of providing the service:

$$f_t^r = F^{r\prime}(K_t^r) = \alpha^r K_t^r. \tag{4}$$

Households obtain the profit from this activity $f_t^r K_t^r - F^r(K_t^r)$.

3.2 Households

Each household consumes and saves. Households save either by lending funds to bankers or by holding capital directly in the competitive market. They may deposit funds in either retail or wholesale banks. In addition to the returns on portfolio investments, every period each household receives an endowment of nondurable goods, $Z_t W^h$, that varies proportionately with the aggregate productivity shock Z_t.

Deposits held in a bank from t to $t+1$ are one period bonds that promise to pay the noncontingent gross rate of return $\bar{R}_{t+1}$ in the absence of a run by depositors. In the event of a deposit run, depositors only receive a fraction x_{t+1}^r of the promised return, where x_{t+1}^r

[q] In general, we have in mind that wholesale and retail banks specialize in different types of lending and, as a consequence, each has developed relative expertise in managing the type of assets they hold. We subsequently make this point clearer by introducing a second asset in which retail banks have a comparative advantage in intermediating. Also relevant are regulatory distortions, though we view this as a factor that leads to specialization in the first place.

is the total liquidation value of retail banks assets[r] per unit of promised deposit obligations. Accordingly, we can express the household's return on deposits, R_{t+1}, as follows:

$$R_{t+1} = \begin{cases} \bar{R}_{t+1} & \text{if no deposit run} \\ x^r_{t+1}\bar{R}_{t+1} & \text{if deposit run occurs} \end{cases} \tag{5}$$

where $0 \leq x^r_t < 1$. Note that if a deposit run occurs all depositors receive the same pro rata share of liquidated assets.

Household utility U_t is given by

$$U_t = E_t\left(\sum_{i=0}^{\infty}\beta^i \ln C^h_{t+i}\right)$$

where C^h_t is household consumption and $0 < \beta < 1$. Let Q_t be the market price of capital. The household then chooses consumption, bank deposits D_t and direct capital holdings K^h_t to maximize expected utility subject to the budget constraint

$$C^h_t + D_t + Q_t K^h_t + F^h(K^h_t) = Z_t W^h + R_t D_{t-1} + (Z_t + Q_t)K^h_{t-1} + f^r_t K^r_t - F^r(K^r_t). \tag{6}$$

Here, consumption, saving, and management costs are financed by the endowment, the returns on savings, and the profits from providing management services to retail bankers.

For pedagogical purposes, we begin with a baseline model where bank runs are completely unanticipated events. Accordingly, in this instance the household chooses consumption and saving with the expectation that the realized return on deposits, R_{t+i}, equals the promised return, $\bar{R}_{t+i}$, with certainty, and that asset prices, Q_{t+i}, are those at which capital is traded when no bank run happens. In a subsequent section, we characterize the case where agents anticipate that a bank run may occur with some likelihood.

Given that the household assigns probability zero to a bank run, the first order condition for deposits is given by

$$E_t(\Lambda_{t,t+1})R_{t+1} = 1 \tag{7}$$

where the stochastic discount factor $\Lambda_{t,\tau}$ satisfies

$$\Lambda_{t,\tau} = \beta^{\tau-t}\frac{C^h_t}{C^h_\tau}.$$

The first order condition for direct capital holdings is given by

$$E_t\left(\Lambda_{t,t+1}R^h_{kt+1}\right) = 1 \tag{8}$$

with

$$R^h_{kt+1} = \frac{Q_{t+1} + Z_{t+1}}{Q_t + F^{h\prime}(K^h_t)}$$

where $F^{h\prime}(K^h_t) = \alpha^h K^h_t$ and R^h_{t+1} is the household's gross marginal rate of return from direct capital holdings.

[r] Under our calibration only retail banks choose to issue deposits. See later.

3.3 Banks

There are two types of bankers, retail and wholesale. Each type manages a financial intermediary. Bankers fund capital investments (which we will refer to as "nonfinancial loans") by issuing deposits to households, borrowing from other banks in an interbank market and using their own equity, or net worth. Banks can also lend in the interbank market.

As we describe later, bankers may be vulnerable to runs in the interbank market. In this case, creditor banks suddenly decide to not rollover interbank loans. In the event of an interbank run, the creditor banks receive a fraction x_{t+1}^{w} of the promised return on the interbank credit, where x_{t+1}^{w} is the total liquidation value of debtor bank assets per unit of debt obligations. Accordingly, we can express the creditor bank's return on interbank loans, R_{bt+1}, as follows:

$$R_{bt+1} = \begin{cases} \bar{R}_{bt+1} & \text{if no interbank run} \\ x_{t+1}^{w}\bar{R}_{bt+1} & \text{if interbank run occurs} \end{cases} \tag{9}$$

where $0 \leq x_t^w < 1$. If an interbank run occurs, all creditor banks receive the same pro rata share of liquidated assets. As in the case of deposits, we continue to restrict attention to the case where bank runs are completely unanticipated, before turning in a subsequent section to the case of anticipated runs in wholesale funding markets.

Due to financial market frictions that we specify below, bankers may be constrained in their ability to raise external funds. To the extent they may be constrained, they will attempt to save their way out of the financing constraint by accumulating retained earnings in order to move toward 100% equity financing. To limit this possibility, we assume that bankers have a finite expected lifetime: Specifically, each banker of type j (where $j = w$ and r for wholesale and retail bankers) has an i.i.d. probability σ^j of surviving until the next period and a probability $1 - \sigma^j$ of exiting. This setup provides a simple way to motivate "dividend payouts" from the banking system in order to ensure that banks use leverage in equilibrium.

Every period new bankers of type j enter with an endowment w^j that is received only in the first period of life. This initial endowment may be thought of as the start up equity for the new banker. The number of entering bankers equals the number who exit, keeping the total constant.

We assume that bankers of either type are risk neutral and enjoy utility from consumption in the period they exit. The expected utility of a continuing banker at the end of period t is given by

$$V_t^j = E_t\left[\sum_{i=1}^{\infty} \beta^i (1-\sigma^j)(\sigma^j)^{i-1} c_{t+i}^j\right],$$

where $(1 - \sigma^j)(\sigma^j)^{i-1}$ is the probability of exiting at date $t + i$, and c_{t+i}^j is terminal consumption if the banker of type j exits at $t + i$.

The aggregate shock Z_t is realized at the start of t. Conditional on this shock, the net worth of "surviving" bankers j is the gross return on nonfinancial loans net the cost of deposits and borrowing from the other banks, as follows:

$$n_t^j = (Q_t + Z_t)k_{t-1}^j - R_t d_{t-1}^j - R_{bt} b_{t-1}^j, \tag{10}$$

where d_{t-1}^j is deposit and b_{t-1}^j is interbank borrowing at $t-1$. Note that b_{t-1}^j is positive if bank j borrows and negative if j lends in the interbank market.

For new bankers at t, net worth simply equals the initial endowment:

$$n_t^j = w^j. \tag{11}$$

Meanwhile, exiting bankers no longer operate banks and simply use their net worth to consume:

$$c_t^j = n_t^j. \tag{12}$$

During each period t, a continuing bank j (either new or surviving) finances nonfinancial loans $(Q_t + f_t^j)k_t^j$ with net worth, deposit and interbank debt as follows:

$$(Q_t + f_t^j)k_t^j = n_t^j + d_t^j + b_t^j, \tag{13}$$

where f_t^r is given by (4) and $f_t^w = 0$. We assume that banks can only accumulate net worth via retained earnings. While this assumption is a reasonable approximation of reality, we do not explicitly model the agency frictions that underpin it.[s]

To derive a limit on the bank's ability to raise funds, we introduce the following moral hazard problem: After raising funds and buying assets at the beginning of t, but still during the period, the banker decides whether to operate "honestly" or to divert assets for personal use. Operating honestly means holding assets until the payoffs are realized in period $t+1$ and then meeting obligations to depositors and interbank creditors. To divert means to secretly channel funds away from investments in order to consume personally.

To motivate the use of wholesale funding markets along with retail markets, we assume that the banker's ability to divert funds depends on both the sources and uses of funds. The banker can divert the fraction θ of nonfinancial loans financed by retained earnings or funds raised from households, where $0 < \theta < 1$. On the other hand, he/she can divert only the fraction $\theta\omega$ of nonfinancial loans financed by interbank borrowing, where $0 < \omega < 1$. Here, we are capturing in a simple way that bankers lending in the wholesale market are more effective at monitoring the banks to which they lend than are households that supply deposits in the retail market. Accordingly, the total amount of funds that can be diverted by a banker who is a net borrower in the interbank market is given by

[s] See Bigio (2015) for a model that explains why banks might find it hard to raise external equity during crises in the presence of adverse selection problems.

$$\theta[(Q+f^j)k_t^j - b_t^j + \omega b_t^j]$$

where $(Q+f^j)k_t^j - b_t^j$ equals the value of funds invested in nonfinancial loans that is financed by deposits and net worth and where $b_t^j > 0$ equals the value of nonfinancial loans financed by interbank borrowing.

For bankers that lend to other banks, we suppose that it is more difficult to divert interbank loans than nonfinancial loans. Specifically, we suppose that a banker can divert only a fraction $\theta\gamma$ of its loans to other banks, where $0 < \gamma < 1$. Here, we appeal to the idea that interbank loans are much less idiosyncratic in nature than nonfinancial loans and thus easier for outside depositors to monitor. Accordingly, the total amount a bank that lends on the interbank market can divert is given by

$$\theta[(Q_t + f_t^j)k_t^j + \gamma(-b_t^j)]$$

with $b_t^j < 0$. As we will make clear shortly, key to operation of the interbank market are the parameters that govern the moral hazard problem in this market, ω and γ.

We assume that the process of diverting assets takes time: The banker cannot quickly liquidate a large amount of assets without the transaction being noticed. For this reason, the banker must decide whether to divert at t, prior to the realization of uncertainty at $t+1$. The cost to the banker of the diversion is that the creditors can force the intermediary into bankruptcy at the beginning of the next period.

The banker's decision at t boils down to comparing the franchise value of the bank V_t^j, which measures the present discounted value of future payouts from operating honestly, with the gain from diverting funds. In this regard, rational lenders will not supply funds to the banker if he has an incentive to cheat. Accordingly, any financial arrangement between the bank and its lenders must satisfy the following set of incentive constraints, which depend on whether the bank is a net borrower or lender in the interbank market:

$$\begin{aligned} V_t^j &\geq \theta[(Q+f^j)k_t^j - b_t^j + \omega b_t^j], \text{ if } b_t^j > 0 \\ V_t^j &\geq \theta[(Q_t + f_t^j)k_t^j + \gamma(-b_t^j)], \text{ if } b_t^j < 0. \end{aligned} \tag{14}$$

As will become clear shortly, each incentive constraint embeds the constraint that the net worth n_t^j must be positive for the bank to operate: This is because the franchise value V_t^j will turn out to be proportional to n_t^j.

Overall, there are two basic factors that govern the existence and relative size of the interbank market. The first is the cost advantage that wholesale banks have in managing nonfinancial loans, as described by Assumption 1. The second is the size of the parameters ω and γ which govern the comparative advantage that retail banks have over households in lending to wholesale banks. Observe that as ω and γ decline, it becomes more attractive to channel funds through wholesale bank funding markets relative to retail markets. As ω declines below unity, a bank borrowing in the wholesale market can relax its incentive constraint by substituting interbank borrowing for deposits. Similarly, as γ declines below unity, a bank lending in the wholesale market can relax its incentive constraint by shifting its composition of assets from nonfinancial loans to interbank loans.

In what follows, we restrict attention to the case in which

$$\omega + \gamma > 1. \tag{Assumption 2}$$

In this instance, the parameters ω and γ can be sufficiently small to permit an empirically reasonable relative amount of interbank lending. However, the sum of these parameters cannot be so small as to induce a situation of pure specialization by retail banks, where these banks do not make nonfinancial loans directly but instead lend all their funds to wholesale banks.[t,u] Since in practice retail banks hold some of the same types of assets held by wholesale banks, we think it reasonable to restrict attention to this case.

We now turn to the optimization problems for both wholesale and retail bankers. Given that bankers simply consume their net worth when they exit, we can restate the bank's franchise value recursively as the expected discounted value of the sum of net worth conditional on exiting and the value conditional on continuing as:

$$\begin{aligned} V_t^j &= \beta E_t[(1-\sigma^j)n_{t+1}^j + \sigma^j V_{t+1}^j]. \\ &= E_t[\Omega_{t+1}^j n_{t+1}^j] \end{aligned} \tag{15}$$

where

$$\Omega_{t+1}^j = \beta\left(1 - \sigma^j + \sigma^j \frac{V_{t+1}^j}{n_{t+1}^j}\right). \tag{16}$$

The stochastic discount factor Ω_{t+1}^j, which the bankers use to value n_{t+1}^j, is a probability weighted average of the discounted marginal values of net worth to exiting and to continuing bankers at t+1. For an exiting banker at $t+1$ (which occurs with probability $1-\sigma^j$), the marginal value of an additional unit of net worth is simply unity, since he or she just consumes it. For a continuing banker (which occurs with probability σ^j), the marginal value is the franchise value per unit of net worth V_{t+1}^j/n_{t+1}^j (ie, Tobin's Q ratio). As we show shortly, V_{t+1}^j/n_{t+1}^j depends only on aggregate variables and is independent of bank-specific factors.

We can express the banker's evolution of net worth as:

$$n_{t+1}^j = R_{kt+1}^j\left(Q_t + f_t^j\right)k_t^j - R_{t+1}d_t^j - R_{bt+1}b_t^j \tag{17}$$

[t] See Appendix A for the formal argument that shows that under Assumption 2 pure specialization of retail bankers cannot be an equilibrium.

[u] Holmstrom and Tirole (1997) make similar assumptions on the levels and sum of the agency distortions for banks and nonfinancial firms in order to explain why bank finance arises.

where R^j_{kt+1} is the rate of return on nonfinancial loans, given by

$$R^j_{kt+1} = \frac{Q_{t+1} + Z_{t+1}}{Q_t + f^j_t} \tag{18}$$

The banker's optimization problem then is to choose $\left(k^j_t, d^j_t, b^j_t\right)$ each period to maximize the franchise value (15) subject to the incentive constraint (14) and the balance sheet constraints (13) and (17).

We defer the details of the formal bank maximization problems to Appendix A. Here, we explain the decisions of wholesale and retail banks informally. Because wholesale banks have a cost advantage over retail banks in making nonfinancial loans, the rate of return on nonfinancial loans is higher for the former than for the latter (see Eq. (18)). In turn, retail banks have an advantage over households in lending to wholesale banks due to their relative advantage in recovering assets in default. Therefore, if the interbank market is active in equilibrium, wholesale banks borrow from retail banks in the interbank market to make nonfinancial loans. Indeed the only reason retail banks directly make nonfinancial loans is because wholesale banks may be constrained in the amount of this type of loan they can make.[v]

In the text, we restrict attention to the case where the interbank market is active, with wholesale banks borrowing from retail banks, and where both types of banks are constrained in raising funds externally.

3.3.1 Wholesale banks

In general, wholesale banks may raise funds either from other banks or from households. Since the kinds of financial institutions we have in mind relied exclusively on wholesale markets for funding, we focus on this kind of equilibrium. In particular, we restrict attention to model parameterization which generate an equilibrium where the conditions for the following Lemma 1 are satisfied:

Lemma 1 $d^w_t = 0, b^w_t > 0$ *and the incentive constraint is binding if and only if*

$$0 < \omega E_t\left[\Omega^w_{t+1}\left(R^w_{kt+1} - R_{t+1}\right)\right] < E_t\left[\Omega^w_{t+1}\left(R^w_{kt+1} - R_{bt+1}\right)\right] < \theta\omega$$

We first explain why $d^w_t = 0$ in this instance. The wholesale bank faces the following trade-off in using retail deposits: If the deposit interest rate is lower than the interbank

[v] We do not mean to suggest that the only reason retail banks make nonfinancial loans in practice is because wholesale banks are constrained. Rather we focus on this case for simplicity of the basic model. Later we extend the model to allow for a second type of lending, which we refer to as commercial and industrial lending, where retail banks have a comparative advantage. In this instance, spillovers emerge where problems in wholesale banking can affect the degree of intermediation of commercial and industrial loans.

interest rate so that $E_t[\Omega^w_{t+1}(R^w_{kt+1} - R_{t+1})] > E_t[\Omega^w_{t+1}(R^w_{kt+1} - R_{bt+1})]$, then the bank gains from issuing deposits to reduce interbank loans. On the other hand, because households are less efficient in monitoring wholesale bank behavior, they will apply a tighter limit on the amount they are willing to lend than will retail banks. If ω is sufficiently low so that $\omega E_t[\Omega^w_{t+1}(R^w_{kt+1} - R_{t+1})] < E_t[\Omega^w_{t+1}(R^w_{kt+1} - R_{bt+1})]$, the cost exceeds the benefit. In this instance, the wholesale bank does not use retail deposits, relying entirely on interbank borrowing for external finance. Everything else equal, by not issuing retail deposits, the wholesale bank is able to raise its overall leverage in order to make more nonfinancial loans relative to its equity base. This incentive consideration accounts for why the wholesale bank may prefer interbank borrowing to issuing deposits, even if the interbank rate lies above the deposit rate.[w]

Next we explain why the incentive constraint is binding. If $E_t[\Omega^w_{t+1}(R^w_{kt+1} - R_{bt+1})] < \theta\omega$, then at the margin the wholesale bank gains by borrowing on the interbank market and then diverting funds to its own account. Accordingly, as the incentive constraint (14) requires, rational creditor banks will restrict lending to the point where the gain from diverting equals the bank franchise value, which is what the wholesale bank would lose if it cheated.

Given Lemma 1 we can simplify the evolution of bank net worth to

$$n^w_{t+1} = [(R^w_{kt+1} - R_{bt+1})\phi^w_t + R_{bt+1}]n^w_t \tag{19}$$

where ϕ^w_t is given by

$$\phi^w_t \equiv \frac{Q_t k^w_t}{n^w_t}. \tag{20}$$

We refer to this ratio of assets to net worth as the leverage multiple.

In turn, we can simplify the wholesale banks optimization problem to choosing the leverage multiple to solve:

$$V^w_t = \max_{\phi^w_t} E_t\{\Omega^w_{t+1}[(R^w_{kt+1} - R_{bt+1})\phi^w_t + R_{bt+1}]n^w_t\} \tag{21}$$

subject to the incentive constraint

$$\theta[\omega\phi^w_t + (1-\omega)]n^w_t \le V^w_t \tag{22}$$

[w] Under our baseline parametrization, wholesale banks borrow exclusively from retail banks. We view this as the case that best corresponds to the wholesale banking system on the eve of the Great Recession. Circumstances do exist where wholesale banks will borrow from households as well as retail banks. One might interpret his situation as corresponding to the consolidation of wholesale and retail bank in the wake of the crisis, or perhaps the period before the rapid growth of wholesale banking when retail banks were performing many of the same activities as we often observe in continental Europe and Japan.

Given the incentive constraint is binding under Lemma 1, we can combine the objective with the binding incentive constraint to obtain the following solution for ϕ_t^w:

$$\phi_t^w = \frac{E_t(\Omega_{t+1}^w R_{bt+1}) - \theta(1-\omega)}{\theta\omega - E_t[\Omega_{t+1}^w (R_{kt+1}^w - R_{bt+1})]} \tag{23}$$

Note that ϕ_t^w is increasing in $E_t(\Omega_{t+1}^w R_{kt+1}^w)$ and decreasing in $E_t(\Omega_{t+1}^w R_{bt+1})$.[x] Intuitively, the franchise value V_t^w increases when returns on assets are higher and decreases when the cost of funding asset purchases rises, as Eq. (21) indicates. Increases in V_t^w, in turn, relax the incentive constraint, making lenders will to supply more credit.

Also, ϕ_t^w is a decreasing function of both θ, the diversion rate on nonfinancial loans funded by net worth, and ω, the parameter that controls the relative ease of diverting nonfinancial loans funded by interbank borrowing relative to those funded by the other means: Increases in either parameter tighten the incentive constraint, inducing lenders to cut back on the amount of credit they supply. Later we will use the inverse relationship between ϕ_t^w and ω to help account for the growth in both leverage and size of the wholesale banking sector.

Finally, from Eq. (21) we obtain an expression from the franchise value per unit of net worth

$$\frac{V_t^w}{n_t^w} = E_t\{\Omega_{t+1}^w[(R_{kt+1}^w - R_{bt+1})\phi_t^w + R_{bt+1}]\} \tag{24}$$

where ϕ_t^w is given by Eq. (23) and Ω_{t+1}^w is given by Eq. (16). It is straightforward to show that $\frac{V_t^w}{n_t^w}$ exceeds unity: ie, the shadow value of a unit of net worth is greater than one, since additional net worth permits the bank to borrow more and invest in assets earning an excess return. In addition, as we conjectured earlier, $\frac{V_t^w}{n_t^w}$ depend only on aggregate variables and not on bank-specific ones.

3.3.2 Retail banks

As with wholesale banks, we choose a parametrization where the incentive constraint binds. In addition, as discussed earlier, we restrict attention to the case where retail banks are holding both nonfinancial and interbank loans. In particular, we consider a parametrization where in equilibrium Lemma 2 is satisfied

[x] This is because $E_t(\Omega_{t+1}^w R_{kt+1}^w) > 1 > \theta$ in equilibrium as shown in Appendix.

Lemma 2 $b_t^r < 0$, $k_t^r > 0$ *and the incentive constraint is binding if and only if*

$$0 < E_t[\Omega_{t+1}^r(R_{kt+1}^r - R_{t+1})] = \frac{1}{\gamma}E_t[\Omega_{t+1}^r(R_{bt+1} - R_{t+1})] < \theta$$

For the retail bank to be indifferent between holding nonfinancial loans vs interbank loans, the rate on interbank loans R_{bt+1} must lie below the rate earned on nonfinancial loans R_{kt+1}^r in a way that satisfies the conditions for the lemma. Intuitively, the advantage for the retail bank to making an interbank loan is that households are willing to lend more to the bank per unit of net worth than for a nonfinancial loan. Thus to make the retail bank indifferent, R_{bt+1} must be less than R_{kt+1}^r.

Let ϕ_t^r be a retail bank's effective leverage multiple, namely the ratio of assets to net worth, where assets are weighted by the relative ease of diversion:

$$\phi_t^r \equiv \frac{(Q_t + f_t^r)k_t^r + \gamma(-b_t^r)}{n_t^r}. \tag{25}$$

The weight γ on $(-b_t^r)$ is the ratio of how much a retail banker can divert from interbank loans relative to nonfinancial loans.

Given the restrictions implied by Lemma 2, we can use the same procedure as in the case of wholesale bankers to express the retail banker's optimization problem as choosing ϕ_t^r to solve:

$$V_t^r = \max_{\phi_t^r} E_t\{\Omega_{t+1}^r[(R_{kt+1}^r - R_{t+1})\phi_t^r + R_{t+1}]n_t^r\} \tag{26}$$

subject to

$$\theta\phi_t^r n_t^r \le V_t^r$$

Given Lemma 2, we can impose that incentive constraint binds, which implies

$$\phi_t^r = \frac{E_t(\Omega_{t+1}^r R_{t+1})}{\theta - E_t[\Omega_{t+1}^r(R_{kt+1}^r - R_{t+1})]}. \tag{27}$$

As with the leverage multiple for wholesale bankers, ϕ_t^r is increasing in expected asset returns on the bank's portfolio and decreasing in the diversion parameter.

Finally, from Eq. (26) we obtain an expression for the franchise value per unit of net worth

$$\frac{V_t^r}{n_t^r} = E_t\{\Omega_{t+1}^r[(R_{kt+1}^r - R_{t+1})\phi_t^r + R_{t+1}]\} \tag{28}$$

As with wholesale banks, the shadow value of a unit of net worth exceeds unity and depends only on aggregate variables.

3.4 Aggregation and Equilibrium without Bank Runs

Given that the ratio of assets and liabilities to net worth is independent of individual bank-specific factors and given a parametrization where the conditions in Lemma 1 and 2 are satisfied, we can aggregate across banks to obtain relations between total assets and net worth for both the wholesale and retail banking sectors. Let $Q_tK_t^w$ and $Q_tK_t^r$ be total nonfinancial loans held by wholesale and retail banks, D_t be retail bank deposits, B_t be total interbank debt, and N_t^w and N_t^r total net worth in each respective banking sector. Then we have:

$$Q_tK_t^w = \phi_t^w N_t^w, \tag{29}$$

$$(Q_t + f_t^r)K_t^r + \gamma B_t = \phi_t^r N_t^r, \tag{30}$$

with

$$Q_tK_t^w = N_t^w + B_t, \tag{31}$$

$$(Q_t + f_t^r)K_t^r + B_t = D_t^r + N_t^r, \tag{32}$$

and

$$E_t[\boldsymbol{\Omega}_{t+1}^r(R_{kt+1}^r - R_{t+1})] = \frac{1}{\gamma}E_t[\boldsymbol{\Omega}_{t+1}^r(R_{bt+1} - R_{t+1})]. \tag{33}$$

Eq. (33) ensures that the retail bank is indifferent at the margin between holding nonfinancial loans vs interbank loans (see Lemma 2).

Summing across both surviving and entering bankers yields the following expression for the evolution of N_t :

$$N_t^w = \sigma^w[(R_{kt}^w - R_{bt})\phi_{t-1}^w + R_{bt}]N_{t-1}^w + W^w, \tag{34}$$

$$\begin{aligned} N_t^r = \sigma^r[(R_{kt}^r - R_t)\phi_{t-1}^r + R_t]N_{t-1}^r + W^r \\ +\sigma^r\left[R_{bt} - R_t - \gamma(R_{kt}^r - R_t)\right]B_{t-1}, \end{aligned} \tag{35}$$

where $W^j = (1 - \sigma^j)w^j$ is the total endowment of entering bankers. The first term is the accumulated net worth of bankers that operated at $t - 1$ and survived to t, which is equal to the product of the survival rate σ^j and the net earnings on bank assets.

Total consumption of bankers equals the sum of the net worth of exiting bankers in each sector:

$$C_t^b = (1 - \sigma^w)\frac{N_t^w - W^w}{\sigma^w} + (1 - \sigma^r)\frac{N_t^r - W^r}{\sigma^r} \tag{36}$$

Total gross output $\bar{Y}_t$ is the sum of output from capital, household endowment Z_tW^h and bank endowment W^r and W^i :

$$\bar{Y}_t = Z_t + Z_tW^h + W^r + W^i. \tag{37}$$

Net output Y_t, which we will refer to simply as output, equals gross output minus management costs

$$Y_t = \bar{Y}_t - [F^h(K_t^h) + F^r(K_t^r)] \tag{38}$$

Eq. (38) captures in a simple way how intermediation of assets by wholesale banks improves aggregate efficiency. Finally, output is consumed by households and bankers:

$$Y_t = C_t^h + C_t^b. \tag{39}$$

The recursive competitive equilibrium without bank runs consists of aggregate quantities,

$$\left(K_t^w, K_t^r, K_t^h, B_t, D_t^r, N_t^w, N_t^r, C_t^b, C_t^h, \bar{Y}_t, Y_t\right),$$

prices

$$\left(Q_t, R_{t+1}, R_{bt+1}, f_t^r\right)$$

and bankers' variables

$$\left(\Omega_t^j, R_{kt}^j, \frac{V_t^j}{n_t^j}, \phi_t^j\right)_{j=w,r}$$

as a function of the state variables $\left(K_{t-1}^w, K_{t-1}^r, R_{bt}B_{t-1}, R_t D_{t-1}^w, R_t D_{t-1}^r, Z_t\right)$, which satisfy Eqs. (1, 4, 7, 8, 16, 18, 23, 24, and 27–39).[y]

3.5 Unanticipated Bank Runs

In this section we consider unanticipated bank runs. We defer an analysis of anticipated bank runs to Section 5. In general, three types of runs are conceivable: (i) a run on wholesale banks leaving retail banks intact, (ii) a run on just retail banks, and (iii) a run on both the wholesale and retail bank sectors. We restrict attention to (i) because it corresponds most closely to what happened in practice.

3.5.1 Conditions for a Wholesale Bank Run Equilibrium

The runs we consider are runs on the entire wholesale banking system, not on individual wholesale banks. Indeed, so long as an asset firesale by an individual wholesale bank is not large enough to affect asset prices, it is only runs on the system that will be disruptive. Given the homogeneity of wholesale banks in our model, the conditions for a run on the wholesale banking system will apply to each individual wholesale bank.

What we have in mind for a run is a spontaneous failure of the bank's creditors to roll over their short-term loans[z]. In particular, at the beginning of period t, before the

[y] In total we have a system of 23 equations. Notice that (16 and 18) have two equations. By Walras' law, the household budget constraint (6) is satisfied as long as deposit market clears as $D_t = D_t^r$.

[z] The approach follows Cole and Kehoe's (2000) model of self fulfilling debt crises.

realization of returns on bank assets, retail banks lending to a wholesale bank decide whether to roll over their loans with the bank. If they choose to "run," the wholesale bank liquidates its capital and turns the proceeds over to its retail bank creditors who then either acquire the capital or sell it to households. Importantly, both the retail banks and households cannot seamlessly acquire the capital being liquidated in the firesale by wholesale banks. The retail banks face a capital constraint which limits asset acquisition and are also less efficient at managing the capital than are wholesale banks. Households can only hold the capital directly and are even less efficient than retail banks in doing so.

Let Q_t^* be the price of capital in the event of a forced liquidation of the wholesale banking system. Then a run on the entire wholesale bank sector is possible if the liquidation value of wholesale banks assets, $(Z_t + Q_t^*)K_{t-1}^w$, is smaller than their outstanding liability to interbank creditors, $R_{bt}B_{t-1}$, so that liquidation would wipe out wholesale banks networth. In this instance, the recovery rate in the event of a wholesale bank run, x_t^w, is the ratio of $(Z_t + Q_t^*)K_{t-1}^w$ to $R_{bt}B_{t-1}$ and the condition for a bank run equilibrium to exist is that the recovery rate is less than unity, ie,

$$x_t^w = \frac{(Q_t^* + Z_t)K_{t-1}^w}{R_{bt}B_{t-1}} < 1. \tag{40}$$

Let R_{kt}^{w*} be the return on bank assets conditional on a run at t :

$$R_{kt}^{w*} \equiv \frac{Z_t + Q_t^*}{Q_{t-1}},$$

Then from (40), we can obtain a simple condition for a wholesale bank run equilibrium in terms of just two endogenous variables: (i) the ratio of R_{kt}^{w*} to the interbank borrowing rate R_{bt} and (ii) the leverage multiple ϕ_{t-1}^w :

$$x_t^w = \frac{R_{kt}^{w*}}{R_{bt}} \cdot \frac{\phi_{t-1}^w}{\phi_{t-1}^w - 1} < 1 \tag{41}$$

A bank run equilibrium exists if the realized rate of return on bank assets conditional on liquidation of assets R_{kt}^{w*} is sufficiently low relative to the gross interest rate on interbank loans, R_{bt}, and the leverage multiple is sufficiently high to satisfy condition (41). Note that the expression $\frac{\phi_{t-1}^w}{\phi_{t-1}^w - 1}$ is the ratio of bank assets $Q_{t-1}K_{t-1}^w$ to interbank borrowing B_{t-1}, which is decreasing in the leverage multiple. Also note that the condition for a run does not depend on individual bank-specific factors since R_{kt}^{w*}/R_{bt} and ϕ_{t-1}^w are the same for all in equilibrium.

Since R_{kt}^{w*}, R_{bt} and ϕ_{t-1}^w are all endogenous variables, the possibility of a bank run may vary with macroeconomic conditions. The equilibrium absent bank runs (that we described earlier) determines the behavior of R_{bt} and ϕ_{t-1}^w. The value of R_{kt}^{w*}, instead, depends on the liquidation price Q_t^*, whose determination is described in the next subsection.

3.5.2 The Liquidation Price

To determine Q_t^* we proceed as follows. A run by interbank creditors at t induces all wholesale banks that carried assets from $t - 1$ to fully liquidate their asset positions and go out of business.[aa] Accordingly they sell all their assets to retail banks and households, who hold them at t. The wholesale banking system then rebuilds itself overtime as new banks enter. For the asset firesale during the panic run to be quantitatively significant, we need there to be at least a modest delay in the ability of new banks to begin operating. Accordingly, we suppose that new wholesale banks cannot begin operating until the period after the panic run.[ab]

Accordingly, when wholesale banks liquidate, they sell all their assets to retail banks and households in the wake of the run at date t, implying

$$\bar{K} = K_t^r + K_t^h. \tag{42}$$

The wholesale banking system then rebuilds its equity and assets as new banks enter at $t + 1$ onwards. Given our timing assumptions and Eq. (34), bank net worth evolves in the periods after the run according to

$$\begin{aligned} N_{t+1}^w &= (1+\sigma^w)W^w, \\ N_{t+i}^w &= \sigma^w\left[(Z_{t+i} + Q_{t+i})K_{t+i-1}^w - R_{bt+i}B_{t+i-1}\right] + W^w, \text{ for all } i \geq 2. \end{aligned}$$

Rearranging the Euler equation for the household's capital holding (8) yields the following expression for the liquidation price in terms of discounted dividends Z_{t+i} net the marginal management cost $\alpha^h K_{t+i}^h$.

$$Q_t^* = E_t\left[\sum_{i=1}^{\infty} \Lambda_{t,t+i}(Z_{t+i} - \alpha^h K_{t+i}^h)\right] - \alpha^h K_t^h. \tag{43}$$

Everything else equal, the longer it takes for the banking sector to recapitalize (measured by the time it takes K_{t+i}^h to fall back to steady state), the lower will be the liquidation price. Note also that Q_t^* will vary with cyclical conditions. In particular, a negative shock to Z_t will reduce Q_t^*, possibly moving the economy into a regime where bank runs are possible.

[aa] Our notion of the liquidation price is related to Brunnermeier and Pedersen's (2009) concept of market liquidity. See Uhlig (2010) for an alternative bank run model with endogenous liquidation prices.

[ab] Suppose for example that during the run it is not possible for retail banks to identify new wholesale banks that are financially independent of the wholesale banks being run on. New wholesale banks accordingly wait for the dust to settle and then begin raising fund in the interbank market in the subsequent period. The results are robust to alternative timing assumptions about the entry of new banks.

4. NUMERICAL EXPERIMENTS

In this section, we examine how the long run properties of the model can account for the growth of the wholesale banking sector and then turn to studying the cyclical responses to macroeconomic shocks that may or may not induce runs. Overall these numerical examples provide a description of the tradeoff between growth and stability associated with an expansion of the shadow banking sector and illustrate the real effects of bank runs in our model.

4.1 Calibration

Here, we describe our baseline calibration. This is meant to capture the state of the economy at the onset of the financial crisis in 2007.

There are 13 parameters in the model:

$$\{\theta,\omega,\gamma,\beta,\alpha^h,\alpha^r,\sigma^r,\sigma^w,W^h,W^r,W^w,Z,\rho_z\}.$$

their values are reported in Table 2, while Table 3 shows the steady state values of the equilibrium allocation.

We take the time interval in the model to be a quarter. We use conventional values for households' discount factor, $\beta = 0.99$, and the serial correlation of dividends $\rho_z = 0.9$. We normalize the steady state level of productivity Z in order for the price of loans to be unity and set W^h so that households endowment income is twice as big as their capital income.

We calibrate managerial costs of intermediating capital for households and retail bankers, α^h and α^r, in order for the spread between the deposit rate and retail bankers' returns on loans as well as the difference between wholesale bankers and retail bankers returns on loans to be 1.2% in annual in steady state.[ac]

The fraction of divertible interbank loans $\theta\gamma$ is set in order to obtain an annualized steady state spread between deposit and interbank rates of 0.8%. The fraction of divertible assets purchased by raising deposits, θ, and interbank loans, $\omega\theta$, are set in order to get leverage ratios for retail bankers and wholesale bankers of 10 and 20, respectively.

Our retail banking sector comprises of commercial banks, open end Mutual Funds and Money Market Mutual Funds (MMMF). In the case of Mutual Funds and MMMF the computation of leverage is complicated by the peculiar legal and economic details of the relationship between these institutions, their outside investors and sponsors.[ad] Hence, our choice of 10 quite closely reflects the actual leverage ratios of commercial banks,

[ac] Philippon (2015) calculates interest rate spreads charged by financial institutions to be around 200 basis points.

[ad] On the relationship between MMFs and their sponsors see, for instance, Parlatore (2015) and McCabe (2010).

Table 2 Baseline parameters

	Parameters	
Households		
β	Discount rate	0.99
α^h	Intermediation cost	0.03
W^h	Endowment	0.006
Retail banks		
σ^r	Survival probability	0.96
σ^r	Intermediation cost	0.0074
W^r	Endowment	0.0008
θ	Divertable proportion of assets	0.25
γ	Shrinkage of divertable proportion of interbank loans	0.67
Wholesale banks		
σ^w	Survival probability	0.88
σ^w	Intermediation cost	0
W^w	Endowment	0.0008
ω	Shrinkage of divertable proportion of assets	0.46
Production		
z	Steady state productivity	0.016
ρ_z	Serial correlation of productivity shocks	0.9

Table 3 Baseline steady state

	Steady state	
Q	Price of capital	1
K^r	Retail intermediation	0.4
K^w	Wholesale intermediation	0.4
R^b	Annual interbank rate	1.048
R_r^k	Annual retail return on capital	1.052
R	Annual deposit rate	1.04
R_w^k	Annual wholesale return on capital	1.064
ϕ^w	Wholesale leverage	20
ϕ^r	Retail leverage	10
Y	Output	0.0229
C^h	Consumption	0.0168
N^r	Retail banks networth	0.0781
N^w	Wholesale banks networth	0.02

which is the only sector for which a direct empirical counterpart of leverage can be easily computed.

To set our target for wholesale leverage we decided to focus on private institutions within the wholesale banking sector that relied mostly on short-term debt. A reasonable range for the leverage multiple for such institutions goes from around 10 for some ABCP issuers[ae] to values of around 40 for brokers dealers in 2007. Our choice of 20 is a conservative target within this range.

The survival rates of wholesale and retail bankers, σ^w and σ^r, are set in order for the distribution of assets across sectors to match the actual distribution in 2007. Finally, we set W^r to make new entrants net worth being equal to 1% of total retail banks net worth and W^w to ensure that wholesale bankers are perfectly specialized.

4.2 Long Run Effects of Financial Innovation

As mentioned in Section 2, the role of wholesale banks in financial intermediation has grown steadily from the 1980s to the onset of the financial crisis. This growth was largely accomplished through a series of financial innovations that enhanced the borrowing capacity of the system by relying on securitization to attract funds from institutional investors. While our model abstracts from the details of the securitization process, we capture its direct effects on wholesale banks' ability of raising funds in interbank markets with a reduction in the severity of the agency friction between retail banks and wholesale banks, which is captured by parameter ω. Hence, in this section we study the long run behavior of financial intermediation in response to a decrease in ω and compare it to the low frequency dynamics in financial intermediation documented in Section 2.

The direct effect of ameliorating the agency problem between wholesale and retail banks is a relaxation of wholesale banks' incentive constraints. The improved ability of retail banks to seize the assets of wholesale bankers in the case of cheating allows wholesale bankers to borrow more aggressively from retail bankers.

Fig. 8 shows how some key variables depend upon ω in the steady state.[af] The general equilibrium effects of a lower ω work through various channels. For an economy with a lower interbank friction ω, the leverage multiple of the wholesale banking sector is higher, with a larger capital K^w and a larger amount interbank borrowing B by wholesale banks. Conversely, capital intermediated by retail banks K^r and households K^h tends to be lower. In the absence of bank runs, the relative shift of assets to the wholesale banking sector implies a more efficient allocation of capital and consequently a higher capital price

[ae] The same caveat as in the case of MMFs applies here because it is very complicated to factor in the various lines of credit that were provided by the sponsors of these programs.

[af] Notice that as ω increases above a certain threshold, two other types of equilibria arise: one in which wholesale bankers are imperfectly specialized and raise funds in both wholesale and retail markets; and one in which the interbank market shuts down completely. See the Appendices for details.

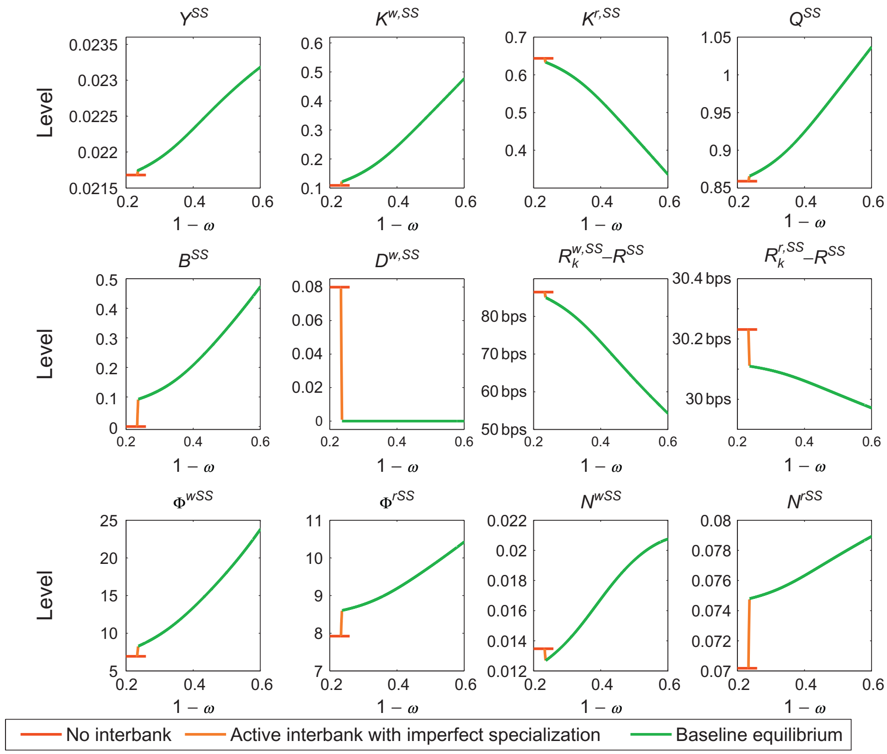

Fig. 8 Comparative statics: a reduction in ω.

Q_t. The flow of assets into wholesale banking, further, reduces the spread between the return on capital for wholesale banks and the interbank rate, as well as the spread between interbank and deposit rates. Despite lower spreads, both wholesale and retail banks enjoy higher franchise values thanks to the positive effect of higher leverage on total returns on equity. A unique aspect of financial innovation due to a lower friction in the interbank market is that the borrowing and lending among banks tends to be larger relative to the flow-of-funds from ultimate lenders (households) to ultimate nonfinancial borrowers. (See Appendix B).

Fig. 9 compares the steady state effect of financial innovations on some key measures of financial intermediation with the observed low frequency trends in their empirical counterparts. In particular, we assume that the value of ω in our baseline calibration results from a sequence of financial innovations that took place gradually from the 1980s to the financial crisis. For simplicity, we divide our sample into 2 periods of equal length and assign a value of ω to each subsample in order to match the observed percentage of intermediation of wholesale bankers over the period. In order to compute leverage of wholesale banks in Fig. 9, we compute leverage of the three sectors within the wholesale banking sector that were mainly responsible for the growth of wholesale

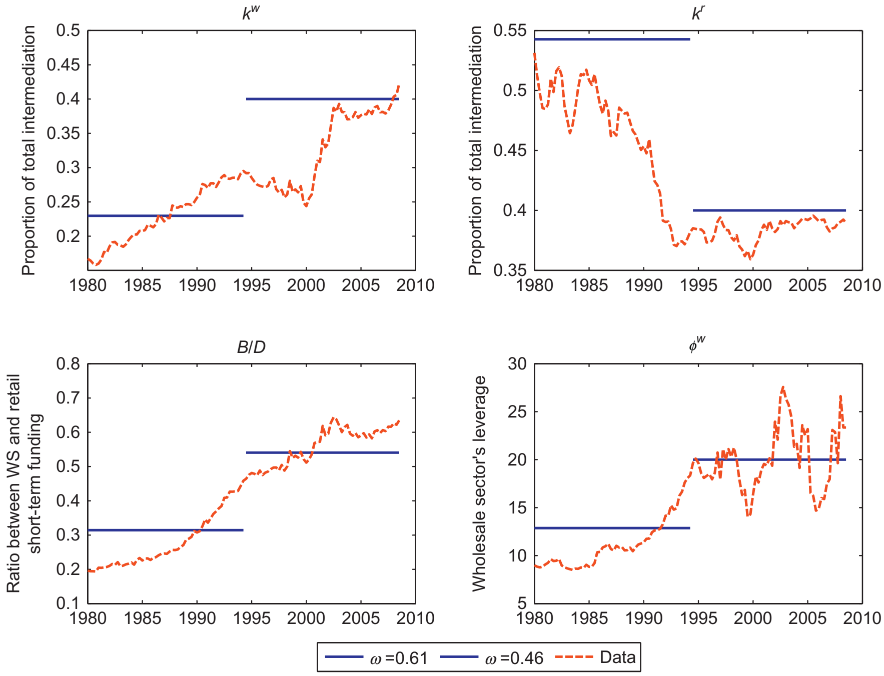

Fig. 9 Low frequency dynamics in financial intermediation.

intermediation. Overall, the steady state comparative statics capture quite well the actual low frequency dynamics in financial intermediation observed over the past few decades.[ag]

4.3 Recessions and Runs

We now turn to the cyclical behavior of our model economy. Fig. 10 shows the response of the economy to an unanticipated negative 6% shock to productivity Z_t, assuming that a run does not happen.[ah] To capture the effects of financial liberalization on the cyclical properties of the economy, we consider both our baseline parameterization and one with a higher ω which we set to be equal to the one associated with the early 1980s in Fig. 9. In both cases the presence of financial constraints activates the familiar financial accelerator mechanism of Bernanke and Gertler (1989) and Kiyotaki and Moore (1997). Leverage amplifies the effects of the drop in Z_t on bankers' net worth, inducing a tightening of

[ag] The model overstatement of the role of retail intermediation relative to household direct holding of assets can be rationalized by the lack of heterogeneity in ultimate borrowers' funding sources since, in the data, households mainly hold equities while intermediaries are responsible for most debt intermediation. Introducing a different type of asset for which intermediaries have a smaller advantage would then help to reconcile the evolution of the distribution of capital across sectors predicted by the model in response to financial innovation with the empirical one.

[ah] We choose the size of the shock to generate a fall in output similar to the one that occurred during the Great Recession.

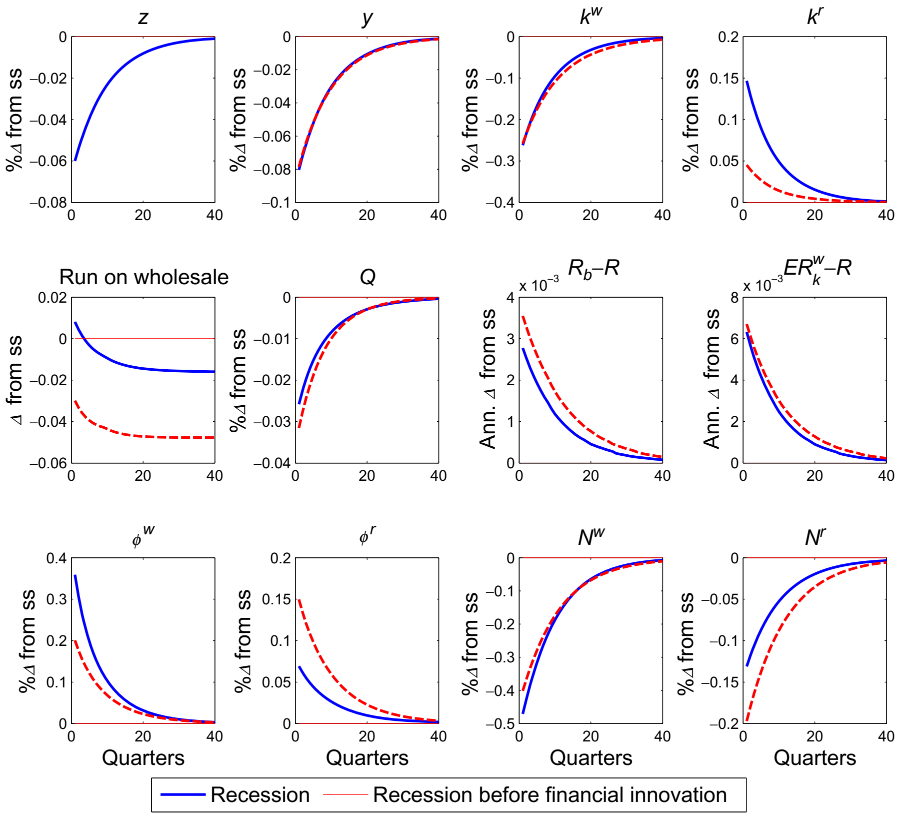

Fig. 10 A recession before and after financial innovation (NO RUN EQUILIBRIUM).

financial constraints, as reflected by an increase in credit spreads. In turn, wholesale banks sell off loans, which reduces asset prices and feeds back into lower net worth. Higher exposure to variations in Z_t and higher leverage make this effect stronger for wholesale banks that are forced into a firesale liquidation of their assets, which in turn leads them to reduce their demand for interbank loans. As a result, retail bankers increase their asset holdings and absorb, together with households, the capital flowing out of the wholesale banking sector.[ai] However, the relative inefficiency of these agents in intermediating assets makes this process costly as shown by the rise in the cost of bank credit and the amplification in the drop in output. Under our baseline calibration, spreads between gross borrowing costs for nonfinancial borrowers and the risk free rate increase by sixty basis points and output drops by 8%, which is two percentage points greater than the drop in Z_t.[aj]

[ai] The increase in households' capital holding is consistent with the shift from intermediated to unintermediated capital observed during the crisis. See, eg, Adrian et al (2012) for evidence.

[aj] Observe also that in a production economy with investment and nominal rigidities, the drop in the asset price would reduce investment and thus aggregate demand, magnifying the overall drop in output.

As we noted earlier, financial innovation makes the economy operate more efficiently in steady state. Fig. 10 shows that, absent bank runs, it also makes the economy more stable as the financial accelerator weakens. In response to the drop in Z_t, the economy with financial innovation features smaller increases in credit spreads and a smaller drop in assets prices. Intuitively, with financial innovation, retail banks provide a stronger buffer to absorb loan sales by wholesale banks, which helps stabilize asset prices. At the same time, the economy with financial innovation is more vulnerable to a bank run.

This is illustrated by the panel titled "Run on Wholesale" in Fig. 10. In this panel we plot a variable that indicates at each time t whether a run is possible at time $t + 1$. To construct this variable we define

$$Run_t^w = 1 - x_t^w$$

where x_t^w is the recovery rate on wholesale debt. Hence, in order for a run to exist the run variable must be positive.

As shown by the Run^w variable, a run on wholesale banks is not possible in the steady state under both parameterization considered. With a 6% drop in Z_t, a run equilibrium remains impossible in the economy absent financial innovation, ie, the one with a high value of ω. However, for the economy with financial innovation (ie, a low ω), the same drop in Z_t is big enough to make a run on wholesale banking possible. Intuitively, in the low ω economy, wholesale bank leverage ratios are higher than would be otherwise, and asset liquidation values are lower, which raises the likelihood that the conditions for a bank run equilibrium will be satisfied.

Fig. 11 describes the effects of bank runs. In particular we assume that two periods after the unanticipated drop in Z_t, retail investors stop rolling over short-term debt issued by wholesale banks, inducing them to liquidate all of their assets and go bankrupt.

As explained in Section 3.5.1, the run on wholesale banks forces them into bankruptcy and results in K^w dropping to 0. Households and retail banks are forced to absorb all of the wholesale banks' assets, inducing asset prices to drop by about 7% in total. The intermediation costs associated with the reallocation of assets to less efficient agents leads to an additional contraction of output of around 7%, resulting in an overall drop of about 15%.

As new wholesale bankers resume operations from the period after the run, high levels of spreads for both retail and wholesale bankers allow them to increase their leverage and recapitalize financial intermediaries thanks to above average retained earnings. The reintermediation process, however, is rather lengthy and output remains depressed for a prolonged period of time.

5. ANTICIPATED RUNS

So far, we have focused on the case in which runs are completely unexpected. In this section we study how the equilibrium changes if agents anticipate that a run will occur

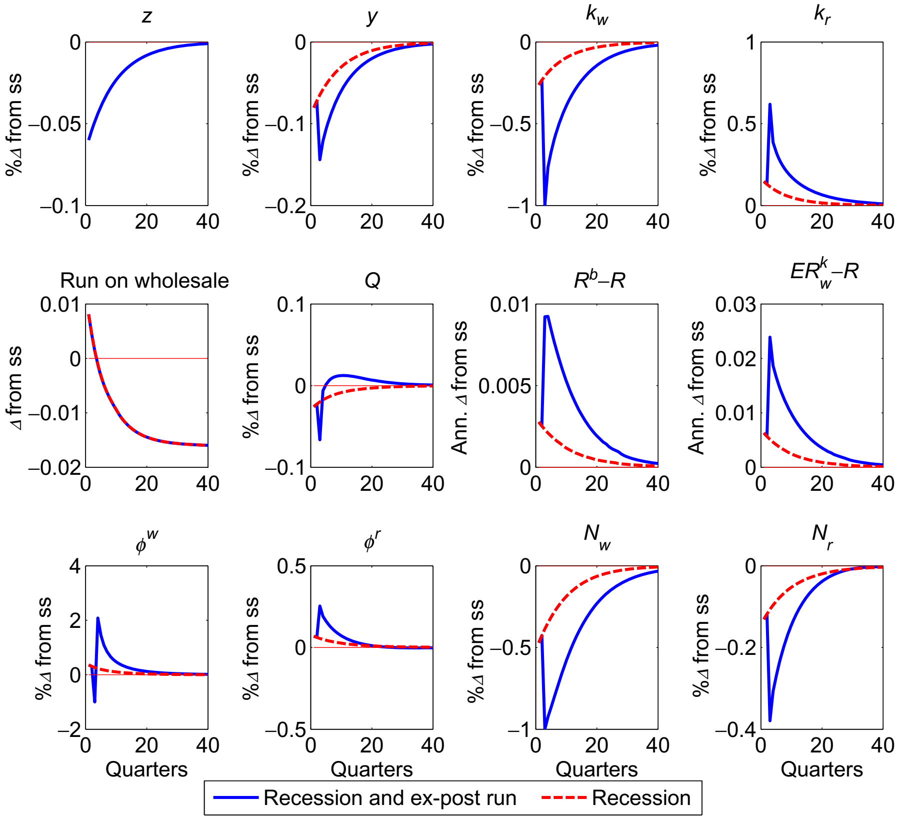

Fig. 11 A recession followed by a run on wholesale bankers.

with positive probability in the future, focusing on the more realistic case of a run on wholesale bankers only. The Appendices contains a detailed description of the equilibrium in this case.[ak] Here, we describe the key forces through which anticipation of a run in the future affects financial intermediation. To keep the analysis as simple as possible, we assume that once a negative shock to Z_t hits, Z_t obeys perfect foresight path back to steady state.

The main difference from the unanticipated case is in the market for interbank loans. In particular, once runs are anticipated, retail bankers internalize how wholesale bankers' leverage affects returns on interbank loans in case of a run and they adjust the required promised rate $\bar{R}_{bt+1}$ accordingly. We denote by p_t the time t probability that retail banks will run on wholesale banks at time t+1.[al] The indifference condition of the retail bank between making interbank loans and nonfinancial loans (33) becomes:

[ak] The analysis of anticipated runs draws heavily on Gertler and Kiyotaki (2015).

[al] The determination of this probability of "observing a sunspot" will be discussed later.

$$\begin{aligned}&E_t[(1-p_t)\Omega^r_{t+1}(\bar{R}_{bt+1}-R_{t+1})+p_t\Omega^{r*}_{t+1}(x^w_{t+1}\bar{R}_{bt+1}-R_{t+1})]\\&=\gamma E_t[(1-p_t)\Omega^r_{t+1}(R^r_{kt+1}-R_{t+1})+p_t\Omega^{r*}_{t+1}(R^{r*}_{kt+1}-R_{t+1})],\end{aligned}\tag{44}$$

where

$$\Omega^{r*}_{t+1}=\beta\left(1-\sigma+\sigma\frac{V^{r*}_{t+1}}{n^{r*}_{t+1}}\right)$$

is the value of the stochastic discount factor if a run occurs at $t+1$.

Using Eq. (41) to substitute for x^w_{t+1} in (44) we obtain a menu of promised rates:[am]

$$\begin{aligned}\bar{R}_{bt+1}(\phi^w_t)=(1-\gamma)R_{t+1}+\gamma\frac{E_t(\Omega^r_{t+1}R^r_{kt+1})}{E_t(\Omega^r_{t+1})}\\+\frac{p_t}{(1-p_t)E_t(\Omega^r_{t+1})}E_t\left\{\Omega^{r*}_{t+1}\left[(1-\gamma)R_{t+1}+\gamma R^{r*}_{kt+1}-\frac{\phi^w}{\phi^w-1}R^{w*}_{kt+1}\right]\right\}\end{aligned}\tag{45}$$

Notice that $\bar{R}_{bt+1}(\phi^w_t)$ is an increasing function ϕ^w_t. This is because as leverage increases, retail bankers suffer larger losses on interbank loans if a run occurs. This induces them to require higher returns in the event of no run, to compensate for the larger losses in the event of a run.

When choosing their portfolios, wholesale bankers will now have to factor in that changes in their leverage affect their cost of credit according to Eq. (45). This preserves homogeneity of the problem but the franchise value of the firm will change to reflect that with probability p_t the bank will be forced to liquidate assets at price Q^*_{t+1} in the subsequent period. This will have the effect of reducing the franchise value of wholesale banks, hence tightening their financial constraints.

In particular the franchise value of a wholesale bank will be given by[an]

$$\frac{V^w_t}{n^w_t}=(1-p_t)E_t\{\Omega^w_{t+1}[\phi^w_t(R^w_{t+1}-\bar{R}_{bt+1}(\phi^w_t))+\bar{R}_{bt+1}(\phi^w_t)]\}.\tag{46}$$

An increase in p_t reduces the franchise value through two channels: First, it decreases the likelihood that the bank will continue to operate next period. Second, it leads to an increase in the interbank loan rate each individual bank faces, $\bar{R}_{bt+1}(\phi^w_t)$, which reduces the franchise value even if the bank continues to operate.

[am] This is the relevant function for values of leverage high enough to induce bankruptcy in case of a run.

[an] Here, we are already assuming that wholesale bankers will choose a leverage high enough to result in bankruptcy when a run occurs. See the Appendices for a detailed description of the wholesale banker's problem when runs are anticipated. There, we derive the conditions that ensure that it is optimal for wholesale bankers to default in the event of a run.

In order to pin down a state dependent probability of a run, we follow Gertler and Kiyotaki (2015). In particular we assume that at each time t the probability of transitioning to a state where a run on wholesale banks occurs is given by a reduced form decreasing function of the expected recovery rate $E_t x^w_{t+1}$ as follows,

$$p_t = \left[1 - E_t\left(x^w_{t+1}\right)\right]^{\delta}. \tag{47}$$

Although we don't endogenize the functional dependence of p_t on the state of the economy, the above formulation allows us to capture the idea that as wholesale balance sheet positions weaken, the likelihood of a run increases. This same qualitative conclusion would follow, for example, if the probability of a run was determined endogenously by introducing imperfect information, as in the global games approach developed by Morris and Shin (1998).[ao]

Fig. 12 demonstrates how anticipation effects work to increase financial amplification of shocks in the model. The solid line is the response of the economy to an unanticipated

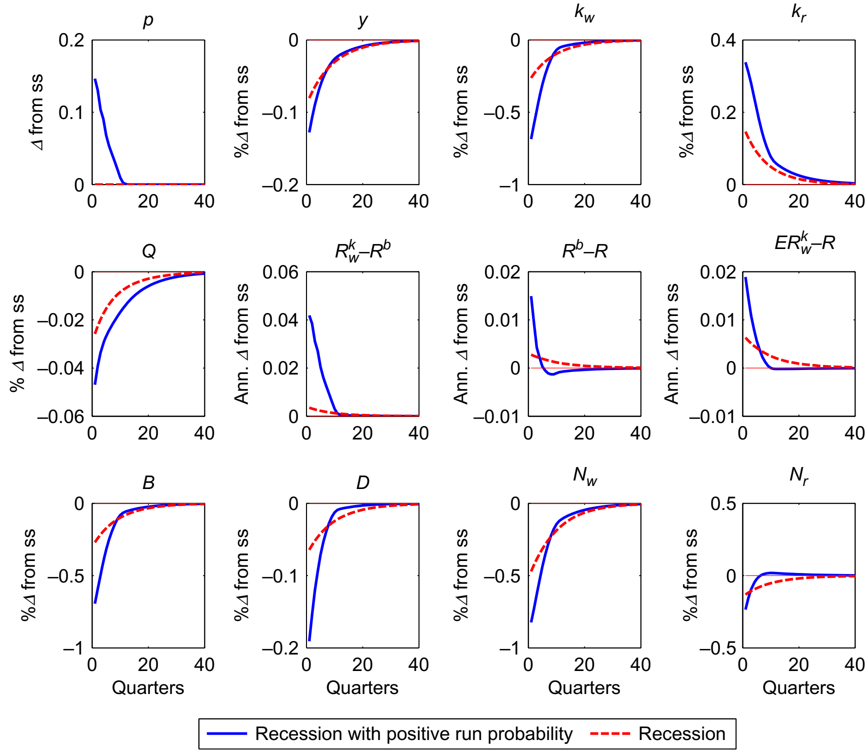

Fig. 12 A recession in the model with anticipated runs.

[ao] See Gertler et al (2016) for an alternative formulation of beliefs in a very similar setup and Goldstein and Pauzner (2005) for an application of the global games approach to bank runs.

6% shock to Z_t when agents anticipate that a run can happen at each time $t + 1$ with probability p_t as determined in Eq. (47).[ap] As we noted earlier, we assume that after the shock Z_t follows a perfect foresight path back to steady state. To isolate the effect of the anticipation of the run, we suppose in this case that the run never actually occurs ex-post. For comparison, the dotted line reports the responses of the baseline economy in which individuals assign probability zero to a bank run.

While it is still the case that in steady state a run cannot occur, the shock to Z_t leads the probability of a run to increase to 15%. As wholesale bankers' balance sheets weaken and the liquidation price decreases, retail bankers expect more losses on interbank loans in case of a run and the probability of coordinating on a run equilibrium increases as a result. The increase in p_t leads to a sharp contraction in the supply of interbank credit and a further tightening of wholesale bankers financial constraints. This, in turn, results in an overall reduction in their net worth of about 80% compared to a 50% in the baseline and to a spike in spreads between nonfinancial loan and interbank loan rates that increase by 400 basis points compared to only 30 in the baseline. As wholesale banks are forced to downsize their operations, total interbank credit falls by about 70%, more than twice the percentage drop in the baseline. These massive withdrawals of funds from wholesale markets is the model counterpart to the "slow runs" on the ABCP market in 2007. These disruptions in wholesale funding markets are then transmitted to the rest of the economy inducing a drop in asset prices of 5% and a total contraction of output of 13%.

Fig. 13 shows the case in which the run actually occurs two periods after the realization of the shock to Z_t. There are two main differences with respect to the analogous experiment performed in the case of unanticipated runs depicted in Fig. 11. First, the initial increase in the probability of a run that precedes the actual run allows the model to capture the "slow runs" followed by "fast runs" in wholesale funding markets that was a central feature of the financial crisis, as discussed in the Introduction. Second, the run induces a further increase in the probability of additional runs in the future, that goes back to about 20% the period after the run occurs. This hampers wholesale bankers ability to increase their leverage and generates higher spreads in the interbank market preventing the relatively smooth increase in asset prices that characterizes the recovery in the baseline model.

Fig. 14 shows how the model with anticipated runs can reproduce some key features of the financial disruptions that occurred in 2007 and 2008. In particular, we compare the model predicted path for interbank spreads, $\bar{R}^b_{t+1} - R_{t+1}$, and excess finance premium, $ER^w_{k,t+1} - R_{t+1}$, with their empirical counterparts over the period going from 2007Q2 to 2009Q4. For the interbank spreads we choose the ABCP spread, since the first "slow runs" in wholesale funding markets in the third quarter of 2007 took place in the ABCP market. The measure of excess borrowing costs is the Excess Bond Premium of Gilchrist

[ap] In the numerical simulations below we pick δ to be $\frac{1}{2}$.

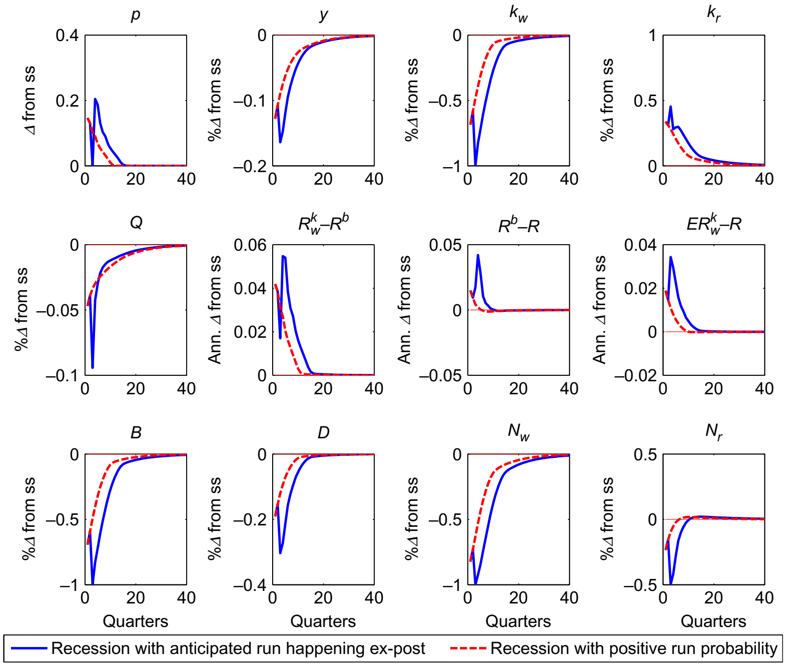

Fig. 13 A recession followed by a run in the model with anticipated runs.

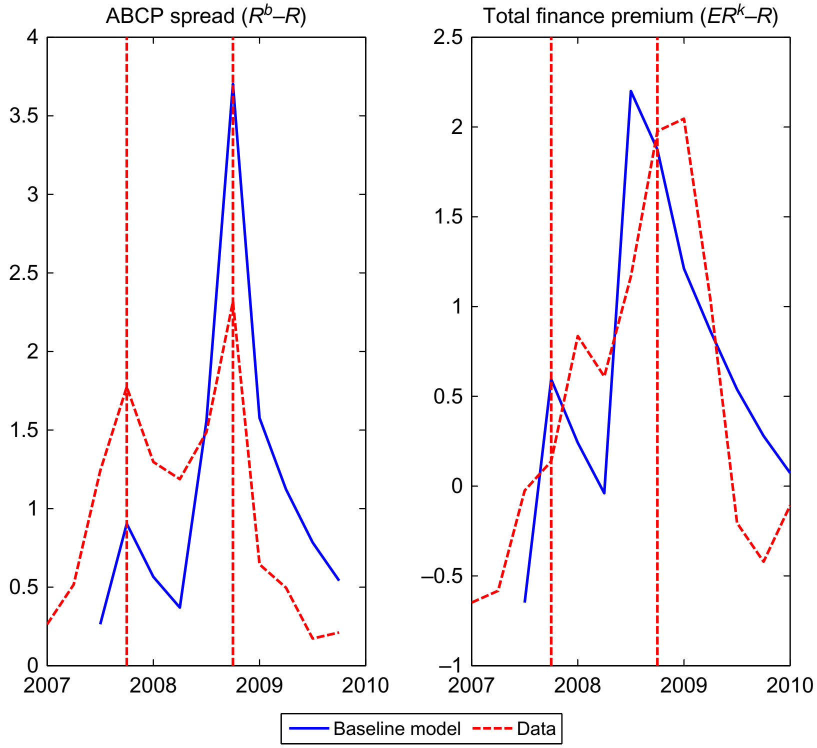

Fig. 14 Total credit spreads and interbank spreads in the model and in the data.

and Zakrajsek (2012). We assume that the economy is in steady state in 2007Q2 and the unanticipated shock hits in 2007Q3 followed by a run on wholesale banks in 2008Q3.[aq] In the data excess borrowing costs lag financial spreads, so the model predicts a stronger initial increase in $ER^{w}_{k,t+1} - R_{t+1}$ and attributes a slightly smaller proportion of the increase to interbank spreads, probably due to the behavior of the risk free rate. On the other hand, the faster decline in spreads in the data after 2009 can be attributed to the effects of government intervention in this period. Overall, the experiment can capture the credit spreads and bank equity dynamics reasonably well.

6. TWO PRODUCTIVE ASSETS AND SPILLOVER EFFECTS

In our baseline model there is only one type of capital. Wholesale banks have an efficiency advantage in holding this capital. Retail banks exist mainly because wholesale banks may be constrained by their net worth; otherwise the latter would hold all the capital. In this section we introduce a second type of capital which retail banks have an efficiency advantage in intermediating. In addition to providing a stronger motivation for the existence of retail banking, the second asset allows us to illustrate spillover effects from a crisis in wholesale banking into retail banking.

In particular, one of the salient features of the recent crisis was the strong contagion effect through which the collapse in subprime mortgage related products within the wholesale banking sector led to a deterioration in financial conditions within the commercial banking sector, ultimately affecting the flow credit through these institutions. Even though on the eve of the crisis, much of the credit provided by the retail sector had no direct reliance on shadow banks, the collapse of the latter ultimately disrupted commercial bank lending, enhancing the downturn.

As is the case with the first type of capital, we suppose the second type is fixed in supply and denote the total as $\bar{L}$. We refer to bank loans made to finance this capital as "C&I" loans (for "commercial and industrial" loans). What we have in mind are the kinds of information-intensive loans that are not easily securitized, which retail banks have historically specialized in intermediating. This contrasts with the kinds of securitized assets, involving mortgages, car loans, credit card debt, trade credit and so on, that were principally held by wholesale banks.

For simplicity, we assume that only retail banks and households fund the second type of capital. Given L_t^r and L_t^h are the amounts funded by retail banks and households, we have:

$$L_t^h + L_t^r = \bar{L} \tag{48}$$

We model retail banks' comparative advantage in making C&I loans by assuming that management costs of intermediating these loans are zero for these types of banks.

[aq] To be closer to the observed dynamics of spreads we resize the innovation to Z_t to five percentage points.

Conversely, we think of management costs for wholesale banks as being infinity. Finally, we allow households to directly fund this asset, where claims on this capital directly held by households may be thought of as corporate bonds. We suppose that households are at disadvantage to retail banks in funding the second type of capital, though at an advantage relative to wholesale banks: They must pay the management fee

$$F^L(K_t^L) = \frac{\alpha^L}{2}(K_t^L)^2$$

with $0 < \alpha^L < \infty$.

In analogy to the first type of capital, there is an exogenous dividend payout Z_t^L that obeys a stationary first order stochastic process. In addition, for simplicity we restrict attention to the case where bank runs are completely unanticipated. Accordingly, let R_{lt+1}^h be the household's rate of return from funding the second asset. Then the household's first order condition for holding the second asset is given by

$$E_t(\Lambda_{t,t+1}R_{lt+1}^h) = 1 \tag{49}$$

with

$$R_{lt+1}^h = \frac{Z_{t+1}^L + Q_{t+1}^L}{Q_t^L + \alpha_h^L L_t^h}$$

where Q_t^L is the asset price and α_h^L controls the degree of inefficiency of households in directly holding this asset.

The optimization problem of wholesale bankers is unchanged. Accordingly, we focus on retail bankers. Given retail banks now have the option of intermediating the second asset, we can rewrite the balance sheet and Flow of Funds constraints as

$$(Q_t + f_t^r)k_t^r + Q_t^L l_t^r + (-b_t^r) = n_t^r + d_t^r$$

$$n_{t+1}^r = R_{kt+1}^r\left(Q_t + f_t^r\right)k_t^r + R_{lt+1}^r Q_t^L l_t^r + R_{bt+1}(-b_t^r) - R_{t+1}d_t^r$$

where R_{lt+1}^r is the rate of return on the type L asset and is given by,

$$R_{lt+1}^r = \frac{Z_{t+1}^L + Q_{t+1}^L}{Q_t^L}.$$

Because the incentive constraint is

$$\theta[(Q_t + f_t^r)k_t^r + Q_t^L l_t^r + (-b_t^r)] \leq V_t^r,$$

the effective leverage multiple for this case ϕ_t^r now includes the holdings of the second type of capital:

$$\phi_t^r \equiv \frac{(Q_t + f_t^r)k_t^r + Q_t^L l_t^r + \gamma(-b_t^r)}{n_t^r}.$$

Proceeding as earlier to solve the retail bank's maximization problem yields a solution for ϕ^r_t which is the same as in the baseline case (see Eq. (27)). In addition, at the margin the retail bank must be indifferent between holding the types of capital, which implies the following arbitrage condition:

$$E_t[\Omega^r_{t+1}\left(R^r_{lt+1}-R^r_{kt+1}\right)]=0. \tag{50}$$

We now consider a numerical example designed to illustrate the contagion effect. The real world phenomenon that motivates the experiment is the fall in housing prices beginning in 2006 that led to the collapse of the wholesales banking sector that in turn disrupted commercial banking. In particular, we suppose that the dividend to asset L is fixed at its steady state value Z^L. Then we consider a negative shock to the dividend on the type K asset and, as in our earlier baseline experiments, allow for an unanticipated run two periods after the initial shock. Tables 4 and 5 describe the changes in the calibration for this experiment.

N^w	Wholesale banks networth	0.03

Fig. 15 reports the results from the experiment and demonstrates the spillover effects of shocks to Z_t on the market for L. The source of contagion in this environment is the balance sheet position of retail bankers.[ar] Losses on their capital investment and, in case of a run, on their interbank loans, result in a decrease in retail bankers' net worth and a tightening of their respective incentive constraints. As long as there are incentive costs associated with intermediating asset L, the tightening of financial constraints leads retail bankers to increase required excess returns in both markets, as shown by Eq. (50). The negative shock to returns on capital and the run on wholesale banks lead to a costly reallocation of assets to households and to an increase in spreads between returns on L_t^r and the deposit rate of about 60 basis points.

7. GOVERNMENT POLICY

In this section we study the effects of two types of policy interventions to combat banking crises: first an ex-post intervention where the central bank acts as a lender of last resort; second, an ex-ante macroprudential regulation that limits banks' risk exposure. Within the literature, these policies have largely been studied in the context of dampening negative financial accelerator effects on the economy. Here, we emphasize a somewhat

[ar] Other similar models of spillover are Bocola (2016) and Ferrante (2015b). An alternative mechanism based on market fragmentation is developed by Garleanu et al. (2015).

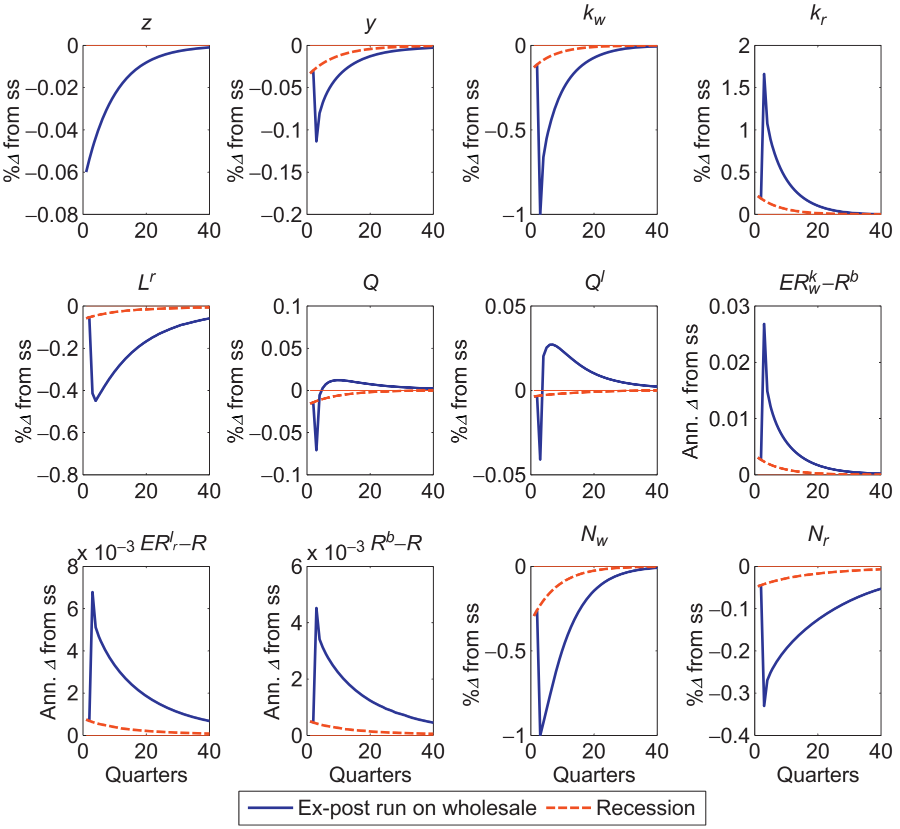

Fig. 15 Spillover.

different perspective: How these policies might be useful in reducing the likelihood of damaging bank runs? As we show, lender of last resort policy that is anticipated ex-ante in the event of an ex-post crisis reduces the likelihood of a run by raising asset liquidation prices. Macroprudential does so by reducing bank leverage.

A case for ex-ante macroprudential regulation arises because banks tend to choose an inefficiently high level of leverage in the laissez-faire economy. Roughly speaking, because individual banks ignore the consequences of their own borrowing decisions on the level of aggregate risk, they are prone to issue more debt than would be socially desirable.[as] In addition, as Farhi and Tirole (2012), Chari and Kehoe (2015), and Gertler et al. (2012) emphasize, the expectations of some type of government interventions ex-post will also encourage excessive leverage in the banking system ex-ante.

[as] See Geanakoplos and Polemarchakis (1986) for the original result of generic constrained inefficiency in a model with incomplete markets. Lorenzoni (2008) and Bianchi (2011) are recent applications to environments with financial frictions.

In this section we explore each of this kinds of policy's within our framework of Anticipated Runs of Section 5.

7.1 Ex-Post Intervention: Lender of the Last Resort

It is well known that if there are limits to arbitrage in private financial intermediation, then a central bank who plays as the lender of last resort during a financial crisis can enhance the flow of credit and in turn mitigate the economic downturn. What makes the lender of last resort effective is that the central bank can elastically obtain funds by issuing interest bearing reserves, while private financial intermediaries may be constrained in their ability to obtain funds by the condition of their balance sheets (Gertler and Karadi, 2011; Gertler and Kiyotaki, 2011).

Following the onset of the recent financial crisis, the Federal Reserve introduced a variety of lender of last resort programs. The most prominent involved large scale asset purchases (LSAPs) of high grade long-term debt, including primarily agency mortgage backed securities (AMBS), instruments that were held primarily in the shadow banking sector. The Fed announced this program in December 2008 following the collapse of the shadow banking system and began phasing it in the following March. The objective of this kind of lender of last resort intervention was to reduce the cost and thereby increase the availability of credit to the nonfinancial sector. There is evidence which suggests the Fed achieved this objective. Beyond these considerations, however, by acting as buyers in the secondary market for AMBS, the Fed raised the price and accordingly the liquidation value of these assets. As we noted, the impact of these policies on liquidation prices has important implications for banking stability. (See Eq. (40), for the condition for a bank run equilibrium.)

To model this type of intervention, we assume that the central bank can directly undertake intermediation by borrowing from retail banks and then making nonfinancial loans. The way the central bank obtains funds from retail banks is to issue interest bearing bank reserves. We assume that retail banks are unable to divert bank reserves, since they are held in an account at the Fed. Given retail banks cannot divert reserves, they are not constrained in their ability to raise deposits to fund reserves. Because there are no limits to arbitrage for banks funding reserves, the interest rate on reserves will equal the deposit rate. Therefore, when the central bank supplies interest-rate bearing reserves to retail banks, it effectively raises funds directly from households by issuing overnight government bond. What gives the central bank an advantage in intermediating assets is that, unlike retail and wholesale banks, it is not balance sheet constrained.

We also assume, following Gertler and Karadi (2011) that the central bank is less efficient than the private sector. As with retail banks and households, the government faces quadratic managerial costs $\frac{1}{2}\alpha^g (K_t^g)^2$, where K_t^g is the size of central bank's intervention and where $\alpha^h > \alpha^g > \alpha^r$. To ensure that it is desirable for the central bank to intervene only in a crisis, we also allow for inefficiency in the average performance of the government's portfolio: In particular, we assume that the return on government intermediated assets is:

$$R^g_{kt+1} = \varphi \frac{Z_{t+1} + Q_{t+1}}{Q_t + \alpha^g K^g_t} \tag{51}$$

where $\varphi \in (0,1)$ controls the relative inefficiency of central bank's intermediation for the average return on assets, independent of scale.

We assume that the central bank intervenes in credit markets whenever expected asset returns exceed its cost of borrowing. That is we posit a policy rule for central bank's intervention given by

$$\begin{array}{ll} K^g_t = 0, & \text{if } E_t\left(R^g_{kt+1} - R_{gt+1}\right) < 0 \\ E_t\left(R^g_{kt+1} - R_{gt+1}\right) = 0, & \text{if } K^g_t \geq 0 \end{array} \tag{52}$$

where R_{gt+1} is the interest paid on reserves issued to retail banks.

As we just noted, since there is no incentive problem associated with central bank intermediation, in equilibrium the interest rate on reserve R_{gt+1} must equal to the deposit rate:[at]

$$R_{gt+1} = R_{t+1}. \tag{53}$$

The key variable to which the central bank responds in determining credit market intervention is the spread between the wholesale bank's return on assets and the deposit rate, $R^w_{kt+1} - R_{t+1}$, which can be thought of as a measure of the degree of inefficiency in private financial markets. The central bank intervenes when this excess return is high.[au] In particular, the policy rule (52) prescribes that the Fed starts intermediating assets as soon as the ratio of the credit spread to the deposit rate exceeds a given threshold that varies inversely with the inefficiency parameter φ :

$$K^g_t > 0, \text{ iff } \frac{E_t(R^w_{kt+1}) - R_{t+1}}{R_{t+1}} > \frac{1-\varphi}{\varphi}.$$

[at] To see formally, first notice that, since retail bankers cannot divert reserves, their incentive constraint (14) is not affected by the amount of reserves held on their balance sheet. Hence the introduction of interest bearing reserves only affects retail bankers' optimization problem by modifying the objective function (26), which becomes

$$V^r_t = \underset{\phi^r_t, d^r_{gt}}{Max} E_t\left\{\Omega^r_{t+1}\left[\phi^r_t(R^r_{kt+1} - R_{t+1}) + R_{t+1} + d^r_{gt}(R_{gt+1} - R_{t+1})\right]n^r_t\right\}$$

where d^r_{gt} is the amount of reserves per unit of networth held by retail bankers. The optimality condition with respect to d^r_{gt} is just given by $R_{gt+1} = R_{t+1}$. Covariance terms are zero since both R_{gt+1} and R_{t+1} are known at date t.

[au] Our policy rule, which has the central bank target credit spreads, is consistent with how the central bank behaved throughout the crisis. What motivated an unconventional intervention in a given credit market was typically a sharp increase in the spread within that market.

From Eq. (52), the size of the intervention in the region where $K_t^g > 0$ is then governed by:

$$K_t^g = \frac{\varphi}{\alpha^g} Q_t \left[\frac{E_t(R_{kt+1}^w) - R_{t+1}}{R_{t+1}} - \frac{1-\varphi}{\varphi} \right].$$

We choose φ in order to ensure that the central bank only intervenes after a run happens: that is, the threshold for the credit spread to justify an intervention is reached only in the event of a run. We choose the management cost parameter α^g in order for the intervention to be around 5% of total capital.

Fig. 16 shows the response of the economy to a recession when agents anticipate that, if a run happens, the monetary authority intervenes with large scale asset purchases according to (52). Even though in this experiment the run does not happen and the central bank accordingly does not intervene, the anticipation of the intervention in the event of a run significantly dampens the downturn. It does so by reducing the probability of a run: The central bank's conditional intervention policy increases the liquidation price of

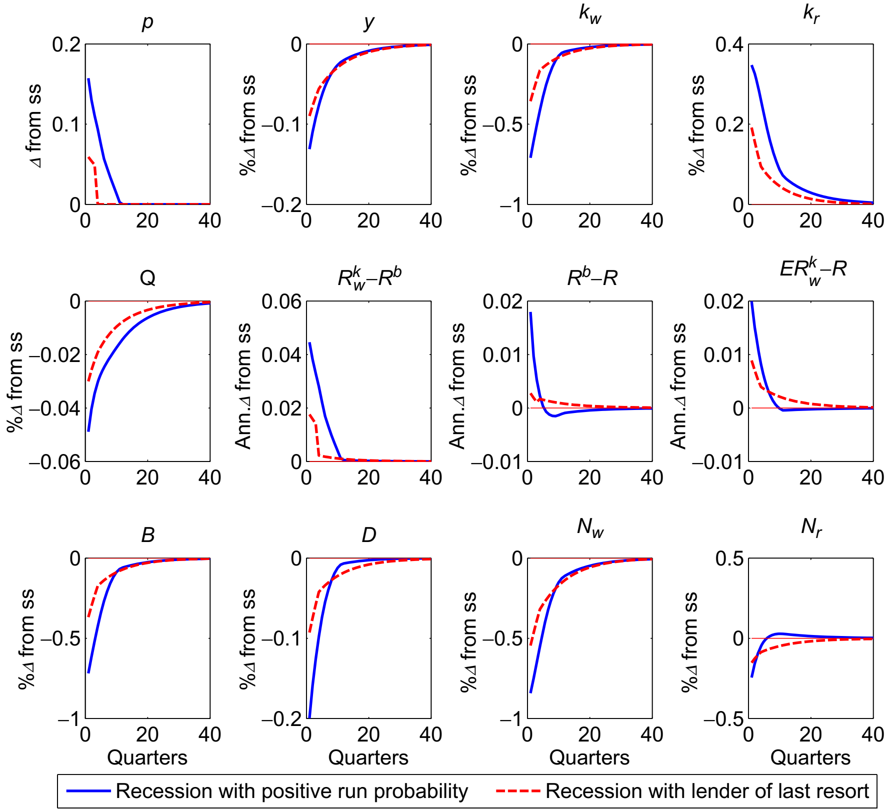

Fig. 16 Anticipation effects of government intervention.

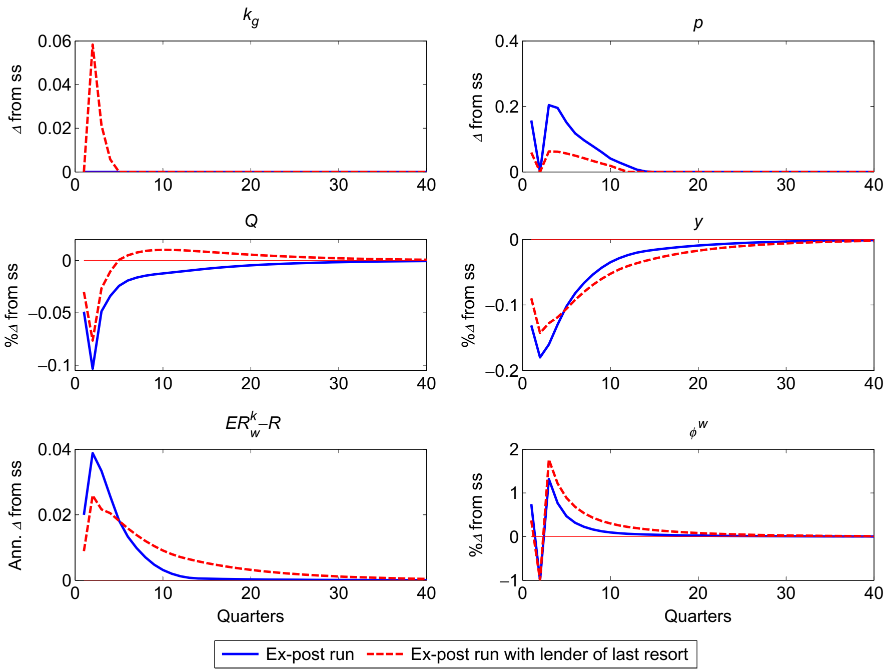

Fig. 17 Government intervention when a run happens at time 2.

wholesale banks assets. In turn, by Eq. (47), the higher recovery rate associated with higher liquidation prices decreases the probability of a run. In the experiment the probability of a run decreases by 10% in the first two periods and becomes zero thereafter. This drastic reduction in the run probability implies that, overall, anticipation of government intervention works to stimulate the economy. Notice that, even though the reduction in the run probability relaxes the incentive constraint and hence allows wholesale bankers to increase their leverage for any given level of spreads, the general equilibrium effects of asset prices on their balance sheet results in better capitalization and lower leverage in both the wholesale and retail bank sectors.

Fig. 17 illustrates the effect of the intervention when a run happens one period after the shock to Z. The intervention is around 5% of total capital and reduces the drop in asset prices and output by about 2.5 and 4%, respectively.

7.2 Ex-Ante Intervention: Macroprudential Policy

One of the most important challenges facing policy makers in the aftermath of the financial crisis is the development of financial regulations that can help prevent the recurrence of similar episodes in the future. In this respect, the most relevant innovation in the policy landscape has been the introduction of various macroprudential measures in the oversight of financial institutions, such as stress tests by central banks and the revised provisions in Basel III. These measures are aimed at ensuring that financial institutions' capital is sufficient to absorb losses during adverse economic conditions.

There is now a significant literature that analyzes the impact of capital requirements on banks for macroeconomic stability (eg, Christiano and Ikeda, 2014; Begenau, 2015; Bianchi and Mendoza, 2013; Chari and Kehoe, 2015; Gertler et al., 2012). Most of this literature analyzes how the introduction of leverage restrictions can dampen financial accelerator effects by dampening fluctuations in bank capital. The need for leverage restrictions, or equivalently capital requirements, stems from an externality that leads individual banks to fail to take into account the effect of their own borrowing on the stability of the system as a whole.[av]

Our framework offers a somewhat different perspective on the potential benefits of leverage restrictions. Not only can these restrictions dampen financial accelerator effects: Importantly, they can also make the banking system less susceptible to runs. As Eq. (41) makes clear, a bank run can only happen if the leverage ratio is high enough. Thus, by limiting the leverage ratio sufficiently, the regulatory authority can in principle eliminate the possibility of a run. The question then is what are the tradeoffs. We turn to this issue next.

We capture macroprudential policies in our model economy by introducing leverage restrictions on wholesale banks. In particular, we assume that a financial regulator can impose an upper bound on wholesale banks' leverage, $\overline{\phi}^w$. This implies that the effective limit to wholesale banks' leverage will be given by the smaller between the market imposed limit and the regulatory limit. Accordingly, constraint (22) becomes

$$\phi^w \leq \min\left\{\frac{\frac{1}{\theta}\frac{V_t^w}{n_t^w}-(1-\omega)}{\omega}, \overline{\phi}^w\right\}$$

In a fully stochastic simulation of the economy, leverage restrictions would tradeoff lower frequency of crises, resulting from reduced variation of bankers' capital, against lower average output, as the impaired ability of wholesale banks to increase their leverage would induce a costly reallocation of capital to less efficient agents. While our numerical experiments in Sections 4.2 and 4.3 provide an illustration of the tradeoff between steady state output and fragility associated to changes in the long run level of wholesale bankers'

[av] Much of the literature, following Lorenzoni (2008), features a pecuniary externality stemming from the presence of asset prices in the borrowing constraint. Farhi and Werning (2015) and Korinek and Simsek (2015) show that if aggregate demand is sensitive to aggregate leverage, a similar kind of externality can emerge.

leverage, here we focus on the conditional effects of leverage restrictions upon the occurrence of a recession that would leave the decentralized economy vulnerable to bank runs.

We focus on two possible levels for $\overline{\phi}^{w}$: the steady state level of wholesale banks' leverage and a level that is higher than steady state but still sufficiently low to prevent a run. Permitting a leverage ratio above the steady state allows banks to issue more debt in a recession, which has the overall effect of dampening the contraction in financial intermediation and thus dampening the downturn in real activity. Indeed, the more forgiving leverage restriction comes closer to mimicking the behavior of the leverage ratio in the decentralized economy, which moves countercylcially.

Figs. 18 and 19 compare the response of the economy with anticipated runs to a negative Z innovation, with and without macroprudential regulation. In Fig. 18 the regulator imposes the tighter leverage restriction, ie, $\overline{\phi}^{w}$ is set to the steady state value of wholesale leverage, while in Fig. 19 the restrictions are more lax and allow maximum regulatory leverage to exceed the steady state value by 15%. As mentioned, in both cases, the leverage restrictions are sufficient to prevent a run and hence avoid the recessionary effects associated to the endogenous increase in the probability of a run that characterizes

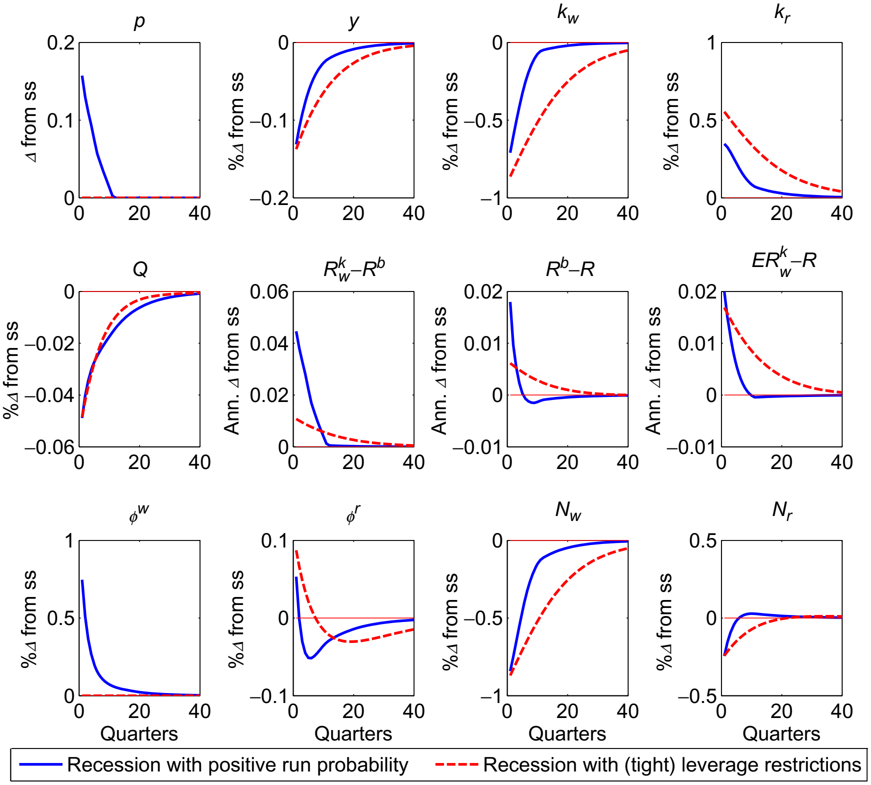

Fig. 18 Macro prudential policy: $\phi^{w} = \phi^{ss}$.

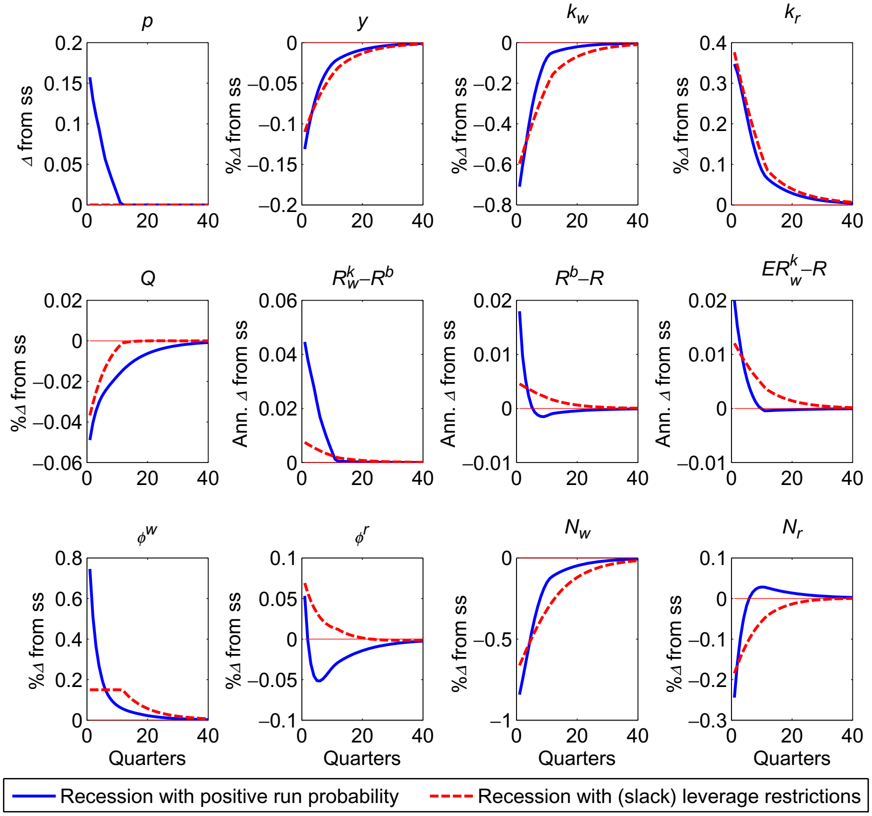

Fig. 19 Macro prudential policy: $\phi^w = 1.15\phi^{ss}$.

the unregulated economy. This results in higher asset prices in the regulated economy throughout the recession. Under the less strict requirements the stimulative effect on asset prices is significantly higher, reaching about 1.5% after the first three years of the recession. On the other hand, by constraining the ability to leverage of the most efficient intermediaries, macroprudential policies induces a costly reallocation of assets. The balance between these two contrasting forces varies overtime, in turn influencing output effects of the policy.

During the early stages of the recession, the stimulative effects of macroprudential policy are strongest because they eliminate the probability of a bank run, which in the unregulated economy is highest at this time. Under the stricter policy, the impact drop in output is very similar to the drop in the unregulated economy, while the more lax stance of policy dampens the drop in output by 2% and is stimulative throughout the first year of the recession. As time passes, the probability of a run becomes small in the unregulated economy, implying that the stimulative effects of policy decreases. On the other hand, the slower recovery of financial institutions' equity in the regulated economy that results from their impaired ability to leverage, implies a more persistent drag on output coming from financial misallocation. In both cases output costs associated with the policy peak at around 10 quarters into the recession and result in an additional drop in output of about 4% under the tighter requirements and 1.5% under the more lax stance.

8. SUMMARY AND DIRECTIONS FOR FUTURE RESEARCH

The financial crisis that triggered the Great Recession featured a disruption of wholesale funding markets, where banks lend to one another, as opposed to retail markets where banks obtain funds from depositors. It is essential to capture the roles and possible disruption of wholesale funding market to understand the financial crisis as well as to draw policy implications. Our goal in this Handbook Paper was to sketch a model based on the existing literature that provides a step toward accomplishing this objective. The model first accounts for how, through innovation in the efficiency of interbank loan markets, a wholesale banking sector emerges that intermediates loans using funds borrowed from retail banks. This wholesale sector bears a close resemblance to the shadow banking system featured in most descriptions of the crisis.

As we show, in "normal" times, the growth of the wholesale banking sector improves both efficiency and stability. Improved efficiency stems from the comparative advantage that wholesale banks having in managing certain types of loans. Improved stability arises because retail banks act as a buffer to absorb loans that wholesale banks sell off, in effect improving the liquidity of secondary loan markets. On the other hand, the growth of wholesale banking system makes the economy more vulnerable to a crisis. As occurred in practice, the high leverage of wholesale banks makes this sector susceptible to runs that can have highly disruptive effects on the economy. A contractionary disturbance that might otherwise lead to a moderate recession, can induce a run on the wholesale banking sector with devastating effects on the economy, as experienced during the Great Recession. We then describe how both lender of last resort and macroprudential policies can help reduce the likelihood of these kinds of banking crises.

Our framework also captures the buildup of safe assets prior to the crisis along with the subsequent collapse that a number of authors have emphasized (eg, Gorton and Metrick, 2015; Caballero and Farhi, 2015). The underlying mechanisms work a bit differently, in somewhat subtle ways: The "safe asset" literature points to an increased demand for safe assets as the driving force in the buildup of the shadow banking system. By making assets riskier, the crisis then reduces the ability of the shadow banking sector to create safe assets. It is this reduction in safe assets that then leads a contraction in spending, essentially for liquidity reasons. Within our framework, the increase in safe assets is a product of innovation in interbank lending markets. Indeed, this is where much of the growth in safe assets occurred. There is also a growth in households deposits as the overall banking system becomes more efficient. The crisis similarly induces a contraction in safe assets: The exact mechanism, though, is that, with an adverse shock to the net worth of banks, the probability of runs on wholesale banks becomes positive, which constrains the ability of both wholesale and retail banks to issue safe liabilities. In turn, a contraction in real activity emerges because the costs of intermediation increase, as manifested by the increase in credit spreads. In future work, it would be interesting to synthesize the role of safe assets in our framework with that in the conventional literature on this topic.

Another important area for further investigation involves the modeling of the growth of wholesale banking. Our approach was to treat this growth as the product of innovation as captured by a reduction in the agency friction in interbank lending markets. Among the factors we had in mind that motivate this reduction is technological improvements that permit less costly monitoring, such as the development of asset-backed securities and repo lending. Of course, more explicit modeling of this phenomenon would be desirable. Also important is integrating regulatory considerations. While financial innovation was important for the development of shadow banking, regulatory factors also played an important role. For example, tightening of capital requirements on commercial banks in conjunction with innovation in asset securitization induced movement of a considerable amount of mortgage lending from the retail to the wholesale banking sector. A careful integration of the roles of regulation and innovation in the development of wholesale banking would be highly desirable.

Finally, consistent with what occurred in the recent crisis, what makes the financial system within our model so vulnerable is high degree of leverage in the form of short-term debt. Here, we simply rule out a richer set of state-contingent financial contracts that would permit banks to hedge against the systemic risk implied by this liability structure. Why in practice we don't seem to observe the kind of seemingly desirable hedging is an important question for future research.[aw]

APPENDICES

Appendix A Details of the Equilibrium

From (13, 15–17), we get

$$
\begin{aligned}
\frac{V_t^j}{n_t^j} &= E_t\left(\Omega_{t+1}^j \cdot \frac{n_{t+1}^j}{n_t^j}\right)\\
&= E_t\left\{\Omega_{t+1}^j\left[R_{kt+1}^j + \left(R_{kt+1}^j - R_{t+1}\right)\frac{d_t^j}{n_t^j} + \left(R_{kt+1}^j - R_{bt+1}\right)\frac{b_t^j}{n_t^j}\right]\right\}\\
&= \nu_{kt}^j + \mu_{dt}^j\frac{d_t^j}{n_t^j} + \mu_{bt}^j\frac{b_t^j}{n_t^j},
\end{aligned}
$$

[aw] Some efforts to address this issue include Krishnamurthy (2003), Di Tella (2014), Gertler et al. (2012), and Dang et al. (2012).

where

$$\nu^j_{kt} \quad = E_t(\Omega^j_{t+1} R^j_{kt+1}) \tag{A.1}$$

$$\mu^j_{dt} \quad = E_t\left[\Omega^j_{t+1}\left(R^j_{kt+1} - R_{t+1}\right)\right] \tag{A.2}$$

$$\mu^j_{bt} \quad = E_t\left[\Omega^j_{t+1}\left(R^j_{kt+1} - R_{bt+1}\right)\right]. \tag{A.3}$$

From (13), the incentive constraint (14) can be written as

$$V^j_t \geq \theta\left[n^j_t + d^j_t + \omega b^j_t \cdot I_{b^j_t > 0} + (1-\gamma) b^j_t \cdot I_{b^j_t < 0}\right],$$

where $I_{b^j_t>0} = 1$ if $b^j_t > 0$ and $I_{b^j_t>0} = 0$ otherwise, (and $I_{b^j_t<0} = 1$ if $b^j_t < 0$ and $I_{b^j_t<0} = 0$ otherwise).

In order to save the notations, we normalize $n^j_t = 1$ and suppress the suffix and time subscript. The generic choice of a bank is given by

$$\psi = \underset{b,\,d}{Max}(\nu_k + \mu_d d + \mu_b b) \tag{A.4}$$

subject to

$$\theta[1 + d + \omega b \cdot I_{b>0} + (1-\gamma) b \cdot I_{b<0}] \leq \nu_k + \mu_d d + \mu_b b, \tag{A.5}$$

$$d \geq 0,$$

$$1 + d + b \geq 0.$$

Figs. A.1 and A.2 depict the Feasible set and an Indifference Curve for Wholesale Bankers and Retail Bankers under our baseline.

Defining λ and λ_k as Lagrangian multipliers of the incentive constraint and the non-negativity constraint of capital, we have the Lagrangian as

$$\mathcal{L} = (1+\lambda)(\nu_k + \mu_d d + \mu_b b) - \lambda\theta[1 + d + \omega b \cdot I_{b>0} + (1-\gamma) b \cdot I_{b<0}] + \lambda_k(1 + d + b).$$

For the case of $b \geq 0$, we know $\lambda_k = 0$ and the first order conditions are

$$(1+\lambda)\mu_b \leq \lambda\theta\omega,$$

where $=$ holds if $b > 0$, and $<$ implies $b = 0$.

$$(1+\lambda)\mu_d \leq \lambda\theta,$$

where $=$ holds if $d > 0$, and $<$ implies $d = 0$.

In the following we restrict the attention to the case of $\mu_d > 0$, and will verify the inequality later. Thus for the case of $b > 0$, we learn

$$d > 0, \text{ if } \frac{\mu_b}{\mu_d} = \omega,$$

$$d = 0, \text{ if } \frac{\mu_b}{\mu_d} > \omega.$$

d

Fig. A.2 Retail banker's optimization.

Thus for the case of $b < 0$ and $d > 0$, we learn

$$k > 0, \text{ if } \frac{\mu_b}{\mu_d} = 1-\gamma,$$

$$k = 0 \text{ and } \lambda_k > 0, \text{ if } \frac{\mu_b}{\mu_d} < 1-\gamma.$$

Therefore, under Assumption 2: $\omega + \gamma > 1$, we can summarize the bank's choice as:

(i) $b > 0,\ d = 0,\ k > 0$, if $\mu_b > \omega\mu_d$

(ii) $b > 0,\ d > 0,\ k > 0$, implies $\mu_b = \omega\mu_d$

(iii) $b = 0$, $d > 0$, $k > 0$, if $(1-\gamma)\mu_d < \mu_b < \omega\mu_d$
(iv) $b < 0$, $d > 0$, $k > 0$, implies $\mu_b = (1-\gamma)\mu_d$
(v) $b < 0$, $d > 0$, $k = 0$, if $\mu_b < (1-\gamma)\mu_d$.
In the steady state equilibrium, we know

$$\frac{\mu_b}{\mu_d} = \frac{R_k - R_b}{R_k - R}.$$

Because we know $R_k^w \geq R_k^r$ and $R_b \geq R$, we learn

$$\frac{\mu_b^w}{\mu_d^w} \geq \frac{\mu_b^r}{\mu_d^r}.$$

Therefore, market clearing for interbank loans implies that, if the interbank market is active wholesale bankers' choice can only be (i) or (ii) and retail banker's choice (iv) or (v). Otherwise both types must choose according to (iii) and the interbank market is inactive. That is, we have only the following possible patterns of equilibrium in the neighborhood of the steady state.

(A) Perfect Specialization with active Interbank Market: $d^w = 0, k^r = 0, b^w > 0 > b^r$
(B) Perfect Specialized Retail Banks with active Interbank Market: $d^w > 0, k^r = 0, b^w > 0 > b^r$
(C) Perfect Specialized Wholesale Banks with active Interbank Market: $d^w = 0, k^r > 0, b^w > 0 > b^r$
(D) Imperfect Specialization with active Interbank Market: $d^w > 0, k^r > 0, b^w > 0 > b^r$
(E) Inactive Interbank Market: $d^w > 0, k^r > 0, b^w = 0 = b^r$.
We can show that, under Assumption 2, there is no equilibrium of type (A) nor (B):

Proof. Equilibrium of type (A) and (B) require $\mu_b^w \geq \omega\mu_d^w$ and $(1-\gamma)\mu_d^r \geq \mu_b^r$. Thus

$$R_b \leq \omega R + (1-\omega)R_k^w,$$
$$R_b \geq (1-\gamma)R + \gamma R_k^r = (1-\gamma)R + \gamma R_k^w, \text{ as } K^r = 0 \text{ in (A)and (B)}.$$

This implies

$$\omega R + (1-\omega)R_k^w \geq (1-\gamma)R + \gamma R_k^w,$$

or

$$(\omega + \gamma - 1)R \geq (\omega + \gamma - 1)R_k^w.$$

But this is a contradiction as $\omega + \gamma > 1$ and $R_k^w > R$ (as $\mu_d^w > 0$ under our conjecture).

Equilibrium C and D: Active Interbank Market
Suppose that $0 < \mu_{bt}^{w} < \theta\omega$. We will verify this numerically after we characterize the equilibrium. Then the incentive constraint (A.5) holds with equality for wholesale banks. Together with Bellman equation (A.4), we have

$$\begin{aligned}\psi_t^w &= \nu_{kt}^w + \mu_{dt}^w d_t^w + \mu_{bt}^w b_t^w \\ &= \theta\left(1 + d_t^w + \omega b_t^w\right),\end{aligned}$$

or

$$b_t^w = \frac{1}{\theta\omega - \mu_{bt}^w}\left[\nu_{kt}^w - \theta - (\theta - \mu_{dt}^w) d_t^w\right],$$

$$\psi_t^w = \frac{\theta}{\theta\omega - \mu_{bt}^w}\left[\omega\nu_{kt}^w - \mu_{bt}^w + (\omega\mu_{dt}^w - \mu_{bt}^w) d_t^w\right].$$

Maximizing Tobin's Q, ψ_t^w, with respect to $d_t^w \geq 0$, we learn

$$d_t^w = 0, \text{ if } \mu_{dt}^w < \frac{1}{\omega}\mu_{bt}^w$$

$$d_t^w > 0 \text{ implies } \mu_{dt}^w = \frac{1}{\omega}\mu_{bt}^w.$$

This proves Lemma 1 and the argument in the text follows for wholesale banks, noting that we normalize $n_t^w = 1$ above.

Suppose also that $0 < \mu_{dt}^r < \theta$. We will verify this numerically after we characterize the equilibrium. Then the incentive constraint (A.5) holds with equality for retail banks. Together with Bellman equation (A.4), we have

$$\begin{aligned}\psi_t^r &= \nu_{kt}^r + \mu_{dt}^r d_t^r + \mu_{bt}^r b_t^r \\ &= \theta[1 + d_t^r + (1-\gamma) b_t^r].\end{aligned}$$

Then we get

$$d_t^r = \frac{1}{\theta - \mu_{dt}^r}\{\nu_{kt}^r - \theta + [\theta(1-\gamma) - \mu_{bt}^r](-b_t^r)\},$$

$$\psi_t^r = \frac{\theta}{\theta - \mu_{dt}^r}\left[\nu_{kt}^r - \mu_{dt}^r + (\mu_{dt}^r - \mu_{bt}^r - \gamma\mu_{dt}^r)(-b_t^r)\right].$$

Maximizing Tobin's Q, ψ_t^r, with respect to $k_t^r \geq 0$ and $b_t^r \leq 0$, we learn

$$k_t^r > 0 \text{ and } b_t^r < 0 \text{ imply } \mu_{dt}^r - \mu_{bt}^r = \gamma\mu_{dt}^r$$

$$k_t^r = 0 \text{ and } b_t^r < 0 \text{ if } \mu_{dt}^r - \mu_{bt}^r > \gamma\mu_{dt}^r.$$

This proves Lemma 2 and the argument in the text follows for retail banks, noting that we normalize $n_t^r = 1$ above.

Therefore the argument in the text follows for the aggregate equilibrium.

Equilibrium E: No Active Interbank Market $b_t^w = b_t^r = 0$

From Bellman equation and the incentive constraint of each bank (A.4, A.5) with $\left(Q_t + f_t^j k_t^j\right) k_t^j = 1 + d_t^j$, we have

$$\psi_t^j = \theta\left(Q_t + f_t^j k_t^j\right) k_t^j = \nu_{kt}^j - \mu_{dt}^j + \mu_{dt}^j \left(Q_t + f_t^j k_t^j\right) k_t^j,$$

or

$$\begin{aligned} \left(Q_t + f_t^j k_t^j\right) k_t^j &= \frac{\nu_{kt}^j - \mu_{dt}^j}{\theta - \mu_{dt}^j}, \\ \psi_t^j &= \theta \frac{\nu_{kt}^j - \mu_{dt}^j}{\theta - \mu_{dt}^j} \end{aligned} \tag{A.6}$$

The aggregate balance sheet conditions of wholesale and retail banking sectors are

$$Q_t K_t^w = \frac{\nu_{kt}^w - \mu_{dt}^w}{\theta - \mu_{dt}^w} N_t^w = N_t^w + D_t^w \tag{A.7}$$

$$\left(Q_t + f_t^r K_t^r\right) K_t^r = \frac{\nu_{kt}^r - \mu_{dt}^r}{\theta - \mu_{dt}^r} N_t^r = N_t^r + D_t^r. \tag{A.8}$$

The recursive competitive equilibrium without bank runs consists of 24 variables-aggregate quantities $\left(K_t^w, K_t^r, K_t^h, D_t^w, D_t^r, N_t^w, N_t^r, C_t^b, C_t^h, \bar{Y}_t, Y_t\right)$, prices $\left(Q_t, R_{t+1}, f_t^r\right)$ and bankers' franchise values and leverage multiples $\left(\Omega_t^j, R_{kt}^j, \nu_{kt}^j, \mu_{dt}^j, \psi_t^j\right)_{j=w,r}$- as a function of the state variables $\left(K_{t-1}^w, K_{t-1}^r, R_t D_{t-1}^w, R_t D_{t-1}^r, Z_t\right)$, which satisfy 24 equations (1, 4, 7, 8, 16, 18, 34–39, A.1, A.2, A.6–A.8) where each of (16, 18, A.1, A.2, A.6–A.8) contain two equations.

After finding the equilibrium, we need to check the inequalities

$$\begin{aligned} \mu_{bt}^w &< \omega \mu_{dt}^w, \\ \mu_{bt}^r &> (1-\gamma)\mu_{dt}^r. \end{aligned}$$

In the neighborhood of the steady state, it is sufficient to show

$$(1-\omega)E_t\left(\frac{Q_{t+1} + Z_{t+1}}{Q_t}\right) + \omega R_{t+1} < \gamma E_t\left(\frac{Q_{t+1} + Z_{t+1}}{Q_t + \alpha^r K_t^r}\right) + (1-\gamma)R_{t+1}. \tag{A.9}$$

Appendix B Steady State of the Economy Without Run

In order to characterize the steady state of (C,D,E), define x^j as the growth rate of the net worth of continuing bank j in the steady state:

$$x^j = \frac{n^j_{t+1}}{n^j_t} = R^j_k \frac{(Q+f^j)k^j}{n^j} - R_b \frac{b^j}{n^j} - R\frac{d^j}{n^j}$$

$$= \left(R^j_k - R_b\right)\frac{b^j}{n^j} + \left(R^j_k - R\right)\frac{d^j}{n^j} + R^j_k.$$

Then we have the aggregate net worth of bank j as

$$N^j = \sigma^j x^j N^j + W^j$$

$$= \frac{W^j}{1-\sigma^j x^j} \equiv N^j(x^j),$$

if $\sigma^j x^j < 1$, which we guess and verify later. Tobin's Q of bank j is

$$\psi^j = \beta(1-\sigma^j + \sigma^j\psi^j)x^j$$

$$= \frac{\beta(1-\sigma^j)x^j}{1-\beta\sigma^j x^j} \equiv \psi^j(x^j).$$

The ratio of bank loans to net worth is

$$\frac{Qk^w}{n^w} = \frac{\psi^w(x^w)}{\theta\omega} - \frac{1-\omega}{\omega}\left(1+\frac{d^w}{n^w}\right), \text{ if } b^w > 0,$$

$$\frac{Qk^w}{n^w} = \frac{\psi^w(x^w)}{\theta}, \text{ if } b^w = 0,$$

$$\frac{(Q+f^r)k^r}{n^r} = \frac{\psi^r(x^r)}{\theta} - \gamma\left(-\frac{b^r}{n^r}\right).$$

Case of Active Interbank Market: C and D

From the condition for the retail banks, we have

$$1-\gamma = \frac{\mu^r_b}{\mu^r_d} = \frac{R^r_k - R_b}{R^r_k - R},$$

or

$$R_b = \gamma R^r_k + (1-\gamma)R.$$

$$\begin{aligned}
x^r - R &= (R_k^r - R_b)\frac{b^r}{n^r} + \left(R_k^r - R\right)\left(1 + \frac{d^r}{n^r}\right) \\
&= \left(R_k^r - R\right)\left[1 + \frac{d^r}{n^r} + (1-\gamma)\frac{b^r}{n^r}\right] \\
&= \left(R_k^r - R\right)\left[\frac{(Q+f^r)k^r}{n^r} + \gamma\left(-\frac{b^r}{n^r}\right)\right] \\
&= \left(R_k^r - R\right)\frac{\psi^r(x^r)}{\theta}.
\end{aligned}$$

Thus from $R = \beta^{-1}$,

$$\beta(R_k^r - R) = \theta\frac{\beta x^r - 1}{\psi^r(x^r)} = \theta\frac{(\beta x^r - 1)(1-\sigma^r\beta x^r)}{(1-\sigma^r)\beta x^r} \equiv \varphi^r(\beta x^r),$$

$$\beta(R_b - R) = \gamma\theta\frac{\beta x^r - 1}{\psi^r(x^r)} = \gamma\varphi^r(\beta x^r).$$

Thus R_k^r and R_b are functions of only x^r :

$$R_k^r = R_k^r(x^r), R_b = R_b(x^r).$$

Differentiating log of the right hand side (RHS) of the above equation with respect to x^r, we learn

$$\begin{aligned}
\frac{d\ \ln\varphi^r(\beta x^r)}{d(\beta x^r)} &= \frac{1}{\beta x^r - 1} - \frac{\sigma^r}{1-\beta\sigma^r x^r} - \frac{1}{\beta x^r} \\
&\propto 1 - \sigma^r(\beta x^r)^2 \\
&> 0, \text{ iff } \sigma^r(\beta x^r)^2 < 1.
\end{aligned}$$

Thus if $\sigma^r(\beta x^r)^2 < 1$, R_k^r and R_b are increasing functions of only x^r :

$$R_k^r = R_k^r(x^r), R_k^{r\prime}(\cdot) > 0,$$

$$R_b = R_b(x^r), R_b'(\cdot) > 0.$$

Similarly

$$\begin{aligned}
x^w - R_b &= (R_k^w - R_b)\left(1 + \frac{b^w}{n^w}\right) + \left(R_k^w - R\right)\frac{d^w}{n^w} \\
&= (R_k^w - R_b)\left(1 + \frac{b^w}{n^w}\right) + \frac{1}{\omega}\left(R_k^w - R_b\right)\frac{d^w}{n^w} \\
&= \left(R_k^w - R_b\right)\left(\frac{Qk^w}{n^w} + \frac{1-\omega}{\omega}\frac{d^w}{n^w}\right) \\
&= \left(R_k^w - R_b\right)\left(\frac{1}{\omega\theta}\psi^w - \frac{1-\omega}{\omega}\right).
\end{aligned}$$

Thus

$$\begin{aligned}
R_k^w - R_b &= \omega\theta\frac{x^w - R_b}{\psi^w - \theta(1-\omega)}, \\
R_k^w - R &= \frac{1}{\psi^w - \theta(1-\omega)}\left[\omega\theta(x^w - R) + (\psi^w - \theta)(R_b - R)\right].
\end{aligned}$$

Because

$$\begin{aligned}
&\frac{d}{dx^w}\ \ln\left[\frac{\omega\theta(x^w - R)}{\psi^w - \theta(1-\omega)}\right] \\
&\propto \frac{1}{\beta x^w - 1} - \frac{\sigma^w}{1 - \sigma^w\beta x^w} - \frac{\Delta}{\Delta\beta x^w - \theta(1-\omega)}, \text{ where } \Delta = 1 - \sigma^w + \theta(1-\omega)\sigma^w \\
&\propto (1-\sigma^w)\left[1 - \sigma^w(\beta x^w)^2\right] - \theta(1-\omega)(1 - \sigma^w\beta x^w)^2,
\end{aligned}$$

R_k^w is an increasing function of x^w and x^r

$$R_k^w = R_k^w(x^w, x^r),$$

if

$$\begin{gathered}
(1-\sigma^w)\left[1 - \sigma^w(\beta x^w)^2\right] > \theta(1-\omega)(1 - \sigma^w\beta x^w)^2, \\
\sigma^r(\beta x^r)^2 < 1.
\end{gathered}$$

In the following we assume these conditions to be satisfied.

In the steady state, we know the rates of returns on capital for wholesale and retail banks and households are

$$R_k^w = \frac{Z+Q}{Q}$$

$$R_k^r = \frac{Z+Q}{Q+\alpha^r K^r}$$

$$R_k^h = \frac{Z+Q}{Q+\alpha^h K^h} = R.$$

Thus we have

$$Q = \frac{Z}{R_k^w - 1},$$

$$\alpha^r K^r = \frac{Z-(R_k^r-1)Q}{R_k^r} = Z\frac{R_k^w - R_k^r}{R_k^r(R_k^w-1)},$$

$$\alpha^h K^h = \frac{Z-(R-1)Q}{R} = Z\frac{R_k^w - R}{R(R_k^w-1)},$$

and Q, K^r and K^w are functions of (x^w, x^r).

Equilibrium C: $D^w = 0$

Here, the market clearing condition of capital is given by

$$\begin{aligned} QK^w &= \frac{Qk^w}{n^w}N^w \\ &= \frac{\psi^w(x^w) - \theta(1-\omega)}{\theta\omega}N^w(x^w) \\ &= Q(x^w,x^r)\left[\bar{K} - K^r(x^w,x^r) - K^h(x^w,x^r)\right] \end{aligned} \tag{B.1}$$

The market clearing condition of interbank credit is given by

$$\begin{aligned} B &= \left(\frac{Qk^w}{n^w} - 1\right)N^w \\ &= \frac{\psi^w(x^w) - \theta}{\theta\omega}N^w(x^w) \\ &= \frac{1}{\gamma}\left\{\frac{\psi^r(x^r)}{\theta}N^r(x^r) - [Q(x^w,x^r) + \alpha^r K^r(x^w,x^r)]\cdot K^r(x^w,x^r)\right\} \end{aligned} \tag{B.2}$$

The equilibrium value of $(x^w, x^r)$is given by (x^w, x^r) which satisfies (B.1 and B.2) simultaneously.

In order to verify $\mu_d^w > 0$ and $\mu_d^r > 0$, it is sufficient to check the inequalities

$$x^w > x^r > R = \beta^{-1}.$$

For the other inequality $\mu_b^w > \omega \mu_d^w$, it is sufficient to check

$$R_k^w - R_b > \omega\left(R_k^w - R\right),$$

or

$$(1-\omega)(R_k^w - R) > R_b - R.$$

This is equivalent with

$$(1-\omega)\frac{\beta x^w - 1}{\psi^w(x^w)} > \gamma \frac{\beta x^r - 1}{\psi^r(x^r)}. \tag{B.3}$$

Equilibrium D: $D^w > 0$

For this type of equilibrium, we need $\mu_{kb}^w = \omega \mu_d^w$, or

$$R_k^w - R_b = \omega\left(R_k^w - R\right).$$

Thus

$$\begin{aligned} x^w - R &= \left(R_k^w - R\right)\left(1 + \frac{d^w}{n^w} + \omega \frac{b^w}{n^w}\right) \\ &= \left(R_k^w - R\right)\frac{\psi^w}{\theta}, \end{aligned}$$

Thus being similar to the expression for $\beta(R_k^r - R)$, we get

$$\beta(R_k^w - R) = \theta \frac{\beta x^w - 1}{\psi^w(x^w)} = \theta \frac{(\beta x^w - 1)(1 - \sigma^w \beta x^w)}{(1-\sigma^w)\beta x^w} \equiv \varphi^w(\beta x^w).$$

R_k^w is an increasing function of x^w if $\sigma^w(\beta x^w)^2 < 1$.

Also we learn

$$R_b - R = (1-\omega)\left(R_k^w - R\right) = \gamma\left(R_k^r - R\right),$$

or

$$(1-\omega)\varphi^w(\beta x^w) = \gamma \varphi^r(\beta x^r), \tag{B.4}$$

and thus x^r is an increasing function of x^w. We can solve Q and K^h as functions of x^w as

$$\begin{aligned} Q &= \frac{Z}{R_k^w - 1} \\ &= \frac{\beta Z}{\varphi^w(\beta x^w) + 1 - \beta} \equiv Q(x^w), \end{aligned}$$

$$\begin{aligned} K^h &= \frac{1}{\alpha^h}[\beta Z - (1-\beta)Q] \\ &= \frac{1}{\alpha^h}\frac{\beta Z \varphi^w(\beta x^w)}{\varphi^w(\beta x^w) + 1 - \beta} \equiv K^h(x^w). \end{aligned}$$

We also get

$$\begin{aligned} K^r &= \frac{1}{\alpha^r}\frac{Z - (R_k^r - 1)Q}{R_k^r} = \frac{Z}{\alpha^r}\frac{R_k^w - R_k^r}{R_k^r(R_k^w - 1)} \\ &= \frac{1}{\alpha^r}\frac{\beta Z \varphi^w(\beta x^w)}{\varphi^w(\beta x^w) + 1 - \beta}\frac{\gamma + \omega - 1}{\gamma + (1-\omega)\varphi^w(\beta x^w)} \\ &= \frac{\gamma + \omega - 1}{\gamma + (1-\omega)\varphi^w(\beta x^w)}\frac{\alpha^h}{\alpha^r}K^h \equiv K^r(x^w) \end{aligned}$$

The capital market equilibrium is given by

$$\begin{aligned} QK^w &= \frac{1}{\theta\omega}\psi^w N^w - \frac{1-\omega}{\omega}(N^w + D^w) \\ &= \frac{1}{\theta\omega}\psi^w N^w - \frac{1-\omega}{\omega}(QK^w - B) \\ &= \frac{1}{\theta}\psi^w N^w + (1-\omega)B \\ &= \frac{1}{\theta}\psi^w N^w + \frac{1-\omega}{\gamma}\left[\frac{\psi^r}{\theta}N^r - (Q + \alpha^r K^r)K^r\right] \\ &= Q\left(\bar{K} - K^h - K^r\right). \end{aligned}$$

Thus

$$\begin{aligned} &\frac{\psi^w}{\theta}N^w + \frac{1-\omega}{\gamma}\frac{\psi^r}{\theta}N^r \\ &= \frac{\psi^w}{\theta}\left[N^w + \frac{\beta x^r - 1}{\beta x^w - 1}N^r\right], (\because (\text{B.4})) \\ &= Q\left[\bar{K} - K^h - K^r + \frac{1-\omega}{\gamma}\frac{Q + \alpha^r K^r}{Q}K^r\right] \\ &= Q\left[\bar{K} - K^h - K^r + \frac{1-\omega}{\gamma}\frac{R_k^w}{R_k^r}K^r\right] \\ &= Q\left[\bar{K} - K^h - \frac{\gamma + \omega - 1}{\gamma + (1-\omega)\varphi^w(\beta x^w)}K^r\right], \end{aligned}$$

or

$$\begin{aligned}&\frac{\psi^w(x^w)}{\theta}\left[N^w(x^w)+\frac{\beta x^r-1}{\beta x^w-1}N^r(x^r)\right]\\&=Q(x^w)\left[\overline{K}-K^h(x^w)-\frac{\gamma+\omega-1}{\gamma+(1-\omega)\varphi^w(\beta x^w)}K^r(x^w)\right].\end{aligned}\tag{B.5}$$

The equilibrium is given by (x^r, x^w) which satisfies (B.4 and B.5).

We need to check $D^w > 0$, or

$$0<\left(\frac{\psi^w}{\theta\omega}-\frac{1-\omega}{\omega}\right)N^w-\frac{1}{\theta}\psi^w N^w-\frac{1-\omega}{\gamma}\left[\frac{\psi^r}{\theta}N^r-(Q+\alpha^r K^r)K^r\right],$$

or

$$\gamma\left[\frac{\psi^w(x^w)}{\theta}-1\right]N^w(x^w)>\omega\left[\frac{\psi^r(x^r)}{\theta}N^r(x^r)-[Q(x^w)+\alpha^r K^r(x^w)]\cdot K^r(x^w)\right].$$

Equilibrium E: No Active Interbank Market

We have for $j = w, r$ that

$$\frac{(Q+f^j)k^j}{n^j}=\frac{\psi^j(x^j)}{\theta},$$

$$x^j-R=\left(R_k^j-R\right)\frac{(Q+f^j)k^j}{n^j}=\left(R_k^j-R\right)\frac{\psi^j(x^j)}{\theta},$$

or

$$R_k^j-R=\theta\frac{x^j-R}{\psi^j(x^j)},$$

or

$$R_k^j=R_k^j\left(x^j\right),\ R_k^{j\prime}(\cdot)>0$$

if $\sigma^w(\beta x^j)^2 < 1$. Thus

$$Q=Q(x^w),\ Q'(\cdot)<0$$

$$K^h=K^h(x^w), K^{h\prime}(\cdot)>0.$$

The aggregate capital of retail banks satisfies

$$\begin{aligned}QK^r&=Q\frac{Z-(R_k^r-1)Q}{\alpha^r R_k^r}=Q(x^w)\frac{Z}{\alpha^r}\frac{R_k^w(x^w)-R_k^r(x^r)}{R_k^r(x^r)[R_k^w(x^w)-1]}\\&=\frac{\psi^r(x^r)}{\theta}N^r(x^r)\end{aligned}\tag{B.6}$$

The capital market clearing condition is

$$\begin{aligned} QK^w &= \frac{\psi^w(x^w)}{\theta} N^w(x^w) \\ &= Q(x^w)\left[\bar{K} - K^r(x^r, x^w) - K^h(x^w)\right] \end{aligned} \tag{B.7}$$

The equilibrium is given by (x^r, x^w) which satisfies (B.6 and B.7).

Appendix C Anticipated Bank Run Case

Here, we describe the conditions determining agents policy functions in the case of anticipated runs. As in the text, we focus on the case in which variation in Z_{t+1} is negligible. Moreover, we follow the notation by which for any given variable $\widetilde{\xi}_t$

$$E_t^*\left(\widetilde{\xi}_{t+1}\right) = (1-p_t)\xi_{t+1} + p_t\xi_{t+1}^*$$

where ξ_{t+1}^* is the value taken by $\widetilde{\xi}_{t+1}$ when a run occurs.

Appendix C.1 Households

Households optimal choices of capital holdings and deposits are given by

$$E_t^*\left(\widetilde{\Lambda}_{t,t+1}\right)R_{t+1} = 1$$

$$E_t^*\left(\widetilde{\Lambda}_{t,t+1}\widetilde{R}_{kt+1}^h\right) = 1$$

Appendix C.2 Retail Bankers

The conditions in Lemma 2 that guarantee that retail banks are constrained are now modified as follows:

Lemma C.1 $b_t^r < 0$, $k_t^r > 0$ *and the incentive constraint is binding off*

$$0 < E_t^*\left[\widetilde{\Omega}_{t+1}^r\left(\widetilde{R}_{kt+1}^r - R_{t+1}\right)\right] = \frac{1}{\gamma}E_t^*\left[\widetilde{\Omega}_{t+1}^r\left(\widetilde{R}_{bt+1} - R_{t+1}\right)\right] < \theta.$$

The optimal choice of leverage is

$$\phi_t^r = \frac{E_t^*\left(\widetilde{\Omega}_{t+1}^r\right)R_{t+1}}{\theta - E_t^*\left[\widetilde{\Omega}_{t+1}^r\left(\widetilde{R}_{kt+1}^r - R_{t+1}\right)\right]}.$$

Appendix C.3 Wholesale Bankers

The optimization problem of wholesale banks when bank runs are anticipated is complicated by the fact that the banker can avoid bankruptcy by reducing its leverage in case a run materializes. Here, we derive conditions under which he does not wish to do this. For simplicity, we focus on the problem of a wholesale banker that only funds himself in the interbank market.

In this case we can derive a threshold level for leverage, ϕ_t^{wM}, under which the banker will survive a bank run, which is given by

$$\bar{R}_{bt+1} = R_{f,t+1} \equiv \frac{E_t^*\left(\widetilde{\Omega}_{t+1}^r \widetilde{R}_{\gamma,t+1}^r\right)}{E_t^*\left(\widetilde{\Omega}_{t+1}\right)} = R_{kt+1}^{w*} \frac{\phi_t^{wM}}{\phi_t^{wM}-1}$$

where

$$\widetilde{R}_{\gamma,t+1}^r \equiv \gamma \widetilde{R}_{kt+1}^r + (1-\gamma)R_{t+1}$$

and $R_{f,t+1}$ is the risk free interbank rate that satisfies Eq. (44) with $x_{t+1}^w = 1$.

The objective function of wholesale bankers displays a kink at ϕ_t^{wM}, so that in order to derive their optimal leverage choice we need to study separately the optimal choice in the region where leverage is high enough to induce bankruptcy when a run happens, $[\phi_t^{wM}, \infty)$, and in the region where bankruptcy is avoided even if a run happens, $\left[0, \phi_t^{wM}\right]$. As long as wholesale bankers objective is strictly increasing in leverage in both of these regions, the incentive constraint holds with equality.

In the bankruptcy region, $[\phi_t^{wM}, \infty)$, (45) with deterministic Z_{t+1} is simplified to

$$\bar{R}_{bt+1}(\phi_t^w) = R_{\gamma,t+1}^r + \frac{p_t}{1-p_t}\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left(R_{\gamma,t+1}^{r*} - \frac{\phi_t^w}{\phi_t^w - 1}R_{t+1}^{w*}\right).$$

Then the objective function of a wholesale bank with one unit of networth is given by

$$\begin{aligned}
\psi^w\left(\phi_t^w\right) &= (1-p_t)\left\{\Omega_{t+1}^w\left[\phi_t^w\left(R_{kt+1}^w - \bar{R}_{bt+1}\left(\phi_t^w\right)\right) + \bar{R}_{bt+1}\left(\phi_t^w\right)\right]\right\} \\
&= (1-p_t)\Omega_{t+1}^w\left[\phi_t^w\left(R_{t+1}^w - R_{\gamma,t+1}^r\right) + R_{\gamma,t+1}^r\right] \\
&\quad + p_t\Omega_{t+1}^w\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left[\phi_t^w\left(R_{k,t+1}^{w*} - R_{\gamma,t+1}^{r*}\right) + R_{\gamma,t+1}^{r*}\right]
\end{aligned}$$

which is strictly increasing in ϕ_t^w if and only if

$$(1-p_t)\left(R_{kt+1}^w - R_{\gamma,t+1}^r\right) + p_t\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left(R_{kt+1}^{w*} - R_{\gamma,t+1}^{r*}\right) > 0 \qquad \text{(C.1)}$$

Notice that condition (C.1) is implied by the condition that guarantees that retail bankers are constrained, $E_t^*\left[\tilde{\Omega}_t^r\left(\tilde{R}_{kt+1}^r - R_{t+1}\right)\right] > 0$, together with the fact that retail bankers are less efficient at intermediating capital than wholesale bankers $\alpha^r > 0$:

$$
\begin{aligned}
&(1-p_t)\left(R_{kt+1}^w - R_{\gamma,t+1}^r\right) + p_t\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left(R_{kt+1}^{w*} - R_{\gamma,t+1}^{r*}\right)\\
&> (1-p_t)\left(R_{kt+1}^r - R_{\gamma,t+1}^r\right) + p_t\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left(R_{k,t+1}^{r*} - R_{\gamma,t+1}^{r*}\right)\\
&= \frac{(1-\gamma)}{\Omega_{t+1}^r}E_t^*\left\{\tilde{\Omega}_t^r\left(\tilde{R}_{kt+1}^r - R_{t+1}\right)\right\} > 0
\end{aligned}
$$

In the region where the banker is able to avoid bankruptcy even when a run happens, $\left[0, \phi_t^{wM}\right]$, the objective is instead

$$
\begin{aligned}
\psi^{w,n}\left(\phi_t^w\right) &= E_t^*\left\{\tilde{\Omega}_{t+1}^w\left[\phi_t^w\left(\tilde{R}_{kt+1}^w - R_{f,t+1}\right) + R_{f,t+1}\right]\right\}\\
&= \begin{array}{c} (1-p_t)\left\{\Omega_{t+1}^w\left[\phi_t^w\left(R_{kt+1}^w - R_{f,t+1}\right) + R_{f,t+1}\right]\right\}\\ +p_t\left\{\Omega_{t+1}^{w*}\left[\phi_t^w\left(R_{kt+1}^{w*} - R_{f,t+1}\right) + R_{f,t+1}\right]\right\} \end{array}
\end{aligned}
$$

and the condition that guarantees that the objective is strictly increasing in ϕ_t^w in this region is

$$
E_t^*\left[\tilde{\Omega}_{t+1}^w\left(\tilde{R}_{kt+1}^w - R_{f,t+1}\right)\right] > 0. \tag{C.2}
$$

Given this we can modify the conditions in Lemma 1 as follows:

Lemma C.2 *Under the conditions of Lemma C.1, the incentive constraint is binding off*

$$
0 < E_t^*\left[\tilde{\Omega}_{t+1}^w\left(\tilde{R}_{kt+1}^w - R_{f,t+1}\right)\right]
$$

$$
\theta\omega > (1-p_t)\left(R_{kt+1}^w - R_{\gamma,t+1}^r\right) + p_t\frac{\Omega_{t+1}^{r*}}{\Omega_{t+1}^r}\left(R_{kt+1}^{w*} - R_{\gamma,t+1}^{r*}\right).
$$

Appendix D Measurement

We use data from the Flow of Funds in order to construct empirical counterparts of the financial flows in the simplified intermediation process described in Fig. 1. The first step in constructing our time series is a definition of the wholesale and retail sector within the broad financial business sector.

Our classification is based on the sectors and instruments reported in the Flow of Funds. We use the liability structure of the different sectors included in the "Financial

Business" sector of the Flow of Funds in order to aggregate them into a Retail sector, a Wholesale sector, and Others. To do this, we proceed in two steps: we first classify the funding instruments in the Flow of Funds into four categories that we name Retail Funding, Wholesale Funding, Intermediated Assets, and Other Instruments; then we assign financial intermediaries to the Retail/Wholesale sector if the funding instruments they mostly rely on belong to the Retail/Wholesale category.

Table D.1 describes the four categories of funding we use. The labels in parentheses are the identifiers in the Flow of Funds.

The criterion we use to define the above categories is the composition of demand and supply for each instrument. Instruments that are supplied by financial intermediaries and demanded by households fall in the Retail category, while instruments that are mainly traded among financial intermediaries are included in Wholesale Funding. Intermediated Assets consist of all of the claims issued by domestic nonfinancial business and households. Others is a residual category.

To define our Retail and Wholesale sectors, we start by excluding some types of intermediaries from the ones that we are trying to study in our model economy. These are the intermediaries listed in the "Others" category in Table D.2. The remaining financial intermediaries appearing in the Flow of Funds are included in the Retail/Wholesale sector if they mostly rely on Retail/Wholesale funding. The resulting aggregation is described in Table D.2.

Table D.1 Classification of instruments in the flow of funds

Retail funding	Checkable deposits and currency (L.204) Time and saving deposits (L.205) Money market mutual fund shares (L.206) Mutual fund shares (L.214)	
Wholesale funding	*Short term*	Repurchase agreements (L.207) Security credit (L.224) Financial open market paper (L.208) Agency/GSE backed securities (L.210)
	Long term	Financial corporate bonds (L.212) Retail loans to wholesale (L.215)
Intermediated assets	Non-financial corporate bonds (L.212) Non-financial equity (L.213) Non-financial open market paper (L.208) Retail loans to non-financial (L.215) Mortgages (L.217) Consumer credit (L.222) Other loans (L.216)	
Other types of funding	All other instruments in the flow of funds	

Table D.2 Aggregation of financial sectors in the flow of funds

Retail sector	Private depository institutions (L.110) Money market mutual funds (L.121) Mutual funds (L.122)
Wholesale sector	Security brokers dealers (L.129) ABS issuers (L.126) GSE and GSE mortgage pools (L.124–125) Real estate investment trusts (L.128) Finance companies (L.127) Funding corporations (L.131) Holding companies (L.130)
Other intermediaries	Monetary authority (L.109) Private and public pension funds (L.117) Closed end and exchange traded funds (L.123) Insurance companies (L.115–116) Government (L.105–106) Rest of the world (L.132)
Households	L.101
Firms	L.102

Given this we construct the following measures:

1. K_t^h, K_t^r, K_t^w

   The intermediation shares are constructed by computing aggregate short and long positions of Households, Retail Banks, and Wholesale banks in the markets that make up the Intermediated Assets category in Table D.1. The matrix below describes each sectors' activity in each market. If sector J has a long/short position in market X the corresponding entry is given by X_+^J / X_-^J. If sector J has both long and short positions in market X, the corresponding entry also displays its net position, $X_{net}^J(+)/X_{net}^J(-)$.

Markets	**Bonds** *L*.**212**	**Equity** *L*.**213**	**Comm paper** *L*.**208**	**Loans** *L*.**215**	**Mortgages** *L*.**208**	**Consumer credit** *L*.**222**
Sectors Retail banks	BO_+^R BO_-^R $BO_{net}^R(+)$	EQ_+^R NA ?	CP_+^R CP_-^R $CP_{net}^R(+)$	L_+^R	M_+^R	CC_+^R
Wholesale banks	BO_+^W BO_-^W $BO_{net}^W(-)$	EQ_+^W NA ?	CP_+^W CP_-^W $CP_{net}^W(-)$	L_-^W	M_+^W	CC_+^W
Other item	BO_+^O BO_-^O $BO_{net}^O(+)$	EQ_+^O NA ?	CP_+^O CP_-^O $CP_{net}^O(+)$	L_-^O	M_+^O	CC_+^O

Markets	Bonds *L*.212	Equity *L*.213	Comm paper *L*.208	Loans *L*.215	Mortgages *L*.208	Consumer credit *L*.222
Households	BO^H_+	EQ^H_+	0 0	L^H_-	M^H_-	CC^H_-
Firms	BO^F_-	EQ^F_-	CP^F_+ CP^F_- $\mathrm{CP}^F_{net}(-)$	L^F_-	M^F_+ M^F_- $\mathrm{M}^F_{net}(-)$	CC^F_+

We make several assumptions in order to conduct our measures.First, in the markets for bonds and commercial paper, some positions are potentially inconsistent with our intermediation model. This is because some sectors within the retail category are short in these markets and some in wholesale are long, $\mathrm{BO}^R_- > 0$, $\mathrm{CP}^R_- > 0$, $\mathrm{BO}^W_+ > 0$ and $\mathrm{CP}^W_+ > 0$. This allows for the possibility that retail banks were borrowing from wholesale in these markets. However, we rule out this possibility in constructing our measures for two reasons: given the heavy reliance on these types of instruments in financial transactions among industries within the respective categories and among financial firms within the same industry, it is reasonable to assume that the vast majority of these offsetting positions were actually arising from cross holdings among firms within the same category; moreover, the actual size of BO^R_- and CP^R_- with respect to BO^W_- and CP^W_- was very small, ie, $\frac{CP^R_-}{CP^W_-} \simeq 0.1\%$ and $\frac{CP^R_-}{CP^W_-} \simeq 3\%$ in 2007. This implies that we can safely work with the net positions for wholesalers and retailers. Given the assumptions we make in these markets we can construct model consistent measures from bonds and commercial paper data by assuming that households lend to nonfinancial firms, which is part of K^h, while retail banks (and Other intermediaries) lend to both Wholesale banks, which is part of B, and firms, which is part of K^r.[ax] We also assume that portfolio weights on nonfinancial and financial issued instruments in these markets are the same for retail banks and other intermediaries.[ay] That is, letting $F^{i,F}_{bo}$ and $F^{i,F}_{cp}$ be the proportions of lender's $i's$ holdings of bonds and commercial paper that are issued by nonfinancial firms, we have

[ax] The Households' sector in the Flow of Funds is a residual category that includes Hedge Funds, private equity funds and personal trusts, which are intermediaries that our model does not directly capture. In any case, households' intermediation in bonds and commercial paper market is a small component of household intermediation so that very little would change if we instead made different assumptions about households positions in these markets.

[ay] We include long positions of nonfinancial firms in the commercial paper within intermediation performed by "Others."

$$F^{H,F}_{bo} = 1; F^{R,F}_{bo} = \left(\frac{BO^F_- - BO^H_+}{BO^F_- + BO^W_{net} - BO^H_+}\right);$$[az]

Similarly for commercial paper: $F^{H,F}_{cp} = 0; F^{R,F}_{cp} = \frac{CP^F_-}{CP^F_- + CP^W_{net}}$ Second, for corporate equities the Flow of Funds does not report a disaggregated measure of equity issued by individual industries or the type of equity held by the various industries. Since we use this market only in measuring K^i, we simply assume that each sector holds a scaled version of the same equity portfolio consisting of the three sectors for which we have issuance data: Foreign equities, Financial Business equities, and Non-Financial Business Equities, denoted by EQ^{ROW}, EQ^{FIN}, and EQ^{NFI}, respectively. That is, in order to compute how many funds flow to nonfinancial firms from each other sector we simply scale their total equity holdings by

$$\eta = \frac{EQ^{NFI}}{EQ^{NFI} + EQ^{FIN} + EQ^{ROW}}$$

Given this we can compute

$$K^h_t = \eta EQ^H + BO^H_+$$

$$K^r_t = \eta EQ^R + F^{R,F}_{bo} BO^R_{net} + F^{R,F}_{cp} CP^R_{net}$$
$$+ L^F_- + L^H_- + M^R_+ + CC^R_+$$

$$K^W_t = \eta EQ^W + M^W_+ + CC^W_+$$

2. *B*,*D*

   B is simply computed as wholesale net borrowing in all of the short-term wholesale instruments: Repo, Commercial Paper, Agency Debt, and Security credit. *D* is given by Households and nonfinancial Business holdings of retail funding instruments.

3. Leverage multiple for broker dealers, finance companies, and GSE

   We compute financial leverage multiple for these three sectors by dividing total financial assets by financial assets minus financial liabilities plus equity investment by holding companies. We do not have a measure of nonfinancial assets in the Flow of Funds so the leverage multiple reported here overstates financial leverage multiple that would include nonfinancial assets in the computation. We compute average leverage multiple by using time varying weights corresponding to the relative sizes of these three sectors as measured by total financial assets.

[az] Notice that we attribute all household's lending in this market, BO^H_+, to "nonfinancial loans" K^h; we then allocate retail bankers supply of funds in this market to nonfinancial loans, K^r proportionally to the weight of nonfinancial firms demand for funds that is not met by households, $BO^F_- - BO^H_+$, in the total demand for funds that is not met by households, $BO^F_- + BO^W_{net} - BO^H_+$

Appendix E Computation

It is convenient for computations to introduce the ex-ante optimal values of surviving bankers at time t in the two sectors:

$$\begin{aligned}\bar{V}_t^w &= \left[1-\sigma+\sigma\theta\left(1-\omega+\omega\phi_t^w\right)\right]\frac{N_t^w - W^w}{\sigma^w}\\ &= \Omega_t^w \frac{N_t^w - W^w}{\sigma^w}\end{aligned} \tag{E.1}$$

$$\begin{aligned}\bar{V}_t^r &= \left[1-\sigma+\sigma\theta\phi_t^r\right]\frac{N_t^r - W^r}{\sigma^r}\\ &= \Omega_t^r \frac{N_t^r - W^r}{\sigma^r}\end{aligned} \tag{E.2}$$

Let the state of the economy if a run has not happened be denoted by $x=(N^w, N^r, Z)$, and the state in case a run has happened be denoted by $x^* = (0, N^r, Z)$. We use time iteration in order to approximate the functions

$$\left\{\mathbf{Q}(x), \mathbf{C}^h(x), \bar{\mathbf{V}}^r(x), \bar{\mathbf{V}}^w(x), \Gamma(x)\right\} \quad x\in[W^w, \bar{N}^w]\times[W^r, \bar{N}^r]\times[(0.95)Z, Z]$$

and

$$\left\{\mathbf{Q}^*(x), \mathbf{C}^{h*}(x^*), \bar{\mathbf{V}}^{r*}(x^*), \Gamma^*(x^*)\right\} \quad x^*\in\{0\}\times[W^r, \bar{N}^r]\times[(0.95)Z, Z]$$

where $\Gamma(x)$ and $\Gamma^*(x^*)$ are the laws determining the stochastic evolution of the state (see later).

The computational algorithm proceeds as follows:

1. Determine a functional space to use for approximating equilibrium functions. (We use piecewise linear).
2. Fix a grid of values for the state in case no run happens $G\subset[W^w, \bar{N}^w]\times[W^r, \bar{N}^r]\times[0.95, 1]$ and for the state in case a run happens $G^*\subset\{0\}\times[W^r, \bar{N}^r]\times[0.95, 1]$.
3. Set $j=0$ and guess initial values for

$$NRPol_{t,j} = \left\{Q_{t,j}(x),\, C_{t,j}^h(x),\, \bar{V}_{t,j}^r(x),\, \bar{V}_{t,j}^w(x), \Gamma_{t,j}(x)\right\}_{x\in G}$$

and

$$RPol_{t,j} = \left\{Q_{t,j}^*(x),\, C_{t,j}^{h*}(x^*),\, \bar{V}_{t,j}^{r*}(x^*), \Gamma_{t,j}^*(x^*)\right\}_{x^*\in G^*}.$$

The guess for $\Gamma_{t,j}(x)$ involves guessing $\left\{p_{t,j}(x), N_{t,j}^{r\prime}(x), N_{t,j}^{w\prime}(x), N_{t,j}^{r\prime *}(x), Z'(x)\right\}$ which implies

$$\Gamma_{t,j}(x) = \begin{cases}\left(N_{t,j}^{w\prime}(x), N_{t,j}^{r\prime}(x), Z'(Z)\right) & w.p.\ 1-p_{t,j}(x)\\ \left(0, N_{t,j}^{r\prime *}(x), Z'(Z)\right) & w.p.\ p_{t,j}(x)\end{cases}.$$

We denote by $x_{t,j}^{\prime NR}(x)=\left(N_{t,j}^{w\prime}(x),\, N_{t,j}^{r\prime}(x), Z^{\prime}(Z)\right)$ the state evolution if there is no run in the following period and $x_{t,j}^{\prime R}(x)=\left(0,\, N_{t,j}^{r\prime *}(x), Z^{\prime}(Z)\right)$ the evolution if a run happens in the following period.

Similarly the guess for $\Gamma_{t,j}^{*}(x^{*})$ involves guessing $\left\{\hat{N}_{t,j}^{r\prime}(x^{*}), Z^{\prime}(Z)\right\}$ which implies

$$\Gamma_{t,j}^{*}(x^{*})=\left((1+\sigma^{w})W^{w},\, \hat{N}_{t,j}^{r\prime}(x^{*}), Z^{\prime}(Z)\right)$$

4. Assume that $NRPol_{t,j}$ and $RPol_{t,j}$ have been found for $j\leq i<M$ where M is set to 10,000. To find $NRPol_{t,i+1}$ and $RPol_{t,i+1}$, first use $NRPol_{t,i}$ and $RPol_{t,i}$ to find functions in the approximating space that take on these values on the grid, eg, $\mathbf{Q}_{i}\text{:}\,[W^{w},\bar{N}^{w}]\times[W^{r},\bar{N}^{r}]\times[0.95,1]\rightarrow\mathbf{R}$ is the price function that satisfies $\mathbf{Q}_{i}(x)=Q_{t,i}(x)$ for each $x\in G$.
5. Derive $NRPol_{t,i+1}$ and $RPol_{t,i+1}$ by assuming that from time $t+1$ onwards equilibrium outcomes are determined according to the functions associated to $NRPol_{t,i}$ and $RPol_{t,i}$ found in step 4:
   - NO RUN SYSTEM

   At any point $x_{t}=\left(N_{t}^{w},N_{t}^{r},Z_{t}\right)\in G$ the system determining $\left\{\phi_{t}^{w},\phi_{t}^{r},B_{t},Q_{t},C_{t}^{h},K_{t}^{h},K_{t}^{r}\right\}$ is given by

$$\theta\left[1-\omega+\omega\phi_{t}^{w}\right]N_{t}^{w}=\beta(1-\mathbf{p}_{i}(x_{t}))\bar{\mathbf{V}}_{i}^{w}\left(\mathbf{x}_{i}^{\prime NR}(x_{t})\right)$$

$$\left(\phi_{t}^{w}-1\right)N_{t}^{w}=B_{t}$$

$$\phi_{t}^{w}N_{t}^{w}=Q_{t}\left(1-K_{t}^{r}-K_{t}^{h}\right)$$

$$\theta\phi_{t}^{r}N_{t}^{r}=\beta\left[(1-\mathbf{p}_{i}(x_{t}))\bar{\mathbf{V}}_{i}^{r}\left(\mathbf{x}_{i}^{\prime NR}(x)\right)+\mathbf{p}_{i}(x_{t})\bar{\mathbf{V}}_{i}^{r*}\left(\mathbf{x}_{i}^{\prime R}(x)\right)\right]$$

$$\phi_{t}^{r}N_{t}^{r}=\left(Q_{t}+\alpha^{r}K_{t}^{r}\right)K_{t}^{r}+(1-\gamma)B_{t}$$

$$\beta E_{i}\left\{\frac{C_{t}^{h}}{\widetilde{\mathbf{C}}_{i}^{h}(\Gamma_{i}(x))}\left(\mathbf{Z}^{\prime}(Z_{t})+\widetilde{\mathbf{Q}}_{i}(\Gamma_{i}(x))\right)\right\}=Q_{t}+\alpha^{h}K_{t}^{h}$$

$$C_{t}^{h}+\frac{(1-\sigma_{w})\left(N_{t}^{r}-W^{w}\right)}{\sigma_{w}}+\frac{(1-\sigma_{r})\left(N_{t}^{r}-W^{r}\right)}{\sigma_{r}}+\frac{\alpha^{h}\left(K_{t}^{h}\right)^{2}}{2}+\frac{\alpha^{r}\left(K_{t}^{r}\right)^{2}}{2}= \\ Z_{t}\left(1+W^{h}\right)+W^{r}+W^{w}=$$

where E_{i} is the expectation operator associated with the stochastic realization of a run according to $\mathbf{p}_{i}$ and tildes denote random variables whose values depend on the realization of the sunspot. For instance,

$$\widetilde{\mathbf{C}}_i^h(\Gamma_i(x)) = \begin{cases} \mathbf{C}_i^h\left(\mathbf{N}_i^{w\prime}(x), \mathbf{N}_i^{r\prime}(x), \mathbf{Z}'(Z)\right) & w.p.\ 1 - \mathbf{p}_i(x) \\ \mathbf{C}_i^{h*}\left(\mathbf{N}_i^{r\prime *}(x), \mathbf{Z}'(Z)\right) & w.p.\ \mathbf{p}_i(x) \end{cases}$$

One can then find $\left\{R_t, \bar{R}_t^b\right\}$ from

$$R_t = \frac{1}{\beta E_i \left\{ \dfrac{C_t^h}{\widetilde{\mathbf{C}}_i^h(\Gamma_i(x))} \right\}}$$

$$\bar{R}_t^b = \frac{E_i \left\{ \widetilde{\Omega}^r(\Gamma_i(x)) \left(\gamma \dfrac{\left(\mathbf{Z}'(Z_t) + \widetilde{\mathbf{Q}}_i(\Gamma_i(x))\right)}{Q_t + \alpha^r K_t^r} + (1-\gamma) R_t \right) \right\}}{(1 - \mathbf{p}_i(x_t)) \boldsymbol{\Omega}^r(\mathbf{x}_i^{\prime NR}(x_t))} - \frac{-\mathbf{p}_i \boldsymbol{\Omega}^{r*}\left(x_i^{\prime R}(x_t)\right) \left(\dfrac{\left(\mathbf{Z}'(Z_t) + \widetilde{\mathbf{Q}}_i(\Gamma_i(x))\right)}{Q_t} \dfrac{\phi_t^w}{\phi_t^w - 1} \right)}{(1 - \mathbf{p}_i(x_t)) \boldsymbol{\Omega}^r(\mathbf{x}_i^{\prime NR}(x_t))}$$

where

$$\widetilde{\Omega}^r(\Gamma_i(x)) = \begin{cases} \sigma^r \dfrac{\bar{\mathbf{V}}_i^r\left(\mathbf{N}_i^{w\prime}(x), \mathbf{N}_i^{r\prime}(x), \mathbf{Z}'(Z)\right)}{\mathbf{N}_i^{w\prime}(x) - W} & w.p.\ 1 - \mathbf{p}_i(x) \\ \sigma^r \dfrac{\bar{\mathbf{V}}_i^{r*}\left(\mathbf{N}_i^{r\prime *}(x), \mathbf{Z}'(Z)\right)}{\mathbf{N}_i^{w\prime}(x) - W} & w.p.\ \mathbf{p}_i(x) \end{cases}$$

and finally $\left\{\bar{V}_t^r, \bar{V}_t^w, t\right\}$ are given by

$$\bar{V}_t^w = \left[1 - \sigma + \sigma\theta\left(1 - \omega + \omega\phi_t^w\right)\right] \frac{N_t^w - W^w}{\sigma^w}$$

$$\bar{V}_t^r = \left[1 - \sigma + \sigma\theta\phi_t^r\right] \frac{N_t^r - W^r}{\sigma^r}$$

$$\Gamma_t = \begin{cases} \left(N_{t+1}^w, N_{t+1}^r, Z'(Z)\right) & w.p.\ 1 - p_t \\ \left(0, N_{t+1}^{r*}, Z'(Z)\right) & w.p.\ p_t \end{cases}$$

where

$$N_{t+1}^w = \sigma^w N_t^w \left[\phi_t^w \left(\frac{\mathbf{Z}'(Z_t) + \mathbf{Q}_i\left(\mathbf{x}_i^{\prime NR}(x)\right)}{Q_t} - \bar{R}_t^b \right) + -R_t^b \right] + W^w$$

$$N_{t+1}^r = \sigma^r \left(\left[\mathbf{Z}'(Z_t) + \mathbf{Q}_i\left(\mathbf{x}_i^{\prime NR}(x)\right)\right] K_t^r + B_t \bar{R}_t^b - D_t R_t \right) + W^w$$

$$N_{t+1}^{r*} = \sigma^r\left(\left[Z'(Z_t) + \mathbf{Q}_i^*\left(\mathbf{x}_i'^R(x)\right)\right]\left(K_t^r + K_t^w\right) - D_t R_t\right) + W^w$$

$$p_t = \left[1 - \frac{\dfrac{Z'(Z_t) + \mathbf{Q}_i^*\left(\mathbf{x}_i'^R(x)\right)}{Q_t}}{\bar{R}_{bt}} \cdot \frac{\phi_t^w}{\phi_t^w - 1}\right]^\delta$$

- RUN SYSTEM

 Analogously at a point $x_t^* = \left(0, N_t^r, Z_t\right) \in G^*$ the system determining $\left\{\phi_t^{r*}, Q_t^*, C_t^{h*}, K_t^{h*}\right\}$ is given by

$$\theta\phi_t^{r*} N_t^r = \beta - \mathbf{V}_i^r\left(\Gamma_i^*\left(x_t^*\right)\right)$$

$$\phi_t^{r*} N_t^r = \left(Q_t^* + \alpha^r K_t^{r*}\right) K_t^{r*}$$

$$\beta\left\{\frac{C_t^{h*}}{\mathbf{C}_i^h\left(\Gamma_i^*\left(x_t^*\right)\right)}\left(Z'(Z_t) + \mathbf{Q}_i\left(\Gamma_i^*\left(x_t^*\right)\right)\right)\right\} = Q_t^* + \alpha^h K_t^{h*}$$

$$C_t^{h*} + \frac{(1-\sigma_r)}{\sigma_r}\left(N_t^r - W^r\right) + \frac{\alpha^h}{2}\left(K_t^{h*}\right)^2 + \frac{\alpha^r}{2}\left(1 - K_t^{h*}\right)^2 = Z_t\left(1 + W^h\right) + W^r$$

and $\left\{R_t^*, \bar{V}_t^{r*}, \Gamma_t^*\right\}$ are given by

$$R_t^* = \frac{1}{\beta E_i\left\{\dfrac{C_t^{h*}}{\mathbf{C}_i^h\left(\Gamma_i^*\left(x_t^*\right)\right)}\right\}}$$

$$\bar{V}_t^{r*} = \left[1 - \sigma + \sigma\theta\phi_t^{r*}\right]\frac{N_t^r - W^r}{\sigma^r}$$

$$\Gamma_i^*(x^*) = \left((1 + \sigma^w)W^w, \hat{N}_{t+1}^r, Z'(Z)\right)$$

$$\hat{N}_{t+1}^r = \sigma^r N_r^r\left[\phi_t^{r*}\left(\frac{Z'(Z_t) + \mathbf{Q}_i\left(\Gamma_i^*\left(x_t^*\right)\right)}{Q_t} - R_t^*\right) + R_t^*\right] + W^r$$

6. Compute the maximum distance between $NRPol_t = \left\{Q_t, \bar{V}_t^r, \bar{V}_t^w, C_t^h, p_t, N_{t+1}^r, N_{t+1}^w, N_{t+1}^{r*}\right\}$ and $NRPol_{t,i}$

$$dNR = \max_{x_t \in G} \max\left|NRPol_t - NRPol_{t,i}\right|$$

and similarly for $RPol_t = \left\{Q_t^*, -V_t^{r*}, C_t^{h*}, \hat{N}_{t+1}^r\right\}$ and $RPol_{t,i}$

$$dR = \max_{x_t \in G^*} \max\left|RPol_t - RPol_{t,i}\right|$$

if dNR and dR are small enough, in our case $e - 6$, set

$$NRPol_{t,i+1} = NRPol_{t,i}$$
$$RPol_{t,i+1} = RPol_{t,i}$$

Otherwise set

$$NRPol_{t,i+1} = \alpha NRPol_{t,i} + (1-\alpha)NRPol_t$$
$$RPol_{t,i+1} = \alpha RPol_{t,i} + (1-\alpha)RPol_t$$

where $\alpha \in (0,1)$.

Abstract

Prompted by the recent US experience, in this chapter, we study the interaction between cycles in credit markets and cycles in housing markets. There is a large growing literature exploring two different approaches: on the one hand, a boom–bust in house prices can generate a boom–bust in credit market and, on the other hand, a boom–bust in credit markets can generate a boom–bust in house prices. We start by presenting a stark mechanical model to formalize the interaction between housing prices

and credit markets and explore these two channels in a mechanical way. Next, we present two simple models that highlight the two approaches. First, we propose a catastrophe model, where an increase in credit availability can generate first a boom and then a bust in mortgage markets because of multiple equilibria due to adverse selection: as lending expands, the composition of borrowers worsens and at some point this can generate a crash in credit market. Second, we propose a sentiment model, where house prices increase above fundamentals because investors buy assets under the irrational belief that there is always going to be an ever more foolish buyer, willing to buy at a higher price. In the course of the chapter, we relate our simple models to the large existing literature on these topics. At the end, we also point to some empirical papers that propose related facts.

1. INTRODUCTION

In the recent years, the United States has experienced, at the same time, a boom–bust episode in house price and a boom–bust episode in credit markets, as reflected in Figs. 1 and 2.

The purpose of this chapter is to explore the connection between financial markets and the housing market and its effects on the macroeconomic activity. There is a large and growing literature that separately explores credit cycles and house price bubbles and busts. In this chapter, we will try to connect these two streams of literature and understand the potential feedbacks between the two.

In particular, we will explore two different broad approaches to think about this connection:

1. the house price boom–bust generates the credit boom–bust;
2. the credit boom–bust generates the house price boom–bust.

Moreover, we embrace the view that, in both cases, these connected boom–bust episodes generate a boom–bust episode in aggregate activity, which, in turns, can feedback and amplify the boom and bust in the financial and housing markets. Given that the relationship between the house price boom–bust episode and the credit boom–bust episode can be itself quite rich, in this chapter we will mostly focus on that, and less on the connection with the real economy.

We start the chapter by discussing a simple mechanical baseline model in Section 2, which is meant to describe the interaction between the credit cycle and house prices, highlighted above. On purpose, it makes a number of stark assumptions to avoid several thorny issues that arise in a fully specified equilibrium model. In particular, we take as given the dynamics of both leverage and house prices. We then perform two types of

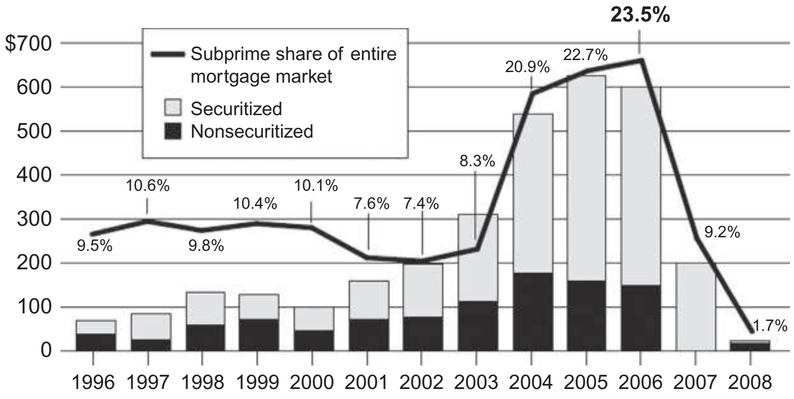
Subprime Mortgage Originations

In 2006, $600 billion of subprime loans were originated, most of which were securitized. That year, subprime lending accounted for 23.5% of all mortgage originations.

In billions of dollars



Note: Percent securitized is defined as subprime securities issued divided by originations in a given year. In 2007, securities issued exceeded originations.

Fig. 2 Subprime mortgage originations. *The Financial Crisis Inquiry Report, National Commission, January 2011.*

exercises: first, we keep house prices constant and study the response to a boom and bust in leverage; and second, we keep the leverage constant and study the response to a boom and bust in house prices. In the rest of the chapter, we try to go deeper in understanding where these dynamics are coming from and connect these two types of exercises to the existing literature.

We next explore the idea that the boom and bust in the credit market was the fundamental shock that spilled over the housing market and the real economy. We first discuss several papers related to this idea. In Section 3, we discuss a large class of papers that explore in particular the role of leverage in the households' sector. We focus on papers that study the effects of credit constraints on house prices and, more generally, on the real economy.

In this spirit, in Section 4, we completely abstract from the housing price dynamics and focus on the boom and crash in the credit market. In particular, we propose a stylized static model of households who borrow to become homeowners and intermediaries who lack information about the quality of the borrowers. The main idea is that a simple increase in the credit availability in the economy, what we interpret as "saving glut," can endogenously generate first a boom and then a crush in lending activity because of multiple equilibria due to adverse selection issues. The basic idea that a saving glut can generate an endogenous credit cycle because of multiplicity of equilibria is inspired by Boissay et al. (2016), although the mechanism is quite different. In our model, the increase in credit availability first increases the lending activity and hence increases the "subprime market." However, as the quality of the pool of borrowers decreases, good borrowers may decide to pay a cost to separate themselves and get better credit terms. This, in turns, may make the subprime market to collapse.

Next, we move to the idea that the boom and crash in housing prices is the key element of the interaction between housing and credit markets. In particular, if house prices are expected to rise, banks are more willing to lend, although this means to lend to worse creditors, eg, subprime borrowers. Moreover, speculating households are more willing to buy as house prices appreciate. While appealing, formalizing this intuition tends to run into the "conundrum of the single equilibrium": if prices are expected to be high tomorrow, then demand for credit and thus housing demand should be high today, and that should drive up prices today, making it less likely that prices will increase. Or, put differently, as prices rise, they eventually must get to a near maximum at some date: call it "today." At that point, prices are expected to decline in the future. But if so, banks and speculating households are less likely to buy today: but then, the price should not be high today. The issue is that in a rational expectations equilibrium there should be no "fool" willing to buy at the highest price, when prices can only go down from there.

In Section 5, we discuss two strands of literature that focus on two types of bubble models. In Section 5.1, we refer to a class of bubble models, where the interest rate demanded on assets is below or at most equal to the growth rate of the economy. This can give rise to rational bubbles and stochastically bursting bubble in, essentially, dynamically inefficient (or borderline efficient) overlapping generations models, as in Carvalho et al. (2012) or Martin and Ventura (2012). These authors employ various versions of OLG models, in which, ideally, resources should be funneled from inefficient investors or savers to efficient investors or entrepreneurs. They assume that there is a lending friction: entrepreneurs cannot promise repayment. They can only issue securities, where the buyer hopes that someone else buys them: call them "bubble," "cash," or "worthless pieces of paper." Equilibria then exist, where newborn entrepreneurs create "bubble" paper. The existing bubble paper in the hands of old agents and bubble paper created by newborn entrepreneurs get sold to savers. Savers find investing in these bubbles more attractive than investing in their own inefficient technology. This technology needs to be inefficient enough so that its return is on average below the growth rate of the economy, creating the dynamic inefficiency for bubbles to arise. In that case, the "fundamental" value of any asset paying even a tiny amount per period is actually infinite. Or, put differently, the last fool to buy the bubble at the highest price is happy to do so, since the value of the bubble next period will not have gone down too much and since that fool is desperate to save.

In Section 5.2, we discuss a second class of bubble models, where the interest rate demanded on assets is above the growth rate of the economy. Here, an aggregate bubble eventually must stop growing, being bounded by the resources in the hands of "newborn" agents purchasing these assets. Rationality considerations typically rule out such bubbles, see the "conundrum" above. We therefore investigate models with irrational optimism and changing sentiments. A benchmark example in the literature, exploiting changing sentiments, is the "disease" bubble model of Burnside et al. (2013). There is some intrinsically worthless bubble component, which could be part of the price of a house. An initially pessimistic population may gradually become infected to be "optimistic" and believe that the bubble component actually has some intrinsic value: once, everyone is optimistic (forever, let's say), there is some constant price that everyone is willing to pay. However, "truth" may be revealed with some probability every period and reveals that the bubble component is worthless indeed. Then, during the pessimistically dominated population epoch, prices rise during the nonrevelation phase, since the rise in prices compensates the pessimistic investors for the risk of ending up with a worthless bubble piece, in case the truth gets revealed. The price will rise until the marginal investor is optimistic: at that point, the maximum price may be reached.

In the spirit of this stream of sentiment literature, in Section 6, we propose a simple model where prices are above fundamentals because investors buy assets under the irrational belief that there is always going to be an ever more foolish buyer, willing to buy for a higher price.

Finally, in Section 7, we juxtapose our findings to some lessons we have drawn from the existing literature regarding the empirical evidence.

We wish this chapter will trigger further research and thinking on this important connection. As shall become clear, the issues are far from resolved.

2. A STARK MODEL

In the financial crisis of 2008, the following interplay might be at work, amplifying any initial shock: (1) as house prices fell, banks became more reluctant to lend to new home buyers, and (2) as banks became more reluctant to lend to new home buyers, demand for houses and thus prices for houses fell as a consequence. In particular, banks became more reluctant to lend because the drop in house prices negatively impacted their balance sheets, hence generating a more general credit crunch, depressing real activity.

In this section, we introduce a very simple mechanical model, featuring some of that interplay, but without describing the deep reasons for some key elements. The model features a potential mismatch between the long-term assets in the form of a pool of mortgages and the short-term assets in the form of saver deposits. It allows us to study the evolution of bank balance sheets during a house price boom. The model is useful for providing some key insights regarding price crashes and leverage crashes, and their impact on the financial system. In particular, we will use it to conduct numerical experiments, illustrating the two channels emphasized in the introduction:

1. House prices are constant and there is a boom and bust in the leverage ratio.
2. The leverage ratio is constant, and there is a boom and bust in house prices.

Furthermore, the model and its analysis sets the stage for discussing the related literature and for the latter sections of the chapter.

Time is discrete and infinite, $t = \ldots, -1, 0, 1, \ldots$. There is a continuum of households, who are the borrowers. There is a competitive sector of bankers, each operating a bank. There is a group of savers who exogenously supply deposits to the banks, and a government which assumes the role of a special saver. Finally, there is a numeraire consumption good and a housing good (or simply houses).

Each period, a fraction λ of the households exit (or "die"), and they are replaced with a fraction λ of newborn households. Each period all alive households earn some exogenously fixed income y and consume a nonnegative amount of goods, while newborn households earn some initial income $\widetilde{y}$ and buy a house. We allow $\widetilde{y}$ to differ from y, reflecting a potential period of saving-up before purchasing the first home. Just before a household exits, it sells its house. Houses are in fixed supply and are identical to each other.

We assume that a household born at time s is willing to buy a house for any price $p_s \leq \bar{p}_s$, where the process for $\bar{p}_s \geq 0$ is exogenously given.[a] When $\widetilde{y}$ is not large enough, households have to borrow in order to make that purchase. Restrictions to borrowing may then imply that the newly born households have less than $\bar{p}_s$ resources at hand.

[a] In principle, one could introduce preferences giving rise to this behavior.

We assume that the sellers get to extract all the rents, ie, we assume that the newly born households pay the lesser between the resources available and $\bar{p}_s$. Thus, only borrowing restrictions may force the market price p_s below $\bar{p}_s$.

To buy their house, households borrow from a banking sector. Consider a household born at date s who buys the house at the prevailing market price p_s. We assume that the following mortgage contract is the only type of contract offered by banks and available to households. In the initial period, households have to make a down payment of $\theta < \tilde{y}$ and borrow the remainder $l_s = \max\{p_s - \theta, 0\}$. We shall focus on parameter specifications such that in equilibrium $p_s \geq \theta$ for all s. The contract requires that households repay the principal l_s when they exit and sell their house. Failing that, they pay all resources available to them in that exiting period. In all other periods, including the period of purchase, households pay a flow interest r per unit of principal borrowed. We treat θ and r as parameters of the model. We assume that $r > 0$, while we do not necessarily restrict θ to be positive, allowing for a cash out at the time of purchase of a house when $\theta < 0$.

We will focus the analysis on equilibria with $l_s = p_s - \theta \geq 0$, where equality is the autarkic case when households do not borrow from banks. Hence, the consumption of a household born at time s in her first period of life is equal to $c_{s;s} = \tilde{y} - \theta - r(p_s - \theta)$, where the first index of $c_{s;s}$ refers to the date of consumption and the second index refers to the year of birth. As we do not allow for negative consumption, that is, $c_{s;s} \geq 0$, prices are bounded above by

$$p_s \leq p^{\max} = \frac{\tilde{y} - (1 - r)\theta}{r}. \tag{1}$$

In any subsequent period, the household will learn if she exits at the end of that period. The nonexiting households then consumes $c_{t;s} = y - r(p_s - \theta) \geq 0$, imposing another constraint on house prices:

$$p_s \leq \frac{y}{r} + \theta. \tag{2}$$

We will concentrate on parameter specifications, where (2) is tighter than (1), that is, we assume that $\tilde{y} - y > \theta$. If the household exits at time t, she sells her house at current market price p_t. If $p_t + y \geq (1 + r)(p_s - \theta)$, she can repay the interest and the principal, and before exiting can consume $c_{t;s}^{f} = p_t + y - (1 + r)(p_s - \theta)$, where f is meant to indicate her "final period." If $p_t + y < (1 + r)(p_s - \theta)$, the household defaults, consumes zero, and the bank receives $p_t + y$ in total, which one can split into $r(p_s - \theta)$ as the interest portion and $p_t + y - r(p_s - \theta)$ as the partial repayment of principal. One can then calculate the fraction $\phi_{t;s}$ of principal repaid by households born at date s and exiting at date t by solving for $\phi_{t;s}$ the following equation:

$$\phi_{t;s}(p_s - \theta) = \min\{p_s - \theta, p_t + y - r(p_s - \theta)\}. \tag{3}$$

The default rate is then $1 - \phi_{t;s}$.

We assume that banks discount future periods at the same rate r that they charge as interest payments on the mortgages: this is the easiest case to analyze. Consider a scenario in which households never default. Then, the date-t value $v_{t;s}$ of a contract signed at date s is independent of t, $v_{t;s} \equiv v_s$ and satisfies the recursion

$$v_s = \frac{1}{1+r}\left(r(p_s - \theta) + (1-\lambda)v_s + \lambda(p_s - \theta)\right),$$

which gives

$$v_s = p_s - \theta. \tag{4}$$

Banks only invest in mortgages. We assume that banks allow newly born households to borrow as much as they wish to borrow, provided banks have the resources to let them do that.

On the liability side, we assume that banks have deposits d_t by a group of savers as well as a deposit or loan L_t by the government. The bank pays some rate r_D per unit of deposit by savers. On the government loans, the bank pays an interest r_L, which is treated as an exogenous parameter. Additionally, banks are required to repay an exogenously given fraction μ of the principal.

To close the model, we need to specify the evolution of d_t and L_t. We choose an exogenous process for the banks' leverage ratio and set d_t to match such a process, given the endogenous value of the banks' assets. This is meant to be a simple stand-in for the view that banks finance projects by maximizing the amount of outside financing, subject to constraints on their leverage from regulatory restrictions or repayment concerns by depositors.

To calculate the value of a bank's assets, we need to take a stand on how the bank or, implicitly, some (unmodeled) regulator values the portfolio of its mortgages. We shall assume v_s to be the **book value** of a mortgage issued in period $s \leq t$ and which has not been repaid, even if the expected value or **market value** of this mortgage has been declining, due to house price decline and default considerations. Let a_t be the sum of all end-of-period book values of remaining mortgages, that is,

$$\begin{aligned} a_t &= \sum_{j=0}^{\infty} \lambda(1-\lambda)^j (p_{t-j} - \theta) \\ &= \lambda(p_t - \theta) + (1-\lambda)a_{t-1}, \end{aligned} \tag{5}$$

given that only young households, that is, a fraction λ of the population, purchase a home in each period and given Eq. (4). For example, if prices are constant forever, $p_t \equiv p^*$, then

$$a_t \equiv p^* - \theta. \tag{6}$$

Consider the balance sheet at the end of the period. We assume that the liabilities are recorded at their face value. The differences between assets and liabilities is the net worth

n_t of the bank. The (book value) net worth n_t of the bank then results from the balance sheet equation

$$a_t = d_t + L_t + n_t \tag{7}$$

We define the capital requirement or net worth requirement κ_t per

$$\kappa_t a_t = n_t + L_t, \tag{8}$$

or

$$(1 - \kappa_t) a_t = d_t, \tag{9}$$

effectively treating the government loan L_t as a perfect substitute for net worth. We choose an exogenous stochastic process for $\kappa_t \in [0, 1]$ and assume that d_t is set so as to satisfy Eq. (9). Note that $1/\kappa_t$ is the book-value leverage ratio on $n_t + L_t$.

For the evolution of L_t, we consider two alternative versions of the model. The central issue is how to treat a shortfall of funds, should it occur. For simplicity, we seek specifications of the model that avoid potential defaults on depositors, although it would be interesting to explore an extension of the model with default. In the baseline version of the model, we assume that bankers themselves inject any needed funds and hence we assume $L_t \equiv 0$. In the alternative version of the model, we shut down the channel of the injection of bank equity, and instead assume that the government provides loans, if necessary, to avoid a default on depositors and to avoid a shortfall of regulatory capital. For both versions, we need to calculate the evolution of the balance sheet.

Consider the beginning of a new period, after exiting households have sold their houses to newly born households. Let us trace out the impact of each transaction on the residual net worth. The bank receives interest payments ra_{t-1} on all outstanding mortgages, increasing net worth by that amount. A fraction λ of outstanding mortgages exits. Let us define ϕ_t the fraction of principal exiting mortgages that is repaid to the bank, so that the bank receives $\phi_t \lambda a_{t-1}$ in total. Using Eq. (3), we obtain

$$\phi_t a_{t-1} = \sum_{j=0}^{\infty} \lambda (1-\lambda)^j \min\{p_{t-1-j} - \theta, p_t + \gamma - r(p_{t-1-j} - \theta)\} \tag{10}$$

The resulting net worth loss is $(1 - \phi_t) a_{t-1}$, as the book value a_{t-1} of the exiting mortgages is replaced by their payoff $\phi_t a_{t-1}$. In particular, if the current market price is at least as high as all past market prices, then $\phi_t = 1$ and there is no change in net worth.

The bank also receives an inflow of new deposits $d_t - d_{t-1}$, new government loans L_t, and makes new mortgage investments $\lambda(p_t - \theta)$ which do not change net worth, but just lengthen the balance sheet.

On the liability side, banks pay the market interest rate r_D per unit of deposit, so that net worth decreases by the total payments $r_D d_{t-1}$. Furthermore, the bank pays $(r_L + \mu)$ L_{t-1}, the interest and a fraction μ of the principal on the beginning-of-period government loans. After all these transactions, but excluding the new government loan position L_t, the bank has a residual cash position m_t on the asset side, expressed in units of the consumption good. This position may be negative and can be expressed as follows:

$$m_t = (r + \phi_t \lambda) a_{t-1} + d_t - (1 + r_D) d_{t-1} - (\mu + r_L) L_{t-1} - \lambda(p_t - \theta).$$

Finally, we assume that the banker consumes some amount $c_{b,t}$, reducing the net worth of its bank by that amount. It may be useful to think of this consumption as a payment to bank shareholders. In the baseline version of the model, we assume that $L_t = 0$ and that $c_{b,t} = m_t$, that is it exactly equals the cash position, so that the postbanker consumption cash position is equal to zero. Since that cash position can be negative, we must allow $c_{b,t}$ to be negative as well. One might wish to think of this as an injection of equity by the existing bank owners.

The equilibrium of the baseline model with the assumption that $L_t = 0$ can be characterized by the following equations:

$$a_t = \lambda(p_t - \theta) + (1 - \lambda) a_{t-1}, \tag{11}$$

$$d_t = (1 - \kappa_t) a_t, \tag{12}$$

$$m_t = (r + \phi_t \lambda) a_{t-1} + d_t - (1 + r_D) d_{t-1} - \lambda(p_t - \theta), \tag{13}$$

$$c_{b,t} = m_t, \tag{14}$$

$$n_t = a_t - d_t, \tag{15}$$

where ϕ_t is given by Eq. (10). Note that substituting for a_t and d_t using Eqs. (11) and (12) in (13) we obtain

$$\begin{aligned} m_t = & [r - r_D + r_D \kappa_{t-1} + \lambda \kappa_t + \kappa_{t-1} - \kappa_t - (1 - \phi_t)\lambda] a_{t-1} \\ & - \kappa_t \lambda (p_t - \theta) \end{aligned} \tag{16}$$

This equation has an intuitive appeal. Consider the bracket, multiplying a_{t-1}. The first term, $r - r_D$ is the interest arbitrage collected. The second term $r_D \kappa_{t-1}$ is the interest earned on the net worth portion of a_{t-1}. The third term, $\lambda \kappa_t$ concerns the repayment of principal. The difference $\kappa_{t-1} - \kappa_t$ means that cash is freed up, if the capital requirement κ_t decreases. The final term $(1 - \phi_t)\lambda$ reduces cash flow only if there are defaults, $\phi_t < 1$.

Moreover, substituting for a_t using Eq. (11) into (15), and using Eq. (15) one period backward, after some manipulation we obtain

$$n_t = n_{t-1} - \lambda a_{t-1} + \lambda(p_t - \theta) - d_t + d_{t-1}. \tag{17}$$

One can use this equation to examine the evolution of net worth. As one special case, suppose that the evolution for the exogenous process κ_t implies that deposits are constant, $d_{t-1} = d_t = d$. Then,

$$n_t = n_{t-1} - \lambda a_{t-1} + \lambda(p_t - \theta), \tag{18}$$

ie, the change in net worth is given by the book value difference between newly created and exiting mortgages. At a superficial look, it would appear that net worth is "magically" created by higher prices and that default on exiting mortgages does not matter. However, it needs to be recognized that these movements find their counterpart in the banker's consumption $c_{b,t}$, see (14): to keep d unchanged, higher prices for new houses as well as larger defaults on old mortgages reduce these shareholder payouts or even require equity injection.

Eq. (18) also reveals that net worth stays constant, if deposits are constant and prices are constant, as, according to Eq. (6), constant prices imply $a_{t-1} = p^{*} - \theta$. In this case, Eq. (14) implies that bankers' consumption is equal to

$$c_b^* = r(p^* - \theta) - r_D d^*. \tag{19}$$

This simply says that the interest payments on the assets, reduced by the interest payments on the liabilities, are the flow profits in this steady state situation.

Finally, the house price is easy to characterize in this baseline version of the model:

Proposition 1 *Assume that $\bar{p}_t \leq p^{\max}$, defined in Eq. (1). In the baseline version of the model, the house price is then always equal to the exogenous process, that is, $p_t = \bar{p}_t$.*

Proof This follows from the assumption that sellers extract all the rent from buying households, ie, newly born households are willing to borrow up to $\bar{p}_t - \theta$, and the assumption that banks let them do so, potentially financing the needed resources with negative banker consumption. □

For the alternative version of the model, we impose the restriction that $c_{b,t} \geq 0$, that is, the banks cannot raise equity from their owners. We assume that the government provides loans L_t, making up for any potential shortfall. The equations characterizing the equilibrium are now:

$$a_t = \lambda(p_t - \theta) + (1 - \lambda)a_{t-1}, \tag{20}$$

$$d_t = (1 - \kappa_t)a_t, \tag{21}$$

$$\begin{aligned} m_t = {} & (r + \phi_t \lambda)a_{t-1} + d_t - (1 + r_D)d_{t-1} \\ & - \lambda(p_t - \theta) - (r_L + \mu)L_{t-1}, \end{aligned} \tag{22}$$

$$c_{b,t} = \max\{0; m_t\}, \tag{23}$$

$$L_t = (1 - \mu)L_{t-1} - \min\{0, m_t\}, \tag{24}$$

$$n_t = a_t - d_t - L_t, \tag{25}$$

where again ϕ_t is given by Eq. (10). Eq. (22), compared to (13), includes the payment of the interest and of a portion μ of the principal on the outstanding government loans. Eq. (23) encodes the nonnegativity of $c_{b,t}$, compared to (14). With that, one needs to add Eq. (24) for the evolution of the government loans, which are reduced by the repayment of the principal portion, but are increased by any need of repayment for a shortfall of funds $m_t < 0$.

The alternative model is not yet complete, however. Note that larger p_t in (22) can now be compensated for by correspondingly larger loans L_t by the government. Indeed, there is potentially an interesting range of policies to consider. At the one and most generous extreme, the government may provide sufficiently large loans so as to reestablish the maximal price $p_t = \bar{p}_t$, which households are willing to pay. At the other and most stingy extreme, the government may only provide loans to assure nonnegative banker consumption, with house prices reduced all the way to $p_t = \theta$ and thus not requiring bank loans for purchases (assuming $\theta \geq 0$). In the numerical exercise for the exogenous price crash below, we shall investigate the implications of the latter extreme. Put differently, we pick the highest price p_t with $\theta < p_t \leq \bar{p}_t$, subject to the restriction that the resulting m_t in (22) is nonnegative, provided such a price exists. Note that this price will either equal $\bar{p}_t$ or result in $m_t = 0$. If no such price exists, then $p_t = \theta$, $m_t < 0$ and the newly issued loan will equal $-\min\{0, m_t\}$, as stated in Eq. (24). With that, the house price becomes endogenous, and Proposition 1 ceases to hold. In the case of a bust in the leverage ratio, we assume that the government provides a loan to the banks to make up the missing equity. A better interpretation is to view this as a partial stake in the banking system, at a required rate of return for the government. This stake is then reduced over time at the assumed required rate of the loan repayment.

2.1 Numerical Experiments: Overview

We now conduct two sets of numerical experiments to highlight the two approaches we discussed in the introduction:

1. We assume that house prices are constant and assume a boom and bust in the leverage ratio κ;
2. We assume that the leverage ratio is constant, and assume a boom and bust in house prices dynamics.

For both exercises, we consider the implications both for the baseline specification, when bankers can inject fresh equity, and the alternative specification, when they cannot and when, potentially, government loans are required to cover shortfalls of resources.

The numerical exercises are meant to be illustrative, and are not intended as careful calibrations. The parameters are picked to be broadly reasonable, but the results are quite sensitive to their choices. We shall think of a period as 1 year. An overview of the parameters is in Table 1.

Everything scales with income y, so we arbitrarily set income $y = 1$. Hence, one can read all quantities such as banker consumption, government loans or assets, as multiples of annual GDP. We assume a down payment (relative to income) of $\theta = 2$, which should be assumed to be "saved up" from prior income before agents are born and enter the

housing market. That is, we assume that $\tilde{\gamma}$ is high enough, so that (2) is tighter than (1). Since $\tilde{\gamma}$ does not play a role otherwise, we have not listed an explicit value in Table 1. The exit probability λ has been set equal to 0.1, implying a turnover of a house on average every 10 years. We assume that banks earn 4% on their assets and pay 3% on their liabilities, be they depositors or government loans. We assume that government loans have a maturity of 20 years, ie, that the fraction $\mu = 0.05$ of the outstanding bonds need to be repaid each period.

For the first set of numerical experiments, we set the maximal willingness to pay constant at $\bar{p}_t \equiv p^*$, where $p^* = 5$ y, and thus as five times (annual) income. To model the boom and subsequent bust in leverage, we assume that the required capital ratio is initially at $\kappa = 0.05$ until some date $t = -1$, implying a leverage ratio of 20, and then unexpectedly rises to $\kappa = 0.2$ at date $t = 0$, implying a leverage ratio of 5.

For the second set of numerical experiments, we keep the required capital ratio constant at $\kappa = 0.1$. To capture an initial run-up of house prices and subsequent crash, we assume that the maximal house prices $\bar{p}_t$ increase exponentially until $t = -1$ and then drop to some constant level $\bar{p}_t \equiv p^* \geq \theta$, where $p^*/\gamma = 5$, which is also comparable to the distant past. That is, we assume that

$$\bar{p}_t = p^* + \alpha\gamma^t \tag{26}$$

for $t < 0$, and $\bar{p}_t = p^*$ for $t \geq 0$, where $\gamma \geq 1$.

2.2 An Exogenous Crash in Leverage

Let us examine the first set of numerical experiments, with a constant maximal price $\bar{p}_t = p^*$ and an exogenous crash in leverage. "Case A" is the benchmark version of the model, where we assume that bankers supply fresh equity, if needed. This is

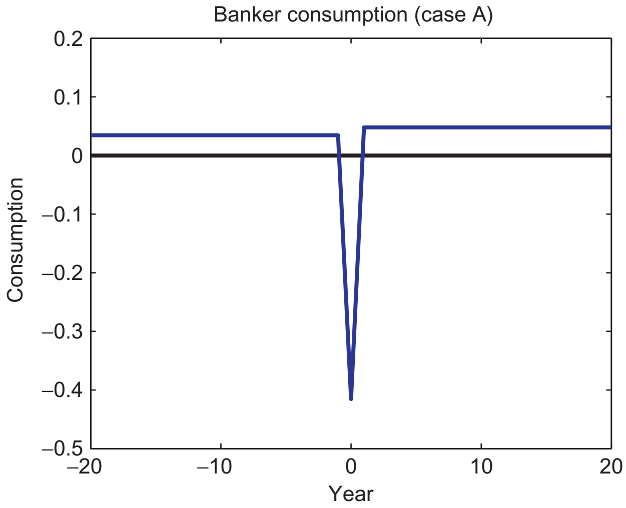

Fig. 3 An exogenous crash in leverage: Implication for banker consumption. Negative values should be interpreted as the injection of fresh bank equity.

shown in Fig. 3. There is a single period, when the leverage ratio suddenly changes, necessitating an infusion of extra cash, modeled as negative banker consumption. Once the fresh equity is injected, everything continues as before, except that banker consumption is now higher, given the new and lower leverage. The price for houses remains at $p_t = \bar{p}$.

Matters are more dramatic for "case B," the alternative specification of the model, where there is no fresh infusion of bank equity. The results are shown in Fig. 4. Prices crash endogenously, as can be seen in the top left panel. There is a fairly brief period of default, as shown in the top right panel. The government makes up the missing equity by, essentially, obtaining a partial stake in the banking system, at a required rate of return for the government. This stake is then reduced over time at the assumed required rate of the loan repayment. If the payments for interest and repayments are less than the revenue of the banking system, the consumption of the bankers are positive, as can be seen here. Finally, banks gradually rebuild their net worth to the required new ratio, as indicated by the red-dashed line in the left panel of the third row.

2.3 An Exogenous Crash in House Prices

For the second set of numerical experiments, we seek to investigate an exogenous crash in house prices, following a phase of increasing house prices, given by (26), while keeping leverage κ constant.

Consider first the run-up phase for house prices, $t < 0$. In the benchmark specification of the model, houses are always sold at the maximum price that newborn home buyers are

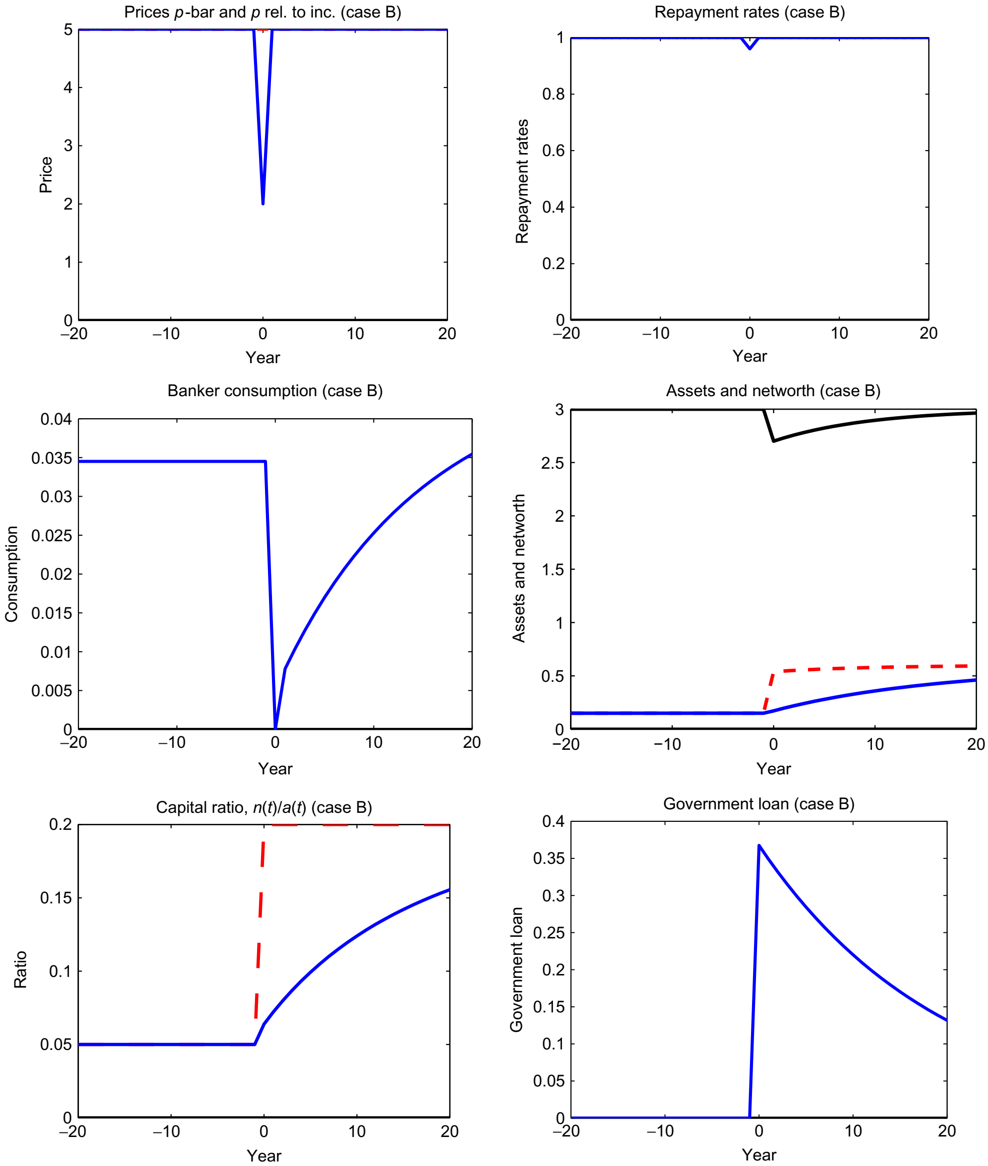

Fig. 4 An exogenous crash in leverage without infusion of bank equity. Prices crash endogenously, as can be seen in the top left panel. There is a fairly brief period of default, as shown in the top right panel. For the parameterization here, the banks gradually rebuild their net worth to the required new ratio, as indicated by the red (gray in the print version)-dashed line in the left panel of the third row.

willing to spend, ie, $p_t = \bar{p}_t$. This will also be true in the alternative specification of the model, provided that banks are able to build up net worth fast enough to finance the new loans, without necessitating the injection of further equity. This imposes some constraints on the parameters, which we shall illuminate.

Using (26) and $p_t = \bar{p}_t$ for all $t < 0$, assets a_t per Eq. (11) can be rewritten as

$$a_t = p^* - \theta + \frac{\lambda\gamma}{\gamma + \lambda - 1}(p_t - p^*)$$

for $t < 0$.

As a useful benchmark, assume $p^* = 0$ and $\theta = 0$. The asset-to-price ratio then is

$$\frac{a_t}{p_t} = \frac{\lambda\gamma}{\gamma + \lambda - 1}.$$

This relationship between current price and the stock of outstanding assets for $t < 0$ is plotted in Fig. 5. As one can see, higher house price growth makes assets look small compared to current house prices. One may interpret this as a reason, why financial institutions are less concerned about default risks during price booms. With (27) and $a_t = \gamma a_{t-1}$ for $t < 0$, Eq. (13) implies

$$\frac{m_t}{a_t} = \frac{1}{\gamma}(r - r_D(1 - \kappa) - \kappa(\gamma - 1)) \tag{27}$$

The balance sheets are growing for $t < 0$. If the banks finance this growth exactly out of earnings, so that $c_{b,t} = m_t = 0$, one obtains

$$\gamma = 1 + \frac{1}{\kappa}(r - r_D(1 - \kappa)) \tag{28}$$

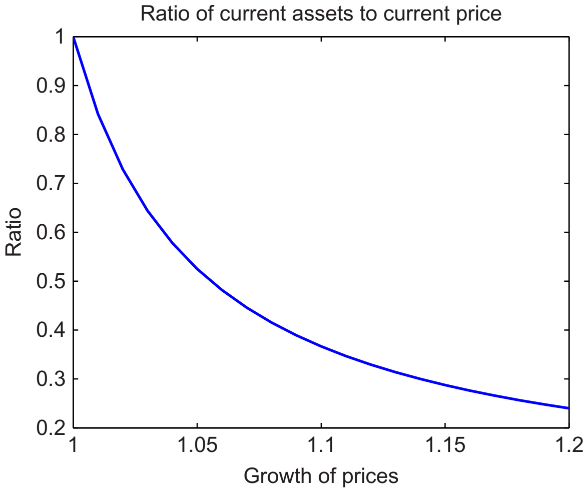

Fig. 5 Ratio of assets to prices, for various values of γ, when $\lambda = 0.05$.

which is intuitive. In particular, if $r = r_D$, then

$$\gamma = 1 + r \tag{29}$$

so that the interest paid on net worth must exactly finance its growth. Put differently, the values calculated for γ in (28) or (29) are the upper bounds for the price growth rates γ to avoid that banker consumption falls into negative territory during the price growth phase, when holding leverage constant, and when assuming that $p^* = 0$ and $\theta = 0$.

With the other parameters as listed in Table 1, Eq. (28) implies that $\gamma = 1.13$ or a 13% appreciation of maximal house prices, during the run-up phase. While the numerical experiments are intended as illustrations only, this number strikes us as perhaps a high, but not entirely unreasonable value during a house boom phase. Indeed, during the pre-2008 years, house prices grew even faster, towards the end, according to the Case-Shiller index. One may also wish to read this as a reasonable upper bound of long-time house price growth, when banks are constrained from raising new equity for financing new mortgages. Consider then the implications for banker consumption in Figs. 6 and 7. For this parameter choice, they are almost flat in the precrash phase, since the rise in higher interest payments on old mortgages is now nearly offset by the rise in resources needed for paying for new mortgages. For other choices for γ, one should not expect nearly flat banker consumption during this run-up phase.

Per Eq. (2), we must be careful in letting prices grow too large. Examining the restriction at the last precrash price $\bar{p}_{-1}$, this equation implies that

$$\alpha \leq \frac{1}{\gamma}\left(\frac{\gamma}{r} + \theta - p^*\right) \approx 19.5\,\gamma \tag{30}$$

We set $\alpha = 19\,\gamma$, so that prices crash in the last possible period. These values for γ and α are listed in Table 1. Arguably, these are pretty much at the extreme end, and chosen to provide the most dramatic numerical experiment.

Consider now the postcrash phase, $t \geq 0$. Here, numerical calculations are required. The results are in Figs. 6 and 7. Fig. 6 shows what happens in the benchmark specification "case A" of the model, when bank equity can be injected, ie, when banker consumption can become negative. House prices trade at the exogenously given levels $\bar{p}_t = p^*$. There is a temporary dip in repayments, but they recover gradually, as the top right panel shows. No government loans are necessary or provided in this case.

"Case B" is the alternative specification of the model, when no fresh injection of bank equity is available. The results are now more dramatic, and shown in Fig. 7. Now, when prices crash, they crash to the down-payment level θ and stay there, for the chosen parameter configuration. Banker consumption never recovers. There is continued

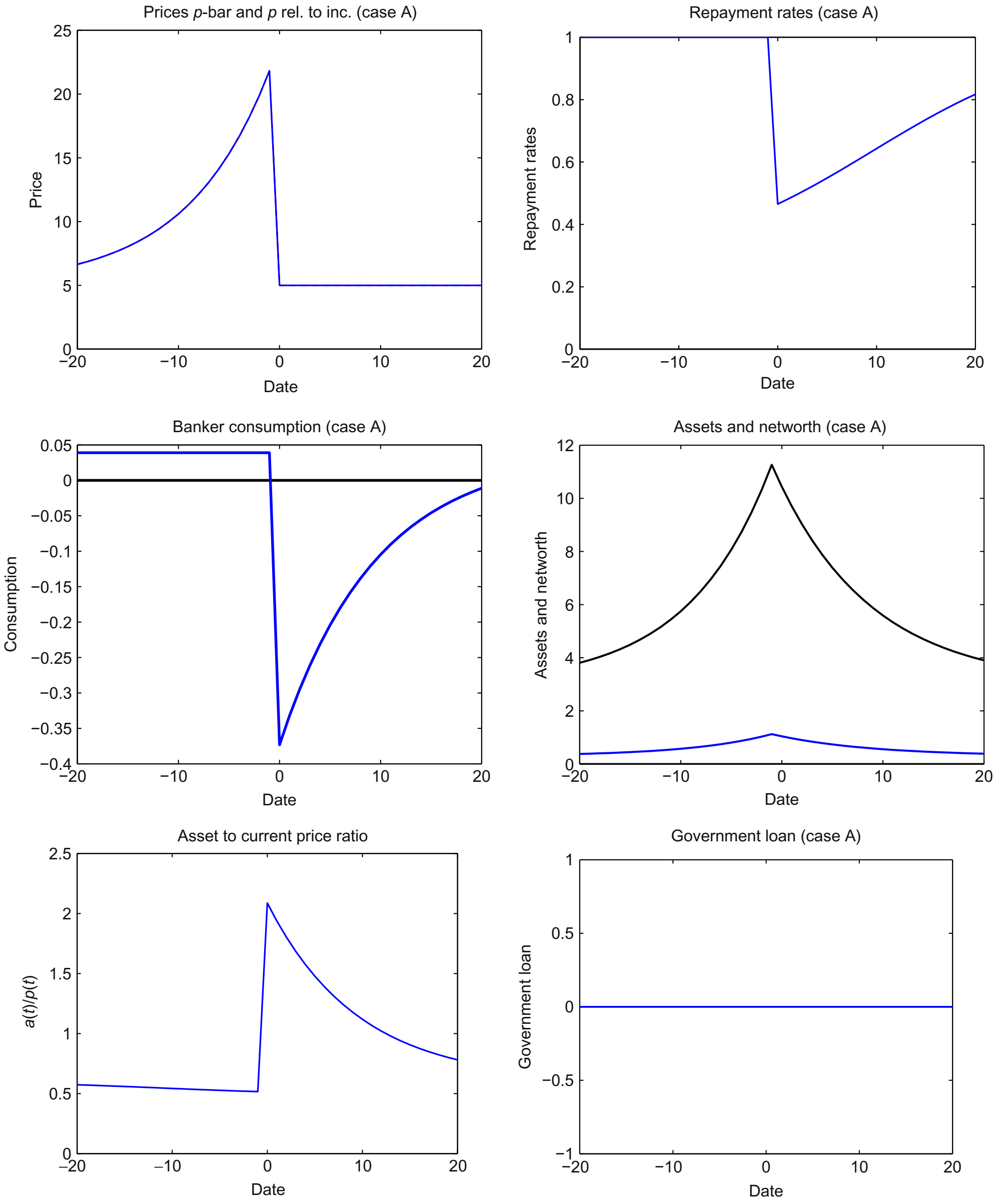

Fig. 6 House price boom and crash: Implications in the benchmark specification, when bankers inject fresh equity to cover shortfalls of funds.

default on banker assets. These are the legacy assets of precrash assets, which gradually disappear over time: households with precrash loans continue to have difficulties repaying these loans. Eventually, the government holds a bond position offset by a negative amount of net worth of bankers, without any corresponding assets.

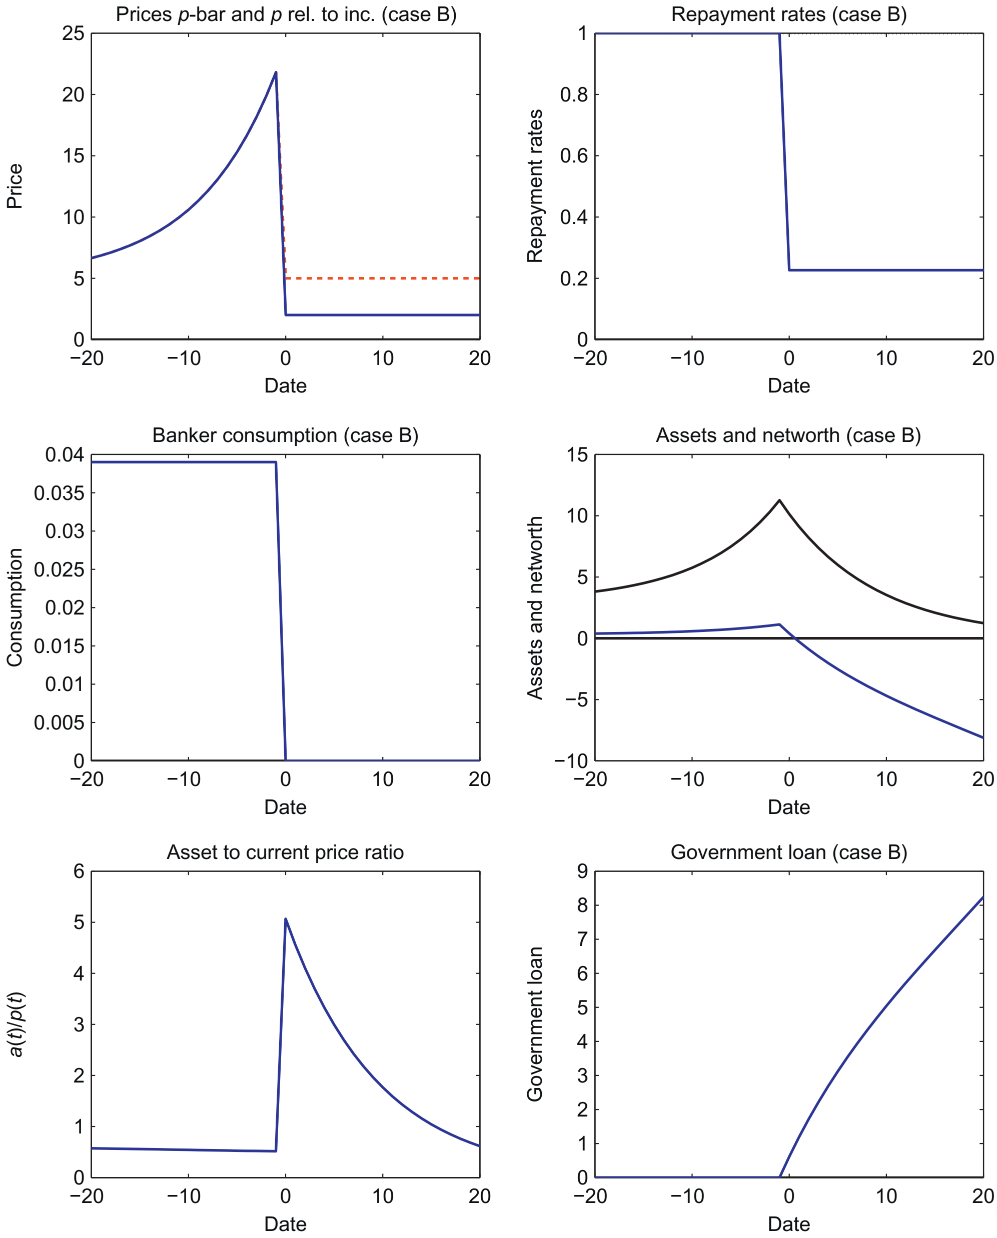

Fig. 7 House price boom and crash: Implications in the alternative specification, when bankers do not inject equity and the government provides the minimal loan to keep banks from defaulting.

2.4 Remarks

The previous numerical experiments are useful to highlight how a boom and bust in housing prices and financial markets can be qualitatively driven either by anything that affects directly house prices or by anything that affects directly banks' leverage. One important ingredient of the model that generates an interesting interaction between house prices and banks' leverage is the presence of long-term loans.

In the experiments above, a permanent decrease in leverage has more modest effects overall than an exogenous crash in house prices. However, as we repeatedly mentioned, these are only illustrative example, and the size of the exogenous crash that we imposed on leverage in the first exercise is difficult to compare to the size of the price crash that we imposed in the second exercise. It would be interesting in future work to calibrate a more realistic version of the model and try to do a horse race between the two types of shocks.

It is also interesting to highlight that in both types of numerical experiments, events unfold always more dramatically in "case B," without the fresh injection of bank equity, than in "case A." This indicates that a quick recapitalization of the banking system may be important in getting things back on track and avoiding long and persistent slumps. There is a self-feeding crisis here: without such an equity infusion, banks cannot fund new mortgages, house prices may remain low, leading to further defaults and leading to further impairments on bank balance sheets. A generous government loan program (not shown here), which supports house prices at the maximum willingness that households are willing to pay, will likewise insulate the housing markets from the drop in bank equity, but may result in keeping the government involved in the banking sector for a long time to come. Clearly, we do not model the costs of a possible government intervention, so conclusive policy recommendations are beyond the scope of this section. This is another interesting avenue for future work.

3. RELATED LITERATURE: HOUSEHOLDS' LEVERAGE

The simple model we introduced in the previous section highlights the interplay between credit cycles and boom–bust cycles in housing prices. One key ingredient in that interplay is that households borrow to become homeowners and are subject to financial constraints. Indeed one defining feature of the recent US experience is a dramatic increase in the households' gross debt to GDP ratio, which reached roughly 128% by 2008, and then sharply dropped. This drew a lot of attention on the effects of households' leveraging and deleveraging not only on housing markets, but, more generally, on aggregate activity.

3.1 Financial Frictions in Macro Models

There is a large growing literature that embeds financial frictions in macro model. Brunnermeier et al. (2011) is a comprehensive survey on this matter. We will just refer here to the seminal papers in this literature and focus next on the specific link between credit markets and house prices. One of the first papers that started a literature of macroeconomics models with financial frictions is Bernanke and Gertler (1989). They focus on long-lasting effects of temporary shocks through the feedback effect of a tightening of the financial frictions. In this model, as well as in Carlstrom and Fuerst (1997) and Bernanke et al. (1999), the key friction is the assumption of costly verification of the entrepreneur's type. Another seminal paper that had a huge impact on the macroeconomic literature is Kiyotaki and Moore (1997) who model financial frictions with a collateral constraint on borrowing rather than with a costly state verification framework. They propose a dynamic economy where durable assets play the dual role of factor of production and collateral for producers' loans. In their model, credit limits are endogenously determined and the interaction between them and asset prices generates a powerful transmission mechanism that allow temporary shocks to technology and income distribution to have large and persistent effects on asset prices and output. The mechanism is the following: after a temporary shock to productivity that reduces firms' net worth, constrained firms have to cut back their investment, hence reducing land value, and this hurts their future borrowing capacity, and reduces investment further down. This mechanism has been largely incorporated in macro models to study the real effects of financial shocks and the amplification of other types of shocks. Another influential paper on financial frictions and macro is Geanakoplos (2009) who focus on the role of leverage in boom and bust episodes. The key idea is that some investors are more optimistic than others and in good times they will lever up and drive asset prices up. However, if bad states realized, they may loose their wealth and the assets may shift in more pessimistic hands, and leverage and prices go down. This is what a leverage cycle is. Another related paper is Myerson (2012) who propose a model of credit cycles generated by moral hazard in financial intermediation.

There is a large recent literature that builds on these models to think about the role of firms' balance sheets in the macroeconomy. See for example Lorenzoni (2008), Mendoza and Quadrini (2010), Geanakoplos (2011), Brunnermeier and Sannikov (2010), He and Krishnamurthy (2013), and Bocola (2014). Gilchrist and Zakrajšek (2012) construct a new credit spread index and show that indeed a reduction in credit availability can have adverse macroeconomic consequences. However, in this chapter we focus more on the households' side and hence we tilt also the discussion of the literature in this direction.

3.2 The Effect of Credit Constraints on House Prices

There is a large strand of literature building models of the housing market where households' credit constraints play a crucial role in affecting house prices. Davis and VanNieuwerburgh (2015) also offers a nice overview of part of this literature. To the best of our knowledge, Stein (1995) is the first paper to explore the effects of down-payment requirements on house price volatility, as well as on the correlation between prices and trading volume. In particular, the paper highlights the self-reinforcing effect that runs from house prices to down payments and housing demand, back to house prices: if house prices decline, the value of households' collateral declines, depressing housing demand and hence pushing house prices further down. This multiplier effect can generate multiple equilibria and account for house price boom–bust episodes. This self-reinforcing effect is in the same spirit of the transmission mechanism in the seminal paper of Kiyotaki and Moore (1997).

In a related paper, Ortalo-Magne and Rady (2006) also explore the key role of down-payment requirements to explain house price volatility, although they focus on a different mechanism. They propose a life-cycle model of the housing market with credit constraints where there are two types of homes, "starter homes" and "trade-up homes." This allows them to focus on the key role of first-time buyers and show that income volatility of young households or relaxation of their credit constraints can explain excess volatility of house prices. Their model also delivers positive correlation between house prices and transaction volume.

More recently, Kiyotaki et al. (2011) develop a quantitative general equilibrium life-cycle model where land is a limited factor of production and is used as collateral for firms' loans. They show that, the more important is land relative to capital in the production of tangible assets, the more housing prices are sensitive to fundamental shocks as productivity growth rate or the world interest rate. Moreover, these type of shocks affect wealth and welfare of different households differently, typically making net house buyers the winners and net house sellers the losers during a housing boom. In contrast, financial innovation that relaxes collateral constraints turn out to have small effects on house prices. Similarly, Sommer et al. (2013) develop a quantitative general equilibrium model with housing and financial constraints and argue that a relaxation of financial constraints has only small effects on house prices, while movements in interest rates have large effects.

In related work, Favilukis et al. (2016) also develop a quantitative general equilibrium model with housing and collateral constraints to explore what drives fluctuations in house prices to rent ratio, but draw very different conclusions. Relative to previous quantitative papers, this model has two new features: aggregate business cycle risk and bequest heterogeneity to generate a realistic wealth distribution. In contrast to the previous literature, the authors find that a relaxation of collateral requirements can generate a large housing boom, while lower interest rates, due to an inflow of foreign capital in the domestic bond market, cannot. In particular, they show that the mechanism through which financial liberalization can generate a house price boom is by reducing the housing risk premium. In a similar spirit, Kermani (2016) propose a model to emphasize the importance of financial liberalization and its reversal to explain the housing boom and bust. He et al. (2015) also propose a model where housing collateralizes loans and house price boom and bust can be generated by financial innovation because the liquidity premium on housing is nonmonotone in the loan-to-equity ratio. In their paper, even without a change in fundamentals, house prices can be cyclical because of self-fulfilling beliefs. In a related paper, Huo and Ríos-Rull (2014) propose a model with heterogenous households, housing and credit constraints, and also show that financial shocks can generate large drops in housing prices.

In a more recent paper, Justiniano et al. (2014) ask what is the best way of formalizing the "credit easing" shock behind the recent US housing boom. Their objective is to model the shock in a way to be able to match a number of stylized facts about the housing and mortgage markets: not only the rise in house prices and households' debt, but also the fairly stable loan-to-value ratio and the decline in mortgage rates. In particular, they distinguish between a loosening of "lending constraints," ie, an increase in the availability of funds to be borrowed for the purpose of home mortgages, and a loosening of "borrowing constraints," ie, the lessening of collateral requirements. They argue that a loosening of the collateral requirements alone cannot explain the recent housing boom in the United States, but there must have been an expansion in the credit supply.

3.3 The Effect of Credit Constraints and Housing Prices on Macro

The impact of changes in credit conditions in the housing market on the overall economy and on economic policy is obviously an important question and the focus on a significant portion of the literature. Iacoviello (2005) has become a work horse model in this literature, embedding nominal households' debt and collateral constraints tied to real estate values, as in Kiyotaki and Moore (1997), into a new Keynesian model. The paper shows that demand shocks move housing and consumer prices in the same direction and hence are amplified. When demand rises due to some exogenous shock, consumer and asset prices increase. The rise in asset prices increases the borrowing capacity of the debtors, allowing them to spend and invest more. The rise in consumer prices reduces the real value of their outstanding debt obligations, positively affecting their net worth. Given that borrowers have a higher propensity to spend than lenders, the net effect on demand is positive. Thus the demand shock is amplified. Guerrieri and Iacoviello (2014) emphasize that collateral constraints drive an asymmetry in the relationship between house prices and economic activity. Brzoza-Brzezina et al. (2014) examine a DSGE model with housing and financial intermediaries. They evaluate the impact of having multiperiod vs one-period contracts on monetary and macroprudential policy, and the role of fixed-rate vs variable-rate mortgages. Garriga et al. (2016) also explore the interaction among long-term mortgages, nominal contracts and monetary policy in a similar general equilibrium model. Benes et al. (2014a) offers a richer structure yet for studying the interplay between the housing market and economic performance and its implications for macroprudential policies. Applications and extensions are in Benes et al. (2014b) and Clancy and Merola (2015).

Corbae and Quintin (2014) are interested in assessing the role of high-leverage mortgages to explain the foreclosure crisis. They propose a model with heterogenous agents who can choose between a mortgage contract with a 20% down payment and one with no down payment and can choose to default. The model show that the increase in number of high-leverage loans can explain more than 60% of the increase in foreclosure rates.

There is another strand of literature that focuses on macroeconomic models with a housing sector and collateral constraints, but takes house prices as given. Among them, Campbell and Hercowitz (2006) explores the macroeconomic consequences of the relaxation of households' collateral constraints that followed the US financial reforms in the early 1980s. They propose a general equilibrium model with heterogenous households who have access to loan contracts that require a down payment and rapid amortization. House prices are taken as given.[b] Reducing the down-payment rate or extending the term of the loans reduces macroeconomic volatility. In particular, they show that the reforms of the early 1980s can explain a large fraction of the volatility decline in hours worked, output, households debt and durables' consumption. In a similar spirit, Iacoviello and Pavan (2013) embed housing in a life-cycle general equilibrium business cycle model where households face collateral constraints. They show that higher income risk and lower down payments can explain the reduced volatility of housing investment, the procyclicality of debt and part of the reduced output volatility during the Great Moderation. They also show that looser credit conditions can make housing and debt more stable in response to small shocks but more fragile in response to large negative shock, as it happened in the Great Recession.

Since the recent boom and bust in housing prices and subsequent long recession, there has been a new wave of macro models that take households' leveraging and deleveraging as the fundamental shock affecting economic activity, even without explicitly modeling the housing market. In his 2011 Presidential Address, Hall (2011) emphasized that the "long slump" that recently hit the United States was driven by a severe decline in aggregate demand, which he attribute to the large deleveraging wave that on the onset of the 2007–08 financial crisis followed a large buildup of consumer debt at the beginning of 2000. On the empirical side, Mian and Sufi (2014) use US zip code data to argue that demand shocks were the main source of the employment decline in the recent recession. In the same spirit, there has been a growing body of work that considers a credit crunch as the fundamental shock of the economy and explores how the subsequent deleveraging affects the overall economy, and the housing market in particular. Together with

[b] In their work, house prices are constant, as in the early literature that included housing in one-sector real business cycle models in the form of capital used for home production, following the seminal papers by Benhabib et al. (1991) and Greenwood and Hercowitz (1991). More recently, Fisher (2007) extends these models by making household capital complimentary to business capital and labor in market production to reconcile the fact that household investment leads nonresidential capital over the business cycle.

Hall (2011), the first papers that develop macro models where the fundamental shock is a credit crunch type of shock (instead for example of a productivity shock) are Eggertsson and Krugman (2012) and Guerrieri and Lorenzoni (2011). Both papers propose an incomplete market model with households facing a borrowing constraint and represent a credit crunch as an unexpected tightening in the borrowing limit. In order to focus on households' gross debt positions, both papers need to introduce some form of households' heterogeneity into the model: Eggertsson and Krugman (2012) use a Keynesian model with two types of agents, borrowers and lenders, while Guerrieri and Lorenzoni (2011) use a Bewley type of model with uninsurable idiosyncratic income risk, so that households delever not only when they hit the borrowing limit, but also for precautionary reason when they are close enough to it. Both paper show that a credit crunch type of shock can have large (also persistent in Guerrieri and Lorenzoni, 2011) effects on the real economy, especially in the presence of sizeable nominal rigidities.

There has been a growing group of papers working on related incomplete market models with heterogenous households and focusing on a similar "credit tightening" shock. On a more quantitative side, Justiniano et al. (2015) and Del Negro et al. (2011) quantify the real effects of this type of shock, using different general equilibrium models and reaching different conclusions. On the one hand, Justiniano et al. (2015) builds on Iacoviello (2005) and Campbell and Hercowitz (2006) and propose a model with two types of households who can borrow using their house as collateral. They show that the leveraging and deleveraging cycle recently experienced by the United States did not have significant real effects. On the other hand, Del Negro et al. (2011) introduce liquidity frictions in an otherwise standard DSGE model and show that the effects of a liquidity shock can be large.

There are number of papers exploring the aggregate effects of a similar shock, focusing on transmission mechanisms that do not rely on nominal rigidities. Huo and Ríos-Rull (2014) study an incomplete market economy where heterogeneous households face a borrowing constraint and the fundamental shock is a tightening in the borrowing limit. The new ingredient in the model that makes the financial shock having real effects is the introduction of search frictions in some consumption markets.[c] That is, households need to engage in costly search to purchase some type of goods and hence, when the borrowing constraint tightens and households want to save more, they will also search less intensively. This will reduce demand and hence generate a recession. Moreover, there is an amplifying effect coming from the fact that consumption tilts more towards the wealthier households who are farther away from the constraint and who are the ones who exert less search effort. Another related paper is Kehoe et al. (2014) who propose a search and matching model a la Diamond–Mortensen–Pissarides with upward-sloping wage profiles

[c] The introduction of search frictions in consumption markets builds on Bai et al. Similar frictions are key in the transmission of financial shocks in Huo and Ríos-Rull (2013) who focus on a small open economy.

and risk-averse consumers who face borrowing constraints. In their model, a tightening in the borrowing limit raise workers' and firm' discount rates, hence reducing vacancy creation and employment, with a similar mechanism as in Hall (2014). This effect is amplified by the presence of on-the-job human capital accumulation and workers' debt constraints. Macera (2015) studies a model with both heterogenous households and heterogenous producers and explores the aggregate effects of a tightening in the borrowing capacity of both types of agents.

Another important related paper is Midrigan and Philippon (2011) who study a cash-in-advance economy with housing, where transactions can be conducted not only with money but also with home equity borrowing. In their economy, there is a continuum of islands that are subject to different collateral constraints. The authors parameterize the model to match the empirical evidence from Mian and Sufi (2011) at the MSA level. When house prices decline in one island, the cash-in-advance constraint tightens reducing aggregate demand in that island. This leads to a recession, thanks to nominal wage rigidities and frictions for the reallocation of labor from different sectors, which prevent households to work harder or to move to tradable sectors. The authors also consider an extension of the model with two types of households, patient and impatient, so that patient households lend to impatient households who can use housing as collateral. The authors distinguish between "liquidity shocks," ie, a tightening in the cash-in-advance constraint which affect all households, and "credit shocks," ie, a tightening the borrowing constraint which affect only impatient households, and show that liquidity shocks are very powerful. The distinction between the two types of constraints is useful to capture the empirical evidence in Johnson et al. (2006), Parker et al. (2013), and Kaplan and Violante (2014) showing that there is a large fraction of wealthy households who are liquidity constrined. In many macro models, as the ones described earlier, there is only one collateral constraint that typically captures both types of shocks.

Incomplete markets models have also been used to emphasize the effect of house prices on consumption, which is sizable according to Mian et al. (2013). There is a large empirical literature that has tried to estimate the effect of house price changes on consumption, using different data samples and different identification strategy, such as Campbell and Cocco (2007), Attanasio et al. (2009), Carroll et al. (2011), Case et al. (2013), and Ströbel and Vavra (2015) (see Iacoviello, 2012 for a more comprehensive survey on this topic). A standard permanent income hypothesis model typically delivers small consumption responses to house prices, as house prices affect households' wealth but also households' implicit rental rates. Berger et al. (2015) show that a simple incomplete market model with heterogenous agents, housing and collateral constraints, can deliver sizable consumption elasticity to house prices consistent with the empirical evidence. They show that the size of such an elasticity is determined by the correlation of marginal propensity to consume out of temporary income shocks and housing values, by deriving a simple sufficient-statistic formula for the individual elasticity. It follows that more levered economy are typically more responsive. They also analyze a boom–bust episode in the house prices similar to the one recently experience by the United States and show that a shock to expected house price appreciation can generate a large boom and bust in consumption and in residential investment at the same time. Kaplan et al. (2015) use a general equilibrium incomplete markets model with heterogeneous agents also to look at the recent boom and bust in house prices and consumption. They allow for different types of shocks: productivity shocks, taste shocks, shocks to the credit markets, and shocks to beliefs about future price appreciation. They show that this last type of shock is the most important to explain the movements in house prices, while shocks to credit conditions are important to explain homeownership, leverage and foreclosure.

Finally, there is another strand of literature that is more interested in understanding fluctuations in residential investment. Most of this literature takes house prices as exogenous. One of the seminal papers in this area is Davis and Heathcote (2005) who actually feature both endogenous housing investment and endogenous house prices. They build a neoclassical multisector stochastic growth model where one sector produces residential structures that, together with land, are used to produce houses. The model does not feature credit constraints, but already capture many facts about dynamics of residential investment. Iacoviello and Neri (2010) extend the multisector structure of Davis and Heathcote (2005) by adding, in particular, nominal rigidities and borrowing constraints. They show that demand shocks, such as housing preference shocks, are important in accounting for fluctuations in house prices. In a more recent paper, Rognlie et al. (2015) propose a model where a house price boom generates overbuilding of residential capital that would require a reallocation of resources among sectors. The authors use this model to think about the Great Recession and argue that, in the presence of a liquidity trap, this "investment hangover" can generate a recession. They show that their model is consistent with an asymmetric recovery where the residential sector has been left behind. In a related paper, Boldrin et al. (2001) use input–output tables to recover the linkages between the construction sector and the other sectors of the economy and evaluating the contribution of the construction sector to the Great Recession. This review has not included the large literature, examining the housing market in the absence of financial frictions. For example, Magnus (2011) has argued that search frictions may well be key to understanding many of the housing market phenomena such as liquidity, prices and vacancies.

4. A SIMPLE MODEL OF CATASTROPHES

In this section, we focus on the boom and bust in the credit cycle, abstracting from the dynamics of house prices. The main idea is that, if credit markets are affected by private information about the quality of the borrowers, a credit cycle can arise endogenously simply because of an increase in credit availability, which can be interpreted as a "saving glut." The idea is that when banks have easier access to credit, for example because the interest rate they face is lower, at first they will offer cheaper loans and increase their lending. However, due to the presence of adverse selection, when borrowing is cheaper worse borrowers will take loans and this can endogenously generate a crash of the credit market.

This idea is inspired by Boissay et al. (2016), but the model that we present here is quite different. The main mechanism in our model is based on adverse selection in the mortgage market, while Boissay et al. (2016) relies on a model of the interbank market affected by moral hazard. In their paper, banks are heterogeneous for their intermediation efficiency and their quality is private information. At the same time, borrowing banks can divert some of the funds to low return assets that cannot be recovered by the lending banks. This mechanism also generates endogenous credit cycles as a result of an increase in credit availability: as interest rates go down, the more efficient banks increase their activity, generating a boom of the banking sector, but as interest rates keep decreasing, worse banks have a higher incentive to divert their funds, increasing counterparty risk and possibly generating an interbank market freeze. Moreover, Boissay et al. (2016) embed their basic interbank market model in a standard DSGE model. Instead, we reduce the dynamics to 2 periods only and leave richer dynamic settings to future research.

4.1 Model

There are two periods $t=1$, 2. The economy is populated by a continuum of three types of agents: households, lenders, and banks. Lenders and banks are homogenous, while households are heterogenous.

Households enjoy utility $u(c, h)$ in period 2, where c is consumption of a nondurable good and h is housing consumption. For simplicity, let us assume that utility is linear, that is,

$$u(c,h)=c+\gamma h.$$

Houses come in fixed size equal to $\bar{h}$, so that $h\in\{0,\bar{h}\}$, and their price is fixed to 1. Households have no endowment in period 1 but receive an income draw y in period 2. They have to decide whether to buy a house or not in period 1, so if they decide to buy a house they have to borrow the full amount.

Households are heterogenous with respect to their income process. Let $\nu \in [0, 1]$ be the household's type. Assume that ν is distributed according to some distribution function $G(\nu)$ and affects the distribution of the household's income $F_\nu(y)$. Throughout, we shall assume

Assumption 1 $F_{\nu_B}(y)$ first order stochastic dominates $F_{\nu_A}(y)$ whenever $\nu_B > \nu_A$.

Thus, higher household types have a "better" income distribution.

To buy a house in period 1, a household has to borrow 1 unit of funds from the banks at some mortgage "price" p and promise to repay $1/p$ in period 2. Let us note that the label "price" (and notation p) might be a bit confusing. It does not refer to the price of the house (which remains fixed at 1), but is period-1 price for one unit of period-2 resources.

Alternatively, one may wish to think of p as the "payment" the household receives in period $t = 1$ for each unit of promised repayment at date $t = 2$. We shall continue to refer to it as the mortgage price.

At the beginning of period 2, the household's income y is realized and then the household decides whether to repay its debt or not. If it does default on its debt it does not pay anything back to the lender, but it suffers a penalty $\delta > 0$.[d] This implies that households with higher ν are better potential borrowers, in the sense that they have a lower probability of bad income realizations. Let us denote by $\chi \in\{0, 1\}$ the repayment decision, with $\chi = 1$ denoting repayment.

The household's type ν is private information of the household. However, at the beginning of period 1, households have the option to verify their type at a utility cost $\kappa > 0$.[e] Let $v(\nu) \in \{0, 1\}$ be the decision of verifying their type ($v = 1$) or not ($v = 0$). If a household verifies its type, banks can make the lending terms type-contingent, so that the mortgage price p is going to be equal to $\widetilde{p}(\nu)$. If instead a household does not verify its type, banks do not know the type of the borrower and will offer a pooling mortgage price p^P. Note that we assume that banks are restricted to offer only one mortgage price to all that have not verified. It would be interesting to extend the model allowing banks to offer more general contracts.

To sum up, households have three options: (1) do not verify their type and borrow accepting a pooling contract, that is, $h(\nu) = 1$ and $v(\nu) = 0$ and borrow at the pooling mortgage price $p = p^P$; (2) verify their type and access type-contingent contracts, that is, $h(\nu) = v(\nu) = 1$ and borrow at the type-contingent mortgage price $p = \widetilde{p}(\nu)$; and (3) do not borrow at all, that is, $h(\nu) = v(\nu) = 0$.

Let us proceed backward and consider the repayment decision, conditional on borrowing in the first period, that is, on $h(\nu) = 1$. Recall that the household suffers a penalty δ, if it defaults, and that the lender does not get anything back. Then, a household with realized income y who borrows at the mortgage price p would like to repay if

$$y - 1/p + \gamma\bar{h} \geq y - \delta.$$

We assume throughout that δ is large enough so that in equilibrium any household would like to pay back its debt if it can.[f] However, it may not be able to repay because its realized

[d] The assumption that a defaulting household does not pay anything back to the lender and only suffers a penalty is stark, but simplifies the analysis. The idea is that the household could run away, at a cost which is summarized by δ. One could relax that and assume that the lender can seize only part of the income of the borrower, as it is reasonable to assume that part of it must be lost in legal fees.

[e] The household decides whether to verify its type or not before banks make their offers. Also, we assume that the verification costs is in terms of utility, because for simplicity we assume that the households start period 1 with no endowment. However, it would be easy to extend the model to make it a monetary cost.

[f] We will show below that this is a necessary condition to have a nonempty set of borrowers at the pooling mortgage price.

income is not high enough, so that $\chi(y, p) = 1$ iff $y \geq 1/p$. Let $\pi(\nu, p)$ be the ex-ante repayment probability of a household of type ν who borrows at the mortgage price p, that is,

$$\pi(\nu,p) = E[\chi(y,p) = 1|\nu,p] = 1 - F_\nu\left(\frac{1}{p}\right)$$

Then we can show the following proposition.

Proposition 2 *The repayment probability* $\pi(\nu$, p*) is increasing in* ν *and increasing in* p.

Proof First, $\pi(\nu, p)$ is increasing in ν, since F_ν are ordered by first-order stochastic dominance. Second, $\pi(\nu, p)$ is increasing in p, since $1 - F_\nu(y)$ is decreasing in y for any ν. □

This means that a household with higher type has a higher repayment probability, for any given mortgage price p.

Let us now focus on the lending market. Let us assume that the banks can borrow from the lenders at some rate R, which is exogenously given.[g] Also, they trade the loans, which we will refer to as assets from now on, on the secondary market.[h] Each asset is characterized by the type of the associated borrower ν and has a different repayment probability $\pi(\nu, p) \in [0, 1]$. This implies that the pooling mortgage price is determined by the no-arbitrage condition

$$p^P = \frac{E\left[1 - F_\nu\left(\frac{1}{p^P}\right)|\nu \in \mathcal{S}\right]}{R}, \tag{31}$$

where $\mathcal{S} \equiv \{\nu|v(\nu) = 0\}$ is the set of households who decide not to verify their type. Likewise, the type-contingent mortgage price is determined by the no-arbitrage equation

$$\tilde{p}(\nu) = \frac{1 - F_\nu\left(\frac{1}{\tilde{p}(\nu)}\right)}{R}. \tag{32}$$

In principle, there may be none, one or several solutions to this equation. Borrowing the logic in Mankiw (1986), we assume that the highest of these prevails in equilibrium: at a lower mortgage price and thus higher promised return to all other banks, a bank could profitably deviate by offering a higher mortgage price and a better deal to the household, under mild conditions. Define ν_L as the lowest type, beyond which a type-contingent mortgage price exists for some types,

[g] The interest rate R can be interpreted as the rate at which lenders can borrow in the international market.

[h] One can potentially generalize the model to create MBS that pool different loans and a similar mechanism would go through as long as there is a constraint on the measure of types that can be pooled together.

$$\nu_L = \inf_{\nu}\{\nu \mid \text{ there is a solution to Eq. (32)}\}$$

We can then show that a type-contingent mortgage price exists for all types better than ν_L.

Proposition 3 *There exist a type-contingent mortgage price $\tilde{p}(\nu)$ for any $\nu > \nu_{\mathrm{L}}$.*

Proof Consider some ν. Let $\nu' \in [\nu_L, \nu]$ be such that there is a solution $\tilde{p}(\nu')$ to Eq. (32). Define

$$\mathcal{P}(\nu) = \{p \geq \tilde{p}(\nu') \mid p \leq \frac{1 - F_\nu\left(\frac{1}{p}\right)}{R}\}$$

Since F_ν second-order stochastically dominates $F_{\nu'}$, $\tilde{p}(\nu') \in \mathcal{P}(\nu)$ and $\mathcal{P}(\nu)$ is therefore nonempty. Let $\bar{p} = \sup\mathcal{P}(\nu)$, the supremum of $\mathcal{P}(\nu)$. Note that $\bar{p} \leq 1/R < \infty$. Consider an increasing sequence $p_j \to \bar{p}$ with $p_j \in \mathcal{P}(\nu)$. Calculate that

$$\bar{p} = \lim_{j\to\infty} p_j \leq \lim_{j\to\infty} \frac{1 - F_\nu\left(\frac{1}{p_j}\right)}{R} \leq \frac{1 - F_\nu\left(\frac{1}{\bar{p}}\right)}{R}$$

and thus $\bar{p} \in \mathcal{P}$. This shows that $\bar{p}$ is a maximum and that there is therefore at least one solution to Eq. (32). □

Obviously, households who verify their type will be able to borrow at terms that are more favourable the better their type is. That is, we can prove the following proposition.

Proposition 4 *For $\nu > \nu_{\mathrm{L}}$, the type-contingent mortgage price $\tilde{p}(\nu)$ is increasing in ν and decreasing in* R.

Proof First, let us make a change of variable and define $\tilde{R}(\nu) \equiv 1/\tilde{p}(\nu)$. Rewrite Eq. (32) as

$$1 - \frac{R}{x} = F_\nu(x). \tag{33}$$

which we seek to solve for $\tilde{R}(\nu) = x$, for a given ν. Assume then that there is at least one solution for (32), ie, that the curves defined by the left-hand side and right-hand side of that equation cross at least once. As assumed above per the logic in Mankiw (1986), pick the lowest solution to (33) or, equivalently, the highest of the solutions for (32), if there are several. This pins down a unique $\tilde{R}(\nu)$ and unique $\tilde{p}(\nu)$ for each ν. Fix some ν and its solution $\tilde{R}(\nu) = x$. Note that the left-hand side of (33) diverges to $-\infty$, as $x \to 0$, while the right-hand side converges to a nonnegative number. Thus, at the lowest solution and as a function of x, the right-hand side of (33) approaches and then either crosses or touches the left-hand side from above, as x approaches the solution from below. Per the definition of second-order stochastic dominance, the right-hand side shifts to the right, as ν is increased. Therefore a solution continues to exist for higher ν and they are to the left of the solution fixed at the beginning of this argument. As ν is decreased, the right-hand side function shifts to the left. By the similar logic, the solution either moves to the right, when the intersection between the two sides moves locally, or will jump to a solution at a higher value, if the current intersection disappears or a solution will cease to exist altogether. In sum, if a solution $\tilde{R}(\nu)$ exists, it is decreasing in ν. Equivalently, if a solution $p(\nu)$ exists, it is increasing in ν. Likewise, consider now an decrease in R. This shifts the left-hand side of (33) upward, a solution will continue to exist and will be lower than the previously fixed solution. If R increases, the current intersection may move locally or disappear: in either case, if a solution continues to exist, it will be higher than the previously fixed solution. This shows that $\tilde{R}(\nu)$ is increasing and $p(\nu)$ therefore decreasing, as a function of R. □

Consider now the household's problem. Define

$$U^B(\nu,p)=\int_{\frac{1}{p}}^{\infty}(y-\frac{1}{p}+y\bar{h})dF_\nu(y)+\int_0^{\frac{1}{p}}(y-\delta)dF_\nu(y), \tag{34}$$

which is the expected utility of a household of type ν who decides to buy a house at the mortgage price p and does not verify its type ($h(\nu)=1$ and $v(\nu)=0$). For $\nu>\nu_L$, define

$$U^V(\nu)=U^B(\nu,\tilde{p}(\nu))-\kappa, \tag{35}$$

which is the expected utility of a household who decides to borrow at mortgage price $p=\tilde{p}(\nu)$ and verify its type ($h(\nu)=v(\nu)=1$). For $\nu<\nu_L$, no such type-contingent mortgage price exists: thus define

$$U^V(\nu)=-\infty \tag{36}$$

in that case. For $\nu=\nu_L$, use (35), if there is a solution to (32), and (36), if not. Finally, define

$$U^N(\nu)=\int ydF_\nu(y)=E[y\,|\,\nu], \tag{37}$$

which is the expected utility of a household of type ν who decides not to buy a house ($h(\nu)=v(\nu)=0$), and equal to the expected income, given our assumption of linear utility. For a given pooling mortgage price p^P, the utility of the household of type ν and its maximization problem is now

$$\bar{U}(\nu,p^P)=\max\left\{U^B(\nu,p^P),U^V(\nu),U^N(\nu)\right\},$$

To make more progress, we need an assumption regarding the income uncertainty as expressed by F_ν.

Assumption 2 There is some $x^*\in\mathbb{R}$ so that $F_\nu(x)$ has nondecreasing slopes above x^*: for all x_1 and x_2 with $x^*\leq x_1\leq x_2$ and all ν_A and ν_B with $\nu_L\leq\nu_A\leq\nu_B$, we have

$$F_{\nu_A}(x_2)-F_{\nu_A}(x_1)\leq F_{\nu_B}(x_2)-F_{\nu_B}(x_1) \tag{38}$$

The assumption is trivially satisfied at some x^*, where $F_1(x^*) = 1$, if such a value x^* exists, ie, if the income distribution is bounded. Obviously then, this assumption is only useful, if x^* is fairly small and smaller than some upper bound on income. Indeed, it will be particularly convenient to assume that $x^* = R$, the safe return.

The following lemma is a bit technical, and useful for an intermediate step in the proof of the next proposition.

Lemma 1

1. *Define*

$$Z(\nu,p) \equiv \left(1 - F_\nu\left(\frac{1}{p}\right)\right)\left(\gamma\bar{h} - \frac{1}{p} + \delta\right). \tag{39}$$

and suppose that $\gamma\bar{h} - (1/p) + \delta > 0$. *Then* Z($\nu$, p) *is increasing in both* ν *and* p.

2. *For* $\nu > \nu_L$, *define*

$$g(\nu,p) = Z(\nu, \tilde{p}\,(\nu)) - Z(\nu,p) \tag{40}$$

For $\nu < \nu_L$, *define* $g(\nu,p) = -\infty$. *For* $\nu = \nu_L$, *define* $g(\nu_L, p)$ *as in Eq.* (40), *if there is a solution to Eq.* (32) *and* $g(\nu_L,p) = -\infty$ *otherwise. Suppose that* $p \leq \tilde{p}\,(\nu) \leq 1/x^*$ *for all* $\nu > \nu_L$ *and that* $\gamma\bar{h} - (1/p) + \delta > 0$. *Impose the Assumption 2 of nondecreasing slopes. Then g is increasing in* ν *and decreasing in p.*

Proof It is easy to see that $Z(\nu, p)$ is increasing in both ν and p. It follows that $g(\nu, p)$ is decreasing in p. It remains to show that g is increasing in ν for $\nu \geq \nu_L$. Suppose that $\nu_A \leq \nu_B$. We need to show that

$$g(\nu_A,p) \leq g(\nu_B,p) \tag{41}$$

Excluding the trivial case of $\nu_B = \nu_L$ with $g(\nu_L,p) = -\infty$, calculate

$$\begin{aligned} g(\nu_B,p) - g(\nu_A,p) &= Z(\nu_B, \tilde{p}(\nu_B)) - Z(\nu_A, \tilde{p}(\nu_A)) - (Z(\nu_B,p) - Z(\nu_A,p)) \\ &\geq Z(\nu_B, \tilde{p}(\nu_A)) - Z(\nu_A, \tilde{p}(\nu_A)) - (Z(\nu_B,p) - Z(\nu_A,p)) \end{aligned}$$

where we have exploited that $\tilde{p}(\nu_A) \leq \tilde{p}(\nu_B)$ per Proposition 4, and that $Z(\nu, p)$ is increasing in p. Define $x_1 = 1/\tilde{p}(\nu_A)$ and $x_2 = 1/p$ and note that $x^* \leq x_1 \leq x_2$. With that, rewrite the right-hand side of the last equation as

$$\begin{aligned} &g(\nu_B,p) - g(\nu_A,p) \\ &\geq (F_{\nu_A}(x_1) - F_{\nu_B}(x_1))(\gamma\bar{h} - x_1 + \delta) - (F_{\nu_A}(x_2) - F_{\nu_B}(x_2))(\gamma\bar{h} - x_2 + \delta) \\ &= ((F_{\nu_A}(x_1) - F_{\nu_B}(x_1)) - (F_{\nu_A}(x_2) - F_{\nu_B}(x_2)))(\gamma\bar{h} - x_1 + \delta) \\ &\ + (F_{\nu_A}(x_2) - F_{\nu_B}(x_2))(x_2 - x_1) \\ &\geq 0 \end{aligned}$$

with Assumption 2. □

The following proposition shows that the households' optimal behavior can be characterized by two cutoffs values, such that, households with low types do not buy a house,

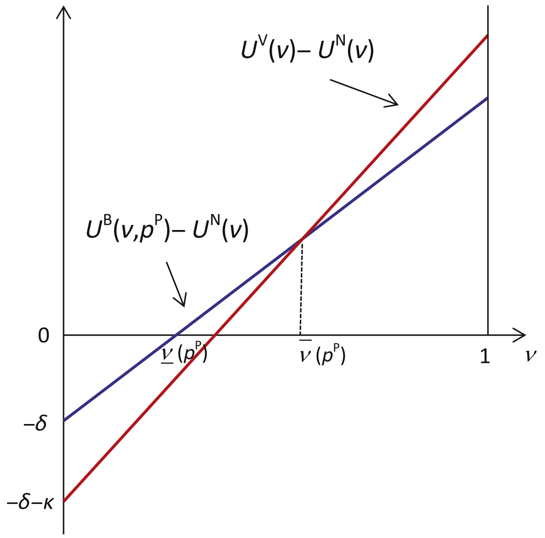

Fig. 8 Households' problem (curves are linear just for illustration).

households with high types buy a house and may verify their type, and households in the middle range, buy a house but choose to borrow at the pooling mortgage price. The logic is illustrated in Fig. 8.

Proposition 5 *Impose the Assumption 2 of nondecreasing slopes. Assume that $x^* = R$, the safe return. Then, there exists a value $\underline{p}$ so that no household buys a house at a mortgage price $p < \underline{p}$, whereas for all $p^P > \underline{p}$ there are two cutoffs $\underline{\nu}(p^P) \leq \overline{\nu}(p^P)$ such that*

1. *$h(\nu) = 0$, ie, no house purchase, if $\nu < \underline{\nu}(p^P)$.*

2. *$h(\nu) = 1$, $v(\nu) = 0$, ie, house purchase without verification at the pooling mortgage price p^P, if $\underline{\nu}(p^P) < \nu < \overline{\nu}(p^P)$.*

3. *$h(\nu) = 1$, $v(\nu) = 1$, ie, house purchase with verification at the type-contingent mortgage price $\tilde{p}\,(\nu)$, if $\nu > \overline{\nu}(p^P)$.*

4. *$\mathcal{S} = [\underline{\nu},\overline{\nu}]$ or $\mathcal{S} = (\underline{\nu},\overline{\nu}]$ or $\mathcal{S} = [\underline{\nu},\overline{\nu})$ or $\mathcal{S} = (\underline{\nu},\overline{\nu})$, for $\underline{\nu} = \underline{\nu}(p^P)$ and $\overline{\nu} = \overline{\nu}(p^P)$.*

Moreover, $\underline{\nu}(p^P)$ and $\overline{\nu}(p^P)$ are respectively decreasing and increasing in p^{P}.

Proof Let us rewrite

$$U^B(\nu,p) = E[y\,|\,\nu] + Z(\nu,p) - \delta,$$

$$U^V(\nu) = E[y\,|\,\nu] + Z(\nu,\tilde{p}\,(\nu)) - \delta - \kappa,$$

and

$$U^N(\nu) = E[y\,|\,\nu],$$

where $Z(\nu, p)$ is defined in Eq. (39).

Note that a type ν-household will choose to buy a house at mortgage price p without verification, iff $U^B(\nu, p) \geq U^N(\nu)$, that is, iff

$$Z(\nu,p)\geq\delta. \tag{42}$$

Let $\underline{p}$ be the infimum of all p, so that there exists a ν, satisfying Eq. (42). Therefore, no household of any type will purchase a house at a mortgage price $p<\underline{p}$ without verification and certainly not either, when paying the verification cost.

Consider now any $p>\underline{p}$. Since $Z(\nu, p) > 0$ for some ν, it follows that $\gamma\bar{h}-(1/p)-\delta>0$. Since $Z(\nu, p)$ is increasing in ν per Lemma 1, there is a unique cut-off $\underline{\nu}(p)$ such that such that $U^B(\nu, p)\geq U^N(\nu)$ if $\nu>\underline{\nu}(p)$. If $Z(1, p)>\delta$ and $Z(0, p) < \delta$, the cutoff $\underline{\nu}$ is implicitly defined by the infimum of all $\nu\in[0, 1]$ such that

$$Z(\nu,p)\geq\delta. \tag{43}$$

If $Z(1, p) < \delta$, then $\underline{\nu}(p)=1$ and if $Z(0, p) > \delta$, then $\underline{\nu}(p)=0$. Since $Z(\nu, p)$ is increasing in p, it follows that $\underline{\nu}(p)$ is decreasing (more precisely: nonincreasing) in p.

Note that a type ν-household will choose to verify and buy a house at the type-contingent mortgage price $\tilde{p}(\nu)$ rather than a mortgage pooling price p, iff $U^V(\nu)\geq U^B(\nu, p)$, that is, iff

$$Z(\nu,\tilde{p}(\nu))-\kappa\geq Z(\nu,p) \tag{44}$$

provided a type-contingent mortgage price $\tilde{p}\,(\nu)$ exists, or, equivalently, iff

$$g(\nu,p)\geq\kappa \tag{45}$$

where g is defined in Eq. (40). Let $\overline{\nu}(p)$ be the infimum over all $\nu\in[0, 1]$, for which (45) holds, with the convention that $\overline{\nu}(p)=1$, if no such ν exists. Consider some $\nu_A>\overline{\nu}(p)$ such that (45) holds. Since $Z(\nu, p)$ is increasing in p, it follows that $p\leq\tilde{p}(\nu)$. Eq. (32) implies that $\tilde{p}(\nu)\leq 1/x^*$ for all ν. Let $\nu_B>\nu_A$. Lemma 1 now implies that $g(\nu_B, p)\geq g(\nu_A, p)\geq\kappa$, ie, Eq. (45) also holds at ν_B. This proves that Eq. (45) holds for all $\nu>\overline{\nu}(p)$.

Finally, recall that $g(\nu, p)$ is decreasing in p, per Lemma 1. Therefore, if (45) holds at some ν and p, it continues to hold at some $p'<p$. It follows that $\overline{\nu}(p)\geq\overline{\nu}(p')$, ie, that $\overline{\nu}(p)$ is increasing in p. □

We have been careful to allow for discontinuities in all equations, and expressing solutions as infima or suprema for variables appearing in inequalities. In practice, it may be simpler to proceed with enough continuity and to assume that these equations hold with equality at the limiting points. Furthermore, it may be best to impose that $G(\nu)$ has no mass points. With that and in sum, an equilibrium can be represented by a separating mortgage price schedule $\tilde{p}\,(\nu)$ solving Eq. (32) for $\nu\geq\nu_L$, a pooling mortgage price p^P, which satisfies

$$p^P=\frac{\int_{\underline{\nu}}^{\overline{\nu}} 1-F_\nu\left(\frac{1}{p^P}\right)G(d\nu)}{R}, \tag{46}$$

and two cutoffs $\underline{\nu}$ and $\overline{\nu}$ satisfying the two conditions

$$\left[1-F_{\underline{\nu}}\left(\frac{1}{p^P}\right)\right]\left(\gamma\bar{h}-\frac{1}{p^P}+\delta\right)=\delta, \tag{47}$$

and

$$\left[1-F_{\overline{\nu}}\left(\frac{1}{p^P}\right)\right]\left(\gamma\bar{h}-\frac{1}{p}+\delta\right)=R\,\widetilde{p}(\overline{\nu})(\gamma\bar{h}+\delta)-R-\kappa. \tag{48}$$

We next want to show that multiple equilibria can arise in our model performing some simple numerical exercises.

4.2 Multiple Equilibria

In our model, good households may decide to costly verify their type to signal that they are good and so not to be pooled with bad households. This feature of the model is key to generate multiple equilibria. For some parameters, we can have two equilibria: a good equilibrium where good households do not verify their type, the mortgage price is high and hence it is indeed optimal not to suffer the verification cost; and a bad equilibrium, where good households do verify their type, hence lowering the pooling mortgage price and making it indeed optimal to costly verify their type.

The possibility of multiple equilibria can generate an endogenous credit cycle, driven by a simple increase in credit availability, that is, a decrease in R. As we highlighted earlier, this can be thought as an episode of "saving glut," using Ben Bernanke language: *"I will argue that over the past decade a combination of diverse forces has created a significant increase in the global supply of saving—a global saving glut—which helps to explain both the increase in the U.S. current account deficit and the relatively low level of long-term real interest rates in the world today. The prospect of dramatic increases in the ratio of retirees to workers in a number of major industrial economies is one important reason for the high level of global saving. However, as I will discuss, a particularly interesting aspect of the global saving glut has been a remarkable reversal in the flows of credit to developing and emerging-market economies, a shift that has transformed those economies from borrowers on international capital markets to large net lenders."*

In the next section we will show a numerical example where this is the case. Let us first describe the mechanics behind such an endogenous cycle.

1. Let us imagine that we start in an equilibrium where R is relatively high so that the pool of borrowers is relatively good, that is, $\underline{\nu}$ is large, and all borrowers are pooled together, that is, $\overline{\nu}=1$.
2. Then, assume that R declines, pushing both p and $\widetilde{p}\,(\nu)$ up and hence increasing both U^B and U^V. This implies that $\underline{\nu}$ decreases and more bad households become borrowers. However, let us assume that it is still the case that $\overline{\nu}=1$. The change in the composition of the loans tends to depress mortgage prices.

However, mortgage prices have to go up on net, so the interest rate effect has to dominate.[i]

3. If R decreases further, at some point $\overline{\nu}$ will become smaller than 1 and some borrowers will decide to verify that they are good types, hence worsening the pool of households who borrow at the pooling mortgage price, p^P. There are two possibilities:
   (a) p^P increases, then both U^B and U^V shift further up and both $\underline{\nu}$ and $\overline{\nu}$ decline, dampening the increase in p^P.
   (b) p^P declines, then U^B has to shift down and $\underline{\nu}$ increases. In this case, it must be that the decline in $\overline{\nu}$ is strong enough to more than compensate the pressure upward on p^P played by the increase in R and in $\underline{\nu}$.

   Let us imagine that the second case arises.
4. If R decreases even further, the economy is now stuck in a bad equilibrium with some separation.

The shift from a good equilibrium to a bad equilibrium can be interpreted as a market crash, as mortgage prices suddenly drop or, equivalently, required interest payments on mortgages suddenly increase.

4.3 Some Numerical Examples

In this section, we show some simple numerical examples to illustrate how our model can generate an endogenous credit cycle.

For simplicity, let us assume that the income process follows a binary distribution with $y \in \{0, \overline{y}\}$, where $\overline{y} > R$ is sufficiently high that repayment is guaranteed. Let ν be the probability for the high outcome, that is, $\nu = Pr(y = \overline{y})$. The income distribution F_ν is then given by

$$F_\nu(x) = \begin{cases} 0, & \text{if } x < 0 \\ 1 - \nu, & \text{if } 0 \leq x < \overline{y} \\ 1, & \text{if } x \geq \overline{y} \end{cases}$$

Let x^* be some small, but positive real number, $0 < x^* < R$. Let $\nu_A < \nu_B$. For all x_1 and x_2 with $x^* \leq x_1 \leq x_2 < \overline{y}$ or with $\overline{y} \leq x_1 \leq x_2$, we have

$$F_{\nu_A}(x_2) - F_{\nu_A}(x_1) = 0 = F_{\nu_B}(x_2) - F_{\nu_B}(x_1) \tag{49}$$

Suppose then that $x^* \leq x_1 < \overline{y} \leq x_2$. Now,

$$F_{\nu_A}(x_2) - F_{\nu_A}(x_1) = \nu_A \leq \nu_B = F_{\nu_B}(x_2) - F_{\nu_B}(x_1) \tag{50}$$

Thus, Assumption 2 is satisfied and Proposition 5 applies.

[i] Imagine, by contradiction that p declines, then $\underline{\nu}$ has to increase, but then p has to increase, generating a contradiction.

Eq. (31) now reduces to

$$\tilde{p}(\nu) = \frac{\nu}{R}.$$

The two cut-off $\underline{\nu}$ and $\overline{\nu}$ are given by

$$\underline{\nu} = \frac{\delta}{\gamma\bar{h} + \delta - p^P - 1}, \tag{51}$$

and

$$\overline{\nu} = (R - \kappa)p^P, \tag{52}$$

where the pooling mortgage price p^P is given by condition (46), which can be rewritten as

$$p^P = \frac{E[\nu | \nu \in [\underline{\nu}, \overline{\nu}]]}{R}.$$

For all the numerical examples, we set $\gamma\bar{h} = 2$ and $\delta = 0.1$. We then experiment with different distributions H for ν.

We start by a baseline example where we assume that ν is uniformly distributed on [0, 1]. In this case, the pooling mortgage price can be solved for in closed form and is equal to

$$p^P = \left(\frac{\delta}{R - \kappa} + 1\right)\frac{1}{\gamma\bar{h} + \delta}.$$

This implies that in this simple benchmark the pooling mortgage price is monotonically decreasing in R, and hence a reduction in R is always going to increase p^P and decrease the two cutoffs $\underline{\nu}$ and $\overline{\nu}$, so there is no possibility of multiple equilibria.

Fig. 9 shows the results for this numerical case. The top panel on the left shows the equilibrium manifold for mortgage prices as a function of the exogenous interest rate R and clearly shows that in this case multiple equilibria never arise. The top panel on the right just shows the distribution for ν. The two panels in the middle illustrate that there is a unique equilibrium for any level of R, showing in particular the case of $R = 1.1$, $R = 1.4$, and $R = 1.7$. Finally the bottom panel on the left shows the two cutoffs, $\underline{\nu}$, in red, and $\overline{\nu}$, in blue, as a function of the pooling mortgage price for a specific R. Finally, the bottom right panel shows the volume of loans offered in equilibrium, again for $R = 1.1$, $R = 1.4$, and $R = 1.7$, and shows that, as expected, it is increasing both in the pooling mortgage price and in R.

We then explore the following two alternative distributions:

1. a mixture of two exponential densities,

$$h(\nu) = \omega\frac{\lambda_1 e^{-\lambda_1 \nu}}{1 - e^{-\lambda_1}} + (1 - \omega)\frac{\lambda_2 e^{-\lambda_2 \nu}}{1 - e^{-\lambda_2}};$$

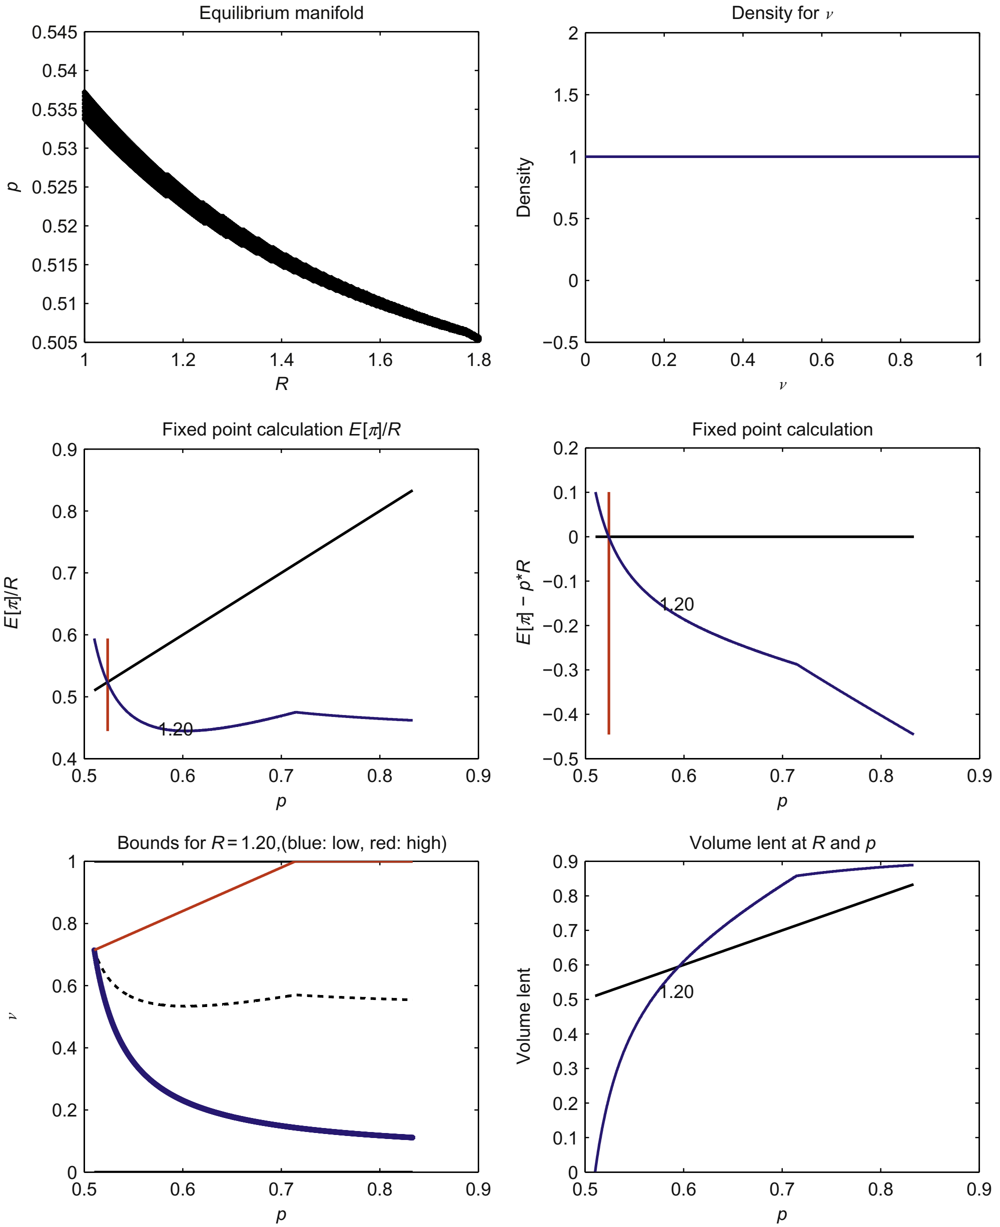

Fig. 9 Uniform distribution for ν on [0, 1]. No multiplicity.

2. a mixture of an exponential density and a truncated normal (where, in terms of the parameterization, we have not normalized the latter to integrate to unity, just the density $h(\nu)$ as a whole),

$$h(\nu) \propto \omega \frac{\lambda e^{-\lambda\nu}}{1-e^{-\lambda}} + (1-\omega)\frac{e^{-(\nu-\nu^e)^2/(2\sigma^2)}}{\sqrt{2\pi\sigma}}.$$

The first example we consider assumes that H is a mixture of an exponential density and a truncated normal, where $\kappa = 0.25$, $\lambda = -20$, $\nu^e = 0.1$, $\sigma = 0.2$, and $\omega = 0.6$. Fig. 10 shows the results for this case. The top panel on the left shows again the equilibrium manifold for mortgage prices as a function of the exogenous interest rate R and shows that for middle-range levels of R, multiple equilibria can arise. The top panel on the right just shows again the distribution for ν. The two panels in the middle show that the number of equilibrium pooling mortgage prices depends on the level of R. For example, we obtain a unique pooling equilibrium when $R = 1.5$, multiple equilibria when $R = 1.4$, and a unique separating equilibrium when $R = 1.3$.[j] In the case of multiple pooling mortgage prices, we have two stable ones and one unstable in the middle. Finally the bottom panel on the left shows again the two cutoffs, $\underline{\nu}$, in red, and $\overline{\nu}$, in blue, as a function of the pooling mortgage price, for the case $R = 1.4$. The bottom right panel shows the volume of loans offered in equilibrium as a function of the pooling mortgage price, for the three different levels of R considered above. This illustrates that if the economy starts at $R = 1.5$ and then R declines, the pooling mortgage price and the loan volume can first increase and then drop as a result of a shift from a good to a bad equilibrium.

For the second case, a mixture of two exponentials, we set the verification cost $\kappa = 0.15$, and the parameters of the H distribution to $\lambda_1 = -20$, $\lambda_2 = 5$, and $\omega = 0.8$. Fig. 11 shows the results for this numerical case. The plots are analogous to the one described earlier. In this case, we show that a unique pooling equilibrium arises when $R = 1.65$, multiple equilibria arise when $R = 1.58$ and a unique separating equilibrium arises when $R = 1.4$. This implies that, also in this case, a decline in R can generate an endogenous boom and bust in the credit markets, represented by an initial increase and a following decline in the pooling mortgage price and in the loan volume. Again, the bust is originated by a shift from a good to a bad equilibrium.

5. RELATED LITERATURE: SENTIMENTS AND BUBBLES

One story about run-ups in house prices and subsequent crashes, which appears to be popular in journalistic descriptions of financial crises, runs as follows: as prices rise,

[j] This is clearly a numerical example, not a calibration. In any case, high interest rates might be justified by the fact that mortgages are long-period contracts.

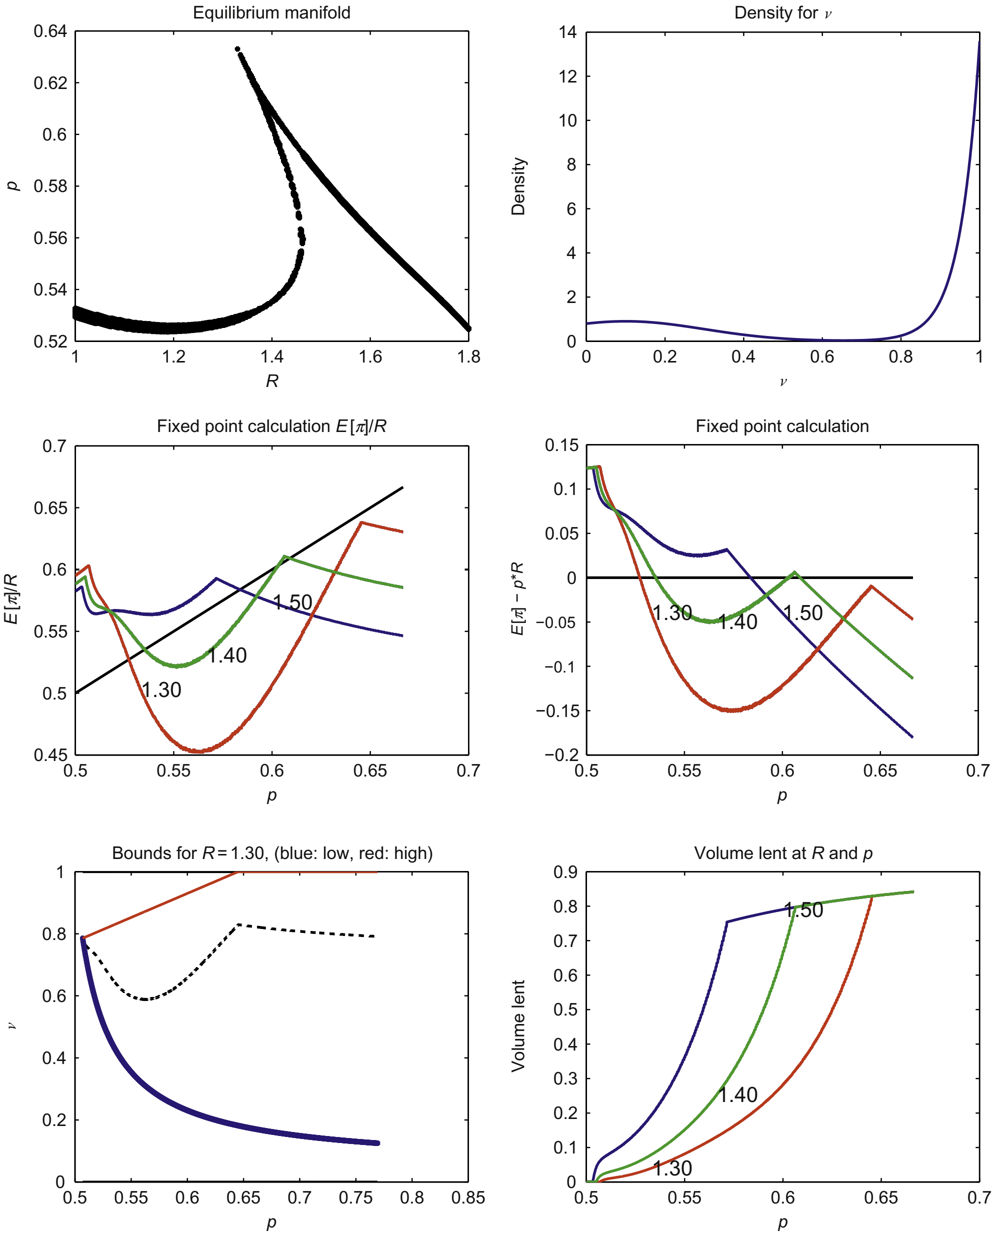

Fig. 10 For the mixture of an exponential density and a truncated normal, where $\gamma\bar{h} = 2$, $\delta = 0.1$, $\kappa = 0.25$, $\lambda = -20$, $v^e = 0.1$, $\sigma = 0.2$, and $\omega = 0.6$, we obtained a unique separating equilibrium for $R = 1.3$, multiple equilibria for $R = 1.4$ and a unique pooling equilibrium for $R = 1.5$.

Fig. 11 For the mixture of two exponentials, where $\gamma\bar{h}=2$, $\delta=0.1$, $\kappa=0.15$, $\lambda_1=-20$, $\lambda_2=5$, and $\omega=0.8$ (with κ the cost for verification), we obtained a unique separating equilibrium for $R=1.4$, multiple equilibria for $R=1.58$ and a unique pooling equilibrium for $R=1.65$.

speculators are drawn to the market, hoping to sell at a higher price tomorrow. Eventually, this comes to an end, the speculators withdraw from the market and prices come crashing down. While appealing, formalizing this intuition tends to run into the obstacle that if prices are expected to be high tomorrow, then demand for credit and thus houses should be high today, and that should drive up prices today, making it less likely that prices will increase. Or, put differently, as prices rise, they eventually must get to a near maximum at some date (unless for some reason agents can buy on credit against the future resale): call that date "today." At that point, prices are expected to decline in the future. But if so, banks and speculating households are less likely to buy today and prices should not be high today to start with. These types of bubbles are typically ruled out by thinking about a "last fool" who is willing to buy at the highest price, when prices can only go down from there: such fools should not exist in rational expectations equilibria. Agents should realize that prices cannot outgrow the economy forever: using backward induction, the bubble then gets stopped dead in its tracks before it can get going at all. That is why formalizing this popular story indeed presents a challenge.

Two strands of the literature have evolved to address this challenge. One strand of the literature, that we refer to as "bubbles," keeps the expected growth rate of bubbles bounded by the growth rate of the economy, thus circumventing the backward induction logic. These models may additionally invoke irrational beliefs or differences in sentiments, but many do not. Another strand of literature, that we define "sentiments," allows agents to believe that bubbles will grow faster than the economy, but then also needs to invoke irrational beliefs for at least some portion of the agents in order to disable the backward induction logic described earlier.

Related to the literature on bubbles, there is another strand of literature that focus on generating momentum in house price changes. Among the papers in this literature, Case and Shiller (1989), Barberis et al. (1998), Hong and Stein (1999), Capozza et al. (2004), Frazzini (2006), Glaeser et al. (2014), Anenberg (2014), Head et al. (2014), Glaeser and Nathanson (2016), and Guren (2016).

5.1 Bubbles

Perhaps the most prominent and earliest example of a model with bubbles is the celebrated overlapping generations model of money by Samuelson (1958). If other means of savings do not produce a rate of return higher than the growth rate of the economy, then an intrinsically worthless asset (fiat money) can have a nonzero price in terms of goods, as it gets sold by the currently old agents to the next generation of currently young agents. Such economies need to be dynamically inefficient, satisfying the Cass criterion or Balasko–Shell criterion, see Cass (1972) and Balasko and Shell (1980). In such economies, the first welfare theorem might not hold, competitive equilibria might not be Pareto optimal. One may achieve a Pareto improvement by giving resources to the current old from the current young, who in turn receive resources, when they are old from the next young generation, ad infinitum. There are various ways to implement or interpret such a transfer scheme. Samuelson interpreted the scheme as fiat money, issued perhaps by the initially old generation. Others have interpreted it as government debt, to be rolled over forever, or as an unfunded pension system.

Another stream of literature that features rational bubbles is the search literatures with fiat money. The seminal paper in this literature is Kiyotaki and Wright (1989) that proposes a model of decentralized trade where agents meet randomly and fiat money can arise as general medium of exchange.

The literature of greatest interest to us here has interpreted this transfer scheme as a bubble, and has discussed how such bubbles might get introduced by various generations. In some of these papers, the transfer scheme is stochastic, and may end in any given period with some probability, generating a crash. For example Carvalho et al. (2012), Martin and Ventura (2010), Martin and Ventura (2012), Martin and Ventura (2014), and Martin and Ventura (2010) employ various versions of OLG models, in which, ideally, resources should be funneled from inefficient investors or savers to efficient investors or entrepreneurs. In particular, Martin and Ventura (2010) have used this framework to think about the financial crisis of 2008. There may, for example, be some lending friction, where entrepreneurs cannot promise repayment. They may be limited in how much paper they can issue against future cash flow from the project, or perhaps they need more financing than can be achieved by issuing such paper. They can additionally issue intrinsically worthless "bubble" securities, valued only because the buyer hopes that someone else buys them in the future. The issuance of such bubble paper starts another sequence of the intergenerational transfer scheme described earlier. The existing bubble paper in the hands of old agents as well as those created by newborn entrepreneurs get sold to savers. Savers find investing in these bubbles more attractive than investing in their own, inefficient technologies. This technology needs to be inefficient enough so that its return is on average below the growth rate of the economy, creating the dynamic inefficiency for bubbles to arise.

He et al. (2015) likewise focus on houses to facilitate intertemporal transactions when credit markets are imperfect, and the resulting liquidity premium for house prices. They obtain deterministic cyclic and chaotic dynamics as self-fulfilling prophecies, though their equilibria do not display an extended price run-up followed by collapse. Differences in beliefs are at the heart of trading in Scheinkman and Xiong (2003): the belief differences create a bubbly, but (on average) nongrowing component of asset prices.

Another paper that generate bubbles with fully rational agents and perfect foresight is Wright and Wong (2014). Here, bubbles arise in a model of bilateral exchange that involve chains of intermediaries in markets with search frictions and bargaining problems.

5.2 Sentiments

The other strand of literature we are going to focus in this section, is what we called "sentiment literature." In Section 6, we are going to propose a simple model that captures the "sentiment" idea that we mentioned in the introduction: asset prices may be above fundamental value because agents "irrationally" believe that there is always a "greater fool" who is going to be willing to buy at an even higher price. and discuss the related literature there. Here, we summarize a number of variants of this story formalized in different ways in the literature, where assets are trading above fundamental values due to diverse beliefs between optimists and pessimists, creating an "add-on" above the fundamental value, possibly requiring short-sale constraints on the pessimists. Static versions can be found in Geanakoplos (2002) or as in Simsek (2013). Dynamic versions are in Harrison–Kreps (1978) or in Scheinkman and Xiong (2003): in the latter paper, agents do understand, however, that the bubble will not grow faster than the economy, on average. Glaeser et al. (2014) study bubbles and their role for the housing market. They claim that rational bubbles can obtain, if there is no new construction. They do not provide a full general equilibrium formulation or description of the underlying credit market for this claim: one interpretation may be that agents can buy on credit against the future resale or have unlimited "deep pockets" to buy at any price. They rule out bubbles with elastic housing supply, and then proceed to use a model of irrational, exuberant buyers to study housing bubbles, relating the length and frequency of bubbles and their welfare consequences to the elasticity of housing supply.

Should asset price movements be taken into account in the central-bank interest rate setting? And if so, how? To answer this question, Adam and Woodford (2012) study the optimal monetary policy in a new Keynesian model with a housing sector, using near-rational equilibria, as developed in Woodford (2010) and allowing for a set of possible and internally coherent probability beliefs, that are not too different from the benchmark.

The papers incorporating diverse beliefs probably come closest to our model in Section 6. However, these models typically focus on the case where agents are either pessimistic or optimistic: by construction then, the optimists must be the "greatest fools." We instead wish to incorporate the idea that the more optimistic buyers are typically not yet the greatest fools themselves, but simply betting on even greater fools out there. At the extreme end, the "greatest fool" must be someone willing to pay for something that is intrinsically worthless (to all others), without ever being able to sell to someone at an even higher price, and there may be quite foolish people out there with overly strong optimism of being able to sell to such "greatest fools." So, at that end, the model may require substantial irrationality. The key here is, however, how this suspected strong irrationality at the upper end of the potential price distribution trickles down to the price and sales dynamic among the less foolish or even rational part of the population.

The model shares many elements with Golosov et al. (2014). There, assets are traded in a sequence of bilateral meetings between agents having different information regarding the fundamental value of the asset. By contrast here, everyone understands the asset to be intrinsically valueless: the differences arise in beliefs regarding the optimism of others. As such, our chapter is more closely related to Abreu and Brunnermeier (2003). A benchmark example for a dynamic model exploiting heterogeneous beliefs and changing sentiments, is the "disease" bubble model of Burnside et al. (2013). There is some intrinsically worthless bubble component, which could be part of the price of a house. An initially pessimistic population may gradually become infected to be "optimistic" and believe the bubble component actually has some intrinsic value: once, everyone is optimistic (forever, let's say), there is some constant price that everyone is willing to pay. However, "truth" may be revealed at some probability every period, and clarify that the bubble component is worthless indeed. Then, during the pessimistically dominated population epoch, prices rise during the nonrevelation phase, since the rise in prices there compensates the pessimistic investor for the risk of ending up with a worthless bubble piece, in case the truth gets revealed. The price will rise until the marginal investor is optimistic: at that point, the maximum price may be reached.

Another related recent paper is Bordalo et al. (2016), where credit cycles arise from "diagnostic expectations," that is, from the assumption that when they form expectations agents overweight future outcomes that seems more likely in light of the recent data. This can generate excess volatility, overreaction to news and predictable reversals.

6. A SIMPLE MODEL OF SENTIMENTS

In this section, we are going to propose a simple model to formalize and examine the following and often-told story about buyers and sellers in asset markets. We wish to use it in particular for thinking about the housing market, but it may apply more generally to the stock market or any other market in which assets get retraded.

The story we have in mind is as follows. Prices for assets sometimes bubble above their fundamental value and then come crashing down. They do so due to buyers betting on greater fools. More precisely, when a buyer buys an asset, she may realize that the price is above its fundamental value, but is betting on being able to sell the asset at a future date at an even higher price to a greater fool. What matters to the buyer is not, how foolish it is to keep the asset itself, but how foolish other participants are.

There are variants of this story formalized in various way in the literature, as we discussed in the literature review in Section 5.2. For our showcase model below and in contrast to the models of rational bubbles discussed in the literature review in Section 5.1, we do not assume that the economy is, effectively, dynamically inefficient. That is, we do not wish to assume that bubbles can be traded forever, because the return to be earned on these assets, as perceived by the agents, does not exceed the growth rate of the economy.

It may be important, however, to examine models in which the required rate of return is higher than the growth rate. It is then clear from the start that the price eventually must hit a ceiling: say, when the value of the asset exceeds all resources in the hands of the buyers. Usual backward induction arguments then rule out such bubbles in the first place, see Tirole (1985). The purpose of this section is to tweak the rationality argument per introducing a mythical "greatest fool," thwarting that backward induction. This "greatest fool" can alternatively be interpreted as a rational "collector," who just happens to value an asset at high price, while nobody else does. We will consider environments where this person is a myth indeed. Agents falsely believe, however, that this mythical collector is out there. Some particularly optimistic believers will buy the assets and hold it, in the hope of ultimately selling to the collector, but more importantly, some traders will buy the assets in the hope of selling to an agent who has an even more optimistic beliefs about the existence of a collector. This is what we mean by a sentiment-driven bubble. Note that it does not actually matter whether such collector agents are present: all that matters is the beliefs by the various agents in the presence of such agents. We allow for the belief in such collectors to suddenly disappear: if that happens, the price crashes.

It should be clear that one can construct higher-layer type theories too. For a second-layer theory, all agents may agree that there are no collectors. However, they may all believe that a certain fraction of "first-layer" agents out there does believe such collectors to be there, and the more optimistic agents may believe that fraction to be higher. Agents in such an economy will then not per se wait to sell to a collector (they know they cannot), but wait to sell to an agent who believes such collectors to be present. Furthermore, the agents that are less optimistic regarding the existence of such believers will sell to agents who are more optimistic regarding such first-layer believers. Once again, a bubble can arise, this time even if actually neither the collector nor first-layer believers are present in the economy. A third-layer theory would be about agents differing in their beliefs of meeting agents who believe that they can meet an original believer, etc. We feel that it would be fascinating to explore the ramifications and variations of the simple model below a lot further than we do. It is just meant as an inspiration and starting point.

6.1 The Model

Time is continuous, $t \geq 0$. There is initially a continuum of agents of total mass one. There is distribution of agent types $\theta \in [0, 1]$ in the economy, characterized by the distribution function $H(\theta)$. We assume that H has a density $h(\theta)$. We call agents of type $\theta = 1$ "collectors." We shall assume that $H(\theta^{\max}) = 1$ for some $\theta^{\max} < 1$, and thus, the distribution H assigns no weight to collector types.

Agents differ in their beliefs about the distribution of beliefs in the population, with θ parameterizing that belief. Specifically, we shall assume that, initially, an agent of type θ believs that other agents' type x is drawn from

$$H_\theta(x) = (1-\theta)H(x) + \theta 1_{x=1}. \tag{53}$$

In other words, agent θ uses a weighted average between the true distribution and a point mass at the collector type. Most of the analysis below carries over to a more general formulation: we leave these extensions to future research. Agents are aware of their differing beliefs, but they individually nonetheless insist on the beliefs they hold. We assume that an aggregate revelation event may arrive at the arrival rate α (or instantaneous probability αdt), at which point all agents suddenly understand that there are no collector types and their beliefs switch to the true distribution H. One might wish to assume that agents are unaware that this revelation event could occur (MIT shock), but it turns out that the mathematics is not much different if they do: so we shall assume that. In the latter case, the better interpretation is that agents believe that, with some probability αdt, the distribution of population types changes from H_θ to H, interpreting this as a taste and belief shift for other agents.

There is a single and indivisible asset (coconut), initially in the hand of an agent of type $\theta = 0$. There are random pairwise meetings between agents: due to our assumption of a single asset available for trading, it suffices to describe the meetings between the agent that currently has the asset and some other agent. If the agent currently holding the asset is of type θ and if the revelation event has not yet happened, then she will believe that she meets an agent drawn from the distribution H_θ at rate λ. The asset-holding agent (who we shall call the "seller") posts a take-it-or-leave-it price q_θ (the posted contract can be generalized, and we leave this to future research). The other agent (who we shall call the "buyer") decides to accept or reject the trade. If the trade is rejected, the seller keeps the asset and keeps on waiting for the next pairwise meeting. If the trade takes place, the buyer produces q_θ units of a consumption good or "cash," at instantaneous disutility q_θ, which the seller consumes, experiencing instantaneous utility q_θ. The future is discounted at rate ρ. The buyer receives the asset and then in turn waits for the next pairwise meeting. If the buyer turns out to be a collector, he will be willing to buy the asset at any price at or below some exogenously fixed value $v(1)$. The asset may provide some intrinsic value to the collector or the collector may simply be the "last fool," failing to understand that he can sell the asset at an even higher value in the future. In any case, the asset offers no intrinsic benefit to any agent who is not a collector. In other words, we assume that noncollector agents have preferences given by

$$U = E\left[\int_0^\infty e^{-\rho t} c_t dt\right] \tag{54}$$

where we allow c_t to be negative, and where c_t is the consumption flow resulting from these trades. We assume that the discount rate is strictly positive, $\rho > 0$.

A few brief remarks may be in order. We have not used time subscripts for q_θ, though there may be equilibria, in which these prices do depend on time. Here, we shall concentrate on time-invariant solutions, for simplicity. More importantly, it may seem odd to consider only a single asset, given that we have a whole continuum of agents at our disposal. This assumption considerably simplifies the analysis, though, as it allows us not to distinguish between meetings, where the potential buyer already owns an asset or not. Furthermore, over time, agents would need to keep track of the distribution of asset-owning types. It is plausible that these distributions shift to the right over time, ie, that it is the higher types holding assets, as time progresses. In the decision problem to be analyzed, selling agents would then need to forecast these evolutions, creating potentially intricate interactions and complications that go beyond the scope of this chapter. These would be good topics to pursue in future research.

Note that, in essence, the bubbly economies described in Section 5.1 can be understood as featuring $\rho \leq 0$ with $\alpha = 0$ (and finite lives), so that agents are willing to agree to a trade, in which they give up more today than they receive later, or at least do not insist on getting more later on. Here, we rule out this channel. Note also that the search theory models of money like Kiyotaki and Wright (1993) and their successors assume that the total sum of consumption is larger than zero, ie, that the seller benefits more from the sale than the buyer is hurt. If trades can only take place, using the intrinsically worthless asset, the asset helps in achieving a better outcome than autarky. Related modeling devices are used in Harrison–Kreps (1978) or Scheinkman and Xiong (2003). Here, by contrast, we shut down any benefits from the trade per se.

6.2 Analysis

We formulate the strategies of buyers as threshold strategies. A buyer of type θ picks some value v_θ, and purchases the asset, if the take-it-or-leave-it price is at or below that value, provided the revelation event has not yet taken place. For the collector type, $v_1 > 0$ is a parameter. A seller of type θ picks a take-it-or-leave-it price q_θ before the revelation event. After the revelation event has taken place, the asset is valued at zero by all and traded at zero price. A Nash equilibrium is then given by two functions $(v_\theta, q_\theta)_{\theta \in [0,1]}$, so that the strategies of agent θ maximize the utility function (54), given the strategies of all other agents. We shall additionally impose that v_θ is measurable. A seller can only hope to sell the asset in the future before the revelation event takes place. Put differently, we can assume that the seller discounts the future at rate $\alpha + \rho$, and that any before-revelation value of the asset to the seller in the future is discounted at that rate too. We could introduce a new symbol for $\alpha + \rho$. In slight abuse of notation (or appealing to the “MIT shock logic”), we shall continue to use ρ for that discount rate.

Consider now the before-revelation phase. We seek to characterize the Nash equilibrium or Nash equilibria. It is straightforward to see that a buyer of type θ will choose to buy at any price not bigger than v_θ, where v_θ is his continuation value of holding the asset. Consider then a seller of type θ, contemplating a sale price $0 \leq q \leq v(1)$

(obviously, it does not make sense to post a price above $v(1)$ or below zero). He assumes that his buyer's type x is drawn from the distribution H_θ, and that buyers follow their equilibrium strategy v_x and buy only if $q \leq v_x$. Hence, conditional on meeting a buyer, a seller of type θ who posts price q expects to sell with probability

$$\phi_\theta(q) = (1-\theta)\int 1_{v_x \geq q} h(x)dx + \theta \tag{55}$$

Proposition 6 *The probability of a sale $\phi_\theta(q)$ is decreasing in q and increasing in θ.*
Proof The proof is immediate, once one rewrite Eq. (55) as

$$\phi_\theta(q) = (1-\theta)\phi_0(q) + \theta. \qquad \square$$

If the trade takes place, the seller receives q. Trading possibilities arrive at rate λ, so in a time interval dt, the sale takes place with probability $\lambda\phi_\theta(q)$. Otherwise, the seller will remain owner of the asset at time $t + dt$, still valuing the asset at $V_\theta(q)$ then (provided the aggregate revelation event has not taken place: remember, that we implicitly took care of that via our discount factor ρ). Therefore, the continuation value of a seller of type θ who chooses a sale strategy q, $V_\theta(q)$, is equal to

$$V_\theta(q) = \lambda\phi_\theta(q)q\,dt + (1-\lambda\phi_\theta(q)\,dt)(1-\rho\,dt)V_\theta(q), \tag{56}$$

or, canceling higher order terms,

$$V_\theta(q) = \frac{q}{\dfrac{\rho}{\lambda\phi_\theta(q)}+1}. \tag{57}$$

The optimal selling strategy $q = q_\theta$ is the one maximizing $V_\theta(q)$, that is,

$$q_\theta \in \operatorname{argmax} V_\theta(q) \tag{58}$$

delivering $v_\theta = V_\theta(q_\theta)$.

It is easy to construct two bounds for the optimal continuation value. On the one hand, consider the suboptimal strategy that agents will only attempt to sell to the collector, per posting the price $q = 1$. This strategy would give

$$\underline{v}_\theta = \frac{v_1}{\dfrac{\rho}{\lambda\theta}+1}. \tag{59}$$

Clearly the optimal value function cannot be lower than $\underline{v}$, as in equilibrium there would be more trade for speculative reasons. On the other hand, consider the widely optimistic assumption, that any potential buyer is willing to purchase the asset at $q = v_1$. The value function would then be given by

$$\bar{v}_\theta = \frac{v_1}{\dfrac{\rho}{\lambda}+1} \tag{60}$$

where the omission of θ is the difference to (60). It is straightforward to show that the equilibrium value function in between these two bounds.

Proposition 7 *Suppose that the function $v : x \mapsto v_x$ used for calculating $\phi_\theta(q)$ in Eq. (55) is measurable and satisfies $\underline{v} \leq v_x \leq \bar{v}$. Then V_θ has a maximum.*

Proof Note that $V_\theta(q)$ is bounded by $\bar{v}_\theta$. Let $q^{(j)}$, $j = 1, 2, \cdot$ be a sequence, so that $V_\theta(q^{(j)})$ is increasing, converging against $\sup V_\theta(q)$. Since $q^{(j)} \in [0, v(1)]$, we can find a convergent subsequence, which we can furthermore assume to be monotone. Wlog, assume that $q^{(j)} \rightarrow q^*$ for some q^* and is monotonically increasing or decreasing. If the sequence $q^{(j)}$ is monotonically increasing,

$$\bigcap_j \{x \mid v_x \geq q^{(j)}\} = \{x \mid v_x \geq q^*\}$$

Therefore $\phi_\theta(q^*) = \lim_{j\rightarrow\infty} \phi_\theta(q^{(j)})$ and hence

$$\frac{q^*}{\dfrac{\rho}{\lambda\phi_\theta(q^*)} + 1} = \lim_{j\rightarrow\infty} \frac{q^{(j)}}{\dfrac{\rho}{\lambda\phi_\theta(q^{(j)})} + 1}$$

If the sequence $q^{(j)}$ are monotonously decreasing, then

$$\bigcup_j \{x \mid v_x \geq q^{(j)}\} \subseteq \{x \mid v_x \geq q^*\}$$

and therefore $\phi_\theta(q^*) \geq \lim_{j\rightarrow\infty} \phi_\theta(q^{(j)})$. Hence

$$\frac{q^*}{\dfrac{\rho}{\lambda\phi_\theta(q^*)} + 1} \geq \lim_{j\rightarrow\infty} \frac{q^{(j)}}{\dfrac{\rho}{\lambda\phi_\theta(q^{(j)})} + 1}$$

Here, though, ">" is ruled out, since the right-hand side is the supremum of $V_\theta(q)$. We can conclude that q^* maximizes $V_\theta(q)$. □

The axiom of choice now implies that q_θ is well defined.

Proposition 8 *The value v_θ of any Nash equilibrium is increasing in θ.*

Proof Let $\tilde{\theta} > \theta$. Note that $V_{\tilde{\theta}}(q) \geq V_\theta(q)$ for all q, since $\phi_{\tilde{\theta}}(q) \geq \phi_\theta(q)$. Since this is true in particular at $q = q_{\tilde{\theta}}$, the claim now follows. □

Now we can define the set of potential value functions

$$\mathcal{V} = \{v : [0,1] \rightarrow \mathbb{R} \mid v \text{ is increasing and } \underline{v} \leq v \leq \bar{v}\}.$$

Given that increasing functions are measurable, we can consider the mapping $T : \mathcal{V} \rightarrow \mathcal{V}$, defined by the following steps:

1. map $v \in \mathcal{V}$, into a function $\phi_\theta(q)$, using Eq. (55);
2. map ϕ into a function $V_\theta(q)$ using Eq. (56);
3. map $V_\theta(q)$ into the function v_θ that maximizes $V_\theta(q)$ (this maximum exists thanks to Proposition 7).

Proposition 9 *The mapping $T:\mathcal{V}\rightarrow\mathcal{V}$ is monotone and has a fixed point in $\mathcal{V}$. Therefore, a Nash equilibrium with $v\in\mathcal{V}$ exists.*

Proof For monotonicity, check that each step of the mapping is monotone. That is, if $\widetilde{v}\geq v$, then $\widetilde{\phi}\geq\phi$ for the first step, and so forth, where the inequalities are understood to hold pointwise for all arguments. Note that $\mathcal{V}$ is a complete lattice, with the usual order structure. Tarski's fixed point theorem now delivers the result that the set of fixed points of T forms a nonempty complete sublattice of $\mathcal{V}$. □

Next proposition shows that the equilibrium exhibits a threshold property.

Proposition 10 *For each sale price q, there is a threshold buyer type $\underline{x}(q)$ such that all buyers of type $x\geq\underline{x}(q)$ will buy the asset and all buyers of type $x<\underline{x}(q)$ will not, ie,*

$$x\geq\underline{x}(q)\quad\Leftrightarrow v_x\geq q. \tag{61}$$

The function $\underline{x}(q)$ is increasing in q. Furthermore, for $q\leq v_1$,

$$\phi_\theta(q)=(1-\theta)(1-H(\underline{x}(q)))+\theta. \tag{62}$$

Proof The proof follows immediately from Proposition 8. □

To obtain a bit more analytic insight, consider a price q, where $\underline{x}(q)$ is differentiable.

Proposition 11 *Suppose $\underline{x}(q)$ is differentiable at $q=q_\theta$. Then, the optimal q_θ satisfies the first-order condition*

$$0=1+\frac{\lambda}{\rho}\phi_\theta(q)-\eta_\theta(q) \tag{63}$$

where $\eta_\theta(q)$ is the elasticity of the sale probability,

$$\eta_\theta(q)=-\frac{\phi_\theta'(q)q}{\phi_\theta(q)}=\frac{h(\underline{x}(q))\underline{x}(q)'q}{\frac{1}{1-\theta}-H(\underline{x}(q))} \tag{64}$$

Proof Differentiate $V_\theta(q)$ with respect to q, and note that $V_\theta'(q)=0$ at $q=q_\theta$. □

One can rewrite the sales probability elasticity a bit further. Let

$$\psi_\theta(x)=(1-\theta)(1-H(x))+\theta$$

be the probability of meeting a buyer of type x or better (including the collector), from the perspective of a type-θ seller. Define its elasticity

$$\eta_{\theta,\psi}(x)=\frac{\psi_\theta'(x)x}{\psi_\theta(x)}=-\frac{h(x)x}{\frac{1}{1-\theta}-H(x)}$$

Define the elasticity of the threshold buyer type,

$$\eta_{\underline{x}}(q)=\frac{\underline{x}(q)'q}{\underline{x}(q)}$$

Then

$$\eta_\theta(q) = \eta_{\theta,\psi}(\underline{x}(q))\eta_{\bar{x}}(q).$$

This is the usual chain rule for elasticities, of course, applied to $\phi_\theta(q) = \psi_\theta(\underline{x}(q))$.

The results earlier suggest a strategy for characterizing an equilibrium. Suppose, one has some conjectured threshold buyer type function $\underline{x}(q)$, which is increasing and differentiable in q. With that, solve (63) for the optimal strategy q_θ and thereby for the value $v_\theta = V_\theta(q_\theta)$. With the value, calculate the resulting buyer threshold type function

$$\underline{x}^*(x) = \text{argmin}_x v_x \geq q$$

If $\underline{x}^*(q) = \underline{x}(q)$, one has obtained an equilibrium.

It may be possible to obtain analytical examples, for smart choices for H, exploiting this strategy. We leave this to future research to pursue. Here instead, we shall provide a numerical example.

6.3 Numerical Example

Rather than employing the first-order conditions above, we compute equilibria, using a rather brute-force grid-maximization algorithm. We create a suitable grid in q and θ. We start the iteration at the lower bound $v^{(0)} = \underline{v}$, defined over a grid in θ. We iterate on the mapping $T : \mathcal{V} \to \mathcal{V}$ described earlier. Specifically for step j, calculate $\phi_\theta^{(j)}(q)$ on the q-grid, using $\underline{x}^{(j-1)}$ on the right-hand side of Eq. (62). Now, calculate $V_\theta^{(j)}(q)$ per (57) for all grid values θ and q. For each grid value θ, find $v_\theta^{(j)}$ as the maximum of $V_\theta^{(j)}(q)$ over the grid values q. For each grid value q, find the smallest x, so that $v_x^{(j)} \geq q$, exploiting (61). This is the new $\underline{x}^{(j)}(q)$ and the next iteration step can commence. Iterate sufficiently often to obtain a reasonable degree of accuracy with the last solution.

As parameters, we chose $\lambda = 1$, $\rho = 0.1$ and let H be a uniform distribution on [0, 0.25]. The "collector price" was normalized at $v_1 = 1$. We used an evenly spaced grid of 500,001 points for q and 1001 points for $\theta \in [0, 1]$ or 251 points in the relevant range [0, 0.25]. As a starting point, we set $v^{(0)} = \underline{v}$, as defined in (60). For each grid value q, we then find the smallest $x = \underline{x}^{(0)}(q)$, so that $v_x^{(0)} \geq q$, exploiting (61).

The results are in Figs. 12 and 13. As one can see, agents with low θ pursue a strategy of seeking to sell to higher-θ agents, but beyond (approximately) $\theta = 0.1$, agents now only wait for the collector to make the sale. This can also be seen from the probability of sales. The black-dashed horizontal line shows the price chosen by the $\theta = 0$ types. This indicates that this market proceeds in two stages only, starting from the asset initially in the hands of a $\theta = 0$ agent (or an agent with a low θ). That agent will charge a price q_θ such that a sale only takes place, when meeting an agent with a fairly high $\tilde{\theta}$, who in turn hopes to sell to the collector, at $q_{\tilde{\theta}} = v_1 = 1$. It would be interesting to find examples, in

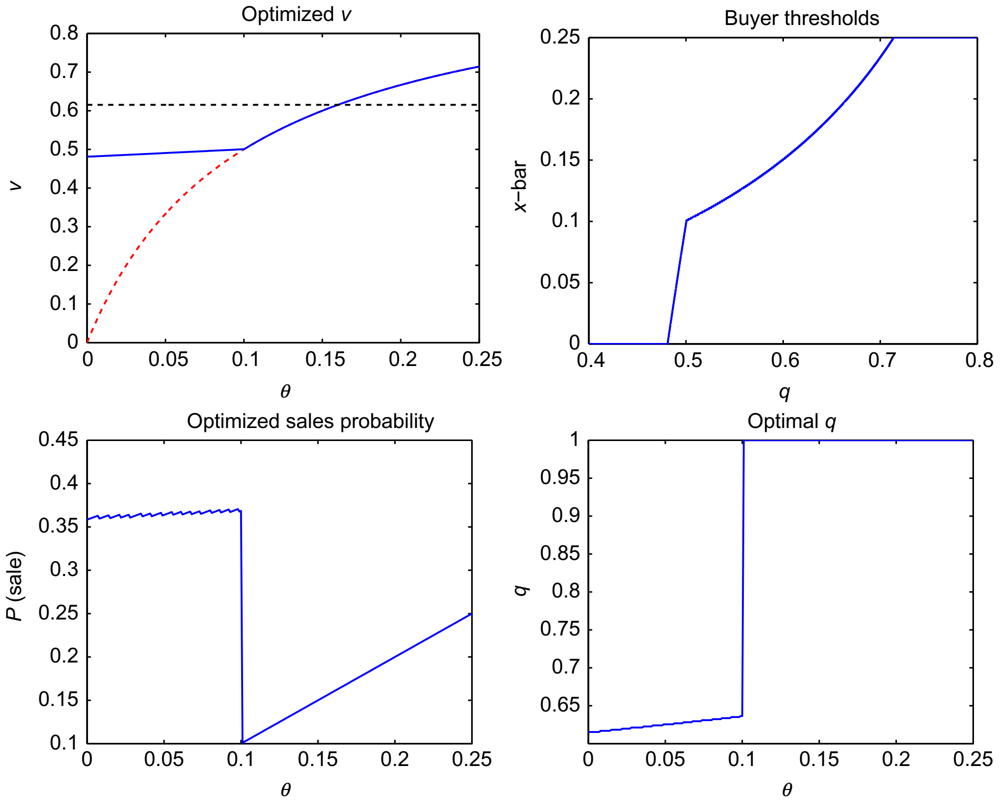

Fig. 12 Results from a numerical example. As parameters, we chose $\lambda = 1$, $\rho = 0.1$, and H to be a uniform distribution on $[0, 0.25]$. The "collector price" was normalized at $v_1 = 1$. In the top left panel, we compare the optimal value function to the value function $\underline{v}$ obtained per only selling to the collector. As one can see, agents with low θ pursue a strategy of seeking to sell to higher-θ agents, but beyond $\theta = 0.1$, agents now only wait for the collector to make the sale. This can also be seen from the probability of sales. The black-dashed horizontal line shows the price chosen by the $\theta = 0$ types. The top-right panel is essentially the top-left panel, flipped at the 45 degree line.

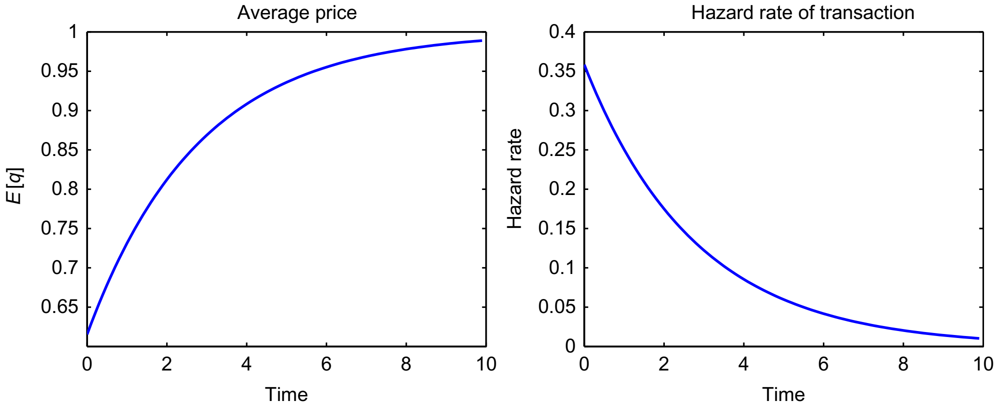

Fig. 13 Averaging over many posted price paths. The left panel shows the average price and how it is increasing over time. The right panel shows the hazard rate of a transaction and how it is decreasing over time.

which there are several stages of sale and resale to ever-more optimistic agents: we leave this to future research on this topic.

Consider now averaging across many simulations or individual markets, where the asset is initially held by the least optimistic agent $\theta = 0$. In principle, one can obtain the average price as well as the average hazard rate of a sale by simulation, using the results calculated thus far. Due to the two-stage structure of the sales process, it is easier to proceed analytically instead (and these arguments can be generalized to a multistage structure as well). If the asset is still in the hands of the initial $\theta = 0$ agent, it will be sold at the hazard rate $\xi = \phi_0(q_0)$, where we introduced the new symbol ξ for this hazard rate, to save on subsequent notation. Once the asset is sold, it will be posted at price $q_{\tilde{\theta}} = 1$ and not trade again, since there is no collector in the market. The unconditional date-t probability π_t, that the asset remains in the hands of initial $\theta = 0$ agent, solves the linear differential equation $\dot{\pi}_t = -\xi\pi_t$, with the solution given by $\pi_t = \exp(-t\xi)$. The average price is given by

$$E[q_t] = v_1 - (v_1 - q_0(q_0))\exp(-t\xi)$$

The unconditional or average hazard rate of a sale occurring is $\xi\pi_t$. Fig. 13 shows the resulting average price path and average sales hazard rate $E[\phi_\theta(q_\theta)]$. As one can see, the average posted price rises, while the average sales probability falls over time. The price path is conditional on the revelation event not occurring. Once the revelation event happens, the price crashes to zero. This captures the original story, with which this section got started.

The logic of the calculation just presented can also be used to calculate the results in Fig. 12 directly. Calculate first $v_\theta^{(0)} = \underline{v}_\theta$ for all θ per Eq. (60). Invert that function and use the distribution function H to calculate $\phi_\theta(q)$. With that, calculate $V_\theta(q)$ and find its maximum, for each q and the resulting $v_\theta^{(1)}$. The last step appears tedious, but may be solvable in closed form. This is the final result, in the situation that there are at most two stages of selling (first, sell to a more optimistic agent, second, attempt to sell to the collector), as here. One has to verify that indeed there are no further stages. Put differently, one now has to check that less optimistic agents would not now want to "change their mind" and sell to even more optimistic agents, who now value the assets higher, due to their reselling to optimistic agents. We leave the details of the calculations and the verification condition to the interested reader.

7. EVIDENCE

What caused the subprime crisis and, by extension, the financial crisis of 2008? What moved first, what moved later? What was cause and what was effect? The chapter has focused on two possible stories. One possibility is that house prices fell first for exogenous reasons, impairing bank balance sheets and leading to a financial collapse. Another possibility is that the banking system collapsed, leading to a reduction in mortgage lending and a fall in house prices. Perhaps, the fall in house prices triggered greater reluctance by banks to issue subprime loans, or perhaps and conversely, mortgage lending and, in particular, subprime borrowing, was reduced first, triggering a fall in house prices. Perhaps, subprime lending was reduced in the wake of higher delinquency rates on subprime mortgages or perhaps subprime lending was reduced, and the subsequent fall in house prices triggered delinquencies. Perhaps delinquencies rose because the pool of borrowers worsened or perhaps short-term interest rates rose, leading to higher rates for ARM mortgages and thereby higher delinquency rates. There are various ways of thinking through the interactions and tell the story. And how much did the interplay and feedback loop enhance the original shock?

Considerable research has been undertaken to seek to sort out these channels empirically: much more work still awaits to be done. We shall not attempt to give a full-fledged overview of the existing and large literature. We instead select some figures and facts from parts of the literature, and give them a somewhat impressionistic interpretation. Clearly, this is no substitute for careful empirical research on these data, but it may provide a good guide to questions and to developments to look at in the raw data. Most of the facts concern the United States. This generates a frontier of research interest and common ground for researchers to discuss, but it may miss important relationships and facts, compared to employing a world-wide perspective. We return to the latter towards the very end.

Figs. 1 and 14 show the S&P/Case-Shiller Home Price Indices. There is a run-up in house prices up to somewhere in the middle of 2006. According to the 20-city index

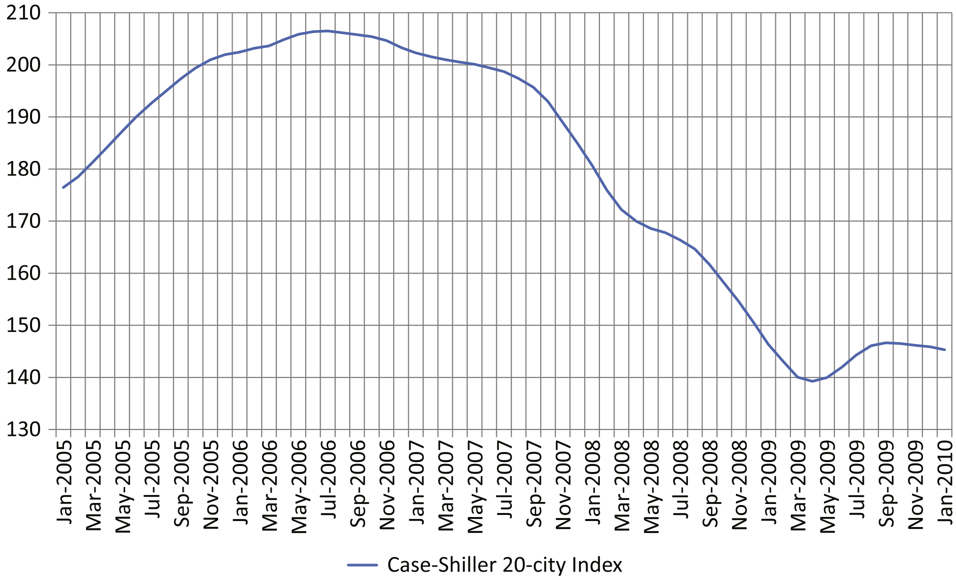

Fig. 14 The S&P/Case-Shiller home price 20 city index. *http://us.spindices.com/indices/real-estate/sp-case-shiller-20-city-composite-home-price-index*.

in Fig. 14, the peak is in July 2006. From there, prices started to drop, falling by 6.5% in October 2007, a relatively small drop. However, by October 2008, the date of the Lehman Brothers crisis and, in essence, the date of the financial collapse, house prices were at 25% below their July-2006 peak level, having fallen rather quickly and continuously from October 2007. House prices fell a bit more subsequently, reaching their bottom in April 2009, having fallen 32.6% from the original peak. From the sequence of these events, it appears plausible that house prices fell first, and the financial system collapsed subsequently.

However, the share of mortgages in the form of subprime fell quite substantially much earlier, as Fig. 2 reveals. Again, the peak subprime lending share of all mortgage originations occurred in 2006, at 23.5%, with a dramatic fall to 9.2% in 2007 and a near-zero in 2008. The peak occurred roughly at the same time as the peak of the S&P/Case-Shiller index in Figs. 1 and 14 and one might even wish to argue that the hump near the peak looks rather similar here. The decline in the peak subprime lending share from 2006 to 2007 was very sharp.

From this comparison, it appears plausible that subprime lending rose and fell together with house prices. If anything, subprime lending collapsed and decreased sharply, before house prices did. Thus, it may have been the reduction in subprime lending, causing the fall in house prices rather than vice versa.

One might wish to blame the decline in subprime lending on delinquency rates. Here, Fig. 15 is revealing. First, it shows that delinquency rates on fixed rate mortgages, be they prime or subprime, did not noticeably increase in 2006 and 2007: if anything, subprime fixed rate delinquency rates were near their all-time low of 2005.

The story is different for adjustable rate mortgages or ARMs. Here, rates did go up somewhat in 2006 and then somewhat more from their all-time low in 2004, but even there, the level in 2007 is rather comparable to the levels before 2002, both for prime adjustable rates as well as subprime adjustable rates, as Fig. 15 shows.

These movements are important for interpreting the course of events leading up to the crisis, but they are fairly small, compared to the subsequent development of delinquency rates shown in Fig. 16. Delinquencies later rose to unprecedented levels (at least for this time interval), peaking at rates somewhat above 40% for subprime adjustable rate mortgages around the end of 2009. In particular, delinquencies on subprime mortgages and prime adjustable rate mortgages had risen already considerably until October 2008, the date of the financial collapse. Overall, though, it does not seem plausible to argue that subprime lending was reduced in 2007, because delinquency rates had increased already at that point.

If anything, perhaps the delinquency rates in 2007 and the overall movement of delinquency rates on adjustable rate mortgages up to 2007 are linked to short-term interest rates. These rates are shown in Fig. 17. The Federal Reserve Bank increased the Federal Funds Rate in a sequence of small steps, starting at 1% in June 2004 to 5.25% in July 2006,

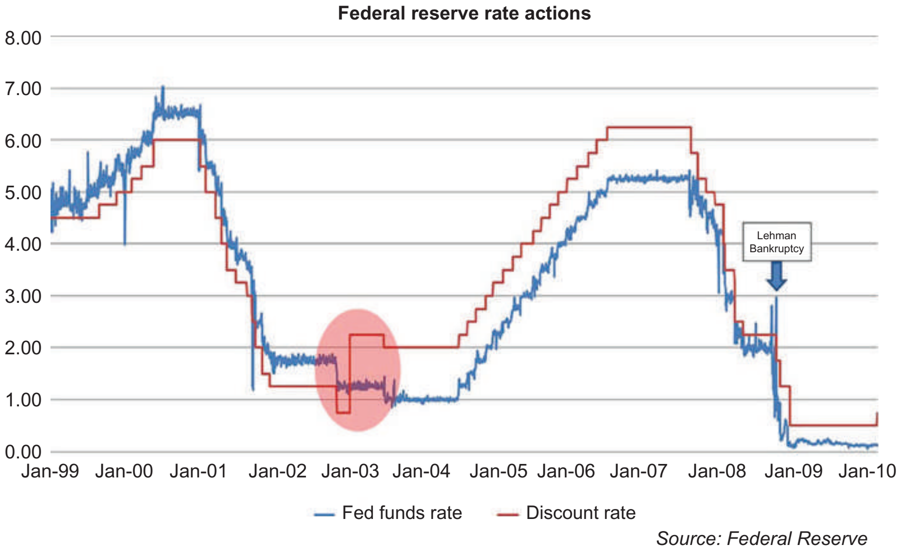

Fig. 17 Federal funds rate. *http://www.zerohedge.com/article/comparing-fed-funds-rateprimary-credit-discount-rate-over-past-decade*.

and then leveling off, before dramatically reversing course at the end of 2007. It is fairly plausible that the rise in short-term market interest rates from mid-2004 to mid-2006 resulted in the rise of delinquencies on adjustable rate mortgages from mid-2004 to mid-2006, seen in the previous figures.

Justiniano et al. (2015) have argued that house prices rose from 2000 to 2007 without an expansion of leverage, ie, at rather constant rates of mortgages to real estate, see the bottom-right panel of Fig. 18. The subsequent fall in house prices then went along with an increase in leverage and not necessarily a reduction in the volume of outstanding mortgages, see the top left panel.

These authors point to the fact that, first, there was an increase in available funds without an increase in leverage, leading to more mortgages at stable interest rates and stable leverage ratios, leading to a run-up in house prices.

For 2007 and beyond, they argue that the collateralizability of houses relative to available funds increased (or that available funds for lending decreased), leading to a rise in mortgage rates and a collapse in house prices. There certainly are some interesting comovements in Fig. 18 that deserve explanation, though not all readers may buy into the hypothesis that the collapse in house prices was caused by their relatively better collateralizability.

Most notably, Jorda, Schularick, Taylor and their coauthors have investigated the interplay between credit booms, house price booms and economic performance in a series of papers, constructing and providing new data sets along the way. Schularick

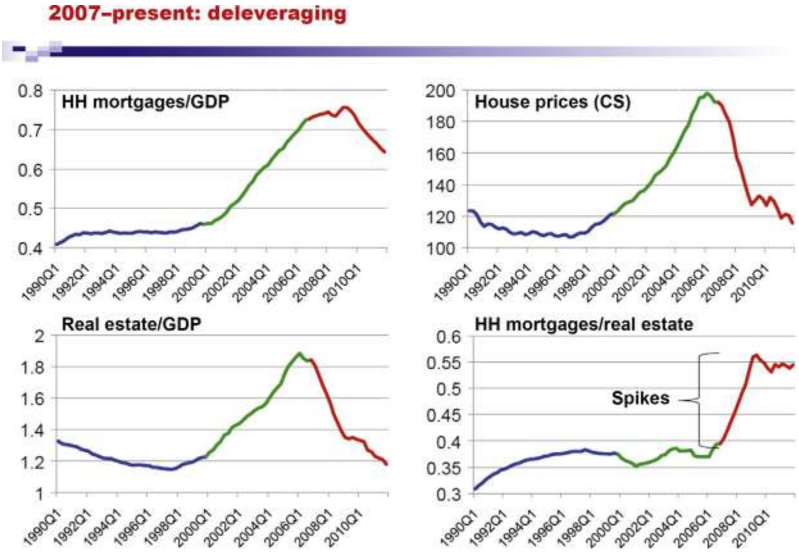

Fig. 18 The Justiniano–Primiceri–Tambalotti facts. *Justiniano, A., Primiceri, G.E., Tambalotti, A., 2015. Household leveraging and deleveraging. Rev. Econ. Dyn. 18, 3–20.*

and Taylor (2012) provide "a new long-run historical dataset for 14 developed countries over almost 140 years" and show how credit growth is a powerful predictor of financial crises. Jorda et al. (2013) subsequently argue that financial crisis recessions are costlier than typical recession. These data sets are updated and extended in Jorda et al. (2016a) for 17 advanced economies from 1870, covering disaggregated bank credit to the domestic nonfinancial private sector, with special attention to mortgage lending. They claim that "mortgage lending booms were only loosely associated with financial crisis before WWII, but …[have] become a more important predictor of impeding financial fragility" subsequently. Knoll et al. (2014) construct a house price index for 14 advanced economies from 1870 to 2012, assembling a variety of data sources. They argue that real house prices have largely followed a "hockey stick" pattern: fairly constant for a long time initially, followed a pronounced appreciation towards the end of the sample. They furthermore say that most of the price increase can be attributed to the increase in the price of land. Knoll (2016) subsequently argues that the rise in house prices coincides with a rise in the price–rent ratio. Combining data from these papers for 14 advanced economies, Jorda et al. (2015) claim that the 20th century has been an era of increasing "bets on the house." They write that "mortgage credit has risen dramatically as a share of banks' balance sheets from about one third at the beginning of the 20th century to about two thirds today." Using IV regressions, they show that "mortgage booms and house price bubbles have been closely associated with a higher likelihood of a financial crisis." Jorda et al. (2016b) provide further insights into the nature of these interactions, extending their data sets once more. They point to the fact that the build-up of leverage leads to higher tail risk. In a related paper, Mondragon et al. (2016), using a spatial IV-strategy, document empirical evidence that local credit supply shocks generate quantitatively significant boom–bust cycles in local house prices. In a similar spirit, Favara and Imbs (2015) show that an expansion in mortgage credit has significant effects on house prices, using the US branching deregulation between 1994 and 2005 as an instrument for credit. More recently, Di Maggio and Kermani (2016) show that a credit expansion can generate a boom and bust in house prices and real activity, using the change in national banks' regulation in 2004 by banning the antipredatory lending laws that a number of states adopted in 1999.

These series of papers and insights are completely in line with the fact that "a rise in household debt to GDP ratio predicts lower output growth," as shown by Mian et al. (2015).

We now show some figures taken from these papers to highlight some of these insights. Fig. 19, from Jorda et al. (2016b), show the "hockey stick" both for real house prices and mortgages.

The data can be sliced in other ways too, as Fig. 20 shows. That figure plots results both for the United States alone, their "benchmark economy," and for the sample of 17 countries investigated in Jorda et al. (2016b). House price growth and mortgage growth generally comove. In relation to real GDP, the real house price hockey stick, visible in Fig. 19, now becomes a downward trend, while the mortgage hockey stick becomes an upward trend. These figures raise intriguing, additional issues, concerning the attribution of changes in these series to their underlying causes.

Knoll et al. (2014) use Fig. 21 and additional analysis to show that house prices have risen faster than income in recent decades, while they have fallen relative to income in the first half of the 20th century and especially in the interwar period. Knoll (2016) argues that the rise in house prices coincided with a rise in the house price to rent ratio, as shown in Fig. 22. The price-to-rent ratio is similar to the often used price–dividend ratio for stocks, which has been shown to be useful for predicting stock returns. It is plausible that a similar phenomenon is at work for the housing market, as Knoll (2016) investigates.

The data sets created by these authors will be useful for further empirical investigations of the issues at hand. Luigi Bocola, in his discussion of a first draft of this chapter, combined the quarterly house price dataset from 1975 for a number of advanced countries, described by Mack and Martínez-García (2011), with the data for the 19 crisis events for advanced economies after 1975, described in Schularick and Taylor (2012). He constructed Fig. 23 to shed light on the relationship between house price growth, credit growth and GDP performance. The figure compares all crisis events (blue line) to the five events with the highest house price drop (red line) in the group: Denmark-87, Spain-08, Uk-91, Norway-88, Swe-91. This figure indicates once more the comovement of house prices and credit growth, but may suggest that the size of house price boom does not matter much for the average size of the subsequent recession.

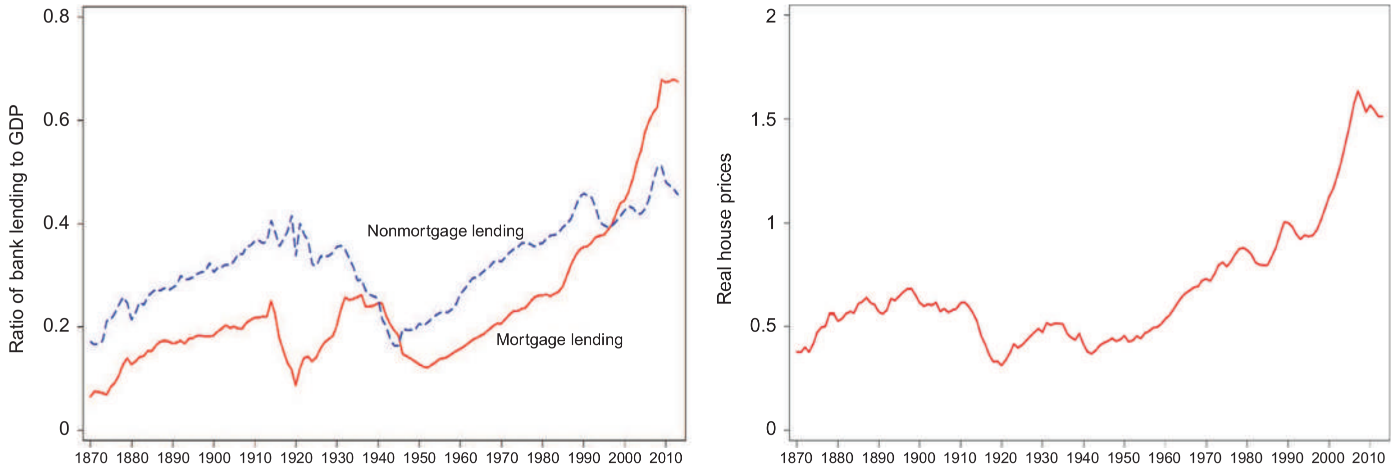

Fig. 19 Hockey sticks for real house prices and mortgages.

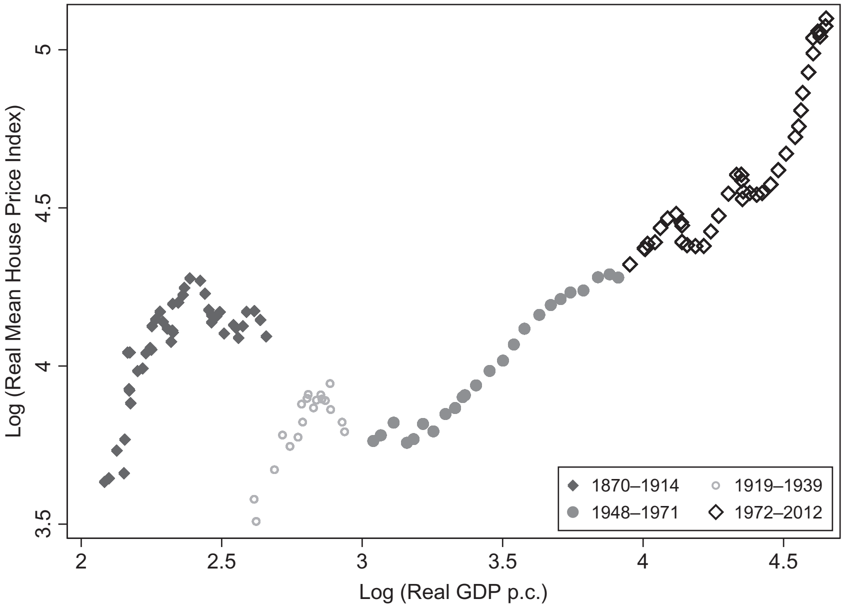

Fig. 21 House prices have risen faster than incomes in recent decades, while they have fallen relative to incomes in the first half of the 20th century and especially in the interwar period.

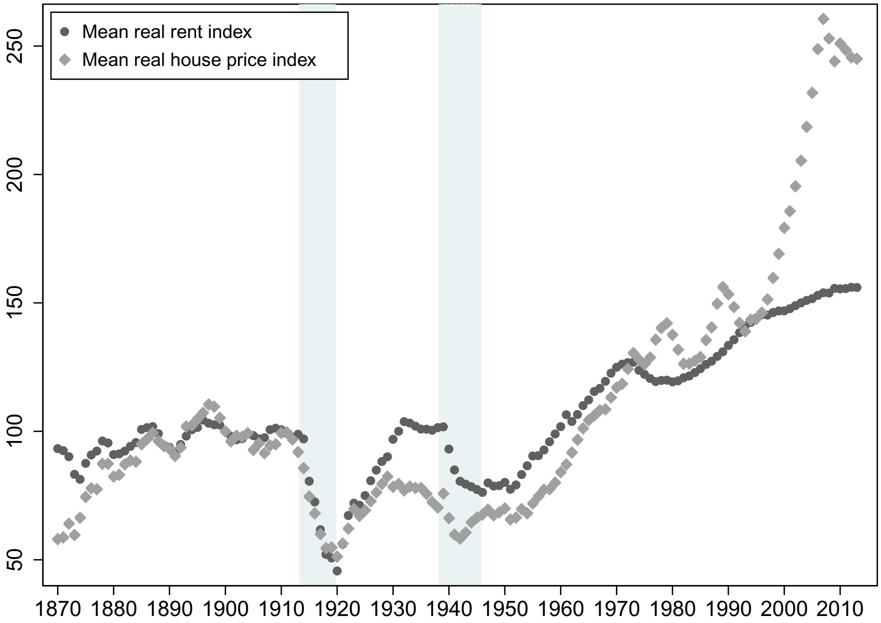

Fig. 22 The rise in house prices coincided with a rise in the house price to rent ratio.

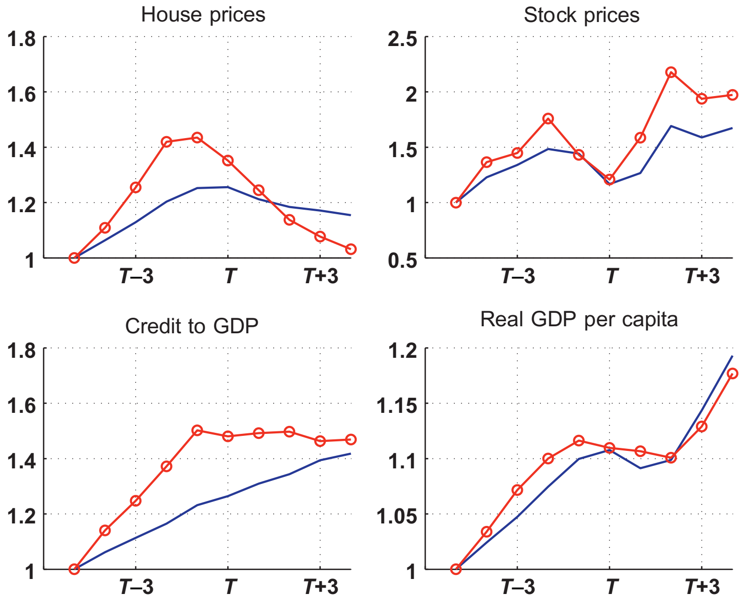

Fig. 23 Date "*T*" denotes the Schularick–Taylor crisis dates. The panels compare all crisis events (blue (dark gray in the print version) line) to the five events with the highest house price drop (red (black in the print version) line with circles) in the group: Denmark-87, Spain-08, Uk-91, Norway-88, Swe-91. The lines are cross-country averages for the four variables and normalized to equal unity at $T - 5$.

Once more, we want to stress that this section is not meant to be a comprehensive review of the empirical literature on this topic. Our objective was just to report a subsample of facts and empirical papers that relate to the theoretical literature we have focused on in this chapter. These are all suggestive figures. However, the debate on whether house prices have been the main driving source of the credit cycle or financial conditions the main driving force of house price cycle is still open and hopefully future research will sheds more light on this topic.

8. CONCLUSIONS

The purpose of this chapter was to explore a key connection between boom–bust episodes in housing markets and boom–bust episodes in credit markets and to point to their effects on macroeconomic activity. To do so, we investigated several benchmark approaches and channels, and related them to the existing literature. It is already a challenge to understand the house price boom–bust together with the credit boom–bust, without analyzing the aggregate activity repercussions. We therefore mostly focused on the interaction of the first two. In particular, there are two broad possible approaches to think about this interaction:

1. The house price boom–bust generates the credit boom–bust.
2. The credit boom–bust generates the house price boom–bust.

We started the chapter by proposing a stark mechanical model to think about this interaction. On purpose, it is designed to avoid several thorny issues that arise in a fully specified equilibrium model. Next, we explored these two main approaches in more detail.

First, we proposed a simple model of catastrophes, where we focused on the credit cycle. The idea is that an increase in credit availability can generate first a boom and then a bust in mortgage markets because of adverse selection issues. In particular, in a world where banks do not know the quality of their borrowers, that is, their expected default rate, and borrowers can either pool or pay a cost to verify their type, multiple equilibria can arise. If we start from an equilibrium with pooling, an increase in credit supply translates into a decrease in the quality of the pool of active borrowers (like "subprime borrowers"). This, in turns, can generate a switch to an equilibrium where good borrowers separate themselves and the pooling market crashes.

Second, we proposed a simple model of sentiments, where we focus on the housing price cycle. The main idea is that a house price bubble can arise when speculating households believe that there is always a "bigger fool" out there that is going to be willing to buy housing at a higher price. While appealing, formalizing this intuition tends to run into the "conundrum of the single equilibrium": if prices are expected to be high tomorrow, then demand for credit and thus houses should be high today (see above), and that should drive up prices today, making it less likely that prices will increase. Or, put differently, as prices rise, they eventually must get to a near maximum at some date: call it "today." At that price, prices are expected to decline in the future. But if so, banks and speculating households are less likely to buy today: but then, the price should not be high today. That is, in rational expectations models, there should not be anybody willing to buy at the highest price when prices can only go down from there. We break the curse of the conundrum by departing from the rational expectations framework and assuming that households always believe that with some positive probability there is a bigger fool, although he does not really exists.

In the course of the chapter, we related our simple models to the large literature on these topics. At the end, we also point to some empirical papers that propose facts related to these two theoretical approaches.

We wish this chapter is going to trigger further research and thinking on this important connection. As has become clear, the issues are far from resolved.

ACKNOWLEDGMENTS

We are grateful to Chiara Fratto, Ken Kikkawa, and Chao Ying for their excellent research assistance. For helpful comments, we are grateful to Fabrice Collard, Matteo Iacoviello, Oscar Jorda, Guido Lorenzoni, Moritz Schularick, Alan M. Taylor, and, in particular, to Luigi Bocola, Zhen Huo, and Nicolas Trachter for their thoughtful discussions as well as John Taylor for his detailed and useful comments. We are also grateful to audiences at the handbook conference at the University of Chicago, the "Multiple Equilibria and Financial Crises" conference at NYU, the "Mad Money" conference at the University of Wisconsin, and the seminar audience at the University of Toronto. This research has been supported by the NSF grant SES-1227280 and by the INET grant #INO1100049, "Understanding Macroeconomic Fragility." H.U. has an ongoing consulting relationship with a Federal Reserve Bank, the Bundesbank, and the ECB. V.G. has an ongoing consulting relationship with the Chicago Federal Reserve Bank.

Abstract

This chapter puts forward a manual for how to setup and solve a continuous time model that allows to analyze endogenous (1) level and risk dynamics. The latter includes (2) tail risk and crisis probability as well as (3) the Volatility Paradox. Concepts such as (4) illiquidity and liquidity mismatch, (5) endogenous leverage, (6) the Paradox of Prudence, (7) undercapitalized sectors (8) time-varying risk premia, and (9) the external funding premium are part of the analysis. Financial frictions also give rise to an endogenous (10) value of money.

Keywords

Macroeconomic modeling, Monetary Economics, (Inside) Money, Endogenous Risk Dynamics, Volatility paradox, Paradox of Prudence, Financial frictions

1. INTRODUCTION

The recent financial crisis in the United States and the subsequent Euro Crisis are vivid reminders of the importance of financial frictions in understanding macroeconomic trends and cycles. While financial markets are self-stabilizing in normal times, economies become vulnerable to a crisis after a run up of (debt) imbalances and (credit) bubbles. In particular, debt, leverage, maturity and liquidity mismatch tend to rise when measured volatility is low. Vulnerability risk tends to build up in the background, and only materializes when crises erupt, a phenomenon referred to as the "Volatility Paradox."

Adverse feedback loops can make the market spiral out of balance. The dynamics of an economy with financial frictions are highly nonlinear. Small shocks lead to large economic dislocations. In situations with multiple equilibria, runs on financial institutions or sudden stops on countries can occur even absent any fundamental trigger. Empirically, these phenomena show up as fat tails in the distribution of real economic variables and asset price returns.

Our research proposes a continuous time method to capture the whole *endogenous risk dynamics* and hence goes beyond studying simply the persistence and amplification of an individual adverse shock. Instead of focusing only on levels, the first moments, the second moments, and movements of risk variables are all an integral part of the analysis, as they drive agents' consumption, (precautionary) savings and investment decisions. After a negative shock, we do not assume that the economy returns to the steady state deterministically, but rather uncertainty might be heightened making the length of the slump stochastic. As agents respond to the new situation, they affect both the risk and the risk premia.

Endogenous risk is time-varying and depends on illiquidity. Liquidity comes in three flavors. Technological illiquidity refers to the irreversibility of physical investment.

Instead of undoing the initial investment, another option is to sell off the investment. This is only reasonable when market liquidity is sufficiently high. Finally, with sufficient funding liquidity one can issue claims against the payoffs of the assets. Incentive problems dictate that these claims are typically short-term debt claims. Debt comes with the drawback that risk is concentrated in the indebted sector. In addition, short-term debt leads to liquidity risk exposure. Agents may be forced to fire-sell their assets if they cannot undo the investment, market liquidity is low and funding is restricted, eg, very short term. In short, when there is a liquidity mismatch between technological and market liquidity on the asset side and funding liquidity on the liability side of the balance sheet, the economy is vulnerable to instability.

Models with financial frictions necessarily have to encompass multiple sectors. Financial frictions prevent funds from flowing to undercapitalized sectors, create debt overhang problems, and/or preclude optimal ex-ante risk sharing. This is in contrast to a world with perfect financial markets in which only aggregate risk matters, as all agents' marginal rate of substitutions are equalized in equilibrium and consequently aggregation to a single representative agent is possible. In models with financial frictions and heterogeneous agents the wealth distribution matters.

Importantly, financial frictions also give rise to the value of money. Money is a liquid store of value and safe asset. This approach provides not only a complementary perspective to New Keynesian models, in which price and wage rigidities are the primary drivers of money value, but also enables the revival of the traditional literature on "money and banking."[a]

Ultimately, economic analysis should guide policy. It is important to go beyond partial equilibrium analysis since general equilibrium effects can be subtle and counterintuitive. A model has to be tractable enough to conduct a meaningful welfare analysis to evaluate various policy instruments. A welfare analysis lends itself to study the interaction of various policy instruments.

In sum, the goal of this chapter is to put forward a manual for how to setup and solve a continuous time macrofinance model. The tractability that continuous time offers allows us to study a host of new properties of fully solved equilibria. This includes the full characterization of endogenous (1) level and risk dynamics. The latter includes (2) tail risk and crisis probability as well as (3) the Volatility Paradox. In addition, it should help us think about (4) illiquidity and liquidity mismatch, (5) endogenous leverage, (6) Paradox of Prudence, (7) undercapitalized sectors, (8) time-varying risk premia, and (9) the external funding premium. From a welfare perspective, we would like to ask normative questions about the (10) inefficiencies of financial crises and (11) the effects of policies using various instruments.

[a] See, eg, Chandler (1948).

We start with a brief history of macro and finance research since the Great Depression in the 1930s. We then put forward arguments in favor of continuous time modeling before surveying the ongoing continuous time literature. The main part of the paper builds up a step by step outline how to solve continuous time models starting with the simplest benchmark and enriching the model by adding more building blocks.

1.1 A Brief History of Macroeconomics and Finance

Macroeconomics as a field in economics was born during the great depression in the 1930s. At that time, economists like Fisher (1933), Keynes (1936), Gurley and Shaw (1955), Minsky (1957), and Kindleberger (1978) stressed the importance of the interaction between financial instability and macroeconomic aggregates. In particular, certain sectors in the economy including the financial sector can become balance sheet impaired and can drag down parts of the economy. Patinkin (1956) and Tobin (1969) also emphasized that financial stability and price stability are intertwined and hence that macroeconomics, monetary economics and finance are closely linked.

As economics became more analytical and model based, macroeconomics and finance went into different directions. See Fig. 1. Hicks' (1937) IS-LM Keynesian macro model is both static and deterministic. Macroeconomic growth models, most prominently the Solow (1956) growth model, are dynamic and many of them are in continuous time. However, they exclude stochastic elements: risk and uncertainty play no role. In contrast, the formal finance literature starting with Markowitz (1952) portfolio theory focused exclusively on risk. These models are static models and ignore the time dimension.

In the 1970s and early 1980s macroeconomists introduced stochastic elements into their dynamic models. Early "fresh water" models that included time and stochastic elements were Brock and Mirman's (1972) stochastic growth model and real business cycle models à la Kydland and Prescott (1982). The influential graduate text book of

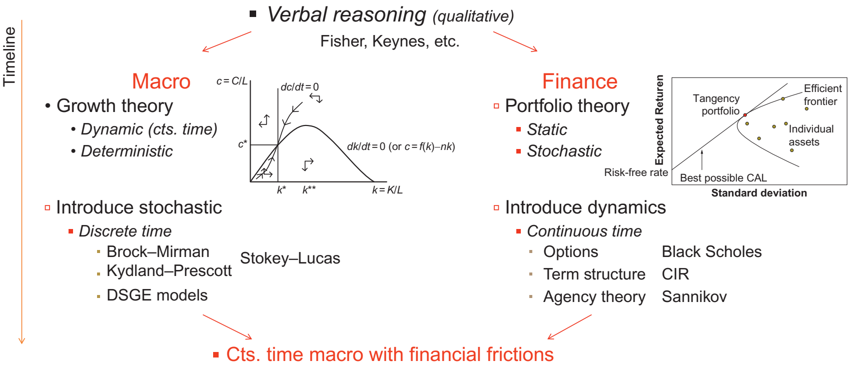

Fig. 1 Methods in macroeconomic and financial research since the great depression.

Stokey and Lucas (1989) provided the necessary toolkit for a fully microfounded dynamic and stochastic analysis. The "salt water" New Keynesian branch of macro introduced price rigidities and studied countercyclical policy in rational expectations models, Taylor (1979) and Mankiw and Romer (1991). The two branches merged and developed DSGE models which were both dynamic, the D in DSGE, and stochastic, the S in DSGE. However, unlike in many of the earlier growth models, time is discrete in real business cycle and New Keynesian DSGE models à la Woodford (2003). Most DSGE models capture only the log-linearized dynamics around the steady state. The log-linearized theoretical analysis squared nicely with its empirical counterpart, the linear Vector Autoregression Regression (VAR) estimation technique pioneered by Sims (1980).

Finance also experienced great breakthroughs in the 1970s. Stochastic Calculus (Ito calculus), which underlies the Black and Scholes (1973) option pricing model, revolutionized finance. Besides option pricing, term structure of interest rate models like Cox et al. (1985) were developed. More recently, Sannikov (2008) developed continuous time tools for financial contracting, which allow one to capture contracting frictions in a tractable way.

Our line of research is the next natural step. It essentially merges macroeconomics and finance using continuous time stochastic models. In terms of financial frictions, it builds on earlier work by Bernanke et al. (1999) (BGG), Kiyotaki and Moore (1997) (KM), Bianchi (2011), Mendoza (2010), and others. Our approach replicates two important results from the linearized versions of classic models of BGG and KM, that (1) temporary macro shocks can have a *persistent* effect on economic activity by making borrowers "undercapitalized" and (2) price movements *amplify* shocks. In KM, the leverage is limited by an always binding collateral constraint. In Bianchi (2011) and Mendoza (2010) it is occasionally binding. Our approach focuses mostly on incomplete market frictions, where the leverage of potentially undercapitalized borrowers is usually endogenous. In particular, it responds to the magnitude of fundamental (exogenous) macroeconomic shocks and the level of financial innovations that enable better risk management. Interestingly, leverage responds to a much lesser extent to the presence of endogenous tail risk. Equilibrium leverage in normal times is a key determinant of the probability of crises.

1.2 The Case for Continuous-Time Macro Models

As economists we have no hesitation in assuming a continuous action space in order to ensure nice first order optimality conditions that are free of integer problems. In the same vein, we typically assume a continuum of agents to guarantee an environment with perfect competition and (tractable) price taking behavior.

Assuming a continuous time framework has two advantages: it is often more tractable and might conceptually be a closer representation of reality. In terms of tractability, continuous time allows one to derive more analytical steps and more closed form characterizations of the equilibrium before resorting to a numerical analysis. For example, in our case one can derive explicit closed form expressions for amplification terms. The reason is that only the slope of the price function, ie, the (local) derivative w.r.t. state variables, is necessary to characterize amplification. In contrast, in discrete time settings the whole price function is needed, as the jump size may vary. Also, instantaneous returns are essentially log-normal, which makes it easy to take expectations. It is also easy to derive the portfolio choice problem and to link returns to net worth dynamics via the budget constraint. In discrete-time models, this feature can only be achieved through a (Campbell–Shiller) log-linear approximation. It is therefore not surprising that the term structure literature uses continuous time models. Admittedly, some of these features are due to the continuous nature of certain stochastic processes, like Brownian Motions and other Ito Processes. Hereby, one implicitly assumes that agents can adjust their consumption or portfolio continuously as their wealth changes. The feature that their wealth never jumps beyond a specific point, eg, the insolvency point, greatly simplifies the exposition.

Conceptually, in certain dimensions a continuous time representation might also square better with reality. People do not consume only at the end of the quarter, even though data come in quarterly. Discrete time models implicitly assume linear time aggregation within a quarter and a nonlinear one across quarters. In other words, the intertemporal elasticity of consumption within a quarter is infinite while across quarters it is given by the curvature of the utility function. Continuous time models treat every time unit the same. Similarly, it is well known that for multivariate models mixing data with different degrees of smoothness and frequency (such as consumption data and financial data) can seriously impair inference.

The biggest advantage of our continuous-time approach is that it allows a full characterization of the whole dynamical system including the risk dynamics instead of simply a log-linearized representation around the steady state. Note that impulse response functions capture only the expected path after a shock that starts at the steady state. Also, the stationary distribution can be bimodal and exhibit large swings, unlike stable normal distributions that log-linearized models imply.

1.3 The Nascent Continuous-Time Macrofinance Literature

This chapter builds on Brunnermeier and Sannikov (2014).[b] It extends this work by allowing for more general utility functions, precautionary savings and for endogenous equity issuance. Work by Basak and Cuoco (1998) and He and Krishnamurthy (2012, 2013) on intermediary asset pricing are part of the core papers in this literature.

[b] For an alternative survey on continuous time macro models, see, eg, Isohätälä et al. (2016).

Isohätälä et al. (2014) study a partial equilibrium model. DiTella (2013) introduces exogenous uncertainty shocks that can lead to balance sheet recessions even when contracting based on aggregate state variables is possible.

Phelan (2014) considers a setting in which banks issue equity and leverage can be procyclical. Adrian and Boyarchenko (2012) achieve procyclical leverage by introducing liquidity preference shocks. Adrian and Boyarchenko (2013) consider the interaction between two types of intermediaries: banks and nonbanks. Huang (2014) studies shadow banks, which circumvent regulatory constraints but are subject to an endogenous enforcement constraint. In Moreira and Savov (2016)'s macro model shadow banks issue money-like claims. In downturns they scale back their activity. This slows down the recovery and creates a scarcity in collateral. Klimenko et al. (2015) show that regulation that prohibits dividend payouts is typically superior to very tight capital requirements. In Moll (2014) capital is misallocated since productive agents are limited by collateral constraints to lever up.

Several papers also tried to calibrate continuous time macrofinance models to recent events. For example, He and Krishnamurthy (2014) do so by including housing as a second form of capital. Mittnik and Semmler (2013) employ a multi-regime vector autoregression approach to capture the nonlinearity of these models.[c]

In international economics, these methods are employed in Brunnermeier and Sannikov (2015b). In a two-good, two-country model, the overly indebted country is vulnerable to sudden stops, and hence capital controls might improve welfare. Maggiori (2013) models risk sharing across countries which are at different stages of financial development.

Models with financial frictions also open up an avenue for new models in monetary economics thereby reviving the field "money and banking." In Brunnermeier and Sannikov (2015a)'s "The I Theory of Money" money is a bubble like in Samuelson (1958) or Bewley (1977). Inside money is created endogenously by the intermediary sector, and monetary policy and macroprudential policy interact. Achdou et al. (2015) provide a solution algorithm for Bewley models with uninsurable endowment risk in a continuous time setting. In Drechsler et al. (2016) banks are less risk averse and monetary policy affects risk premia. Silva (2016) studies how unconventional monetary policy reallocates risk. Werning (2012) studies the zero lower bound problem in a tractable deterministic continuous time New Keynesian model.

Rappoport and Walsh (2012) setup a discrete-time macro model, which has similar economic results, and which converges in the continuous-time limit to the model of Brunnermeier and Sannikov (2014).

[c] Note that in the estimation of DSGE models, Fernandez-Villaverde and Rubio-Ramirez (2010) show that parameter estimates and the moments generated by the model depend quite sensitively on whether a linearized DSGE is estimated via Kalman filtering or whether the true DSGE model is estimated via particle filtering.

2. A SIMPLE REAL ECONOMY MODEL

We start first with a particularly simple model to illustrate how equilibrium conditions—utility maximization and market clearing—translate into an equilibrium characterization. This simple model trivializes most of the issues we are after, eg, the model has no price effects or endogenous risk. We do get some interesting takeaways, such as that risk premia spike in crises. After establishing the conceptual framework for what an equilibrium is, we move on to tackle more complex models.

2.1 Model Setup

This model is a variation of Basak and Cuoco (1998). The economy has a risky asset in positive net supply and a risk-free asset in zero net supply. There are two types of agents—experts and households. Only experts can hold the risky asset—households can only lend to experts at the risk-free rate r_t, determined endogenously in equilibrium. The friction is that experts can finance their holdings of the risky asset only through debt—by selling short the risk-free asset to households. That is, experts cannot issue equity. We assume that all agents are small, and behave as price-takers. That is, unlike in microstructure models with noise traders, agents have no price impact.

2.1.1 Technology

Net of investment, physical capital, k_t, generates consumption output at the rate of

$$(a-\iota_t)k_t\,dt,$$

where a is a productivity parameter and ι_t is the reinvestment rate per unit of capital. The production technology is constant returns to scale.

The productive asset (capital), k_t, evolves according to

$$\frac{dk_t}{k_t}=(\Phi(\iota_t)-\delta)dt+\sigma\,dZ_t, \tag{1}$$

where $\Phi(\iota_t)$ is an investment function with adjustment costs, such that $\Phi(0)=0$, $\Phi'>0$ and $\Phi''\leq 0$. Thus, in the absence of investment, capital simply depreciates at rate δ. The concavity of $\Phi(\cdot)$ reflects decreasing returns to scale, and for negative values of ι_t, corresponds to *technological illiquidity*—the marginal cost of capital depends on the rate of investment/disinvestment.

The aggregate amount of capital is denoted by K_t, and q_t is the price of capital. Hence, the aggregate net worth in the economy is q_tK_t. If N_t is the aggregate net worth of experts, then the aggregate net worth of households is $q_tK_t - N_t$.

Experts' wealth share is denoted by

$$\eta_t=\frac{N_t}{q_tK_t}\in[0,1].$$

2.1.2 Preferences

For *tractability*, all agents are assumed to have logarithmic utility with discount rate ρ, of the form

$$E\left[\int_0^\infty e^{-\rho t}\log c_t dt\right],$$

where c_t is consumption at time t.

2.2 A Step-By-Step Approach

Definition An equilibrium is a map from histories of macro shocks $\{Z_s, s \leq t\}$ to the price of capital q_t, risk-free rate r_t, as well as asset holdings and consumption choices of all agents, such that

1. agents behave to maximize utility and

2. markets clear.

To find an equilibrium, we need to write down equations that the processes q_t, r_t, etc., have to satisfy, and that characterize how these processes evolve with the realizations of shocks Z. It will be convenient to express these relationships using a state variable. Here the relevant state variable, which describes the distribution of wealth, is the fraction of wealth owned by the experts, η_t. When η_t drops, experts become more balance sheet constrained.

We solve the equilibrium in three steps. First, we postulate some endogenous processes. As a second step, we use the equilibrium conditions, ie, utility maximization and market clearing, to write down restrictions q_t and r_t need to satisfy. In this simple model, we will be able to express q_t and r_t as functions of η_t in closed form. Third, we need to derive the law of motion of the state variable, the wealth share η_t.

Step 1: Postulate Equilibrium Processes. The first step is to postulate certain endogenous price processes. For example, suppose that the price per unit of capital q_t follows an Ito process

$$\frac{dq_t}{q_t} = \mu_t^q dt + \sigma_t^q\, dZ_t, \tag{2}$$

which, of course, is endogenous in equilibrium.

An investment in capital generates, in addition to the dividend rate $(a - \iota)k_t dt$, the capital gains at rate

$$\frac{d(k_t q_t)}{k_t q_t}.$$

Ito's Lemma for the product of two stochastic processes can be used to derive this process.

Ito's Formula for Product

Suppose two processes X_t and Y_t follow

$$\frac{dX_t}{X_t} = \mu_t^X dt + \sigma_t^X dZ_t \quad \text{and} \quad \frac{dY_t}{Y_t} = \mu_t^Y dt + \sigma_t^Y dZ_t.$$

Then the product of two processes follows

$$\frac{d(X_t Y_t)}{X_t Y_t} = (\mu_t^X + \mu_t^Y + \sigma_t^X \sigma_t^Y)dt + (\sigma_t^X + \sigma_t^Y)dZ_t. \tag{3}$$

Using Ito's Lemma, the investment in capital generates capital gains at rate

$$\frac{d(k_t q_t)}{k_t q_t} = (\Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q)dt + (\sigma + \sigma_t^q)dZ_t.$$

Then capital earns the return of

$$dr_t^k = \underbrace{\frac{a - \iota_t}{q_t}dt}_{\text{dividend yield}} + \underbrace{(\Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q)dt + (\sigma + \sigma_t^q)dZ_t}_{\frac{d(k_t q_t)}{k_t q_t}, \text{ the capital gains rate}}. \tag{4}$$

Thus, generally a part of the risk from holding capital is fundamental, σdZ_t, and a part is endogenous, $\sigma_t^q dZ_t$.

Remarks

- For general utility functions one also has to postulate the stochastic discount factor process or equivalently a process for the marginal utility or the consumption process dc_t/c_t. For details see Section 3.1.
- Note that in monetary models like Brunnermeier and Sannikov (2015a, 2016) one also has to postulate a process p_t for the value of money which can be stochastic due to inflation risk. In Section 4 we present a simple monetary model.

Step 2: The Equilibrium Conditions.

Equilibrium conditions come in two flavors: Optimality conditions and market clearing conditions.

Optimal internal investment rate. Note that the rate of internal investment ι_t does not affect the risk of capital. The optimal investment rate that maximizes the expected return satisfies the first-order condition

$$\Phi'(\iota_t) = \frac{1}{q_t}. \tag{5}$$

Optimal consumption rate. Logarithmic utility has two convenient properties, which we derive formally for a more general case in Section 3.1. These two properties help reduce the number of equations that characterize equilibrium. First, for agents with log utility

$$\text{consumption} = \rho \cdot \text{net worth} \tag{6}$$

that is, they always consume a fixed fraction of wealth (permanent income) regardless of the risk-free rate or risky investment opportunities. The consumption Euler equation reduces to a particularly simple form.

Optimal portfolio choice. The optimal risk exposure of a log-utility agent in the optimal portfolio choice problem depends on the attractiveness of risky investment, measured by the Sharpe ratio, defined as expected excess returns divided by the standard deviation. Formally, the equilibrium condition is

$$\text{Sharpe ratio of risky investment} = \text{volatility of net worth}, \tag{7}$$

where the volatility is relative (measured as percentage change per unit of time).[d]

Goods Market clearing. We use Eqs. (6) and (7) to formalize equilibrium conditions, and characterize equilibrium. First, from condition (6), the aggregate consumption of all agents is $\rho q_t K_t$, and aggregate output is $(a - \iota(q_t))K_t$, where investment ι is an increasing function of q defined by (5). From market clearing for consumption goods, these must be equal, and so

$$\rho q_t = a - \iota(q_t). \tag{8}$$

This determines the equilibrium price of the risky capital. The aggregate consumption of experts must be $\rho N_t = \rho \eta_t q_t K_t$, and the aggregate consumption of households is $\rho(1 - \eta_t) q_t K_t$. Condition (8) alone leads to a *constant* value of the *price of capital* q. That is, $\mu_t^q = \sigma_t^q = 0$.

Example with Log Investment Function

Suppose the investment function takes the form

$$\Phi(\iota) = \frac{\log(\kappa\iota + 1)}{\kappa},$$

where κ is the adjustment cost parameter. Then $\Phi'(0) = 1$. Higher κ makes function Φ more concave, and as $\kappa \to 0, \Phi(\iota) \to \iota$, a fully elastic investment function with no adjustment costs. The optimal investment rate is $\iota = (q - 1)/\kappa$, and the market-clearing condition (8) leads to the price of

$$q = \frac{1 + \kappa a}{1 + \kappa \rho}.$$

The price converges to 1 as $\kappa \to 0$, ie, the investment technology is fully elastic. The price q converges to a/ρ as $\kappa \to \infty$.

[d] For example, if the annual volatility of S&P 500 is 15% and the risk premium is 3% (so that the Sharpe ratio is 3%/15% = 0.2), then a log utility agent wants to hold a portfolio with volatility 0.2 = 20%. This corresponds to a weight of 1.33 on S&P 500, and −0.33 on the risk-free asset.

Second, we can use condition (7) for experts to figure out the equilibrium *risk-free rate*. We first look at the return on risky and risk-free assets to compute the Sharpe ratio of risky investments. We then look at balance sheets of experts to compute the volatility of their wealth. Finally, we use Eq. (7) to get the risk-free rate.

Because q is constant, the risky asset earns a return of

$$dr_t^k = \underbrace{\frac{a-\iota}{q}dt}_{\rho,\ \text{dividend yield}} + \underbrace{(\Phi(\iota)-\delta)dt + \sigma\, dZ_t}_{\text{capital gains rate}},$$

and the risk-free asset earns r_t. Note that the dividend yield equals ρ by the goods market clearing condition. Hence, the Sharpe ratio of risky investment is

$$\frac{\rho + \Phi(\iota) - \delta - r_t}{\sigma}.$$

Note that since the price-dividend ratio is constant any change in the risk premium must come from the variation in the risk-free rate r_t.

Because experts must hold all the risky capital in the economy, with value q_tK_t (households cannot hold capital), and absorb risk through net worth N_t, the volatility of their net worth is

$$\frac{q_tK_t}{N_t}\sigma = \frac{\sigma}{\eta_t}.$$

Using (7),

$$\frac{\sigma}{\eta_t} = \frac{\rho + \Phi(\iota) - \delta - r_t}{\sigma} \quad \Rightarrow \quad r_t = \rho + \Phi(\iota) - \delta - \frac{\sigma^2}{\eta_t}. \tag{9}$$

Step 3: The Law of Motion of $\boldsymbol{\eta_t}$. To finish deriving the equilibrium, we need to describe how shocks Z_t affect the state variable $\eta_t = N_t/(q_tK_t)$. First, since η_t is a ratio, the following formula will be helpful for us:

Ito's Formula for Ratio

Suppose two processes X_t and Y_t follow

$$\frac{dX_t}{X_t} = \mu_t^X dt + \sigma_t^X dZ_t \quad \text{and} \quad \frac{dY_t}{Y_t} = \mu_t^Y dt + \sigma_t^Y dZ_t.$$

Then ratio of two processes follows

$$\frac{d(X_t/Y_t)}{X_t/Y_t} = (\mu_t^X - \mu_t^Y + (\sigma_t^Y)^2 - \sigma_t^X\sigma_t^Y)dt + (\sigma_t^X - \sigma_t^Y)dZ_t. \tag{10}$$

Second, it is convenient to express the laws of motion of the numerator and denominator of η_t in terms of total risk and the Sharpe ratio given by (9). Specifically,

$$\frac{dN_t}{N_t} = r_t dt + \underbrace{\frac{\sigma}{\eta_t}}_{\text{risk}} \underbrace{\frac{\sigma}{\eta_t}}_{\text{Sharpe}} dt + \frac{\sigma}{\eta_t} dZ_t - \underbrace{\rho dt}_{\text{consumption}} \quad \text{and}$$

$$\frac{d(q_t K_t)}{q_t K_t} = r_t dt + \underbrace{\sigma}_{\text{risk}} \underbrace{\frac{\sigma}{\eta_t}}_{\text{Sharpe}} dt + \sigma dZ_t - \underbrace{\rho dt}_{\text{dividend yield}} .$$

In the latter equation, we subtract the dividend yield from the total return on capital to obtain the capital gains rate.

Using the formula for the ratio,

$$\begin{aligned} \frac{d\eta_t}{\eta_t} &= (r_t + \sigma^2/\eta_t^2 - \rho - r_t - \sigma^2/\eta_t + \rho + \sigma^2 - \sigma^2/\eta_t) dt + (\sigma/\eta_t - \sigma) dZ_t \\ &= \frac{(1-\eta_t)^2}{\eta_t^2} \sigma^2 dt + \frac{1-\eta_t}{\eta_t} \sigma dZ_t. \end{aligned} \tag{11}$$

Step 4: Expressing $q(\eta)$ as a function of η is not necessary in this simple model, since q is a constant.

2.3 Observations

Several key observations about equilibrium characteristics are worth pointing out. Variable η_t fluctuates with macro shocks—a positive shock increases the wealth share of experts. This is because experts are levered. A negative shock erodes η_t, and experts require a higher risk premium to hold risky assets. Experts must be convinced to keep holding risky assets by the increasing Sharpe ratio

$$\frac{\sigma}{\eta_t} = \frac{\rho + \Phi(\iota) - \delta - r_t}{\sigma},$$

which goes to ∞ as η_t goes to 0. Strangely, this is achieved due to the risk-free rate $r_t = \rho + \Phi(\iota) - \delta - \sigma^2/\eta_t$ going to $-\infty$, rather than due to a depressed price of the risky asset, as illustrated in the top right panel of Fig. 2.

Because q_t is constant, as illustrated in the top left panel, there is no endogenous risk, no amplification and no volatility effects. Therefore, in this model, assumptions that allow for such a simple solution also eliminate any price effects that we are so interested in. We have to work harder to get those effects.

Besides the absence of price effects, in this model it is also the case that in the long run the expert sector becomes so large that it overwhelms the whole economy. To see this,

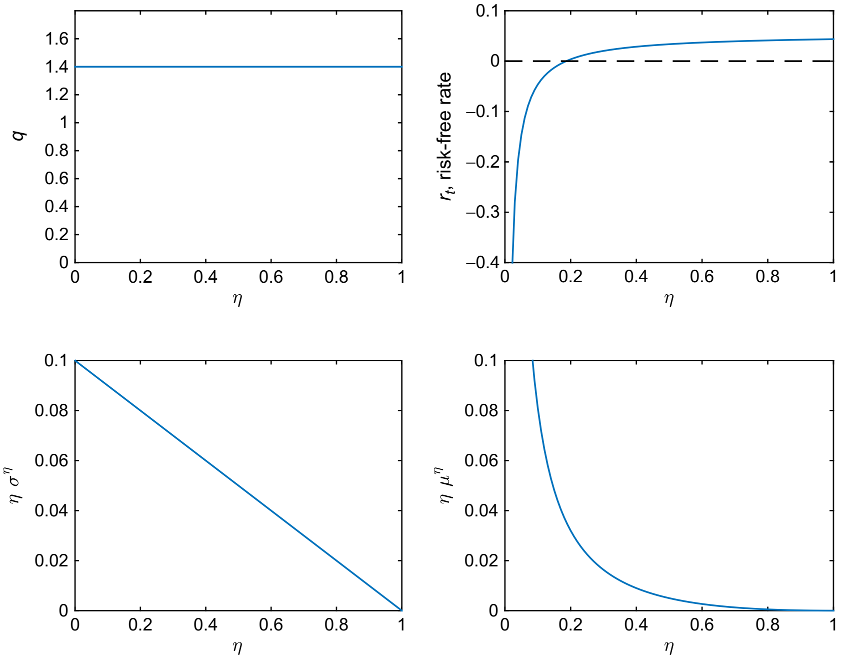

Fig. 2 Equilibrium in the simple real model, $a = 0.11$, $\rho = 5\%$, $\sigma = 0.1$, and $\Phi = \log(\kappa\iota + 1)/\kappa$ with $\kappa = 10$.

note that the drift of η_t is always positive. This feature is typical of models in which one group of agents has an advantage over another group—in this case only experts can invest in the risky asset. It is possible to prevent the expert sector from becoming too large through an additional assumption. For example, Bernanke et al. (1999) assume that experts are randomly hit by a shock that makes them households. Alternatively, if experts have a higher discount rate than households, then a greater consumption rate prevents the expert sector from becoming too large.

The main purpose of this section was to show how equilibrium conditions can be translated into formulas that describe the behavior of the economy. Next, we can consider more complicated models, in which the price of the risky asset q_t reacts to shocks. We also develop a methodology that allows for agents to have more complicated preferences and for a nontrivial distribution of assets among agents.

3. A MODEL WITH PRICE EFFECTS AND INSTABILITIES

We now illustrate how our step approach can be used to solve a more complex model, which we borrow and extend from Brunnermeier and Sannikov (2014). We will be able to get a number of important takeaways from the model:

1. Equilibrium dynamics are characterized by a relatively stable steady state, where the system spends most of the time, and a crisis regime. In the steady state, experts are adequately capitalized and risk premia fall. The experts' consumption offsets their earnings—hence the steady state is formed. Experts have the capacity to absorb most macro shocks, hence prices near the steady state are quite stable. However, an unusually long sequence of negative shocks causes experts to suffer significant losses, and pushes the equilibrium into a crisis regime. In the crisis regime, experts are undercapitalized and constrained. Shocks affect their demand for assets—market liquidity at the macro level can dry up—and thus affect prices of the assets that experts hold. This creates feedback effects, which generate fire-sales and *endogenous risk*. Volatility is endogenous and also feeds back in agents' behavior.
2. High volatility during crisis times may push the system into a very depressed region, where experts' net worth is close to 0. If that happens, it takes a long time for the economy to recover. Thus, the system spends a considerable amount of time far away from the steady state. The stationary distribution may be bimodal.
3. Endogenous risk during crises makes assets more correlated.
4. There is a "*volatility paradox*," because risk-taking is endogenous. If the aggregate risk parameter σ becomes smaller, the economy does not become more stable. The reason is that experts take on greater leverage, and pay out profits sooner, in response to lower fundamental risk. Due to greater leverage, the economy is prone to crises even when exogenous shocks are smaller. In fact, endogenous risk during crises may actually be higher when σ is lower.
5. Financial innovations, such as securitization and derivatives hedging, that allow for more efficient risk-sharing among experts, may make the system less stable in equilibrium. The reason, again, is that risk-taking is endogenous. By diversifying idiosyncratic risks, experts tend to increase leverage, amplifying systemic risks.

Before going into details of how we can extend our simple real economy model from Section 2 to display these additional features, we take a detour to discuss the classic problem of optimal consumption and portfolio choice in continuous time.

3.1 Optimal Portfolio Choice with General Utility Functions

We start with a brief description of how to extend the optimal consumption and portfolio choice conditions (such as (6) and (7)) to the case of a general utility function. The key result is that any asset, which an agent can hold, can be priced from the agent's marginal utility of wealth θ_t. The first-order condition for optimal consumption is $\theta_t = u'(c_t)$, so the marginal utility of wealth is also the marginal utility of consumption (unless the agent is "at the corner").[e]

[e] If the agent is risk-neutral, then his marginal utility of consumption is always 1, but the agent may choose to not consume if his marginal utility of wealth is greater than 1.

If the agent has discount rate ρ, then $\xi_t = e^{-\rho t}\theta_t$ is the stochastic discount factor (SDF) to price assets. We can write

$$\frac{d\xi_t}{\xi_t} = -r_t dt - \varsigma_t dZ_t, \tag{12}$$

where r_t is the (shadow) risk-free rate and ς_t is the price of risk dZ_t.

For any asset A that the agent can invest in, with return

$$dr_t^A = \mu_t^A dt + \sigma_t^A dZ_t,$$

we must have

$$\mu_t^A = r_t + \varsigma_t \sigma_t^A. \tag{13}$$

Eqs. (12) and (13) are simple, yet extremely powerful.

3.1.1 Martingale Method

To derive Eq. (13) consider a trading strategy of investing 1 dollar into asset A at time 0 and keep on reinvesting any dividends the asset might pay out. Denote the value of this strategy at time t by v_t (then $v_0 = 1$, obviously). Clearly, its capital gains rate is

$$\frac{dv_t}{v_t} = dr_t^A.$$

For an arbitrary $s \le t$ consider an investor who can only trade at s and t. That is, he faces a simple two-period portfolio problem. The Euler equation for the standard two-period portfolio problem is

$$v_s = E_s\left[\frac{\xi_t}{\xi_s} v_t\right] \Rightarrow \xi_s v_s = E_s[\xi_t v_t].$$

That is, $\xi_t v_t$ must be a martingale on the time domain $\{s, t\}$. For an investor who can trade continuously $\xi_t v_t$ must be a martingale for any t, since we picked s, t arbitrarily. Next, by Itô's formula

$$\frac{d(\xi_t v_t)}{\xi_t v_t} = (\mu_t^\xi + \mu_t^v + \sigma_t^\xi \sigma_t^v)dt + (\sigma_t^\xi + \sigma_t^v)dZ_t = (-r_t + \mu_t^A - \varsigma_t \sigma_t^A)dt + (\sigma_t^A - \varsigma_t)dZ_t.$$

This is a martingale if and only if the drift vanishes, ie, Eq. (13) holds.

3.1.2 Derivation via Stochastic Maximum Principle

One can also derive the pricing equations and consumption rule using the stochastic maximum principle. Let us consider an agent who maximizes

$$E\left[\int_0^\infty e^{-\rho t} u(c_t)dt\right],$$

and whose net worth follows

$$dn_t = n_t\left(r_t dt + \sum_A x_t^A((\mu_t^A - r_t)dt + \sigma_t^A dZ_t)\right) - c_t dt,$$

with initial wealth $n_0 > 0$ and where x_t^A are portfolio weights on various assets A. Investment opportunities are stochastic and exogenous, ie, they do not depend on the agent's strategy.

The stochastic maximum principle allows us to derive first-order conditions for maximization from the Hamiltonian. Introducing a multiplier ξ_t on n_t (ie, marginal utility of wealth) and denoting the volatility of ξ_t by $-\varsigma_t\xi_t$, the Hamiltonian is written as

$$H = e^{-\rho t}u(c) + \xi_t\{\underbrace{(r_t + \sum_A x^A(\mu_t^A - r_t))n_t - c}_{\text{drift of } n_t}\} - \varsigma_t\xi_t \underbrace{\sum_A x^A\sigma_t^A n_t}_{\text{volatility of } n_t}.$$

By differentiating the Hamiltonian with respect to controls, we get the first-order conditions, and by differentiating it with respect to the state n_t, we get the law of motion of the multiplier ξ_t.

The first-order condition with respect to c is

$$e^{-\rho t}u'(c_t) = \xi_t,$$

which implies that the multiplier on the agent's wealth is his discounted marginal utility of consumption. The first-order condition with respect to the portfolio weight x^A is

$$\xi_t(\mu_t^A - r_t) - \varsigma_t\xi_t\sigma_t^A = 0,$$

which implies (13).

In addition, the drift of ξ_t is

$$-H_n = -\xi_t r_t,$$

where we already used the first-order conditions with respect to x^A to perform cancellations. It follows that the law of motion of ξ_t is

$$d\xi_t = -\xi_t r_t\, dt - \varsigma_t\xi_t\, dZ_t,$$

which corresponds to (12).

3.1.3 Value Function Derivation for CRRA Utility

Macroeconomists are most familiar with this method. With CRRA utility, the agent's value function takes a power form

$$\frac{u(\omega_t n_t)}{\rho}. \tag{14}$$

This form comes from the fact that if the agent's wealth changes by a factor of x, then his optimal consumption at all future states changes by the same factor—hence ω_t is determined so that $u(\omega_t)/\rho$ is the value function at unit wealth. Marginal utility of consumption and marginal utility of wealth are equated if $c_t^{-\gamma} = \omega_t^{1-\gamma} n_t^{-\gamma}/\rho$, or

$$\frac{c_t}{n_t} = \rho^{1/\gamma}\omega_t^{1-1/\gamma}. \tag{15}$$

For log utility, $\gamma = 1$ and this equation implies that $c_t/n_t = \rho$ as we claimed in (6).

For $\gamma \neq 1$, by expressing ω_t as a function of the consumption rate c_t/n_t, we find that the agent's continuation utility is

$$\frac{c_t^{-\gamma} n_t}{1-\gamma}. \tag{16}$$

This remarkable expression shows that the agent's net worth and consumption rate are sufficient to compute the agent's welfare, and no additional information about the agent's stochastic investment opportunities is needed.

Given the agent's (postulated) consumption process of

$$\frac{dc_t}{c_t} = \mu_t^c dt + \sigma_t^c dZ_t,$$

by Ito's Lemma, marginal utility $c^{-\gamma}$ follows

$$\frac{d(c_t^{-\gamma})}{c_t^{-\gamma}} = \left(-\gamma\mu_t^c + \frac{\gamma(\gamma+1)}{2}(\sigma_t^c)^2\right)dt - \gamma\sigma_t^c dZ_t. \tag{17}$$

Substituting this into (13), we obtain the following relationship for the pricing of any risky asset relative to the risk-free asset:

$$\frac{\mu_t^A - r_t}{\sigma_t^A} = \gamma\sigma_t^c = \varsigma_t. \tag{18}$$

Recall that $\xi_t = e^{-\rho t}u'(c_t)$ and hence $\frac{d\xi_t}{\xi_t} = -\rho - \frac{d(c_t^{-\gamma})}{c_t^{-\gamma}}$. Minus the drift of the SDF is the risk-free rate, ie,

$$r_t = \rho + \gamma\mu_t^c - \frac{\gamma(\gamma+1)}{2}(\sigma_t^c)^2. \tag{19}$$

Two special cases with particularly nice analytical solutions deserve special attention.

Example with CRRA and Constant Investment Opportunities

With constant investment opportunities, then ω_t is a constant, hence (15) implies that $\sigma_t^c = \sigma_t^n$, just like in the logarithmic case. Hence, (18) implies that

$$\underbrace{\frac{\mu_t^A - r}{\sigma_t^A}}_{\varsigma} = \gamma\sigma_t^n,$$

ie, the volatility of net worth is the Sharpe ratio divided by the risk aversion coefficient γ. Note that this property also holds when ω_t is not a constant as long as it evolves deterministically.

Now, the agent's net worth follows

$$\frac{dn_t}{n_t} = rdt + \frac{\varsigma^2}{\gamma}dt + \frac{\varsigma}{\gamma}dZ_t - \frac{c_t}{n_t}dt,$$

and, since consumption is proportional to net worth, (19) implies that

$$r = \rho + \gamma\left(r + \frac{\varsigma^2}{\gamma} - \frac{c_t}{n_t}\right) - \frac{\gamma(\gamma+1)}{2}\frac{\varsigma^2}{\gamma^2} \quad \Rightarrow \quad \frac{c_t}{n_t} = \rho + \frac{\gamma - 1}{\gamma}\left(r - \rho + \frac{\varsigma^2}{2\gamma}\right).$$

Hence, consumption ratio increases with better investment opportunities when $\gamma > 1$ and falls otherwise.

Example with Log Utility

We can verify that the consumption and asset-pricing relationships for logarithmic utility of equation. Note from (15) follows directly (6),

$$c_t = \rho n_t.$$

Since the SDF is $\xi_t = e^{-\rho t}/c_t = e^{-\rho t}/(\rho n_t)$ (for any ω_t) it follows that $\sigma_t^n = \sigma_t^c = \varsigma_t$ (ie, minus the volatility of ξ_t). Hence, (13) implies that

$$\frac{\mu_t^A - r_t}{\sigma_t^A} = \sigma_t^n,$$

where the left hand side is the Sharpe ratio, and the right hand side is the volatility of net worth.

3.2 Model with Heterogeneous Productivity Levels and Preferences

In order to study endogenous risk, market illiquidity, fire-sales, etc., we now assume that the household sector can also hold physical capital, but households are assumed to be less productive. Specifically, their productivity parameter $\underline{a} < a$, and hence their willingness to pay for capital, is lower than that of experts. In this generalized setting, experts now have only two ways out when they become less capitalized and want to scale back their operation: fire-sell the capital to households at a possibly large price discount (market illiquidity) or "uninvest" and suffer adjustment costs (technological illiquidity).

Less productive households earn a return of

$$d\underline{r}_t^k = \underbrace{\frac{\underline{a} - \iota_t}{q_t} dt}_{\text{dividend yield}} + \underbrace{(\Phi(\iota_t) - \delta + \mu_t^q + \sigma\sigma_t^q)dt + (\sigma + \sigma_t^q)dZ_t}_{\frac{d(q_t k_t)}{q_t k_t},\ \text{the capital gains rate}} \tag{20}$$
